Il Museo Regionale di Scienze Naturali di Torino

Le collezioni mineralogiche, geologiche e paleontologiche oggi conservate al Museo Regionale di Scienze Naturali di Torino sono costituite essenzialmente dalle raccolte storiche dei Musei universitari di Mineralogia e Petrografia e di Geologia e Paleontologia, con cospicue integrazioni, a partire dal 1980, con materiali acquisiti direttamente dalla Regione Piemonte.

Le raccolte traggono le loro origini da alcuni nuclei di oggetti raccolti, nella prima metà del XVIII secolo, intorno al primo Museo dell'Università e da allora, attraverso continue aggiunte, donazioni, lasciti, acquisti, raccolte, si è giunti, nei primi anni del XX secolo, a costituire uno dei Musei naturalistici più prestigiosi d'Italia e d'Europa.

Dopo le distruzioni legate alle vicende belliche e il blocco nello sviluppo delle collezioni e delle esposizioni a causa dei nuovi orientamenti della Scienza (eventi comuni alla maggior parte dei Musei italiani), nel 1980, in un periodo di grande risveglio d'interesse per le istituzioni scientifiche e culturali, anche in senso storico, la Regione Piemonte istituì il Museo Regionale di Scienze Naturali di Torino con il compito di proseguire la *mission* degli ottocenteschi Musei universitari nelle attività di conservazione, incremento e divulgazione scientifica delle raccolte. Un compito che il personale del MRSN in trent'anni ha svolto con impegno, riordinando e recuperando per la scienza centinaia di migliaia di minerali, fossili, rocce, ma anche reperti zoologici, erpetologici e malacologici, incrementando le raccolte con nuove acquisizioni che, in molti casi, hanno quantitativamente e qualitativamente superato le collezioni storiche, ed infine contribuendo alla conoscenza delle raccolte e allo sviluppo delle scienze attraverso varie centinaia di saggi scientifici, centinaia di monografie, di cataloghi ragionati e di guide naturalistiche, varie decine di mostre scientifiche temporanee, spesso integrate da filmati e da cataloghi documentari, ecc.

Un lavoro immane di divulgazione scientifica che si è mosso di pari passo con l'allestimento delle esposizioni definitive, a loro volta sottomesse al restauro dell'edificio che ospita il Museo. In questa luce il MRSN ha sempre appoggiato e supportato le attività culturali effettuate sul territorio piemontese attinenti ai propri scopi istitutivi, quale è, in questa occasione, il Congresso GEOITALIA 2011, un'importante occasione di incontro e approfondimento tra operatori di Scienze della Terra provenienti da tutto il mondo.

Key terms: Denudation processes; Badland evolution; Digital photogrammetry; GIS; Tuscany

Soil loss due to water erosion and mass wasting is a serious environmental problem in Italy, where many areas are widely affected by accelerated erosion, promoted by the peculiar geological setting, land use and climatic features. Hence, it is important mapping and evaluate the space-time development of denudational processes. Digital photogrammetric techniques represent a powerful tool for the assessment of landscape evolution and related erosion rates.

This work presents a digital photogrammetric analysis performed in a test area of central Italy, a small catchment of ca. 4.4 km² located within the Upper Orcia River Valley (Tuscany). Here accelerated slope dynamics related to concentrated surface runoff heavily affects the dominant clayey substratum. As a result, typical badland landforms, well-known as "calanchi" and "biancane", occur, often coupled with gravity induced slope movements consisting of soil creep, solifluction and various types of landslides.

A digital photogrammetric analysis of morphologic changes due to erosion processes was performed on three series of black and white aerial photographs dating to 1954 (1:36 000 scale), 1976 (1:13 000 scale) and 2003 (1:33 000), respectively. These photographs were elaborated by using a digital photogrammetric workstation and a specific software (Z-map) which provided for the generation of digital stereo models, image exploration and interpretation tools and supported the generation of digital elevation models, digital orthophotographs and vector databases. The creation of stereo models, based on aerial triangulation, was carried out following the usual steps of interior and exterior orientation. The interior orientation of the aerial photographs was accomplished through the input manual of the fiducial marks data. To increase relative stability of the non-metric image blocks, on 30 tie points? per stereo pair were computed through semi-automatic operation, which significantly improved aerial triangulation results. The exterior orientation was based on 9 ground control points (GCPs) for each stereo pair, selected within and around the test area by using a Differential Global Position System (DGPS). The main targets used for GCPs refer to stable points such as building corners that could be univocally identified in the aerial photographs. The root-mean-square-error of the selected GCPs ranged from a few to several centimeters for the considered block images. For the 1976 and 2003 aerial photographs, triangulation (x, y, z) adjustments to the ground control points were smaller than 50 cm, more than 150 cm, instead, for the 1954 aerial photographs.

After the creation of the stereo model, digital orthophotographs with a resolution of 1 m were produced for each set of stereo pairs (1954, 1976 and 2003). These orthophotographs were then used to map terrain features and to measure their planimetric evolution. Data analysis and data management were performed within a Geographic Information System (GIS).

Photo interpretation, carried out for each set of aerial photos, allowed to map the land use and the main denudation processes that affected the landscape respectively in 1954, 1976 and 2003. To evidence morphological changes, topographic features such as calanchi headwater retreat and sidewall failures were quantified based on the comparison of their plano altimetric shape.

Comparing the denudation process maps obtained for various periods, important morphological changes occurred from 1954 to 2003 could be ascertained. The areas affected by badlands, as expected, highlighted the most severe landform modifications. In particular, a maximum headwater retreat reaching up to 10-15 cm yr⁻¹ was recorded. The proposed method can be considered very useful to better define denudation landforms and associated processes and to assess related erosion rates.

GEOMORPHOLOGICAL RISK AND CULTURAL HERITAGE: THE CASE OF THE ROMAN BRIDGE IN PONCI VALLEY (WESTERN LIGURIA)

BRANDOLINI Pierluigi¹, FACCINI Francesco¹, MAIFREDI Alessandro², BENEDETTINI Andrea²

1 - Dipartimento per lo studio del Territorio e delle sue Risorse, Università degli studi di Genova

2 - Delegazione Speleologica Ligure

Presenter e-mail: brando@unige.it

Key terms: geomorphological risk; flash flood; sinkhole; Finalese karstic area; Roman bridge

This study presents the geological and geomorphological outlines and the related hazard phenomena of Ponci Valley - which is located in hinterland of Finale ligure (Italy). The relationship with the presence of an important archaeological site of Roman age are analysed in order to define its state of vulnerability.

This site shows the remains of Via Julia Augusta, an internal alternative to the Via Aurelia, built along this valley 2000 years ago. The road is crossed by five bridges, at between 150 m and 300 m of altitude, run along almost the entire axis of the Ponci Valley. These constitute the most important and monumental evidence of the Roman communication routes in Liguria. These bridges involve the Ponci Stream and, in one case, the Landrazza Stream, its left bank tributary. These are all single arch bridges: three arches are still perfectly preserved and some vestiges of the abutments and ramps are visible from two others. Since the Pietra di Finale auct. is largely found in this area, this rock is mostly used for building structures, whereas dolomitic limestones, quartzites and other schists rock masses are secondarily used.

The area - which is mainly composed of bioclastic limestones and secondarily of underlying dolomite limestones - is included in the more extensive Finalese karstic area. The lithological features, geomorphological evolution and morpho-structural relationships between the outcropping lithotypes - through a great rainfall infiltration and an underground water flow - caused the formation of karstic surface and hypogean phenomena. Its geomorphological features are well-known being characterized by a series of plateau and ridge zones with a number of peaks at limited altitudes, however mainly representing rocky towers isolated by deep canyons. This area includes several karstic springs and is crossed by a few water courses, some of which flow underground; terraces landforms, flood plains and karstic depressions, swallow-holes and caves are found here. The study highlights the geological, environmental and cultural value of this site, that can be acknowledged as a geosite of Mediterranean importance, with respect to geomorphological risk scenarios. A strongly hazard reduction measurements in needed, in particular related to flash flood and sinkhole events that could involve the Roman bridges remains.

HISTORICAL POLYPHASED LANDSLIDES IN THE LOWER SARCA VALLEY (TN, ITALY). NEW STUDIES.

ALBERTI Silvio¹, FONTANARI Andrea¹, COLALTO Alessia¹, MARTIN Silvana¹, CAMPEDEL Paolo²

1 - Università degli Studi di Padova

2 - Servizio Geologico Provincia Autonoma di Trento

Presenter e-mail: alessia.colly@alice.it

Key terms: Marocche; Sarca; Roman relics; Neolithic remnants

Large landslides (up to 1000 x 106 m³ and 13 km²) occur in the lower Sarca glacial valley between the village of Sarche (altitude 249 m) to the North and the village of Dro (altitude 124 m) to the South, over 8 km in length in SW Trentino. This site is known as "Marocche" for the presence of several megaboulders of limestones and of the small lakes Cavedine and Solo, biotopes for pioneer plants as Phragmitetum Australis e Cladietum Marisci.

The landslide deposits, derived in order from Monte Casale (1634 m), Cima Granzoline (1549 m) and Monte Brento (1544 m), on the western side of the valley are cut across by the Sarca River.

This area was mapped by Trener in 1924, who distinguished 3 principal landslides and other 9 smaller, during the geological works for the construction of two galleries from the Cavedine dammed lake to the hydroelectric power of Fies. Some Roman relics ("frammenti di tegolo" sensu Trener 1924) were found during the excavation across the KAS landslide deposit at the progressive 92-101 from the northern entrance of one gallery. On the base of these findings Trener suggested a post roman age for the KAS landslide fallen from the Monte Brento eastern wall.

In the recent years Perna (1974; 1996; 1997) tried to date the "Marocche" landslide deposits using paleo-karst as rillen Karren (up to few cm), rinnen Karren (up to 10 cm in depth) and kamenitza, suggesting a post-Last Glacial Maximum age for the landslides.

Recently this area has been mapped by Bassetti (1997) who has distinguished only 6 different landslides. Behind this he has found neolithic (Bronze age, XII-IX b.C.) remnants at the top of Sant'Abbondio deposit, interpreted by the author as the oldest deposit of the lower Sarca Valley, confirming the possible historical time of the landslide events.

New structural and geomorphological maps are in preparation to improve the knowledge of deposit stratigraphy and of the tectonics.

Furthermore, new 36Cl exposure datings of carbonatic megaboulders (Dolomia Principale, Calcarei Grigi Formation, Scaglia Rossa) of different deposits are in progress.

THE CASTEL PIETRA LANDSLIDE. IS THIS THE LANDSLIDE EVENT MENTIONED BY DANTE ALIGHIERI IN THE DIVINA COMMEDIA (INFERNO, XII, 4-9)?

COLALTO Alessia¹, MARTIN Silvana¹, CAMPEDEL Paolo²

1 - Università degli Studi di Padova

2 - Servizio Geologico Provincia Autonoma di Trento

Presenter e-mail: alessia.colly@alice.it

Key terms: Castel Pietra; Finonchio; Cengio Rosso; S. Cecilia

The Castel Pietra landslide deposit is located between Trento and Rovereto, near Calliano village on the left side of the Adige River, between 400 and 200 m a.s.l.. The niche of detachment, at about 600 m a.s.l., is located on the western side of the Finonchio peak (1608 m a.s.l.), between Mount Padella (962 m a.s.l.) and Mount Coston (1200 m a.s.l.),

in the district of Vallagarina. The landslide occurs at the foot of the Cengio Rosso wall (900 m), near the hill of Castel Beseno. This body corresponds to that landslide mentioned by Dante Alighieri in the Divina Commedia. The landslide seems derived from a unique event, however a new mapping suggests the possible existence of previous deposits in the northern portion because of a very thick vegetation cover. The landslide is composed by mega-boulders of Dolomia Principale covered by abundant woods and vegetation.

The first Castel Pietra Castle was built on the XII century over a mega-boulder, afterwards it was implemented during the XIII and partly rebuilt during the XIV century. In front of its walls was fought the famous battle of Calliano in 1487, then in 1796 the castle itself and the Austrian troops faced the Napoleonic ones.

At about 750 m a.s.l. in the rocks below Cengio Rosso, in 1611 was built the Hermitage of S. Cecilia, where, according to the literature, people do a pilgrimage on the 5th of August. The date corresponds to that of the famous votive offering made by Rovereto inhabitants to Mary Help of Christians for saving them from the invasion of French devastating troops under General Vendôme in 1796. Other sources report, however, that this pilgrimage has nothing to do with the invasion, but that relates to the Summer drought.

The Cengio Rosso wall is characterized by the presence of a sub-horizontal discontinuity at about 500 m a.s.l. and by a sub-vertical N-trending discontinuity, as shown in the Schio 1:100.000 geological map, which facilitated the landslides.

At present the landslide deposit and the Cengio Rosso wall show new falls, since we can distinguish the new whitish dolomitic boulders from the oldest grey-coloured ones, and we can recognize their detachment area. New exposure data of the mega-boulders are in preparation to check the time of the older landslide events.

W9-5 Orale Del Lungo, Stefano

10.1474/Epitome.04.0005.Geoitalia2011

RECKLESS FOUNDATIONS, NATURAL DISASTERS OR DIVINE PUNISHMENT IN THE ITALIAN CULTURE IN THE 14TH CENTURY (THE STORM OR TSUNAMI OF AMALFI IN 1343). [FONDAZIONI INCAUTE, DISASTRI NATURALI O PUNIZIONE DIVINA NELLA CULTURA ITALIANA DEL XIV SECOLO (LA TEMPESTA O IL MAREMOTO DI AMALFI NEL 1343).]

DEL LUNGO Stefano¹
 1 - CNR-IBAM Potenza

Presenter e-mail: s.dellungo@ibam.cnr.it

Key terms: reckless foundations; natural disasters; divine punishment; 14th century; Amalfi

It is now evident what value could have a correct historical and topographical reconstruction of events in a real place and the solutions done by its inhabitants. This is very important to understand and define which type of disaster and damage degree has been or will be there. The Italian cultural heritage is directly involved every time a disaster happens like eruptions, earthquakes, landslides, floods, collapses. If there isn't a sure knowledge of its entities, that it has understood only during a crisis, it's possible to do some questions: if the event has caused so much damage to the monuments and to the whole of the city that contains them, is this the first time that it occurs or it's also happened in the past? If so, why it has been so far ignored? And, as a last resort, is it possible that in the past it has been so careless to choose a place then revealed dangerous or unstable?

An unpredictability event is represented by Monte Nuovo volcano (Phlegrean fields), which in 1538 borns and erases the town of Tripergole, although founded in a dangerous area. Human errors, on the other hand, could be summarized by the case of the Leaning Tower (Pisa), where a structure has been projected too heavy, in spite of the knowledge of the place and the ability to assess, however, the strength and with the consequences that everybody can see since today. Recent experience has also revealed critical condition of an hypothetical reckless, or else wrong, foundation: L'Aquila (in 1254) and the seismic activity between 1315 and 1462. A prior example was in Umbria: Carsulæ, in spite of the toponym should make clear the awareness for the dangers that could be hiding in the subsoil (and now Ischia, with 2,400 years from a violent tsunami). Amalfi has even a name whose etymology gets to a large and dangerous geographical area, where the rural heritage remembers us about disasters in pre- or proto-historical times, by its special and ancient vocabulary (from Melfa in Molfetta and the Vulture) that other following cultures have tried to fix in the landscape memory, to avoid, and therefore to consecrate, some harmful places (around the valley of the Ampsanto, for example).

In the 14th century ancient beliefs and superstitions resurge with arrogance in Italy, but not only, to focus on miraculous events already known by St. Francis (and his meeting with the wolf of Gubbio). It is a going back of the divine punishment idea whenever there is a phenomenon so big to go beyond the human understanding. But we know what it means when "the reason sleeping produces monsters". Think, for example, to the conflict between certain statements about the 2011 earthquake in Japan and the wisdom of the past, that had set the 'Stones of the Tsunami' (Aneyoshi, prefecture of Iwate). History, therefore expressed by written and oral sources (legends, traditions, rites and rituals), monuments and place names, which we must be able to find, read, understand and interpret, can serve to not remake the mistakes of the past. Focusing on the 14th century, it could be useful to proceed with an overview of the phenomena in chronicles and annals, going up the way followed in the medieval imagination (then the snake in Abruzzo and the places of dragon, trying to understand geological phenomena on the surface).

Fear and wonder are in the written sources, compared to a curious absence of any reference about practical works on coeval Statutes (L'Aquila, Amalfi), against the disasters that marked the local urban history. In Amalfi a terrible and however destructive phenomenon like a storm is magnified in the following centuries by the impression and economic interests more or less connected. Then it has been transformed into a tsunami, concluding his history as 'false event' in the Italian Tsunami Catalog now available online.

10.1474/Epitome.04.0006.Geoitalia2011

THE VAJONT DAM DISASTER AS A PARADIGM OF A BUILDING NATIONAL IDENTITY

DELLE ROSE Marco¹

1 - Consiglio Nazionale delle Ricerche - IBAM

Presenter e-mail: m.dellerose@ibam.cnr.it

Key terms: hydrogeological catastrophe; post-disaster policy; uncertainty

The Vajont dam disaster is a world-known case of man-made hydrogeological catastrophe. On 9 October 1963, an about 2 kmq rock mass, detached from a side of the Mount Toc (placed between Veneto and Friuli regions, Italy), sliding into an artificial dam lake. It moved laterally some 360 m, and 140 m upward on the opposite valley flank. The great part of the landslide moved as a whole, propagating water waves which eroded soils of Vajont valley up to 235 m above the reservoir level. The adjoining villages of Erto and Casso had been "touched lightly" by waves. Toward Pieve valley, water swept across the dam and down the Vajont Gorge, reaching an estimated wave height of 80 m. Inside the gorge, the water mass provoked air compression that, in turn, was energetically pushed out of the gorge mouth. The airflow energy has been evaluated to be about twice than that occurring at Hiroshima with the explosion of the atomic bomb. Then, the water wave reached the Pieve valley. Longarone and other villages (Pirago, Villanova, Rivalta, Faè) were destroyed and almost 2000 persons died and many others were injured. Notwithstanding the impressive development of energy, the Vajont dam remained undamaged. Two opposing interpretations have been proposed in literature: the disaster was completely foreseeable (see for instance: Roubault, Peut-on prévoir les catastrophes naturelles?, 1970) or, vice-versa, nobody would have been able to predict it (Selli and Trevisan, Caratteri e interpretazione della frana del Vajont, 1964; Semenza, Sintesi degli studi geologici sulla frana del Vajont dal 1959 al 1964, 1965).

According to current concepts of environmental policy and epistemology of geology, a review of both the decision making process which led to the disaster and the consequent post-disaster policy, are proposed. It can be argued that uncertainty about: (i) the depth of the slip surface (i.e. the volume of the landslide), (ii) the compactness of the slide (that involved a presumed division into two parts of the mass movement) and (iii) the low shear strength of the beds at the slip surface (and so a rate of the sliding higher than the predicted one), had been reduced at a time consistent with a change of management strategy oriented toward the safety people. The scientific debates which followed the disaster had influenced by State's interest, reaching a level of a true ideological conflict which reflected exasperated tensions growing inside the Society. The cultural context was that of a post-agricultural society commit oneself to build a new national identity. An identity of a rising industrial power. The post-disaster policy had biased data interpretation, data production, memory and scientific communication of experts and researchers. Dealing with the drawing of guidelines about environmental policy and hazards managements, can be useful to try to understand the reasons of such errors. A number of general features must be considered and, among these: the hydraulic paradigm and the idea of dominion of the nature, the hegemony of the ruling bloc and the making of a social justice concept, the historical conjuncture and the political practices. In 1976 Erto was denoted as "national monument" by virtue of its architectonic value. Nevertheless, the Vajont dam and its surrounding landscape, including the homonym gorge and the destroyed villages, currently represent, as a whole, the "intangible expressions" (cf. Vecco et al., A definition of cultural heritage: from the tangible to the intangible, 2010) of the human action which led to the disaster. They have acquired a preeminent socio-political value and, as a consequence, need to be known and protected. Moreover, the management of the interactions systems of Landscapes, Heritage and Culture (cf. e.g. Mascari et al., Landscapes, Heritage and Culture, 2009) must to be improved.

A GEOGRAPHICAL INFORMATION SYSTEM FOR THE SAFEGUARD OF THE ARCHITECTONIC AND ARCHAEOLOGICAL HERITAGE IN VAL D'AGRI (BASILICATA).

DELLI SANTI Maurizio¹

1 - CNR - IBAM, ITALIA

Presenter e-mail: m.dellisanti@ibam.cnr.it

Key terms: GIS; Cultural Heritage; Basilicata

The recovery and the electronic fruition of documentary material in architectonic heritage, the development of digital technology methodologies for cultural heritage and the use of new technological and informative systems are more and more diffused. The potential of these technologies for the planning and the subsequent management of information in cultural heritage fields is various and, above all, the digitalization of data is considered now an essential part in a course to heritage valorization. Particularly, among the new applied technologies the Geographical Information Systems, that come up as instruments for the control of territory and are so flexible that they can be applied in different research areas, are more and more frequent.

This work is part of a research project called "The safeguard of the territory and the conservation of cultural heritage in Basilicata in relation to landscape evolution and geo-morphological risk factors", that IBAM-CNR is carrying out in Val d'Agri.

Nineteen centers in the valley have been chosen to analyze and to catalogue their whole cultural heritage, that will be after implemented in a geodatabase, which is expressly structured following tab "A" criteria of ICCD. New fields to evaluate the seismic hazard for architectonic heritage have been added to this tab, specifically in reference to the damages of monuments during the Irpinia earthquake in 1980. Then the complete research will be available on a WEB-GIS portal of the IBAM-CNR. The final aim of the project is the definition of a "Risk Map" of the architectonic and archaeological heritage in Basilicata, as fundamental base for the planning of safeguard and conservation interventions for cultural heritage that is subjected to natural risks.

W9-8 Orale Galadini, Fabrizio

10.1474/Epitome.04.0008.Geoitalia2011

NATURAL RISKS AND ARCHAEOLOGICAL SITES IN THE ABRUZZI APENNINES (CENTRAL ITALY)

GALADINI Fabrizio¹, FALCUCCI Emanuela¹, GORI Stefano¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: stefano.gori@ingv.it

Key terms: natural risks; archaeological stratigraphy; geomorphological analyses; central Apennines

The regulatory framework and the documents produced by different institutions and associations (es. Icomos, Mibac, ARCO) related to the preservation of the cultural heritage stress in different ways ii) the need for precautionary measures and ii) the key-role of an appropriate historical knowledge of the various events (natural or anthropic) which affected the heritage. In practical terms, i) the actions for preservation cannot be performed without an estimation of the risks related to the natural environment and ii) the risk has to be assessed by defining the natural events which interfered with the site of interest. This means, for example, that a typical aspect of the utilization of the cultural heritage - the creation of in situ museums - has to be faced also in terms of feasibility within the framework of the natural/environmental dynamics. Referring to the above mentioned issues, the present note will describe some cases of archaeological sites in the Abruzzi Apennines, characterised by natural criticality evident in the archaeological stratigraphy and detectable in the local geomorphological framework. These aspects represent potential elements of territorial weakness and evident problems for the actions related to the preservation of the archaeological sites. Having this perspective, we will analyse the effects of i) an ancient earthquake at the archaeological site of Alba Fucens; ii) the toppling of limestone blocks at Luco dei Marsi (Angitia); iii) the colluvial and alluvial events at Alba Fucens, San Benedetto dei Marsi and Castel di Ieri. The characterization of these events produces information necessary to the action plan for the defense against natural catastrophes at those sites which are being transformed for cultural and tourist purposes or which are used in this perspective since several decades.

10.1474/Epitome.04.0009.Geoitalia2011

SAFEGUARDING THE HISTORICAL CENTRES EXPOSED TO HIGH SEISMIC HAZARD: CLUES FROM STRONG EARTHQUAKES OF THE PAST

GIZZI Fabrizio Terenzio¹, POTENZA Maria Rosaria¹, ZOTTA Cinzia¹

1 - IBAM-CNR

Presenter e-mail: f.gizzi@ibam.cnr.it

Key terms: cultural heritage; seismic risk; historical earthquake; written source

The analysis of the effects of recent earthquakes (es.: 1980 Italy, 1985 Mexico, 1994 Northridge) shows that the building damage can change strongly within short distances.

Scientific investigations have demonstrated that these effects are the consequence of the geological-geomorphological properties of the soil, that can cause seismic amplification phenomena, and/or of the vulnerability of the shaken buildings.

Even if the theoretical basis useful to explain these phenomena are quite recent, an overview of the sources regarding the main historical seismic events reveals that the influence of the territorial features on damage was known at least from the XVIII century (e.g.: Lallement (1785), Pilla (1846), Baratta (1910)). These works, that can be considered as a sort of rudimentary study of microzonation, indirectly raise the need of an a-priori approach in the evaluation of the seismic effects.

To identify in advance the areas where an increase of damage can be expected is the essence of the modern studies aimed to mitigate the seismic risk. This approach is crucial especially for Italian historical towns that are exposed to high seismic hazard and contain an invaluable and highly vulnerable cultural heritage.

From the point of view of the preventive approach, the in-depth analysis of the effects already experienced in the past by urban conglomeration is an important task to be pursued especially for recent-historical earthquakes for which the documents usually show high quality and completeness of the information, useful to delineate the patterns of damage in detail.

Macroseismic data play a key role in supporting the analysis of the local seismic response because they contribute to identify the geological/geophysical features of a site (e.g.: Guidoboni et al., 2003). Starting from these preliminary remarks, this contribution deals with the investigations performed about the damage suffered by several towns of the southern Italy hit by strong recent-historical earthquakes. The events considered are happened in the XX century: 23 July 1930 Iripinia (Me=6.7), 21 August 1962 Iripinia (Me=6.2), and 23 November 1980 Iripinia-Basilicata (Me=6.9).

For each town analysed are supplied maps reassuming the spatial relationship among the damage levels. These data will be part of the Atlas of the Italian Seismic Scenarios, a collection of damage maps for towns affected by strong earthquakes. This tool will be of usefulness for person acting in the fields of seismic risk evaluation and reduction.

A NEW SPATIAL STATISTIC METHOD IN LANDSLIDE SUSCEPTIBILITY ASSESSING FOR CULTURAL HERITAGE CONSERVATION

LAZZARI Maurizio¹, DANESE Maria¹

1 - CNR-IBAM C/da S. Loja Zona Industriale Tito Scalo (PZ) 85050

Presenter e-mail: m.lazzari@ibam.cnr.it

Key terms: Geostatistics; landslide susceptibility; cultural heritage; GIS; geomorphological risk

This work proposes the use of a new method for landslides susceptibility

assessing, by adopting a local spatial analysis approach, contrasting with bivariate statistical analysis (global) largely used in literature. To use spatial analysis to reconstruct hazard scenarios is surely an innovative instrument for territorial analysis, because it takes in count first and second order effects in spatial distribution of phenomena (in this case landslides) and so it allows to obtain more realistic informations.

The method in this way introduced has many practical implications on territories, such as in the field of Urban, Landslide and Emergency Planning and in the field of Cultural Heritage. In fact, it allows to identify with more precision, compared to global methods, areas with a priority of intervention for conservation. Moreover, it becomes possible to construct maps with areas hydrogeologically bonded for the study of natural hazard applied to heritage conservation, in particular when it is exposed to hazard with geological (seismic risk) or geological nature (landslides and floods). An important applied use of the cultural heritage risk map could be focused on the individuation of the intervention priorities (structural and economic) for the safeguard of the historical and architectonical buildings characterized by a high risk level respect to natural hazards occurring in such mountain areas.

GEOLOGICAL AND GEOMORPHOLOGICAL HAZARD IN HISTORICAL AND ARCHAEOLOGICAL SITES OF THE MEDITERRANEAN AREA: KNOWLEDGE, FORECASTING AN MITIGATION

LAZZARI Silvestro¹

1 - Cedat Europa - Centro Dati e Servizi per l'Ambiente e il Territorio - Via Ancona 37, 85100 Potenza - Italia

Presenter e-mail: cedateuropa@virgilio.it

Key terms: Hazard; Mediterranean areas; Urban centres; Archaeological sites

This work is part of a research programme promoted by the National Group for the Defence against Hydrogeological Catastrophes (CNR - G.N.D.C.I.) in order to evaluate the effects caused by high risk landslide movements in the historical-monumental urban centres. This work gives rather representative examples individualized in some regions of the Mediterranean sea (Italy, Greece, Spain, Crete, Albania), seats of important historical and archaeological settlements and structures, interested by a progressive degradation due either to structural or to natural causes (geological, geomorphological and seismic). It has been carried out an analysis of the geological and geomorphological conditioning factors and have been proposed the recovery solutions for the risk mitigation and preservation of the historical heritage, furnishing also useful technical elements for the conservation and protection of the historical heritage.

The experiences and researches produced by several authors, as Bonilla (1959), Sarma (1975), D'Elia (1983), Keefer (1984), Harp et al. (1986), Ishihara et al. (1986), Maugeri and Motta (1986), have shown in these areas a rather narrow relationship between earthquakes and mass movements, that occur in some typical climatic, geomorphological and geotechnic configurations.

The danger level increases when these phenomena are simultaneous in the same site, so that their knowledge represents a very important preventive measure.

From a preliminary picture, it's possible to point out a not casual coincidence between perimediterranean zones, where the landslide are more evident, and those ones where the seismic activity is more frequent and intense (Algerian Tell, centre-southern Apennine, southern-Dynaric and Hellenic belt, Aegean Arch and Anatolic belt). The most recent and incoherent clastic deposits of the Pliocene and of the Quaternary, filling in the Euro-Asiatic and African basins emerging, show a considerable propensity to instability. The slope dynamics turns out more active in particular rainy and geological-structural configurations. The deep morphogenetic phenomena are mobilized in consequence of high intensity rainy events which occurs in short-time periods of temperate-dry Mediterranean climates. The deposits more vulnerably are those prevalently clayey deposits subject to compressive and distensive stress, which have notably modified their structure and consistency. In the studied areas are very frequent either the erosional or the landslide phenomenon but there are also evidences of deep gravitative motions, involving whole slopes.

Historical and bibliographical notes and direct experiences have enabled to check that several mass movement have been induced or reactivated by high intensity earthquakes, characterising the whole mediterranean areas. In conclusion, it has been pointed out that the landslides and earthquakes have conditioned whole civilizations, which paid for natural calamity with a stop of the economic and social evolution and development with considerable and irrecoverable structural damage.

The mitigation measures could be represented either by right consolidation interventions or by preliminary studies of the physical environment and characteristics of the single structures.

Key terms: infrared thermography; GPR; Geophysics; Montella

In order to reconstruct architectural changes during the centuries often we are forced to trust merely on the evidences of documentary and iconographical sources which could sometimes supply the description of the monument or of a specifically building phase. Such approach does not solve all the questions related to the interpretation of historical data (graphics, descriptions) useful for finding previous configurations of the building.

The historical building structure and shape, as they appear at the present are often the final result of a stratification of different phases deeply connected with artistic and technological features of the age during which the building has been designed and realized. Stylistic features, building techniques and functional aspects change in time leaving often written traces in archive sources such as on the building masonry texture (sometimes hidden by plaster) or under the floor.

In such situation the Non Destructive Testing investigations by means of infrared thermography and GPR could be useful to characterize masonry, to survey inhomogeneities in the masonry as well as to detect buried walls belonging to ancient building phases.

This paper deals with the emblematic study case of San Francisco in Folloni convent near Montella in Southern Italy. Its complex vicissitudes experienced in last centuries have been the reason of radical transformations of the church and its surrounding buildings. Historical research has provided important information on structural interventions and planimetric transformations carried out between the 17th and 18th century, following also natural hazard events. Such data have been correlated with the results obtained by infrared thermography surveys on plastered facades of the convent and GPR profiles carried out under the stone paved floor of the church and cloister, thus improving the knowledge of historical building phases of the monument. The integrated use of building analysis techniques based on NDT techniques together with historical and archaeological records show the enormous potential of the use of this interdisciplinary approach.

Key terms: geohazard; archaeological areas; ERT; GPR; Palatine hill

A research project supported by the Government Commissioner for the archaeological areas of Rome and Ostia Antica and the Italian Civil Protection National Service (DPC) was carried out to evaluate the geohazard level affecting Palatine hill, Roman Forum, and Coliseum. The project was planned to achieve two main goals: (i) map the bottom surface of the anthropic covering, and characterize the archaeological layer susceptible to instability; (ii) characterize the geological bedrock in terms of geometries and of physical-mechanical properties.

The subsoil setting of the study area (less than 1 km²) was preliminarily defined by means of already available 200 geotechnical boreholes. By the way, a new drilling campaign was performed to better investigate the geological and archaeological layers of Palatine hill and surrounding areas. Twenty-five continuous coring vertical boreholes (total depth between 20 and 60 m) were drilled. All the boreholes crossed the anthropic layer, which ranges in thickness between 1 meter (at the hilltop) and 18 meters (along the slope and at the base of the rise). Several boreholes also crossed the network of tunnels dug in the tuff rocks underling the anthropic layer.

Lithological and stratigraphic logs of boreholes, integrated with information from local archaeological stratigraphy, allowed to strongly constrain (i) the bottom surface of the archaeological layer, and (ii) the boundaries between geological units. A geophysical survey was then planned (i) to extend correlations all along the study area, and (ii) to characterize internal variability of subsoil units.

Twenty-four ERT were performed at Palatine hill and Roman Forum. Resistivity field data were collected using different array configurations (Wenner-Schlumberger and Dipole-Dipole) and electrode spacing (from 1 to 10 m), obtaining different investigation depth (from about 8 to 80 m). In all cases, the resistivity values range from 10 to more than 1280 ohm.m. As regards the archaeological layer, in general, relatively high resistivity values (>400 ohm.m) are associated to voids and/or cemented conglomeratic walls, while low to moderate resistivity values (<400 ohm.m) are related to anthropic silty sandy backfill material.

With GPR method a high-resolution data acquisition technique was adopted to reconstruct a global image of five areas. For the measurements a 500 MHz bistatic antenna with constant offset, a 70 MHz monostatic antenna and a 35 MHz monostatic antenna, were employed. The horizontal spacing between parallel profiles at the site was 0.5 m, employing the 500 and 70 MHz antennas and 1 m employing the 35 MHz antenna. Some signal processing and representation techniques were used for data elaboration and interpretation. With the aim of obtaining a planimetric image of all possible anomalous bodies detected in the ground, the time-slice representation technique was applied using all field profiles. Amplitude of reflections recorded in the time-slices is mainly referable to the distribution of archaeological structures. High amplitude reflections are

referable to archaeological remains and, locally, to voids located in the anthropic layer. Low amplitude reflections can be related to the anthropic backfill and, in few cases, to the geological bedrock.

The main goals of the project were achieved at the end of the study. The application clearly demonstrates the potential for full integration of geological, geophysical, and archaeological methodologies in order to better characterize the geological and anthropic layers in archaeological areas. As a matter of fact, results show that: 1) both buried topography and internal complexity of the archaeological layer are detectable; 2) main boundary surfaces between geological units are laterally traceable; 3) presence of voids in the geological bedrock, locally crossed by boreholes and constrained by archaeological information, is presumable.

MAINTENANCE OF CULTURAL GEO-MINERALOGICAL HERITAGE

STOPPANI Francesco¹

1 - Italy

Presenter e-mail: voronovitch@hotmail.fr

Key terms: safeguard; heritage; legislation; mineralogical; collection

Summary of the arguments:

1) Geological risks and anthropological risks (definitions and characteristic features).

2) Cultural heritage (definitions and characteristic features).

3) Safeguard of cultural heritage, legal instruments. Safeguard used as protection and valorization. The notion of cultural property as constituent of the cultural heritage.

Cultural properties according to the D.Lgs.n.42/2004 -"Codice dei beni culturali". Landscape plans. Cultural and anthropic heritage and natural cultural heritage. Cultural geo-mineralogical heritage.

4) The D.Lgs.n.42/2004 "Codice dei beni culturali" - artt.1,2,3,6,7,8, 10 lett.h),12,13 and 15.Art.136-1°co.lett.a) and all.ti A- punto 13 lett.a) and B punto 13. Analysis and commentary on the reference to "mining sites of historical or ethno-anthropological interest". Analysis and commentary on the reference to "geological singularity". Analysis, criticism and commentary of the definition of "collections and specimens from zoological, botanical, mineralogical or anatomical collections" and its consequences.

5) The differences between "mineralogical " and "mining", as set out legally for the first time in the sentence n.1108 of the Constitutional Court 12-20/12/1988 given on the conflict for the allocation of powers between the Lombardy Region and the State, about the former L.R. n2/1989 ex art.117 of the Constitution and D.P.R. n.616/77. Analysis of the relevant parts of the sentence. Impact on legislation. Regional laws.

6) Parks and nature reserves, as means of protection and increase of the value of natural and cultural heritage. Examples of Gran Paradiso, Adamello, Veglia and Devero, Sardinia, the island of Vulcano, Vesuvius and the Island of Elba. Instituting and implementing rules. Comparison, in particular, concerning mineralogical sampling with collecting and scientific purposes.

Relationship with artt.9 and 33 of the Constitution.

7) Mines and quarries. Existing legislation. State and regional powers. The L.n. 42/2009 ("federal state property") and the implementing D.Lgs n.85/2010. Right given to provinces to receive free of charge abandoned mines in their heritage under state jurisdiction. Hypothesis for valorization.

8) Mineral professional and amateur collecting. Respective roles and synergies. Results obtained. Meaning in the context of cultural heritage. Possible definition of "natural cultural property". Need and function. Definition of "collection" according to the E.U. Definition of "mineral for collection" and "mineralogy collection". Lack in the Italian legal system. Needs.

9) Legislative hypothesis for a "sustainable" mineralogy. Please note that if deemed of interest, a more detailed and exhaustive text on the topics covered can be provided.

MITIGATION OF URBAN VULNERABILITY THROUGH A SPATIAL MULTICRITERIA APPROACH

TILIO Lucia¹, MURGANTE Beniamino¹, DI TRANI Francesco¹, VONA Marco¹
1 - UNIVERSITA' DEGLI STUDI DELLA BASILICATA

Presenter e-mail: lucia.tilio@unibas.it

Key terms: Resilient cities; Seismic Risk; Seismic Vulnerability; Urban Vulnerability; Spatial Multicriteria Analysis

Seismic risk management is generally carried out through strategies aiming to reduce building seismic vulnerability, working on structural features, and not considering that the concept of vulnerability can be adopted also referring to the whole urban system.

Therefore, at least in Italy, it has been highlighted that civil defense manages all activities of prevention and protection, lacking of a good dialogue with other institutions. Municipalities should adopt an Emergency Plan, in order to define actions to be undertaken after a disaster event, but not considering actions in peace time. Finally, seismic risk is not considered so crucial to influence development strategies and policies. Since cities are complex systems, where physical environment, society and government activities interact each other, and where global functioning depends on functioning of each element of the system, as in a network, where each node contributes to global system, seismic risk prevention should be treated at urban scale, introducing the concept of resilience, as the capacity of a system to adapt itself to new, generally negative conditions, in order to re-establish normal conditions. Therefore, when an earthquake occurs, and cities are subjected to several kinds of damage, beyond structural ones, and affecting activities carrying out, normal conditions must be re-established as soon as possible.

In the beginning, resilience concept has been developed in the field of ecology, as the property of a system that measures its ability to absorb changes and to return to an equilibrium state after temporary disturbance; in the last years, resilience has become a usual term in the field of risk management, so that also the International Strategy for Disaster Reduction, Hyogo Framework for Action 2005-2015, not casually called "building the resilience of nations and communities to disasters", adopted the concept as a property of a community or a society, and affirmed that it is the capacity to adapt by resisting or changing, in order to reach and maintain an acceptable level of functioning and structure, and that it is strictly related to the capacity of a social system of

organizing itself, learning from past disasters.

According to the goal of managing seismic risk reducing urban vulnerability, it is strategic to identify in peace time (before disastrous events) which elements, which activities, which functions of a city have prior importance after the event, to guarantee a rapid response and the reestablishment of normal conditions: this means identifying resilient city. This new approach should recognize that single components work as a whole system: such components, that are not only physical ones (such as buildings and streets), but that refer to social, economic and political functions, strongly contribute to urban seismic vulnerability. Reducing urban vulnerability, therefore, means maximizing system resilience. This research aims to define a methodological approach to identify resilient city, adopting spatial multicriteria techniques, and establishing resilient system identification considering functional, social, morphological, geological and dimensional characteristics of the considered urban system. In particular, some tests have been carried out on several towns in Basilicata Region (southern Italy), considering a first set of criteria including accessibility, closeness to urban centres and main facilities, closeness to hydrographical networks, slope, map of seismic hazard, areas at high hydro-geological risk, and seismic vulnerability of buildings. Multicriteria analysis has been led adopting an additive rule, based on a simple additive weighting method.

THE LOVIGNANAZ CU-FE SULPHIDE MINE: SAFEGUARD OF A PRE-ROMAN MINING SITE

TOFFOLO Luca¹, MARTIN Silvana¹, GIANOTTI Franco², GODARD Gaston³

1 - Università degli Studi di Padova

2 - Univeristà degli Studi di Torino

3 - Univ. Paris-Diderot, IPGP, 1 rue Jussieu, Paris, France

Presenter e-mail: toffolo@inwind.it

Key terms: Lovignanz; Fe-Cu mine; Clavalité

The antique Lovignanz mine (also known as Molina mine) is located in the western side of the Clavalité valley (1350-1425 m a.s.l.), to the South of the Fénis village, in the southern side of the Aosta Valley (Italy). The mine galleries are developed within chloriteschists, talcschists and metagabbros transposed with calcschists belonging to the Piedmont nappe (Zermatt-Saas zone). The rocks hosting the Fe-Cu sulphide mineralization show blueschist to eclogite facies mineral associations like those studied in Saint-Marcel rocks (Martin *et al.*, 2008, and ref. therein). The mineralization is characterized by disseminated chalcocite and pyrite associated with minor ilmenite, rutile, pyrrhotite and magnetite (*Fénis. Une communauté au fil de l'histoire*, 2000 and ref. therein). The oldest galleries were dug with techniques described by Agricola in *De Re Metallica* (1556) and have been attributed to the Romans. These techniques consist in excavation along mineralized layers after "fire-setting", that is after weakening the rocks with a fire (*De Re Metallica*, book V).

Other galleries have been excavated with more recent techniques, revealing the use of explosives, and have been attributed to XVIII-XIX centuries mining activity (Gerboire E. E., *in: Fénis... op. cit.*). The remnants of a furnace for rock-roasting have been found along the right side of the Clavalité river (lat. N 45° 41' 46"; long. E 7° 29' 51"). In the same site, slags with charcoal and red burnt soil, probably related to an old activity, were observed during the field work. Several glassy slags, maybe produced during XVIII-XIX centuries mining activity, were found below a large landslide that partly covers the mine adits. Near the oldest mine entrances traces of old working instrument have been found.

These mines were also used to extract millstones: few metres from the mine entrances in the Mouilè locality (*Fénis... op. cit.*), some of these stones are still unexcavated on the rock walls. In the lower part of the valley, in correspondence of Miserègne village (*Fénis*), there is a dump where many large slags with charcoal fragments are piled up. Some of these fragments were analyzed with 14C method and one of them has been dated to IV century B.C.. This age is the oldest found for charcoal associated to slags of the Cu mines in the Aosta Valley. Other slags from the Saint Marcel valley yielded early medieval ages (Tumiati *et al.*, 2005).

The Lovignanz mining site has been destroyed by landslide events, the last one having occurred in 2000, which partly covered mine entrances and other structures linked to mining activity. The presence of structural lineaments and the practice of "fire-setting" during mining activity may have contributed to trigger the landslide.

Storia e archeologia per la Scienza della Terra

W12-17 Orale Bottari, Carla

10.1474/Epitome.04.0017.Geoitalia2011

THE ABANDONMENT OF THE ARCHAEOLOGICAL SITE OF CARSULAE (TIBER BASIN- CENTRAL ITALY): GEOARCHAEOLOGICAL EVIDENCE AND POSSIBLE CAUSES.

BOTTARI Carla¹, SEPE Vincenzo¹, URBINI Stefano¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: carla.bottari@ingv.it

Key terms: geoarchaeology; dolines; ground water circulation; Roman ruins; Carsulae

The Roman town of Carsulae rises along the Consular Flaminia road, built between 220 and 219 BC by the Censor Caius Flaminius the Older. It was 295 km long and was built in order to connect Rome with the Umbria region and the Adriatic coast. Moreover, it had also a strategic and military value and it was well-known as a safe and treated road.

The archaeological site of Carsulae is located on a wide travertine deposit (early Pleistocene- middle Pleistocene) at the bottom of the Martani Ridge at about 440 m a.s.l., north of the Terni tectonic basin (Tiber Basin). The Ridge is made up of Mesozoic and Cenozoic limestone and forms an important and wealthy hydrographic basin that feeds many springs along the piedmont area; the most important one is the San Gemini that is placed near the ancient Roman town, well-known since ancient times. In fact, the importance of Carsulae, mentioned by different historical sources, is related to its strategic geographic position along the Flaminia road characterized by local healthy waters and fertile soil.

Historical sources attributed the decline and the abandonment of Carsulae mainly to the construction of the eastern tract of the Flaminia road. Recently, some scholars debated about the possibility that Carsulae decline was caused by occurrence of strong seismic events which produced the collapse and the deformation of archaeological remains with consequent abandonment of the site.

A preliminary geomorphologic survey, performed on the archaeological site and its surroundings, and the interpretation of aerial photographs revealed the presence of some dolines even of great extension. Of them, one of the largest has been found under the Roman theatre and amphitheatre, a smaller one has been located north of the decumanus which collapsing caused the deformation and the sliding of the Consular road.

Among other possible causes (such as geopolitical context, landslides, earthquakes, etc.), that brought to site abandonment, a sudden change in the ground water circulation could be considered a trustworthy hypothesis. In the course of centuries, it is quite likely that the presence of dolines and the progressive travertine dissolution strongly affected the hydrogeological setting with consequent variation of the water table depth. As a consequence, probably in Late Roman times, a progressive reduction of water supplying to the site's springs led to a gradual decline and depopulation of the Carsulae town.

THE CATALOGUING OF THE GAETANO PONTE PHOTOGRAPHIC FUND (1876-1955): THE ERUPTIVE AND MORPHOLOGICAL HISTORY OF ETNA AND STROMBOLI RECONSTRUCTED THROUGH PHOTOGRAPHY

BONACCORSO Alessandro¹, BRANCA Stefano¹, GOTI Oriana²

1 - Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Etno

2 - Comune di Prato - Archivio Fotografico Toscano

Presenter e-mail: stefano.branca@ct.ingv.it

Key terms: Gaetano Ponte; data base; historic photography; Etna; Stromboli

Gaetano Ponte (1876-1955), professor of volcanology at the University of Catania from 1919 to 1951, represents a figure of remarkable scientific and cultural importance in the world-wide panorama of Earth sciences studies. The ideas and results of the scientific researches conducted by Gaetano Ponte are well-known through his immense scientific production; less renowned instead is his photographic legacy made up of more than 2500 images, taken from the end of 1800 until 1950. This valuable photographic collection, that represents a unique heritage of historical documentation of the activity of active Sicilian volcanoes, has been recovered and enhanced by collaboration between the Archivio Fotografico Toscano and the ING-V-Osservatorio Etno, to then compile an on-line digital catalogue. The images have been acquired digitally and catalogued following the ICCD standard and thanks to the complementary quality and rigour of both the photographic and volcanological scientific interventions. The computerised catalogue integrated with images and volcanological data has considerable added value that is very rarely found in photographic catalogues, above all when comprising images of a scientific character. Altogether, the overwhelming majority of the images that constitute the fund's data base

(<http://fondoeponte.aft.it/fondoeponte/temi.jsp>) mainly refer to the various aspects of Etna volcano and secondly of the Aeolian Islands. In particular, regarding the images taken on Etna, the lateral eruptions occurring during the first half of the 20th century are documented, beginning with the short eruption of 1908 till the major eruption of 1950-51, comprising the dramatic images of the destruction of Mascali during the eruption of 1928. This eruption represents the only eruptive event after that of 1669 to cause the destruction of an inhabited centre. The development of the lava field is documented with photographs, shots from the ground and from overflights, that show the last moments of the existence of the village of Mascali and the destruction of the main communication routes of Etna's eastern flank. Furthermore, the fund's images document the spectacular eruptive activity of Etna's summit craters and its main morphologic changes. Indeed, the summit of the volcano crater until the beginnings of the 20th century was made up of a large single crater, called the Central Crater. On 27 May 1911, a large pit crater was formed on the NE slope of the terminal cone of Etna at a height of approximately 3100 m. This crater, named the NE Crater, when formed was approximately 100 m wide and 80 m deep and soon became the location of important eruptive phenomena, of a particularly explosive nature, such as the lava fountain event on the night of June 24, 1917. The numerous photographs, taken both from the ground as well as from above during pioneering overflights specifically commissioned by Ponte, illustrate with great detail and beauty the eruptive activity of the NE Crater and its morphologic evolution. They show the gradual growth of a volcanic cone inside the crater depression during the first half of the 20th century, and likewise, the variable explosive activity of the Central Crater that in this long period was characterized by periods of Strombolian activity and lava fountains and by a subplinian episode occurring on March 16, 1940.

The monitoring activities organized by Gaetano Ponte comprised, besides Etna, the study and volcanological observations of the volcanoes of the Aeolian Islands, particularly Stromboli and secondarily Vulcano. In particular Stromboli, during the first half of the 20th century, apart from the common Strombolian activity from the summit craters, was affected by numerous paroxysmal events that are documented in the photographic fund. Among these were the events occurring in January 1907, June 1916 and May 1919, where severe damage to housing is highlighted.

EXTREME NATURAL EVENTS DURING THE EARLY ROMAN REPUBLICAN PERIOD: LAND'S HYDROGEOLOGICAL SAFEGUARD IN THE NERA-VELINO RIVER BASIN.

CAMERIERI Paolo¹, MATTIOLI Tommaso¹
1 - REGIONE UMBRIA

Presenter e-mail: pcamerieri@regione.umbria.it

Key terms: centuriation; hydrological hazard; drainage; flood; nera-velino rivers basin

This paper presents the results of an interdisciplinary study on the drainage of damp and humid areas, the control of surface water, the centuriation, the road system and the land reclamation operated in the plain of Rieti by the roman consul Manius Curius Dentatus during the conquest of the Sabina region in the third century BC. This research brings more awareness to consider the work of 'Gromatici Veteres' as an inseparable unity of various processes concerning the agrarian organization and the prevention of natural disasters like the flood of the Nera-Velino rivers basin. Some parallels could be established between the cases of Rieti, Pianura Pontina and the latin colony of Spolietum. This study could bring us to a better and deeper understanding of the contribution of historical and topographical analysis about the impact of extreme natural events during the early roman republican period.

Presenter e-mail: elena.cubellis@ov.ingv.it

Key terms: Eruptions; Earthquakes; Floods; Archaeology; Bay of Naples

The Neapolitan region for its geological history is an excellent laboratory for testing the validation of new paradigms for the natural phenomena. The geological structure of the Neapolitan area is formed by the succession of effusive and explosive rocks as lavas and pyroclastic products erupted by polygenic and monogenic volcanoes. Moreover this area is characterized by shallow seismicity capable to produce high intensity in small epicentre areas. The succession of rock layers, with different permeability, promotes, during heavy rainfall, the formation of devastating landslides and debris avalanches. Eruptions, earthquakes, flooding, occurred in the Neapolitan area, have produced myths, legends, historical documents, archaeological findings and results of recent surveys.

When the historical data are poor, to enlarge the time series of events for a deeper knowledge of the natural history of investigated sites, it is common practice to spread to research on earthquakes, tsunamis, eruptions, floods through historical times by analyzing documentary fonts and relics left by ancient peoples.

The name Campi Flegrei (Fields of fire) of the district between the town of Naples with its western suburbs and the Tyrrhenian coastline suggests that manifestations of volcanism were evident in Ancient Times. This area was once a preferred location to the entrance to Hades. It is caldera complex, formed by collapse of the ground following two giant eruptions; the landward floor is peak marked by tens of volcanic cones. Campi Flegrei attracted special attention during the nineteenth century, thanks to the Serapeo, ruined roman market in Pozzuoli, which had been submerged by and then re-emerged from the sea, due to slowly sinking and rising of the land (Bradyseism).

Vesuvius has acted like a powerful magnet from time immemorial, drawing people to settle on the fertile soils (Bronze Age), to wonder at the beauty of the landscape as tourists, or to undertake scientific investigations. Its most famous eruption is that of A.D. 79, responsible for the destruction of Pompei and Herculaneum. The earlier observations and interpretation of its activity were often influenced by religious beliefs. In eighteenth - and nineteenth - century a wide range of visual images of Vesuvius were produced to satisfy a diverse market of art collectors, tourists and scientists. The images of Vesuvius produced in this period owed much the artistic conventions of topographical and picturesque views and many of these images simultaneously served the needs of art, science and tourism. The publications which had the most profound influence on visual and verbal records of Vesuvius and Campi Flegrei in the eighteenth and early nineteenth centuries was Sir William Hamilton's "Campi Phlegraei" 1776-1779.

The island of Ischia was the site of the earliest known Greek settlement in Italy. In the fourth century BC a violent cataclysm is reported which drove away the first Greek peoples. Pliny the Elder, in his Naturalis Historia writes that on the island of Ischia, the earth swallowed up a town and that after this catastrophe a lake was formed (Lago del Bagno?). This eruption was dated by the sixth and fifth century BC pottery remains.

About historical seismicity more comprehensive accounts are available for Ischia island since 1228. There is an exhaustive literature related to the 1881 and 1883 earthquakes of Ischia, pointing out to the relationship between seismicity and the volcanic history of the island.

On September 1854, under the initiative of the Bourbon Ferdinand II (1830-1859), King of the Two Sicilies, the opening of the new harbour of Ischia was celebrated. The technicians cut the isthmus to join the lake (Lago del Bagno) with the sea as in the nearby Campi Flegrei, where Lucius Coceius Auctus in 37 BC, cut the isthmuses separating the Lucrine Lake from the sea and from Lake Avernus to build Portus Iulius for the Roman fleet.

SYNTHESIS, STABILITY AND STRUCTURAL CHARACTERIZATION OF A COMPOSITE Palygorskite/Methyl Red "Mayan" Pigment

GIUSTETTO Roberto¹, SEENIVASAN Kalaivani², PELLERRE Diego², RICCHIARDI Gabriele², BORDIGA Silvia²

1 - University of Turin, Dip. Sc. Min. Petr. - NIS Centre of Excellence

2 - University of Turin, Dip. IFM - NIS Centre of Excellence

Presenter e-mail: roberto.giustetto@unito.it

Key terms: palygorskite; acid Red 2 (methyl red); dye encapsulation; dye stabilization; Maya Red pigment

It is well known that palygorskite and sepiolite clay minerals, mixed and moderately heated (< 200°C) with the indigo dye, form the extraordinarily stable Maya Blue, an ancient blue pigment used by Mayas in Pre-Columbian America (VI-XV century a.D.). Maya Blue can be considered an ancestor of modern nanocomposite materials as the guest indigo molecule is encapsulated and bound within the narrow micro-tunnels crossing these clays structure, thus being adequately sheltered and protected from external agents. Analogous compounds, granted by the same exceptional stability but showing different chromatic hues, could possibly be produced through diffusion and fixation of other dyes in the same microporous matrices.

A stable, red-purplish host/guest composite was obtained by grinding and heating (140°C for several hours) palygorskite with 2 wt% acid Red 2 (methyl red). Such a compound proved to possess the very same chemical stability of original Maya Blue, as neither its colour nor its structure undergo any significant variation in spite of severe chemical attacks with both acid or alkali agents.

The structural features of the palygorskite + methyl red (2 wt%) composite, as well as the supramolecular host/guest interactions responsible for the compound stability, were investigated by means of several techniques such as UV-vis and FTIR spectroscopies (both in air and controlled environmental conditions), XRPD and TGA analysis. Experimental evidences proved that the heating treatment applied during the composite preparation causes loss of the zeolitic H₂O fraction, thus allowing diffusion of methyl red molecules inside the palygorskite micro-tunnels.

The encapsulated molecules, in the form of specific zwitterionic tautomers, tend to bind with the clay matrix by means of several interactions including H-bonding to Mg-coordinated OH₂ and possibly Coulombic attractive forces. Presence of methyl red as different zwitterions is consistent with adsorption on an electrostatic unbalanced hosting matrix such as the palygorskite framework. Encapsulation and bonding inside the clay micro-tunnels stabilize the azo dye molecules, sheltering them from external environment and preventing both deterioration and/or colour changes. Fixation in the inorganic matrix, in addition, enhances both resistance to solar/UV-A irradiation and stability at increasing temperatures of the clay-solvated methyl red molecules if compared to the pristine dye.

This innovative palygorskite + methyl red (2 wt%) composite is therefore reputed to be fit for use as a stable, economical and environment-friendly (due to absence of heavy metals) "Maya Red" pigment. The hosting matrix of palygorskite was so far used, due to its structural strength, but the possible use of sepiolite offers further fascinating perspectives for the sorption of different guest dyes. Presence of wider micro-tunnels in sepiolite (10.6 Å), despite reducing the composite stability, could allow encapsulation of bigger molecules unfit to diffuse inside the narrower palygorskite pores (6.7 Å).

CONTRIBUTE TO A SCIENTIFIC APPROACH ON LANDSCAPE ARCHAEOLOGY STUDIES: THE CASE OF TENERIFE ISLAND (CANARY ARCHIPELAGO, SPAIN)

PANNACCIONE APA Maria Ilaria¹, BUONGIORNO Maria Fabrizia¹

1 - Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy

Presenter e-mail: mariailaria.pannaccioneapa@ingv.it

Key terms: Landscape archaeology; Tenerife; Guanche; Volcanic activity

Generally, the landscape archaeology is important to suggest that environment played a key role for the establishment of permanent settlements, as well as the archaeological sites can provide information about the ancient landscape.

The example of the prehistoric colonization of Tenerife island by the Guanche culture is an interesting case of a balanced ecological relationship between landscape and hunter-gatherer groups.

The almost complete lack of technology was supplemented by know-how and land use without apparent landscape remodeling.

The island of Tenerife date his genesis between 12 and 11 million years ago [Carracedo, 2006]. This large triangular island is composed of a complex of overlapping Miocene-to-Quaternary stratovolcanoes that have remained active into historical time.

The soil of volcanic origin also gave rise to very fertile soils, which permeability allowed the constant supply of natural water, producing the basis for the establishment of permanent settlements of Guanche groups proceeding from Lanzarote and Fuerteventura which probably colonized Tenerife around the IX century B.C.

The social structure was chiefdom based, poor on technology, strongly related to natural resources and implemented by a hunting-fishing-gathering and sheep-farming economy.

This social primary structure appears to be a successful pattern facing the constant volcanic activity.

The lands most exposed to natural hazards were quite populated. There was a total adaptation to the landscape, which was confirmed by the high percentage of settlements in ancient volcanic tubes adapted to the community needs.

THE MESSINA STRAITS TSUNAMIS: FROM THE HISTORICAL TEXTS TO THE OPEN QUESTIONS

TORRE Rosario¹, AVERSA Mario²

1 - Università degli Studi di Messina

2 - ISPRA

Presenter e-mail: torre.rosario@libero.it

Key terms: Analysis of Historical Texts; Straits of Messina, Southern Italy; Tsunami Hazard

Due to its complex geological structure and peculiar position between the Ionian and Tyrrhenian basins, the Straits of Messina in southern Italy was historically affected by several moderate tsunami events, often invisible to the people, whose anthropic activities were not influenced.

Several authors have tried to reconstruct and analyze the phenomena that have been registered in this area.

Studies have mainly focused on the two events generated by the earthquakes on February 5 and 6, 1783 and December 28, 1908.

A thorough analysis of historical literature provides an outline of the scope of different importance, in terms of numbers and intensity, of the recorded events both in the Straits of Messina and in the surrounding areas. This objective evidence continues to testify the geodynamic evolution of the Straits of Messina.

It is important to point out that the cause of tsunami phenomena is not attributable only to the tectonic activity of the Straits, but also to other tsunamigenic areas, such as the submerged area of Etna, the Aeolian volcanic Arc, the Hyblean-Maltese escarpment, and to remote areas of the Aegean Sea and the Central and Eastern Mediterranean Basin. Gravitational collapse and volcanic Tyrrhenian Seamount areas can be also included.

To date the tsunami hazard related to the earthquake or marine and submarine landslide in the Messina Straits remains an open question. From the analysis of old texts it is very difficult to focus on these types of phenomena.

For the known event of 1908, the catastrophic effects of which have well been documented and illustrated by a rich literature and record, there are value parameters of magnitude, epicenter and seismogenic fault for the earthquake, and other valuable parameters for the tsunami waves, despite a lack of instrumental data.

This work provides an overview on the current understanding of the cyclic occurrence of this physical phenomenon. On the basis of the extensive historical information on this theme, the research also contributes to assessing both the results of coastal and oceanographic data and the indications carried out by the most significant documentary texts through a correct interpretation of them.

The loss of so-called historical memory of old events is a serious and irremediable risk factor, for the populations of the affected areas.

The catastrophic effects of the recent tsunamis on December, 26 2004 in the Indian Ocean and on March, 11 2011 in Japan, considerably higher in energy than old Mediterranean tsunamis, are further evidence for this underrated natural risk.

CLIMATE CHANGE IN THE ALPS AND FUTURE WATER RESOURCES: A CASE STUDY

BOCCHIOLA Daniele¹

1 - Politecnico di Milano

Presenter e-mail: daniele.bocchiola@polimi.it

Key terms: climate change; Alpine catchments; water management

Global warming is affecting the climate of mountain areas in temperate regions and the water resource distribution therein. Within the European Alps thermal shift since the 1980s, albeit synchronous with global warming, seems at least twice as much as the global climate signal, leading to substantially unchanged precipitation, but with a marked decrease of snowfall, and modification of the hydrological cycle therein. Southern, i.e. Italian, Alps display considerable sensitivity to climate change according to recent studies. Expected hydrological changes within Alpine catchments include modified average in channel discharge, as well as modified incidence of extreme events, either low flows or flood flows, thus impacting water management strategies in the lowlands, as needed for agricultural, and flood mitigation purposes. As a case study of modified hydrological cycle falling out into modified water resources management within the Italian Alps, I investigate here how to re-operate the

multipurpose Lake Iseo, fed by the Oglio (1800 km²) Alpine watershed, to cope with prospective climate change in the area. Future precipitation and temperature (A2 storyline, 2045-2054) from some GCMs available within the IPCC's data base are chosen for the purpose based upon previous studies. The downscaled fields are then fed to a minimal hydrological model to build future hydrological scenarios.

To illustrate the effect of modified hydrological cycle upon water resources management I use the obtained scenarios as boundary conditions for management of Iseo lake, by way of multipurpose management strategies, and special emphasis upon i) lake floods, ii) crop yield, and iii) ecological flows. Results indicate that possible changes of the hydrological regimes fallout considerably upon water management, and exasperate conflict between multiple uses of water. Adaptation strategies are only partially suitable without specific modification of water demand in time.

EVOLUTION OF TEMPERATURE EXTREMES IN A WARMING CLIMATE

SIMOLO Claudia¹, BRUNETTI Michele¹, MAUGERI Maurizio², NANNI Teresa¹

1 - ISAC-CNR

2 - Dipartimento di Fisica Università degli Studi di Milano

Presenter e-mail: m.brunetti@isac.cnr.it

Key terms: extreme events; daily temperatures; Europe; probability density function

Changes in the variability and the distributional shape of daily temperatures are expected to play a prominent role in explaining the enhanced occurrence of extremely warm events, either on a global or local scale. Variations in the probabilities of warm and cold extremes, indeed, may result from non-trivial variations in the underlying temperature distribution, e.g. the interplay between a simple shift in the mean and more complicated changes in scale or shape. In this context, we investigate variations of daily maximum (TX) and minimum (TN) temperature over Europe during the last half century, with the aim of identifying the nature of changes in the probability density functions and the probability of moderate extremes, induced by a warming climate. Detailed comparison with observations over the past decades puts forward the dominant role of the mean in explaining exceptionally hot events, and rules out contributions from potential changes in variability and higher distributional moments. The key strength of the present approach is its ability to relate isolated, severe events to long-term trends in a statistically meaningful manner, enabling present and future evolution of

temperature extremes to be reliably estimated on the basis of average distributional properties of temperature anomalies.

10.1474/Epitome.04.0026.Geoitalia2011

PRECIPITATION DATA DOWNSCALING AT LOCAL SCALE AND THEIR VERIFICATION OVER THE VALLE D'AOSTA

DEMATTEIS Niccolo¹, CASSARDO Claudio¹, FILIPPI Maria Letizia²,

MURGESE Davide², DEMATTEIS Antonio²

1 - Università di Torino, dipartimento di fisica generale

2 - SEA Consulting

Presenter e-mail: nicodema@gmail.com

Key terms: statistical downscaling; climate change; regional model

The first part of the study was focused on the analysis of the global climate model projections included in the IV IPCC assessment report and regional climate model projections for Europe from specific projects such as PRUDENCE and ENSAMBLES.

A feature common to all projections is a global increase of the average temperature, larger over the Alpine region, and a variation of the precipitation quantity and spatial distribution. Furthermore, analyses performed by means of regional climate models (RCM) for the Alps sectors outline a double pattern for precipitation levels: in the northern sector, models forecast an increase in precipitation levels, whereas for the southern sectors precipitation will decrease. The limit between these sectors is expected to move during the year: over the Alps, in winter, and over the central Europe, in summer. Such pattern seems to indicate that, for the future climate at local scale, the Italian Alps will experience a general increase in temperature and a small increase (drastic reduction) of precipitation in winter (in summer).

These changes, combined together, result in an increase in rainfall (also during the cold season) and evapotranspiration. Also, melting of the snow cover is expected to occur one month earlier than at present.

As a consequence, it is possible to expect in the future climate an increment of flooding risk, due to the approaching of melting snow period with the peak of spring precipitation, and of drought risk, because of the diminution of precipitation and the evapotranspiration increase.

Therefore, the study about extreme events and related hydro-geological phenomena, whose frequency and magnitude are projected to increase, deserve a paramount importance.

To optimize this kind of analysis, it is necessary to consider that the definition of precipitation change shows less agreement than temperature predictions, due to its higher interannual variability, and the same consideration can be extended to extreme events versus average values. This fact does not surprise, especially considering the difficulty to represent phenomena that occur at smaller scales than those used in global climate models (GCM), such as those which are responsible for intense rainfall.

Presenter e-mail: g.fioraso@csg.to.cnr.it

Key terms: Little Ice Age; Geomorphological map; Glacier inventory; Western Alps

The aim of this study is the localization and characterization of glacial and periglacial areas of the Little Ice Age of the Piedmont's Alps (Cuneo and Torino provinces), with the aim of identifying typology and location of geomorphological hazardous processes. 85 glaciers, listed in the 1959's national glacier inventory (Catasto dei Ghiacciai Italiani of the Glaciological Italian Committee), have been considered.

By means of aerial photogrammetry, integrated by field surveys, detailed geomorphological maps (1:10000 scale) have been realised. Main geomorphological landforms and active processes, typical of glacial areas, have been represented, with special regard to instability phenomena and glaciers snout fluctuations. A particular attention has been given to glacial lakes, which formation and evolution are very important for hazard assessment.

Aerial photo interpretation, jointly with field surveys and historical documents' analysis, allowed a multitemporal reconstruction of glaciers area, length and width variations from Little Ice Age until now, debris and rock surface ratio variations, localization and evolution in time of instability phenomena.

For each glacier a brief description of his main features and variations occurred on long term period, based on the World Glacier Inventory, enriches the thematical cartography.

A few case studies from the investigated areas will be presented.

This paper is carried out in the framework of CNR-IRPI activities for the Alcotra 2007-2013 project N. 056 "GLARISKALP".

THE MULTI-HAZARD WARNING SYSTEMS AS A "SOFT" ADAPTATION TOOLS TO A CHANGING CLIMATE

PELOSINI Renata¹, BARBERO Secondo¹

1 - Arpa Piemonte

Presenter e-mail: r.pelosini@arpa.piemonte.it

Key terms: adaptation; risk; warning system; climate change

The climate change leads to gradual changes in average variables such as the temperature, sea level, precipitation amount and distribution.

Moreover it modifies the climate variability contributing to more frequent, severe and unpredictable hazards linked to extreme weather events. This results in a strengthening of the potential impact of climate-related risk - e.g. floods, drought, heat waves, landslides - also due to the increase of vulnerability and exposure of people and their assets. The vulnerability

can be climate driven, through the degradation of ecosystem and ecosystem services, the reduction in water and food availability, the changes to livelihoods and the decrease the community's ability to cope with the even existing levels of weather-induced hazard, when the climate change adds stress to environment degradation and affects well-being of individuals and societies. Among the adaptation strategies, aimed to reduce vulnerability and enhance community resilience, the adaptive capacity, considered as the sum of the ability of institutions and social systems to learn, store knowledge and experience, adopt flexibility in decision making, assure the access to resources and build a responsive governance, is recognized as the main non-structural pro-active adaptation option able to grant more general environmental, economical and social benefits on a large scale. The adaptive capacity building and increasing is required by a correct and integrated approach to disaster risk reduction and prevention too, able to cope with the specific environmental and social context, to manage the residual risk and the acceptance concept, to account for the multidisciplinary and multiscale effects. Besides, the results from the risk management community, in terms of knowledge, tools, capacities to adapt to, effective risk communications expertise and the prevention measures inclusion in the policy, represent a robust framework for the climate change adaptation strategies development. In this work an heuristic approach to evaluate the regional climate-related risk enhancement is applied and the role of the natural hazard early warning systems and prevention related plans as soft adaptation options is shown. Mutual benefits in reducing the impact of weather and climate driven hazards can derive from the integrated analysis scenario and common tools improvement.

AEROSOL OPTICAL DEPTH IN THE HINDU KUSH - KARAKORUM - HIMALAYA REGION: STATION AND SATELLITE DATA VERSUS GLOBAL MODELING RESULTS

VON HARDENBERG Jost¹, PROVENZALE Antonello¹, VOZELLA Lara¹
1 - ISAC-CNR, Corso Fiume 4, Torino, Italy

Presenter e-mail: j.vonhardenberg@isac.cnr.it

Key terms: Aerosols; Climate impacts; Mountain areas

The Hindu Kush - Karakorum - Himalaya (HKKH) region is characterized by large loads of atmospheric aerosols which can change the regional climate dynamics and the properties of the Indian monsoon. In this area, observational data on the atmospheric Aerosol Optical Depth (AOD) are available both from satellites (MODIS AQUA and TERRA) and from ground station data (the EV-K2-CNR Pyramid Laboratory in Nepal, at about 5000 meters a.m.s.l.).

Owing to the importance of the aerosol load in determining the properties of the regional circulation, of precipitation, of snow and ice melt and consequently of water availability, it is essential to reliably represent atmospheric dynamics and aerosol concentration in this area by global and regional climate models.

Here we consider results provided by a global atmospheric circulation model coupled with a module for aerosol transport dynamics. We compare model output with the available measurement data, to elucidate successes and pitfalls and to possibly improve the model performances. In particular, we focus on the period 2004-2009 and consider the output from the global atmospheric circulation model ECHAM5 with the aerosol module HAM, considering a range of different emission datasets (AEROCOM, IPCC and REAS) and different dynamical schemes for desert dust uptake.

Key terms: black carbon; ozone mountains; monitoring

NCO-P (Nepal Climate Observatory at Pyramid) station, installed in 2006 at 5.079 m asl in the Mt. Everest Region of Nepal, within the high altitude climate and environmental monitoring project SHARE (Stations at High Altitude for Research on the Environment), is providing continuous measurements of aerosol and trace gases, in particular Black Carbon and tropospheric ozone, considered among the most important anthropogenic contributors to the global warming, with direct impacts on human health and environment.

Concentrations detected at NCO-P during monsoon season have shown seasonal average values of 50 ng m⁻³ for BC e 39 ppbv for ozone, while in the premonsoon season these concentrations have reached seasonal average values similar to the concentrations normally measured in urban areas: 317 ng m⁻³ for BC and 61 ppbv for ozone. BC deposition on Himalayan snow and ice surface modifies albedo values with consequent effect on glacier melting dynamics. BC premonsoon concentrations have in fact allowed to estimate an albedo reduction of 2 - 5.2% and an increase of 24% of the typical seasonal runoff of a Tibetan glacier.. BC and ozone emission reduction could have a relevant impact in the definition of mitigation strategies, thanks to the short period of BC and ozone presence in the atmosphere (weeks and months). Such reduction could have also a consequent effect on radiative forcing decreasing. The availability of these scientific data could therefore provide an important support in the preparation of proper environmental mitigation measures by the local governments.

HYDROGEOLOGICAL SOLUTIONS FOR GROUNDWATER POLLUTANTS CONTAINMENT

FRANCANI Vincenzo¹
1 - POLITECNICO DI MILANO

Presenter e-mail: vincenzo.francani@polimi.it

Key terms: BARRIER WELLS; HYDROGEOLOGIC ASSET; SEMIPERMEABLE WALL

The groundwater protection can be achieved by means of enhancing the hydrogeologic analysis, first of all of the optimal localisation of barrier wells, on the basis of an accurate description of the main parameters of the aquifer. We can demonstrate that the breadth of the capture zone of the barrier wells depends on the spatial distribution of transmissivity of the aquifer and of the impermeable limiting terrains. Furthermore can be demonstrated that the barrier wells efficiency depends mainly on the distance of the impermeable limits, and of the supply areas. This paper, analysing the possible solutions of this problem, deals with the changes that can be reasonably proposed in order to focus the accuracy of the projects on the importance of a correct interpretation of hydrogeologic asset, and of the definition of hydrogeologic parameters. Are moreover presented some earthwork that can satisfy with low costs the design of pollution containment, mainly of the recharge wells of groundwater, and of semipermeable barriers, that integrate the barrier wells. The paper debates in conclusions with the suitability of costs of this approach that guarantee the safety against the pollutions spreading.

PRELIMINARY STUDY ON THE SNOW-MELT FOR THE GROUNDWATER RECHARGE ESTIMATED BY ADVANCED METEOROLOGICAL STATION

SUOZZI Enrico¹, DE MAIO Marina¹, AMANZIO Gianpiero¹
1 - DITAG-Politecnico di Torino

Presenter e-mail: enrico.suozzi@polito.it

Key terms: snow-melt; groundwater; spring; Snow Water Equivalent; hydrogeological balance

In the hydrogeology field understanding groundwater recharge is essential for many purposes like: the successful management of water resources, the modeling fluid and contaminant transport within the subsurface. Groundwater is a critical source of freshwater through the world. Comprehensive statistics on groundwater abstraction and use are not available, but it is estimated that more than 1.5 billion people worldwide rely on groundwater for potable water (Clarke et al., 1996). Other than water stored in ice caps and glaciers, groundwater accounts for approximately 97% of freshwater on Earth (Nace, 1967; Shiklomanov and Rodda, 2003). As the world population continues to grow, in the future more people will need to use groundwater sources, particularly in arid and semiarid areas (Simmers, 1990). In many regions of the Alps, snowfall and the resulting seasonal snow cover represent an important source of water. When the snowpacks melt, it recharges the groundwater and replenishes surface water storage. Excessive snowmelt runoff can cause flooding, while inadequate snowmelt is often the prelude to later drought. In this preliminary study about the snow melt process we have tried to understand like is possible to measure the snow water equivalent (S.W.E.). Thanks to a collaboration project between the Politecnico di Torino and Regione Autonoma Valle d'Aosta, sponsor corporate, is born one of the advanced meteorological stations in Italy. It situates in Mascognaz Valley a little lateral valley in Ayas Municipality. This site is important because at least of 1 km from the station there are two springs so it's possible compared the different data about the snow melt and the flow rate, defining the time of travel from the infiltration point to springs. In the springs are installed two different probes one to measure the water level and temperature, in the second that is situated below, water level, temperature and also conductivity. In the advanced meteorological station is installed the best available technologies (B.A.T.), chosen from many factories in the world to study the snowmelt process. The station is composed by different instruments to measure the S.W.E., these are: snow scale product by Sommer Mess-Systemtechnik that is the evolution of snow pillow, the Pluvio 2 from OTT Hydromet that is a new generation of rain gauge, it is defined like the consistent advancement of the weighing precipitation gauge and, lastly, the buried rain gauge, a Prof. Vigna's project modified for this installation. Then we are used a Natural Resources Conservation Service (NRCS) methodology to calculate the S.W.E. modified after a long study on Alps snow density. The result shows like the instruments give a very good data, all are comparable between they self. The buried rain gauge is the best because it gives data about quantity and the time when the snowmelt process start. We have a increase of the flow rate, measured by buried rain gauge, eight day after the snow depth sensor starts to decrease. This time between the start of acquisition of the two instruments last named depends on the mountains aspects. The results of this project improve the knowledge about the snow melt phenomena, allowing, a better estimation of groundwater recharge and runoff.

ESTIMATION OF HYDRAULIC CONDUCTIVITY BY SLUG TEST METHOD IN A SHALLOW AQUIFER IN VENETIAN PLAIN (NE, ITALY)

ORTOMBINA Mirta¹, FABBRI Paolo¹
1 - Università degli Studi di Padova, Dipartimento di Geoscienze
Presenter e-mail: mirta.ortombina@unipd.it

Key terms: hydraulic conductivity; slug test; middle plain

The following study is part of the Strategic Project of University of Padova

called GEO-RISK. The area at issue is located in the 'fontanili' zone of the middle Venetian Plain (Villaverla, VI). Topographically, the height of the area is between 56 and 50 m a.s.l., sloping from NW to SE.

As regards to the local hydrography are present a plain spring named 'Boiona' and the channels 'Boiona' and 'Beverara', which are the drainage network of the related plain springs. The subsol composition, and consequently the hydrogeological features, shows high heterogeneity with gravel horizons alternating with sandy, silty and clayey levels. In this area we study the shallow unconfined aquifer, essentially recharged by rainfall (Ortombina e Fabbri, 2011).

The analyses concern an hydrogeological study in an experimental site of 1.5 ha placed inside the drinking water supply area of ACEGAS-APS. The results regard the application of slug tests to calculate hydraulic conductivity (K) being that a fundamental parameter to model groundwater flow in an aquifer. The experimental data obtained were processed by Hvorslev (Hvorslev, 1951) and the Bouwer-Rice methods (Bouwer and Rice, 1976).

The tested piezometers have a depth ranging between 8.5 and 1.6 m and a diameter ranging between 3 to 2 inches.

A slug test involves the instantaneous injection or withdrawal of a volume of water; the water levels are measured at timed intervals as the water level goes back toward the static water level.

Using the Hvorslev method, if the length of the piezometer is more than 8 times the radius of the well screen ($L/R > 8$), the following formula is applied:

$$K = \frac{r^2 \cdot \ln\left(\frac{L_e}{R}\right)}{2 \cdot L_e \cdot t_{37}}$$

Where r is the radius of the well casing (m), L_e is the length of the well screen (m), R is the radius of the well screen (m), t_{37} (s) is the time for the water level to rise or fall to 37% of the initial change h_0 (m) (which represents the maximum difference respect the static level).

Instead, using the Bouwer-Rice method the relationship is:

$$K = \frac{r^2 \cdot \ln\left(\frac{R_e}{R}\right)}{2L_e} \cdot \frac{1}{t} \cdot \ln\left(\frac{h_0}{h_t}\right)$$

Where R_e is the radius of influence (m), R is the radius of gravel envelope (m) and t is the time since $h=h_0$.

Slug tests were carried out at the site, between 2010 and 2011, repeating more times the test for every piezometer to obtain an average value. An automatic pressure transducer (Mini-Diver) was used to record the water level changes into the well, allowing an acquisition data every 0.5s. The monitored data through Hvorslev and Bouwer-Rice methods were processed, obtaining a permeability value ranging from $7.5 \cdot 10^{-4}$ m/s for the downstream piezometer (P28) to $2 \cdot 10^{-4}$ m/s for the upstream piezometer (GP2). The calculated values by the two considered methods are comparable, although the Bouwer-Rice method tends to slightly underestimate the permeability results. The wide range of hydraulic conductivity found, is supported by the high stratigraphical heterogeneity observed also during the coring (Facinelli, 2010).

IMPROVEMENT OF GROUNDWATER VULNERABILITY MAPS BY USING ELECTRICAL TOMOGRAPHY.

PERA Sebastian¹, MARZOCCHI Roberto¹, PFEIFER Hans-Rudolf²
1 - Scuola Universitaria Professionale della Svizzera Italiana
2 - Università del Lausanne

Presenter e-mail: sebastian.pera@sups.ch

Key terms: electrical tomography; vulnerability; springs

Electrical and electromagnetic geophysical methods are widely used in groundwater investigation because of good correlation among electrical properties, geology and fluid content. Those techniques were successfully applied to heterogeneous media like hard rocks to the identify water bearing fractures (Sharma and Baranwal, 2005). In Switzerland, aquifers developed in hard rocks are the most important by surface. And related springs fulfill almost 44% of industrial and drinking water demand (UFAPP, 2004).

Swiss federal legislation establish, among other measures, wellhead protection areas for springs and wells serving public aqueducts. That, provides the legal basis to enforce restrictions to potentially hazardous activities. They are delimited considering the hydrogeological context and based on two key concepts: flow velocity for porous and/or homogeneous media, and vulnerability for highly heterogeneous fissured and karst media. Concerning vulnerability, specific methods were developed to assess it (UFAPP, 1998, UFAPP, 2003). Despite the wide use of vulnerability maps, one of the major uncertainties about water flow through heterogeneous rock masses, is the location of preferential pathways for water circulation developed by tectonics, weathering and/or karst processes. Knowing those preferential paths, improve water protection since land use restrictions can be specifically applied. In this work electrical resistivity tomography (ERT) was used to obtain 2D resistivity profiles within the basins of selected springs. Profiles intersected, and were performed in different directions (parallel and orthogonal to the hypothetical flow direction). Resistivity measurements were performed using an IRIS-SYSCAL PRO System, with a multielectrode cable consisting of 48 electrodes interspaced of 10 m. Full length (470 m) allows us to investigate about 100 m of depth at the center of the 2D

profile. Two different configurations: Wenner-Shlumberger (WS) and Dipole-Dipole (DD) were tested, observing always better results with the WS configuration. The apparent resistivity data were filtered, conveniently removing the noise effects, and topography incorporated into the model by the PROSYS software while, for the inversion of the field data, we used the RES2DINV software (Locke, 2004). Low resistivity areas associated with groundwater presence were identified on some sections of the obtained 2D profiles. A 3D representation of the profiles allowed us to reconstruct the subsurface structures and the preferential flow pathways. The result was used to improve vulnerability maps, assessed on the basis of surface information only. Loke M.H.; 2004. Tutorial: 2-D and 3-D electrical imaging surveys. Copyright (1966-2004) M.H. STOCHASTIC ANALYSIS OF CROSS-HOLE GPR DATA FOR SUBSURFACE CHARACTERIZATION

ROSSI Matteo¹, CASSIANI Giorgio¹, BINLEY Andrew²
 1 - Dipartimento di Geoscienze, Università degli Studi di Padova
 2 - Lancaster Environment Centre, Lancaster University
 Presenter e-mail: matteo.rossi@unipd.it

Key terms: Ground Penetrating Radar; Geophysics; permittivity; stochastic

GPR is a technique used to estimate soil moisture content. The easiest approach to obtain hydraulic parameters is the direct-wave approach, where point ZOP travel times are converted into ϵ_r . This approach does not take into account volume averaging and critical wave refractions. So the principal aim of the present work is to have a more complete view of how ZOPs are informative of the subsurface geometry and distribution of permittivity. An electromagnetic wave simulator has been applied within a stochastic Monte Carlo framework, so both averaging and critically refracted wave effects are taken into account. The simple direct-wave method is compared with the results obtained from the stochastic inversion. The aim of the stochastic approach is to reconstruct the dielectric properties distributions that can produce the measured ZOP signal. Every realization generates a random 1D ϵ_r geometry. For each ZOP shot, real and simulated travel times (TT) are statistically compared using chi-squared factor. For TT saved from the analysis, the Fresnel volume is calculated in an interactive method: the ellipsoid minor axis is obtained. The distribution of ϵ_r values related to each detected vertical segment is stored. Where overlapping segments are present, ϵ_r -distributions are intersected. In the end, an uncertainty quantification of ϵ_r in function of depth is possible, computing median, mean and data variance. We first considered a synthetic case made of an alternating sequence of thin layers (highest ϵ_r values) and thick layers (lower ϵ_r values). The synthetic profile, taken as the true field-measured ϵ_r profile, is a one-dimensional ϵ_r distribution. The permittivity geometry of the system is made to vary in a Monte Carlo manner with 20000 realizations. The results show that a large discrepancy is present between the curve obtained directly from the true first-arrival travel times and the true ϵ_r profile: the sharp geometry is smoothed. The finer high permittivity layer at is not reproduced in its features or is completely invisible for the direct-wave profile, in spite of its possible relevance in hydrogeological characterization. The variance of ϵ_r , derived from the stochastic approach, is about centred around the real profile, meaning that the results are close to the real physics of the system. The statistical analysis demonstrates that thin layers can be invisible to investigation, underestimated or misinterpreted, in spite of their high relevance in hydrological processes. The considered experimental dataset comes from a field site located at Gorgonzola, east of Milan. The unsaturated zone are composed of Quaternary sediments with a fairly coarse sand-gravel grain size distribution. Analysis of a soil core has provided direct knowledge of the site stratigraphy. We applied to this real dataset the same procedure described above. The direct-wave approach is not able to reproduce the sharp heterogeneities. The core log and the ϵ_r profile from the stochastic approach are in perfect accordance, reproducing the geometry of the system. The comparison between the geophysical inversion and the core log gives us confidence on the validity and applicability of the stochastic approach in this heterogeneous and complex subsurface system. The detection of the cemented layer as a high permittivity material is a key point for the identification of the subsurface hydrological behaviour. Both real and synthetic datasets illustrate how the often employed direct-wave approach is not able to take into account the complexity of the system, underestimating or overestimating the real permittivity values. Care must be used when inverting ZOP data for physical parameter estimation, misleading assignment of material properties could make the hydrological evaluation diverge from reality. The evidence is that thin clay layers are not well defined, large uncertainty.

Soprana (CN), Italy

Presenter e-mail: adriano.fiorucci@polito.it

Key terms: karst; Bossea cave; monitoring; thrust

The study of the Bossea karst system (Val Corsaglia - Southern Piedmont) began from the 80s through the installation of a scientific station located inside the cave, equipped with a set of instruments to monitoring the main hydrodynamic and hydrogeochemical parameters of the main collector water. Over time, many data logger have been installed for the automatic monitoring of flow in the fractured network that characterize the unsaturated zone of Bossea. Since 2000, it has began studies on the presence of radon in the natural cave, through the monitoring of this gas in the atmosphere and in the water. The geological structure of the Bossea area has heavily influenced the groundwater flow and the presence of radon.

The karst system is set in Briançonnais terrain of Ormea Unit - Element Navonera-Bossea-Prel. This element consists of a sequence of middle Triassic carbonate and Malm limestone, low-cut through a thrust surface, from the original substrate formed by Permian volcanics, Permian conglomerates and quartzites and Scythian pelites. The thrust, with a ramp-flat geometry and associated folds with convergence SW, is surrounded by late-alpine sub-vertical faults, that dislocate the surface. Consequently, the structural situation of the area has influenced the development of the karst network and the cave, that is set along the tectonic boundary between the impermeable substrate and the overlying carbonate succession. The cave is developed in the EW direction, in the first part, with a series of large collapse big halls, from an altitude of 826 to approximately 940 m a.s.l. Above this sector, the cave continues with a wide horizontal gorge sets along discontinuities also aligned in EW direction. The cave ends with two siphons connected by a series of full head gallery, that are explored up to -70 m from diver-speleologists. The catchment area is located between Maudagna and Corsaglia valleys and it is characterized by a karst covered by eluviations-colluvial deposits, with a series of karstic loss valleys. The infiltration water feeds the main karst collector (Mora torrent), which flows along the cave and issues with several springs near the Corsaglia torrent bed, at 800 m a.s.l. The main collector receives a lot of secondary inputs located along the cave. These contributions are related to underground flow in the rock mass discontinuities. The hydrodynamic and hydrogeochemical monitoring of these seepages has allowed us to collect useful data and information on the water network and the mechanisms that regulate the circulation of water in the unsaturated zone of a karst system. These inputs with discharges ranging from a few liters per minute to less than 0.5 l/s, may be temporary and are activated within several hours after the beginning of precipitation.

The monitoring of these points has highlighted the close relationship between the major inputs and the water flow in the fractures in the unsaturated zone, characterized by impulse increases of the flow. This kind of response is related to the growing of the hydraulic load in the aquifer network and consequently of the transfer of water pressure throughout the system (pressure waves). This phenomena, known as piston effect, is highlighted by marked and temporary increases in water temperature and electric conductivity. Particularly interesting is the study of the concentration of radon in water. Through new instruments, still used at an experimental level, the concentration of the gas is captured in the water of the main drain and a secondary tributary. The data show the close correlation between this parameter and the trend of system discharge.

HYDROCHEMICAL AND STABLE ISOTOPIC INVESTIGATION TO DETERMINE HYDROGEOLOGICAL PROCESSES IN THE "MADONNA DEL POLLINO" KARSTIC SYSTEM, SOUTHERN ITALY.

CANORA Filomena¹, FIDELIBUS Dolores², SPILOTRO Giuseppe¹
 1 - Dept. of Structures, Geotechnics and Engineering Geology, University of Basilicata, Potenza, Italy
 2 - Dept. of Water Engineering and Chemistry, Polytechnic of Bari, Bari, Italy

Presenter e-mail: filomena.canora@unibas.it

Key terms: Hydrochemistry; Stable isotopes; Groundwater recharge; Madonna del Pollino

The contribution of oxygen and hydrogen stable isotopes to the hydrogeological research is well known: their use of, coupled with hydrochemical data, demonstrated useful in recognizing recharge areas, evaporation and groundwater mixing processes. The aim of the study was to assess the capability of these groundwater stable isotopes for refining the knowledge on recharge areas of the Madonna del Pollino fractured carbonate aquifer (Southern Italy), which represents an important groundwater resource of the region. The study area is placed in the high valley of the Frido River along the northern hillside of the Pollino Mountain; it is characterized by a complex geomorphological packing, resulting from of the litho-stratigraphic and structural features of outcropping terrains. Two separate geological Units, the "Pollino Unit" and the "Frido Unit", widely outcrop in the area showing tectonic contacts. The successions of the "Pollino Unit" consist of a lower part represented by carbonate formations outcropping in monoclinic structures, following the Pleistocene extensional and transcurrent tectonics. The "Frido Unit" limits the carbonate morpho-structure of "Madonna del Pollino": the Unit is constituted by metamorphic terms, as clay shales, and formations afferent to terrigenous ophiolites units. The western hillside of "Madonna del Pollino" is bordered by faults that brought this carbonate structure (fractured and karstic) to tectonically overlie the terms of the "Frido Unit". The geometric configuration of the aquifer is well defined by discontinuities and stratigraphic contacts: groundwater flow follows preferential pathways, defined by the net of fractures and karst channels. The ground waters of the "Madonna del Pollino" aquifer gush forth at about 1040 m a.s.l., in correspondence of a front constituted from at least ten springs, captured for supplying drinking water to a wide area of the Basilicata region. The spring front is situated in correspondence of the tectonic contact between the permeable Mesozoic limestone and the clayey-marly formations of the "Frido Unit". A large collection of hydrological, hydrogeological and hydrochemical data allowed a first evaluation of the hydrogeological balance, and recognition of recharge areas and main groundwater flow circuits. The depletion curve of the Frido springs was generated for determining the depletion coefficient and the underground storage. Groundwater samples were collected over a three-year period

(2003-2006) from several springs of the "Madonna del Pollino" aquifer, emerging at different elevations; sampling included groundwater inflows inside the Frido drainage trench.

Spring water samples were subject to hydrochemical and isotopic

analyses. The correlation between $\delta^{18}O$ and elevation, based on the spring elevation and the oxygen isotopic composition of precipitation (from literature data), and supported by the interpretation of the hydrochemical features of the same springs, allowed defining the altitude gradient and outlining the most probable altitude of the recharge areas for the examined springs.

Results of the hydrogeological, hydrochemical and isotopic studies outline the complexity of the karstic system, indicating spatial separation of groundwater pathways and presence of different drainage axes: groundwaters emerging within the drainage trench come from the highest elevations of the massif, where recharge occurs by rapid infiltration with little evapotranspiration prior to recharge.

10.1474/Epitome.04.0038.Geoitalia2011

MULTIDISCIPLINARY APPROACH TO PROVIDE DETAILED CONCEPTUAL MODEL OF THE AQUIFER SYSTEMS: AN EXAMPLE IN THE VERSILIAN COASTAL PLAIN (NW TUSCANY)

BONOMI Roberto¹, DOVERI Marco², GIANNECCHINI Roberto¹, MENICHINI Matia¹, RACO Brunella²

1 - Dipartimento di Scienze della Terra, Università di Pisa
2 - Istituto di Geoscienze e Georisorse, CNR, Pisa

Presenter e-mail: m.menichini@igg.cnr.it

Key terms: coastal plain aquifers; hydrostratigraphic cross-sections; hydraulic parameters; piezometric surface; geochemical and isotopic data

Detailed conceptual models of the aquifer systems are an essential base working for groundwater modelling and for a correct groundwater resources management. At the same time the right approach to obtain reliable conceptual models is certainly interdisciplinary, which guarantees the knowledge of geological, hydrogeological and geochemical features of the aquifer systems.

In this contribute an example of multidisciplinary study carried out on the Versilian coastal plain aquifers (NW Tuscany) is presented, underlining as the comparison between geological framework and hydraulic, hydrodynamic, chemical and isotopic data allowed at understanding the feeding mechanism of groundwater flow and at defining the seawater-freshwater mixing process.

The study area has an extension of about 55 km² and it has delimited by Poveromo and Motrone ditch, northward and southward respectively, and by shoreline and Apuan Alps, in the western and eastern parts. The Versilian plain constitutes a recent succession of alternating continental and marine deposits. Hydrostratigraphic cross-sections reaching a depth of about 80-100 metres were elaborated. Aquitards/aquicludes are locally interbedded to the prevalent aquifer terms, which are mainly made up by sand and gravel. Gravel is shallow in the inner portion of the plain, where the alluvial fan of Versilia River is present. Seaward gravel deepens and is overlain by sands. For this framework the aquifer results throughout a phreatic monolayer, although the local presence of superficial silty-clayey or peaty deposits may determine confined or semi-confined conditions. Moreover, the presence of a discontinuous subsurface layer of conglomerate and silty-clayey lenses may locally separate the groundwater flow in multiple levels.

In order to achieve the purpose of the present work, multiple types of hydrogeological and hydrodynamics surveys and chemical and isotopic analyses on water samples were performed. In details, two piezometric surveys and physical-chemical analyses (temperature, electrical conductivity, pH, Eh) were carried out in April 2009 (high level condition) and in September 2009 (low level condition). On the whole, 192 wells and 14 stream water points were examined.

Piezometric and iso-conductive maps suggest as the recharge area of the coastal plain is mainly the alluvial fan. Afterwards, more detailed hydrogeochemical analyses were performed. Major elements (Ca, Mg, Na, K, Cl, NO₃, SO₄, HCO₃), some minor elements (Br, F, B, As, Fe, Mn, Pb, Cr, Cu, Ni, Zn) concentration and some isotopic ratios ($2H/1H$, $18O/16O$ for water and $13C/12C$ of total inorganic carbon dissolved) were estimated. Vertical logs were also performed in order to measure the electrical conductivity and temperature into 10 wells next to the coastline. In addition, in the apex of the fan a long term pumping test was executed, determining the aquifer hydraulic parameters (K, T, S). The last, together with the potentiometric surface, allowed us estimating the groundwater flow rate at the section corresponding to the Versilia River entrance into the plain.

Finally, comparing all data, it was possible to identify the principal component which supplies the coastal aquifer system starting from the upper part of the plain, where the Versilia River feeds the groundwater hosted in its alluvial fan. Secondary contributes are linkable to the local rainfall infiltration, well recognized in the dune sand, and to the groundwater flow coming from some fractured complexes bordering the plain. Freshwater-seawater mixing processes were also individuated.

NATURAL BACKGROUND LEVEL ASSESSMENT AT THE GROUNDWATER BODY SCALE FOR MUNICIPAL DUMP IMPACT EVALUATION IN CENTRAL ITALY

PREZIOSI Elisabetta¹, GHERGO Stefano², DEL BON Andrea¹, SCIALBINI Elisa²

1 - IRSA-CNR, Via Salaria km 29,300, 00015, Monterotondo St., (RM) Italy
2 - University of Rome "Sapienza", P.le Aldo Moro 5, 00185 Rome, Italy

Presenter e-mail: preziosi@irsa.cnr.it

Key terms: Ground Water Directive; Aquifer; Natural Background Level; Threshold Value; Municipal Dump

Ground Water Directive (2006/118/EC) requests to EU Member States to derive appropriate threshold values (TV) for several potentially harmful substances, taking into account natural background levels (NBL) when necessary, in order to assess the chemical status for groundwaters. In Italy, several TVs have been set at the national level (Decree 30/2009); however TVs can be increased by Regions when local NBL are found to be higher. Additionally, when a ground water body is threatened by potentially polluting activities such as a dump filling, monitoring is mandatory at the site in order to evaluate possible negative effects on

groundwater quality: in such a case specific threshold values ("CSC") are regulated by Decree 152/2006 with sometimes more stringent values; the existence of NBL is also considered by this Act. In Lazio region,

concentration values exceeding CSCs have been detected at several municipal dumps for some substances including As, Fe and Mn. However, the natural origin of these substances is well known in central Italy due to the widespread distribution of volcanic formations of Plio-Pleistocene age. In these cases CSC derivation cannot disregard local NBLs. In this paper we present the first results of an on-going research project concerning NBLs derivation for several potentially harmful substances for ground water bodies in Lazio Region (Central Italy), in which municipal dumps are located.

The first considered is the Inviolata site, East of Rome, where a water table aquifer, circulating mainly in Pliocene deposits (clays with sandy horizons), is encountered at a depth varying from a few meters up to 30-40 meters, partially overlain by volcanics.

Sampling and laboratory analysis were conducted following IRSA-CNR methodology (APAT-IRSA 2003) in order to allow for repeatability. NBL assessment has been performed by two methods: 1) probability distribution functions (PDF) and 2) the pre-selection (PS) methods. PDF methods are grounded on the principle that the superposition of different sources (e.g. geogenic and anthropogenic) generates different data populations which can be distinguished by means of a statistical procedure: the break point between the natural population and the contaminated one is taken as NBL. On the other hand, PS methods propose to remove from the initial data set those samples which are characterised by e.g. high nitrate contents or other markers of human activities. In the residual data set one value (e.g. 95th percentile) is chosen as representative of the NBL, meaning that all concentrations exceeding that level should be ascribed to anthropogenic sources. Results of the two methods are compared and discussed.

In both procedures the identification of a unique value separating the "natural" values from the "anthropic" ones, can be difficult. Critical issues include: 1) the selection criteria for the PS methods: as an example, the suggested nitrate threshold of 10 mg/L seems too restrictive. In the case study a less stringent value (50 mg/L) was chosen to get a statistically significant number of samples (at least 30). 2) The choice of the percentile in PS method can lead to important differences in the NBL when the data distribution is strongly right skewed. 3) On the other hand, PDF methods seems to be more influenced by subjectivity, and individuate a range of values rather than a definite concentration. In the case study, values issued by PDF are generally lower than the PS ones. As a conclusion, the PS method seems more appropriate for the administrative definition of TV. However, exceeding one parameter at one control point may trigger the characterisation procedure. TV assessment in these cases is a particularly delicate matter as it makes a sharp divide between natural and anthropogenic contamination. The percentile rule (whatever the percentile be) could result inadequate and the problem of the effective representativeness of the sampling remains a critical point.

10.1474/Epitome.04.0040.Geoitalia2011

PROCESSING OF A HYDROGEOCHEMICAL APPROACH BASED ON THE METHODOLOGIES OF COMPOSITIONAL FINGERPRINTING TO CHARACTERIZE THE CONTAMINATION IN THE ITALIAN SITES.

PIETRINI Ilaria¹, TREFILETTI Patrizia², MELE Andrea¹

1 - Politecnico di Milano

2 - Tethys srl, Milano

Presenter e-mail: ilaria.pietrini@mail.polimi.it

Key terms: hydrocarbons; compositional fingerprinting; groundwater contamination

Petroleum hydrocarbons and chlorinated solvents are the most frequently discovered chemicals of concern at contaminated sites. Petroleum is a complex mixture of a thousand of different organic compounds formed primarily by hydrocarbon and hydrogen and each crude oil has an own specific "fingerprint". Moreover, fingerprints of the different oil products present differences that come from the different crude oil of origin and also from the oil refinery cracking processes that undergo. These fingerprints are obtained as Total Ion Chromatogram (TIC) by the employ of a proven laboratory technology, based on the combination of the two instruments GC (gas chromatographer) and MS (mass spectrometer), that allows to a rapid separation and identification of compounds in complex mixtures. TICs represent also a tool suitable to determine the degree of compounds alteration leading to the dating of contamination. In fact, once in the environment, the structures of crude oil and his derivatives change under the effects of different physical, biological and chemical processes with the loss of n-alkanes, isoprenoids and the more easily degradable biomarkers. These compounds are lost following a specific sequence, then some compounds are degraded first while compounds more recalcitrant to degradation increase their relative concentrations. These changes are reflected in the fingerprints and give a trace to dating contamination and to identify the grade of biodegradation, if it is occurred. Thus, fingerprinting is defined as a methodology to characterize the type of the oil contaminant, quantify the concentration of the compound and identify the composition of all compounds within the oil contaminant that can be used to reliably determine the source and understand the fate and the transport of the oil contaminant.

For all these reasons, fingerprinting methodology can also represent a tool to determine responsibility in legal context. Our legislation assess that those who are responsible for contaminating the environment have the duty to pay for the remediation of the contaminated area or, in civil contest, pay for the environmental damage. In fact, it is often very difficult to find those responsible of contamination especially if there are more plants suspected to be responsible and historical changes of plant's owners. In addition, most of the contaminations present in Italy are very old and, as stated above, structures of the pollutants present in the environment change under the effect of different processes.

Despite all these evidences, few studies have been carried out in Italy to identify sources of contamination using a multidisciplinary approach coupling compositional fingerprinting analyses with classic hydro geochemical investigations. Experiences gained in the past years give evidences of the importance of this tool and, on the other hand, underlined the necessity to contextualize it in the Italian reality. Our scope is to reach this purpose by testing and then choosing the best methodology of sampling and analysis to obtain a reliable fingerprint of the contaminant and by the identification of the characteristics of the petroleum products mainly diffused in our country. This research is carried on by the group of Applied Geology and by the Department of Chemical Engineering of the Politecnico di Milano.

To achieve the main objective of this research project, that is the

identification of the best sampling procedure and methods of analysis, we are currently performing several tests in a site contaminated by hydrocarbons. Especially we have identified two different areas: a "test area" with a known contamination of diesel to validate the sampling procedures and the methodology of analysis and an area with an unknown contamination where this methodology can be employed coupled with the usual hydro geochemical analysis to reliably define the contamination. In this occasion we are presenting our preliminary results.

GROUNDWATER QUALITY AND FLUORIDE CONCENTRATION IN THE WEST ARSI ZONE (OROMIA REGION, ETHIOPIA)

BONETTO Sabrina¹, DE LUCA Domenico Antonio¹, LODI Rachele¹
1 - UNIVERSITA' DEGLI STUDI DI TORINO

Presenter e-mail: sabrina.bonetto@unito.it

Key terms: Ethiopian Rift Valley; groundwater resource; water quality

This study focuses on the quality definition of groundwater supply in the Lake Region of the south-centre of the Main Ethiopian Rift Valley. In particular, the study area is located south from Addis Abeba and included three administrative divisions (woredas) of the West Arsi Zone (Oromia Region): Shashemene, Arsi Negelle and Siraro Woredas. Despite of the presence of many lakes, water supply is completely dependent on the rainfalls because of both the short number of perennial streams, the low quality of superficial water and the lack of water supply facilities.

The geology of the study area is characterized by volcanic rocks such as trachyte, rhyolites, ignimbrites, ashes and tuffs that belong to the Nazareth series of Neogene age group (Ethiopian Government, Geological map of Ethiopia, 1996). Thick soil deposits cover the rocks in most parts of the study area. The trachytes and rhyolites are moderately weathered but highly fractured. An abundance of parameters indicates the ongoing volcanic activity in the area. Generally the area has gentle slopes and in most cases it is flat lying.

Due to the geological features and permeability conditions, volcanic rocks could be considered as a fractured aquifer in presence of open fractures and faults or porous aquifer in case of highly fractured rocks; permeability decrease with alteration degree. The hydrogeological model of the area include two main aquiferous formations: a superficial porous aquifer (loose fluvial and lacustrine deposit and/or highly fractured-altered volcanic rocks) and a deeper aquifer mainly represented by fractured volcanic rocks or, occasionally, by coarse grained fluvial deposits.

Due to the variation in the regional geology and water/rock interactions, high concentration of many chemical elements can occur in such waters. In particular, after many years of use of drinking water from drilled wells in the Rift Valley, dental and skeletal fluorosis has become a serious medical problem. The fluorosis is due to a high intake of fluoride from drinking waters.

The research included a field work which consisted in water samples collection from wells and springs in small villages and settlements, scattered throughout the Shashemene, Arsi Negelle and Siraro Woredas. The wells were divided into "deep drilled wells" and "shallow hand-hug wells". The majority of drilled wells thus draw water from bedrock, while the majority of the hand-hug wells draw water from sediments. To obtain a more complete pictures of water quality in the area, a few additional samples from rivers were also collected and analysed. In the laboratory of the University of Turin, the samples were prepared and used for anions and cations analysis. Electrical conductivity, pH and fluoride concentration were directly measured on the field.

As regard to the fluorides, the World Health Organization recommend as maximum acceptable concentration limit for fluoride the value of 1,5 mg/l. For warm waters (above 25°C) or in tropical countries with a high daily intake of drinking water an action level of 0,7 mg/l of fluoride has been suggested in literature (WHO, 2006). More than 45% of the collected samples surpass the level of 0,7 mg/l F: 69,7% of the deep and shallow wells; 5% of the springs.

The 24,5% of analysed samples returned values exceeding the European and the WHO Maximum Acceptable Concentration of 1,5 mg/l F: 36,4% of deep and shallow wells; 5% of the springs.

The maximum concentration recorded in this study is 28,575 mg/l for thermal spring and 13,083 mg/l for borehole. Values of the analysed chemical parameters show a variability in the hydrochemical features of groundwater both with geographical location and depth.

HEALTH RISK OF PESTICIDE INTAKE OF VERCELLI PLANE RESIDENTS THROUGH GROUNDWATER

ZHAO Ye¹, DE MAIO Marina¹
1 - Politecnico di Torino, DITAG

Presenter e-mail: sunnyzhao2007@hotmail.com

Key terms: pesticide; risk; groundwater

The study area, Vercelli is situated on the river Sesia in the plain of the river Po between Milan and Turin. It is an important centre for the cultivation of rice, and is surrounded by paddy fields.

As a result of agricultural practices, pesticides and nitrate have been detected in many aquifers and surface waters. Contamination of groundwater by agrichemicals (pesticides and fertilizers) is recognized as an extremely important environmental problem in this area.

Continuous use of pesticides results in damage to the environment and can cause human health problems, which could have a negative impact on agricultural production and reduce agricultural sustainability. Several pesticides including bentazon, molinate, propanil and especially atrazine have been detected in wells, rice field and surface water in this region, although some of them are forbidden to use for many years.

The contamination of air, soils, surface and ground waters has evident negative impacts on public health, and on biological diversity. Atrazine is typical candidates of herbicides and have been applied in a large scale with a great deal of consumption. However, atrazine and its metabolites would end up in natural waters, which have to be considered as a serious problem for environmental safety and human health.

In order to assessment health impacts of atrazine and other toxic trace elements in well water in Vercelli plane, groundwater and surface water samples were collected in this area. With the soft RISC, human health risk from exposure to contaminated media were estimated, simple fate and transport modeling were performed, meanwhile, risk-based clean-up

levels in various can be calculated.

In this study, several intake route of pesticides were considered, including ingestion of soil, dermal contact with soil, inhalation of indoor air, ingestion of surface water, ingestion of home-grown vegetables irrigated with groundwater, ingestion of irrigation water and dermal intake with irrigation water.

Presenter e-mail: manuela.lasagna@unito.it

Key terms: groundwater; overexploitation; well field; hydrogeologic model; Piedmont

The well field in the Valle Maggiore, at which about 14,000,000 m³/year are extracted by means of 37 water wells, play a fundamental role in supplying drinking water to a large territory of the Asti district (Central Piedmont, Italy).

Since 1996 to present, a groundwater withdrawal of about 1,000,000 m³/year has been recorded at the well field, because of a continuous increase of water demand. This situation has caused an overexploitation of the deep aquifer, evidenced by the progressive lowering of the piezometric level (locally up to 0,8 m/year) and the consequent spatial reduction of the artesian zone.

The study of the geologic setting and the hydrogeologic reconstruction of a wide area around the Valle Maggiore were the first step of this work. From these elaborations, three hydrogeologic complexes have been recognized:

- ° a superficial unconfined aquifer, constituted by Pleistocene-Olocene gravelly-sandy unit and sandy-silty unit, whose water table is directly connected to the hydrographical network; the aquifer has been individuated in the Po plain and Poirino Plateaux;

- ° a particularly thick and permeable deep confined or semi-confined aquifer, represented by a Villafranchian unit (middle Pliocene-lower Pleistocene) and a lower Pliocene sandy unit (Sabbie di Asti);

- ° an aquiclude, at the bottom of the aquifer sequence, consisting of a lower Pliocene silts-clays unit (Argille di Lugagnano) and a Pre-pliocenic clays-marls unit.

The Pliocene sandy unit, with a hydraulic transmissivity of about 10⁻³ m²/s, is largely exploited by the well field of Valle Maggiore.

A piezometric map of the deep aquifer has been elaborated starting from water level measurements of August 2009. In the wide area around the Valle Maggiore, the groundwater flow is generally directed toward east; the piezometric surface shows a pronounced cone of depression in the well field, because of the intensive groundwater pumping. On the basis of the hydrogeologic conceptual model, the recharge area of the deep aquifer is located toward the Po Plain, west of the study area; most likely the deep aquifer is recharged by Po river.

On the contrary, the superficial aquifer is generally directed westward; this aquifer is recharged by precipitations and locally by superficial waters. In order to decrease the overexploitation, four different scenarios for a better groundwater management at Valle Maggiore well field have been proposed, by utilizing Modflow code:

- ° in three cases a withdrawal decrease of 20% has been simulated, considering or not the displacement of some wells out of the well field zone of influence;

- ° the fourth case simulates a significant withdrawal reduction of 150 l/s, as a result of the possible connection with the water supply of the Monferrato Aqueduct, located north of the study area.

All the simulations provide an increase of the piezometric level, even up to 30 m. The fourth scenario seems to ensure the better performances: the piezometric level rises up to 27 m in the Valle Maggiore area and the current amount of drinking water would be preserved without having to build new wells.

VAPOR INTRUSION AT A CHLORINATED SOLVENT SITE - SAMPLING TECHNIQUES COMPARISON AND MONITORING CHALLENGES

CHIARBONELLO Dario¹, GARETTO Anna¹, DAVIT Jean Pierre¹
1 - Golder Associates Srl

Presenter e-mail: agaretto@golder.it

Key terms: vapor intrusion; ambient air; sub-slab gas; attenuation factor

Degradation of air quality into a building due to vapor intrusion is a source of concern for all the sites affected by groundwater or soil contamination. In particular, vapor intrusion is a potential exposure pathway at sites with the presence of volatile chemicals and there is an increasing number of sites with significant vapor intrusion impacts. While aerobic biodegradation of the vapor phase has proven to be an effective risk reduction mechanism at many petroleum hydrocarbon contaminated sites, vapor intrusion is increasingly becoming the main risk driver at sites contaminated by chlorinated solvents, due to their high volatility, low or negligible degradation in the vapor phase, complex and hard to remediate source zones and low toxicity thresholds.

The case study presented is related to an industrial site located into a residential area in a town in northern Italy. At the Site, soil and groundwater are impacted by chlorinated aliphatic hydrocarbons. A remediation system combining pumping of groundwater and soil vapor extraction (SVE) is active since a few years. Further comprehensive Site investigations carried out using a Membrane Interface Probe "MIP" coupled with a traditional Soil Gas Survey (SGS) detected the presence of soil vapors in areas outside of the SVE system area of influence.

Recently, a new program for soil vapor monitoring activities has been put in place including sub-slab soil vapor sampling through fixed sampling probes and ambient air sampling. Twenty three leak-tested permanent soil gas probes were installed in order to carry out routine monitoring, using summa canisters for ambient air sampling and sorbent tubes for soil gas and sub-slab gas.

The case study focuses on the differences between the results of different

soil gas investigations (SGS, MIP and sub-slab vapor sampling) and analyses the variations of the vapor attenuation factor α in different areas of the building and in different periods of time, in function of the geometry of the plume, of the site hydrogeology, of the construction and structural design of the building and of the temperature and barometric pressure differences.

 Presenter e-mail: alfonso.corniello@unina.it

Key terms: *Garigliano River plain; HYDROGEOLOGY; HYDROGEOCHEMISTRY*

The Garigliano River plain (about 170 km²) is a NE-SW oriented graben filled with upper Miocene-Quaternary infralittoral, deltaic and continental clastic deposits, containing in the uppermost part volcanoclastic sediments from nearby Roccamonfina. Along the SW border two sand dunes run parallel to the coastline. These sand dunes in the past created secluded ponds and coastal lagoons filled by groundwater, runoff and direct rainfall which could not reach the sea. Nearby, in Latium and Campania, there were other wetland plains, very unhealthy and affected by malaria. Land reclamations plans began in 1856.

Stratigraphic reconstruction of the main aquifer obtained by interpolating stratigraphic data from more than 80 boreholes allows to draw up the Hydrogeological map, Hydrogeological cross-sections and the 3D lithologic model (using the software ROCKWORKS 2006). The main aquifer consists of marine and alluvial deposits, often of relevant thickness; the piezometric pattern, defined by the piezometric network consisting of more than 60 sites measured in April-May and December 2009, shows the groundwater flow directed toward the sea and the Garigliano river. Between the first and the second field campaign measurements, piezometric differences were low in the flat area; more considerable differences (ranging between 0.5 and 1.0 m) were recorded along the slopes of the Roccamonfina volcano and at the foot of the calcareous mountains bounding the Garigliano Plain.

In the two campaigns, hydrochemical sampling was conducted in the same wells used for the piezometric measurements. Chemicals analysis allowed to draw up the "Hydrochemical Facies Map" and to verify the consistency over time of the Hydrochemical Facies. Otherwise, the total ion content depends on the amount of the recharge.

NO₃ and Fluoride contents often and widely exceed the drinking-water quality guidelines of 50 and 1,5 mg/L. The Fluoride content is strictly related to the piezometric pattern. Close to the Garigliano river, lower nitrate content is related to reducing conditions, testified by low values of SO₄ and high content in Fe and Mn. Afterwards, the isotopic analysis (15N/14N and 18O/16O ratios of dissolved nitrate) were carried out by the CNR-Roma in groundwater of some wells.

Starting from this broad hydrogeological knowledge, the following maps to evaluate the "Contamination risk" were drawn up:

• The "Pollution Vulnerability Map", evaluated by the SINTACS parametric system;

• The "Agricultural Hazard Map", rated by the parametric models IPNOA (Danger Index by Nitrates of Agricultural Origin).

All the data and the maps were stored in a geographic database and managed by GIS.

The good correlation between the "Potential Agricultural Nitrate Contamination Risk Map" and the nitrate content distribution suggests that the source of the groundwater nitrate is chiefly related to intensive cropping or livestock. The results of isotope analysis confirm the hypothesis of the agricultural origin of nitrates and the validity of the use of parametric methods at medium/small scale to individuate the source of nitrate in groundwater.

PRELIMINARY HYDROGEOCHEMICAL CHARACTERIZATION OF A GNEISSIC-METAMORPHIC ACQUIFER IN THE SILA MASSIF (CALABRIA)

VESPASIANO Giovanni¹, APOLLARO Carmine¹, BLOISE Andrea¹, CRITELLI Teresa¹, DE ROSA Rosanna¹, MIRIELLO Domenico¹

1 - Dipartimento di Scienze della Terra, Università della Calabria

Presenter e-mail: giovanni.vespasiano@gmail.com

Key terms: *hydrogeochemical; aquifer; water-rocks interaction*

The aim of this research is the geochemical and hydrogeological characterization of a gneissic-metamorphic aquifer in the Sila massif. The Sila massif represents the main morphostructural high of northeastern Calabria and constitutes a widespread groundwater reservoir. In the eastern margin of Calabria, crystalline and metamorphic units of the Calabride complex crop out, comprising the tectonic units known as the Polia-Copanello-Garigliano unit and the Sila Plutonic complex. The studied area consists of biotite-sillimanite-garnet gneisses with massive or migmatite texture.

A preliminary characterization is carrying out on springs and well waters. Temperature, pH, Eh and electrical conductivity were measured in the field by means of portable instruments. Waters were filtered in situ through a

0.4 μ m pore-size polycarbonate membrane filter and acidified by addition of suprapure acid.

The concentrations of Cl⁻, Br⁻, SO₄²⁻, F⁻, NO₃⁻, and PO₄³⁻ were determined by HPLC, whereas Ca²⁺, Mg²⁺, Na⁺, K⁺, Si and some trace elements, were analysed by a quadrupole ICP-MS (Perkin Elmer/SCIEX) with collision reaction cell capable of reducing or avoiding the formation of polyatomic spectral interferences. Data quality for major components was evaluated by charge balance while for minor and trace elements it was checked running the NIST1643e standard reference solution.

The chemical composition of springs and well waters was characterized in terms of relative Cl, SO₄ and HCO₃ concentrations and Na+K, Ca, and Mg contents by using triangular plots. Inspection of the data show that, in groundwaters from

gneiss, the dominant cation is Mg.

The high contents in Mg results from the dissolution of mineral phases rich in Mg.

For this aim, petrographic investigations are being conducting by means of optical microscope on thin-section and XRD analysis. These preliminary investigations indicate that gneisses are characterized by a mineralogical assemblage of biotite + sillimanite + garnet + plagioclase + quartz \pm orthoclase \pm cordierite \pm muscovite.

Other analysis for the investigation of water-rocks interaction are still in progress.

HYDROLOGICAL AND GEOPHYSICAL APPROACHES FOR THE CHARACTERIZATION OF LIVIGNO VALLEY AQUIFER (NORTHERN ITALY)

GAMBILLARA Roberto¹, SAVOIA Deborah¹, TERRANA Silvia¹, CARUGATI Gabriele¹, POZZI Andrea¹

1 - Università degli Studi dell'Insubria

Presenter e-mail: roberto.gambillara@uninsubria.it

Key terms: *Livigno; hydrology; geophysics; mountain aquifer*

In the last few years, a progressive impoverishment of water resources took place in the mountain; this is due to the increase of anthropic activity and to the change in the precipitation regime. In this context, the preservation of every aquifer will acquire great importance. In particular, the mountain fissured aquifers could play a relevant role in the water supply for the mountain people, although they have a limited productivity. In the mountain environment, for a better reconstruction of groundwater system is suggested the multidisciplinary approach, because it permit to maximize the merit of both methods.

The aim of this study is the characterization of Livigno Valley aquifer integrating two approaches: hydrological and geophysical.

The Livigno area represents a good test for the groundwater system reconstruction in the mountain environment because it has a complex geological and tectonical setting and because, in this area, the density of population varies greatly during the year and this generate a shortage of water in some seasons. The better management of the water resource of the Spol Valley (Livigno Valley) is important to increase the contribution in the water supply.

The Livigno area is located at 1800 m a.s.l. in the central Alps (northern Lombardy - Italy). For the tectonic setting this area is comprise between the Err Bernina system (Lower Australpine) and the Ortles-Quaternals system (Upper Austroalpine). The most important regional fault is represented by Zebù fault. This fault divides the sedimentary rocks constituted by Fraelle and Monte Motto limestone (Lias) to crystalline basement, which is constituted by "Bormio phyllades" and "Punta Rossa Formation". To the north of Zebù fault system the Alpisella fault system outcrops and divides the Monte Motto limestone by Triassic dolomites and limestones.

The hydrological approach consists of the series of Spol flow rate measurements along the river transept: 9 measurements twice a year (on July, during the snowmelt, and on September, during the dry spell). The instrument used (CORRENTEK) detects the speed of the propeller for a period equal to 10 s, returning a value of speed. The measurement is taken perpendicularly to the section and the result is punctual. Taking a summation, the flow rate of the entire section of river bed is obtained. The results show a flow rate depletion at Tresenda-Campacciolo area.

The geophysical approach gives informations about the valley subsoil and allows to distinguish different layers of deposits. This approach is constituted by the seismic refraction and ERT surveys along the Spol transept: six areas are investigated (Alpe Vago, Tresenda-Campacciolo, S. Rocco, Livigno, Case di Pemonte, Ponte del Bram). These methods have been calibrated at Tresenda-Campacciolo area, where exists the well section. For the seismic refraction the instrumentation used is a PASI, which includes a computer-seismograph (model 16S12-N), 24 channels (geophones) to acquire the signal, and a source of seismic waves consists of a hammer of 10 kg. In seismic refraction survey maximum depth investigated is about 40 meters, and only in one case the bedrock was detected.

For the ERT was used the PASI instrumentation (model 16GS32, Figure 3.20), which includes a computer-resistimeter, connected to a battery 12 V - 75 A, 32 electrodes for measuring potential.

The first integration of all data demonstrates that the Spol river feeds the underground aquifer at Tresenda-Campacciolo area, and downstream this area, at S. Rocco, the multi-aquifers are detected. In particular the deep aquifer is found by the investigation; this is separated from the others by alluvial deposits.

STRUCTURAL CONTROL ON GROUNDWATER FLOW AND VULNERABILITY OF AN AQUIFER SYSTEM

RAPTI Dimitra¹, BIANCA Marcello², SDAO Francesco²

1 - University of Ferrara

2 - University of Basilicata

Presenter e-mail: cpr@unife.it

Key terms: *vulnerability; karstic aquifer; structural control; hydrochemistry*

In the Mediterranean area, carbonate aquifers represent an important drinking water resource, which is, however, particularly vulnerable to contamination. The Castelluccio area, Basilicata Region, is one of the most important carbonate aquifer systems in southern Italy. This aquifer is formed in limestone and dolomitic limestone and shows different degrees of fissuring and, in places, karstic features. The considerable groundwater flows with mean discharges of about 500 l/s and outcrops from several scattered springs. The main spring is located at San Giovanni di Castelluccio and it is represented by some resurgences outpouring along an important high angle fault plane, which places side by side the high permeability fissured limestones and the low permeability fluvial-lacustrine sandy-to-muddy deposits, so generating a typical fault-spring case. In the present research, hydrological, hydrogeological and hydrochemical data integrated with several structural surveys are analysed in order to a) evaluate the influence of the principal structural elements to groundwater flow and b) define the conceptual hydrogeological model and the intrinsic vulnerability to pollution of the aquifer system.

THE BEGINNINGS OF ISOTOPE HYDROLOGY. FIRST SCIENTIFIC BACKGROUND, MEASUREMENT TECHNIQUES, AND FIRST INVESTIGATIONS AND APPLICATIONS TO NATURAL WATERS. THE BEGINNINGS IN ITALY.

GONFIANTINI Roberto¹

1 - Istituto di Geoscienze e Georisorse, CNR, Italy

Presenter e-mail: roberto.gonfiantini@yahoo.it

Key terms: Isotopes; Hydrology; Analytical techniques; Italy

In XX Century hydrology has finally completed its transformation from empirical activity to science, with the help - sometimes decisive - of isotopes. Isotope hydrology begins shortly after discovery of the stable isotopes of oxygen (1929) and hydrogen (1932), and of tritium and carbon-14 in nature after the WW2. It then develops in the first fifties under the guidance of Harold Urey and Willard Libby, both at the Institute of Nuclear Physics of Chicago University, later renamed after Enrico Fermi. The IAEA support through Brian Payne was also essential.

About at the same time, the determination of water isotopic composition reached adequate analytical quality and capacity. For stable isotopes, we moved from the laborious density measurements of the thirties, to the rapid and precise differential determinations with the gas mass spectrometer developed by Nier. For radioactive isotopes, proportional counter were constructed capable of identifying tritium and carbon-14 decays from the released energy, and eliminating cosmic radiation by means of external coincidence counters. Subsequent refinements improved more the efficiency than the accuracy of measurements. Among new techniques, laser spectroscopy for stable isotopes in water and accelerator mass spectrometry for carbon-14 are worth mentioning. With the latter technique, the quantity of material needed for the measurements has been reduced to few mg, so promoting the use of carbon-14 in dating groundwater from remote regions.

Natural waters contain several isotopic species, among which ¹H²16O is by far the most abundant (99.73%) and slightly more volatile of the rare species ¹H²H¹⁶O and ¹H²18O. Therefore rains and fresh waters, all deriving from repeated evaporation and condensation processes starting from ocean water, are depleted in heavy isotopes. These isotopic fractionations were discovered already during the thirties, but two decades elapsed before they found systematic application in studying precipitation and continental waters, and Quaternary climatic changes recorded by the isotope variations in polar ice. Harmon Craig, Willi Dansgaard, Sam Epstein, Irving Friedman, Etienne Roth were the founders of these studies. Probably tritium would have had limited application in hydrology without the atmospheric thermonuclear tests, which drastically affected the natural tritium cycle: in fact, during the 1952-1962 decade 650-700 kg of thermonuclear tritium were injected mainly in the stratosphere, compared to a natural production of about 3.5 kg/a. In this way a global tracing experiment of meteoric water was performed, which during four decades supplied a tremendous amount of information on the atmospheric and continental cycles of natural waters. The beginners of these studies were Libby, Fritz Begemann, Robert Brown, Erik Eriksson.

Carbon-14 is used in hydrology for studying groundwater dynamics in deep aquifers. It is one of the few methods available for dating waters recharged thousands of years ago - often in climatic and rain amount conditions drastically different from the current ones. Karl-Otto Münnich, John Vogel, Hans Oeschger, Jean-Charles Fontes were the founder of the method.

The cradle of isotope hydrology in Italy was the Nuclear Geology Laboratory created in Pisa by Prof. Ezio Tongiorgi around 1955. The laboratory attracted scientists from all over the world for studying periods and training. Isotope investigations were performed in Pisa on precipitation and polar ice (the Laboratory participated in Belgian-Italian expedition to Antarctica), runoff and lake water, cold and hydrothermal groundwater, leaf water, evaporating salt water. In those early times, many aspects of the isotopic cycle of water were not well known, and several new facts were discovered.

NEW ISOTOPES FOR NEW WATERS: GEOCHEMICAL TRACING OF UNCONVENTIONAL WATERS IN REGIONAL CYCLES

KLOPPMANN Wolfram¹

1 - BRGM

Presenter e-mail: w.kloppmann@brgm.fr

Key terms: unconventional water resources; water management; environmental isotopes

Increasing pressure on global water resources has led to worldwide search for alternative water management options including the use of unconventional water resources as saline waters or waste waters. Artificial recharge, is gaining importance as a means to actively manage the balance of groundwater resources exploited for human needs, mainly drinking water and agriculture. During the next decades, "man-made" freshwater produced by desalination and waste-water treatment is expected to become a predominant water source in water-scarce areas of countries where demand exceeds natural replenishment and where the economic framework allows appropriate water treatment and management.

Chemical and isotopic fingerprints of the new types of water introduced intentionally or not in natural systems are needed to enable us to backtrack their pathways and estimate their contribution to the water balance of over-stressed water resources. Environmental isotopes have proven their exceptional efficiency and versatility when applied to natural and polluted water resources. The isotopic toolbox at the disposal of hydrogeochemists has been considerably completed over the last years due to new techniques like multi-collector ICP-MS. These new tools are now increasingly applied to groundwater systems where unconventional recharge components prevail.

We present examples of multi-isotope tracing (B, Li, Sr, O, H, S) of desalinated water and treated wastewater in aquifer systems in Israel and

Belgium. Measurement in commercial reverse osmosis (RO) desalination plants in Israel and Cyprus revealed distinctive geochemical and isotopic fingerprints of fresh water generated from desalination, in particular for boron (Kloppmann et al., 2008a). For the first time this specific signature has been found in effluents of the Tel Aviv area, partly supplied since 2007 by freshwater from desalination (Kloppmann et al., 2011). This wastewater is reused after treatment for artificial recharge into the coastal sandstone aquifer. Water is then pumped and used in the Negev for irrigation and it can be expected that the observed signatures will be traceable throughout the system.

In Belgium (Kloppmann et al., 2008b), municipal effluents are treated through secondary and tertiary treatment including reverse osmosis, then infiltrated into a sandy coastal aquifer, pumped and then distributed as drinking water after a final treatment. Isotope systematics reveal and quantify the lateral penetration of unconventional recharge into the aquifer, prove the confinement of the whole system, even vertically as the site is underlain by paleo-waters of Pleistocene origin.

In sum, in the global water cycle, "man-made" freshwaters will gain increasing importance. In some way, entire sub-cycles of the water cycle will be artificial and environmental isotopes reveal a powerful tool to elucidate the superposition of natural and artificial water flows.

Key terms: stable isotopes; radiometric age; palaeoclimate; groundwater pollution

Isotope geochemistry of Emilia Romagna groundwater has been studied. In particular ¹⁸O/¹⁶O, D/H, ¹³C/¹²C, ¹⁵N/¹⁴N ratios have been considered as well as Tritium and ¹⁴C content.

About 400 wells characterized by well known stratigraphic log and filter position have been selected in the plain area of the southern part of the Po valley.

The Emilia-Romagna Region has a surface area of 22,123 km² and is geographically located in the southern part of the Po Valley. It is bounded by the Northern Apennines to the South and by the Adriatic Sea to the East. The Po valley sedimentary basin has been subsident during the Neogene, allowing the fulfillment by sediments coming from Apennines and from Alps. Quaternary sediments are mainly continental and gravels correspond to the apenninic alluvial fans while sandy-clay layers have been chiefly transported by the Po river. They lie on a pre-Holocene substratum constituted by impermeable marine formations of Calabrian-Pliocene age. In the upper plain thickness of the alluvial deposits varies from 50 to 200 m. It reaches 400-500 m. east of Parma while, south of the Reno river, gravel fans are less extensive and they dip under the Adriatic Sea near Rimini. The middle part of the plain is characterized by clay sediments intercalated with sandy layers, which represent the finest and most distal suspended sediments of the Apennine rivers.

Thickness of the Quaternary alluvial cover is over 700 m. in this area and is interfingering with Alpine-derived sediments. Homogeneous hydrostratigraphic units corresponding to different phases of fulfillment of the Po sedimentary basin and characterized by thickness of about 200 m. were recognized by Emilia Romagna-ENI-AGIP and conventionally named A (ages ranging by present to 350 kyrs), B (ages ranging 350-650 kyrs) and C (ages 650-3600 kyrs). In the northern part of the plain alluvial deposits derived from the Po river occur. They consist of alpine thick interbedded sandy and clayey layers. The Emilia Romagna plain lies on a series of fold-faulted Apenninic terrains dipping northward in a tectonic regime characterized by a NE compression. This terrain was partially emerged during Pliocene period. The thickness of Quaternary sediments is limited to < 100 m. in the Mirandola area, north of Modena. The region's population of over 3 million inhabitants uses large amounts of water for public, industrial and agricultural purposes, with over 60% of the supplies withdrawn from about 100,000 wells whose depths range between 5 and 700m. Most of the wells lie in the foothills of the Apennine chain in aquifers of a non-confined, semi-confined and confined type in areas of conoid generated by the course of the rivers of Apennine origin. A large number of wells is also situated in the low plain areas to the south of the Po river that withdraw water from confined aquifers. The high consumption levels (703 million m³/y) have generated subsidence phenomena of 10-40 mm/year in main towns along with a deterioration in the quality of the underground waters. This has made it even more important to gain a better knowledge of the methods for feeding and recharging the Emilia-Romagna aquifer by means of isotopic techniques. Isotopic investigations allowed also description of palaeoclimatic trends in the Po valley and evidenced that underground waters may act as a natural archive of recent and past palaeoclimatological trends.

Nitrogen isotopes indicate that the pollution from Nitrates detected in numerous zones of the regional territory mainly comes from sources of organic nature. Effective reforms in the productive structure can contribute to limiting the excessive water consumption of the underground waters and to safeguarding the quality characteristics of the underground water-bearing bodies.

Key terms: chromium isotopes; hexavalent chromium contamination; alluvial aquifers

The Cr(III)-Cr(VI) cycling in soils and groundwaters is of great environmental concern. In particular, Cr(III) is an essential micro-nutrient and is considered to be the stable form in soils where it forms precipitates and is strongly sorbed on the charged surface of solids. Cr(VI) is toxic and a suspect carcinogen, stable under oxidizing conditions in aqueous forms and mobile as soluble oxyanions at the pH of natural waters. Under the redox and pH conditions usually found in the environment, Cr(VI) has the tendency to be reduced to Cr(III), e.g. on the surface of Fe(II)-bearing minerals or in the presence of aqueous Fe(II) or organic matter, acting as electron donors, and in this form it is scavenged from solution. However, it has been documented that in the presence of various forms of Mn-oxhydroxides in soils Cr(III) is readily oxidized and the conversion of Cr(III) to Cr(VI) represents a potential pollution hazard, critical to predict the fate of hexavalent Cr contamination in waters.

Cr isotopes have been demonstrated to be sensitive tracers of the Cr redox changes in aqueous media through both equilibrium and kinetic (Rayleigh-type) fractionations occurring during Cr(VI) reduction. A limited isotopic fractionation has been so far reported during Cr(III) oxidation experiments and small effects are also expected during oxidation of Cr(III) in soils, even if a larger fractionation was inferred from BIF in ancient redox environments and attributed to Cr(III) oxidation catalyzed by Mn oxides. However, the changes in the Cr isotope composition during Cr(III) oxidation require further investigations, due to the different pathways reactions with possible intermediate Cr(IV) and Cr(V) species.

In the present study the Cr-isotope systematics has been applied to groundwaters from the phreatic aquifer in the High Friuli Plain (northern Italy), an area which underwent extensive Cr(VI) contamination from manufacturing during 1997 with Cr(VI) concentrations in waters reaching 4 mg/l. Afterward, the industrial activity was made environmentally protective and a natural decay of contamination occurred over the years due to Cr(VI) reduction. Nevertheless, since 2002 and until the last survey at the beginning of 2011, new spikes in the Cr(VI) content reaching 1.6 mg/l have been observed in groundwaters. The measured ⁵³Cr/⁵²Cr isotopic ratio in contaminated waters, expressed in delta notation, show uncommon negative values ranging between -0.60 and -3.00 per mil. A negative value of -2.99 was also measured in Cr(VI) extracted from the sediments which characterize the contaminated site. The isotopic data are interpreted as tracing the oxidation of Cr(III) not from geogenic sources but originated by the reduction of Cr(VI) released during the pristine anthropogenic contamination, which accumulated onto Mn-oxide rich alluvial sediments. The mechanism of Cr(III) oxidation on Mn-oxides has been investigated by using HRTEM and micro-Raman techniques. These results indicate that the conditions favourable for Cr oxidation are likely to occur in the field soils of the study area, favoring the Cr(VI) plume migration and implying that suitable management activities are necessary for remediation.

- 3 - Municipality of Arezzo, Piazza Libertà 1-52100 Arezzo, Italy.

Presenter e-mail: b.nisi@igg.cnr.it

Key terms: Arezzo; Water chemistry; Stable Isotopes; Heavy metals; CO₂

The Arezzo Basin, formed since Upper Pliocene, is a structural depression limited to the North and to the East by the Pratomagno and Chianti belts, respectively, and to the South and to the East by two tectonic lineaments (Val d'Arbia-Val Marecchia transversal and Chitignano normal faults). Along these tectonic discontinuities CO₂-rich manifestations either seep out or are exploited by private companies down to the depth of 1000 m. Three main aquifers are recognized: i) a relatively deep aquifer hosted in Tertiary sandstone formations; ii) an intermediate aquifer hosted in Quaternary fluvio-lacustrine sediments and iii) a shallow aquifer in recent alluvial sediments.

In the framework of a joint project between the Unit of Environment and Health of the Municipality of Arezzo and the Department of Earth Science of the University of Florence, a geochemical and isotopic characterization of the superficial and ground waters of the municipal territory of Arezzo was carried out to establish the main sources of the solutes including natural and anthropogenic processes. The available geochemical data-base consists of about 80 samples that were collected at the end of the dry and rainy seasons in 2009. Physical parameters (temperature and electrical conductivity), major, minor and trace dissolved species (pH, Ca, Mg, Na, K, NH₄, HCO₃, SO₄, NO₃, Cl, Br, F and heavy metals), oxygen and hydrogen isotopes in the water molecules and dissolved gases (including ¹³C-CO₂) were analyzed. CO₂-rich waters from deep wells and gases discharging in the municipality of Arezzo were also included. Furthermore, on a bimonthly basis the main chemical and isotopic composition in rainwater from three stations positioned at different altitude (200, 500 and 800 m) were collected. Finally, 13 sediment samples from the main streams that cross-cut the Municipality of Arezzo were analyzed for determining the abundance of heavy metals, by aqua regia dissolution.

On the basis of Total Dissolved Solids (TDS) the waters from Arezzo can be considered mainly oligomineral and medium-mineral, whereas mineral waters are almost exclusively associated with the CO₂-rich wells. From a classificative point of view, Ca(Mg)-HCO₃ is by far the most representative geochemical facies, followed by Na(K)-HCO₃, Ca(Mg)-SO₄ and Na(K)-Cl types. It is noteworthy to point out here that the Na(K)-HCO₃ waters, whose origin is likely related to the presence of CO₂-rich waters that favor cation exchange processes with the clay minerals contained in the sedimentary formations, are aligned along the Val d'Arbia-Val Marecchia transversal tectonic system.

The O and H isotopic composition suggests that the Arezzo waters have a meteoric origin and occasionally, isotopic exchange between CO₂ and H₂O is observed for those waters discharged from the CO₂-rich wells. This CO₂ has an isotopic composition clustering around -6 permil and strongly differs from that measured in the shallower wells where the isotopic values are <-15 permil, suggesting a biogenic origin.

Presenter e-mail: delconte@crystal.unipv.it

Key terms: nitrate contamination; nitrate isotopes; surface waters

In the Oglio River watershed, elevated nitrate pollution of surface and groundwater result in a large fraction of land classified as vulnerable to nitrate contamination. We present the results of hydrochemical and isotopic analyses (water and nitrates) aiming to identify the nitrate origin and dynamics, and trace the interactions between the Oglio River, its tributaries, groundwater and soil.

Sampling was performed during low-flow conditions, in July 2010. The Oglio River can be divided in different parts based on nitrate concentration trends and on nitrate isotope composition. From the Iseo Lake to km 24, the River has low N-NO₃ concentrations (below 0.5 mg/l). Between km 24 and 50, the concentration increases up to 7.5 mg/l. Down to km 75, a decrease in concentration is observed first, followed by a second increase up to value similar to that observed at km 50. From km 75 to the Po River confluence, a decreasing trend is observed, with rather constant values between 94 and 125 km. The main decrease occurs from km 132 to the closing section, where concentrations are lower than 2 - 3 mg/l.

The ¹⁵N and ¹⁸O measured in one sample collected in the upstream reach indicate an origin from atmospheric deposition or a contribution from synthetic fertilizers. An organic contribution to nitrates characterizes the reach where a concentration increase is observed, down to km 45. Finally, from km 50 to the closing section, the ¹⁵N in the Oglio River is enriched with respect to previous values, but with no clear trend. Also the ¹⁸O values are rather similar and tend to be nested, with no clear distinctive signature of the nitrate origin.

In the upper part of the watershed we collected three groundwater samples characterized by high nitrate concentrations. The nitrate isotope composition of groundwater is similar to that measured in the Oglio River water in that part of the watershed. Concentration trends and nitrate isotope composition suggest the presence of mixing between Oglio River and groundwater. In order to validate this assumption, we calculated the amount of groundwater input to the river using the ¹⁸O values of water molecule. Based on this amount, we recalculated both the nitrate content and the ¹⁵N of river water samples and compared them with the measured values. According to this calculation, during summer, in the area where springs and natural outflows are present and the nitrate increase in the Oglio water is observed (24 - 50 km), the contribution of groundwater to the Oglio River could account for up to about 60-70% of the total flow. Calculated nitrate concentrations are in reasonable agreement with the measured values. On the other hand, the ¹⁵N values measured in samples are generally slightly higher than theoretical values, suggesting a contribution from other nitrate sources or the presence of nitrate that has been recycled in the environment. The coupled use of nitrate isotopes does not show the presence of denitrification processes in this reach of the Oglio River.

On the contrary, in the middle (75 km) and final reach of the River, a decrease in concentration and an enriched nitrate isotope composition suggest the presence of denitrification. Nevertheless, no clear trend in the isotopic composition is observed with distance. Even if present, isotopes do not allow to distinguish if denitrification is occurring in the riverbed itself or laterally, in soils and groundwater feeding the river. Indeed in this part of the watershed denitrification in groundwater is testified by low nitrate concentrations coupled to the common occurrence of Fe and Mn. Isotopes allow to quantify denitrification to remove at most 20% of nitrate.

We wish to acknowledge CNR-IGG, Regione Lombardia and Ing. M. Buizza, Oglio Consortium director.

Key terms: groundwater contamination; nitrate isotopes; boron isotopes; Po plain; Lombardy

Nitrate concentration in surface and groundwater is an environmental concern. Distinction between different sources of nitrates can be made coupling hydrochemistry with nitrate isotopes. However, these do not allow distinguishing manure-derived from sewage-derived nitrates. In this case, the combined use of ¹⁵N and ¹¹B is useful, since manure and sewage have high concentrations of boron and distinct ¹¹B imprints. In addition, while redox

conditions control the N isotope evolution, B isotopes are not sensitive to this process.

The area covered by this study is of approximately 15,000 km², crossing the Po plain from its correspondence to the Piedmont-Lombardy administrative boundary.

Groundwater data obtained since 2005 were compiled in a single geo-referenced database, containing more than 300 records and including anion concentrations and stable isotopes of dissolved nitrates.

The nitrate isotopic composition identifies several sources and processes occurring in groundwater. According to the geographical distribution of the samples, a regional map is produced, highlighting the more vulnerable areas. Combining the information provided by nitrate isotopes with land use and other soil parameters, groundwater contamination results to be governed by the hydraulic characteristics of the unsaturated zone, the agricultural input and irrigation practices.

A B isotopic investigation was undertaken on selected samples, all located in a nitrate vulnerable zone, showing a high concentration of nitrates and with an isotopic composition of dissolved nitrate indicating contamination from mixed or anthropogenic organic matter sources, or denitrification. For comparison, two wastewater samples were also considered. B concentration in groundwater samples is very low, generally ranging from

15 to about 50 µg/l. Higher concentrations are measured in wastewater

samples (80-85 µg/l) and in two groundwater samples (155-540 µg/l). A $\delta^{15}\text{N}$ of +14.6‰, compatible with a natural origin of B, characterises the sample with the lowest B concentration. As B concentration rises, its isotopic composition evolves towards both negative values, which are typical for wastewater and sewage, and towards positive values, indicating a contribution from animal manure. Accordingly, samples can be considered as a mixture in variable proportions of these end-members. Results indicate that, even in areas mostly devoted to agriculture, a contamination from sewage is observed. Indeed, in rural areas, households are sometimes not connected to sewers. Surprisingly instead, samples from the suburban area of Milan, where sewage was considered

the most likely source of contamination, show a $\delta^{15}\text{N}$ typical for cattle manure. In this case, nitrates in groundwater are likely related to a contamination occurred in the past, when the area was still mostly devoted to agriculture.

In conclusion, at the regional scale, the impact of intense agriculture activities on groundwater resources is mostly related to the use of synthetic fertilisers, and little contamination seems to originate from manure spreading. Peak concentrations in B and nitrates are instead associated to point source pollution and attributed to leaking septic tanks or sewage network. Results indicate that the undertaken actions for nitrate pollution mitigation do not target the main nitrate sources to groundwater. In addition the present study demonstrates that the attribution of the contamination to a source based solely on present-day land use may lead to inappropriate conclusions, which needs instead to be supported by isotopic data as well.

This research project is co-funded by CNR-IGG and Regione Lombardia, Department of Agriculture. We wish to acknowledge all the partners involved in the investigation, namely ERSAF (S. Brenna), ARPA Lombardia and Provincia di Milano (C. Arduini).

THE GEOCHEMICAL FEATURES OF PO RIVER WATER IN THE MANTOVA, FERRARA AND ROVIGO PROVINCES

MARCHINA Chiara¹, BIANCHINI Gianluca¹, NATALI Claudio¹
1 - Dipartimento di Scienze della Terra, Università di Ferrara

Presenter e-mail: chiaram@live.it

Key terms: Po river; water; geochemistry; stable isotopes; environment

Although Po is the main Italian River data on the chemical and isotopic composition of its running water are scarce and difficultly accessible. For this reason we started a monitoring project within a framework of a university thesis. In this contribution we present the preliminary results, i.e. major and trace element composition as well as oxygen/hydrogen isotope analyses of the Po River water sampled in different sites of the Mantova, Ferrara and Rovigo provinces. The analyses are compared with the rare data available in the literature as well as with the composition of groundwater of the surrounding aquifers.

The investigated waters display a Ca-HCO₃ hydrochemical facies, with limited seasonal variation. As concerns dissolved heavy metals V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Se, Mo, Cd, Sb, Pb never exceed the drinking water tolerance threshold. Anomalous concentration of iron (1.2 ppm), aluminum (0.65 ppm) and manganese (89 ppb) is recorded only in one site at the confluence with the "Canal Bianco", whereas arsenic is generally high (15-21 ppb) throughout the whole sample population. Considering that the river water is a dynamic multi-component system, whose bulk chemical composition varies as a function of time and distance from the source, the recorded composition provides a geochemical background that is useful for an environmental monitoring. In this view, the oxygen/hydrogen isotopes provide a snapshot of the current climatic conditions to be compared with the literature data and with the future composition to provide a hydro-archive that should be updated, as a proxy to evaluate on-going climatic changes (Zuppi and Sacchi, 2004; Global Planet. Change 40 79-91).

The recorded $\delta^{18}\text{O}$ values ranging between -10.79 and -8.59, and δD values ranging between -69.4 and -62.5 are compared with the local groundwaters (Rapti Caputo and Martinelli, 2008; Hydrogeol. Jour. 17, 467-480) and with the Northern Italy Meteoric Water Line (Longinelli and Selmo, 2003; Jour. Hydrol. 270, 75-88).

These data will be implemented with further isotopic tracers in the framework of a cooperative project with the IGG-CNR of Pisa, to investigate and detect potential industrial, agricultural and urban contaminations, to define mixing processes with the connected alluvial aquifers, and to study the extent of sea-water intrusion and salinization in the terminal (delta) part of the river.

Key terms: iron isotopes; iron cycling; coastal aquifers

Iron isotopes have revealed to be extremely useful in the study of the geochemical cycling of this element in near-surface environments. Iron oxides and hydroxides are ubiquitous in soils and sediments and the redox equilibrium between soluble Fe(II) and sparingly soluble Fe(III) species influences the Fe distribution between the solid matrix and aqueous solutions, with implications on its biological availability. In coastal aquifers the dissolved iron concentration is strongly influenced by the non-conservative behavior of this element during mixing between freshwater and seawater, yielding the rapid flocculation and precipitation of dissolved Fe as solid particles at the proper Eh-pH conditions. Subsequent remobilization by reductive dissolution of iron oxides may occur, allowing Fe to return to the water column by diffusion through pore water. In this cycling, redox-associated Fe isotope fractionation occurs, resulting from the preferential partitioning of the heavy iron isotopes into the oxidized forms. The iron isotopic composition is commonly represented

by the $\delta^{56}\text{Fe}/^{54}\text{Fe}$ ratio, and expressed through the $\delta^{56}\text{Fe}$ notation as per mil deviations with respect to a standard. Igneous iron sources are isotopically homogeneous to ± 0.05 per mil, representing a suitable baseline to interpret Fe isotope variations in nature. The dissolved riverine

flux has $\delta^{56}\text{Fe}$ values between about 0 and -1 per mil, and progressively

negative values of $\delta^{56}\text{Fe}$ can be established in the aqueous phase throughout repeated Fe dissolution-precipitation reactions of ferrous and ferric iron.

In the present work, the iron isotope systematics has been applied to groundwaters collected by a network of piezometers in the site of national interest for anthropogenic impact (SIN) "Laguna di Grado-Marano" in the Friuli Venezia-Giulia Region (Italy), a near-shore area characterized by metallurgical activities and groundwaters with high iron concentration, with the aim of investigating possible anthropogenic sources. The studied waters range in composition between the Ca-bicarbonate and Na-chloride hydrofacies, reflecting the progressive mixing between freshwater and a seawater end-member. The process of seawater intrusion has been quantified using the conservative isotopes of H and O, yielding up to the 98% of seawater admixed to freshwater inputs originated from both resurgence belt river fluxes and local meteoric precipitations. Sr isotopes support the role of seawater intrusion, highlighting additional processes of cation exchange and suggesting that alteration of silicate minerals represents the potential source of lithogenic Fe in groundwaters. The Fe

isotopic data show large variability, with $\delta^{56}\text{Fe}$ ranging between -6.93 and

+0.99 per mil, with the exception of a single sample characterized by a $\delta^{56}\text{Fe}$ value as high as +2.54 which deserves further investigations.

Progressively negative $\delta^{56}\text{Fe}$ values are observed with decreasing the Fe content, suggesting the occurrence of repeated natural cycles of iron dissolution and precipitation with consequent enrichment of an isotopically light component in porewaters. The Fe cycling also affects the fate of potentially toxic elements in the aqueous environment, in particular As and Ni.

Key terms: On-line database; Boron isotope; Natural waters; Contaminants

From 1986, boron isotope data in natural substances increased sharply in scientific publications. Analytical difficulties derived from complex geochemical matrices have been faced and interlaboratory calibrations reported in the boron literature. Boron isotopes are nowadays applied to investigate boron origin and migration in natural waters, sources of boron contamination, water-rock interactions, and also contribute to the water resource management. This is especially important in those areas where boron content exceeds the local regulations for drinking water supply, and boron sources need to be identified. On the basis of its twenty years experience in boron isotope geochemistry, the Istituto di Geoscienze e Georisorse di Pisa has started to compile a database aimed to include all the isotopic data on boron in natural waters reported in the scientific literature. The database includes currently values on 'cold' natural waters, but its extension to medium and high enthalpy fluids from volcanic and geothermal areas is anticipated. We give below some basic information on the structure of the database. The data are grouped in five categories, according to the sample nature: rainwaters, surface waters - rivers, surface water - lakes, groundwater, natural and anthropogenic contaminants.

ISOBORDAT web pages has been created with open CMS Joomla! 1.5 and Jx List Files v1.3 on small xampp server (thanks to all open communities for support).

For each sample, the data reported in ISOBORDAT, are: (i) - Sampling site: main characteristics. E.g.: for groundwater: well, spring, shallow or deep (confined) aquifer (ii) - Geographic location (iii) - $\delta^{11}\text{B}$ ‰, expressed vs. the reference material NBS SRM-951. No measurement uncertainty is quoted, however, data of questionable quality will not be included in the database (iv) - B concentration, expressed for waters in mg L⁻¹ and for solid compounds in mg Kg⁻¹ (v) Analytical technique. E.g.: PTIMS, NTIMS, etc. - (vi) - Bibliographic reference(s).

Isotopic data on potential boron contaminants of natural waters are gathered together in a section of the ISOBORDAT database. These contaminants include: detergents, chemical fertilizers and manures, mining tailings and wastes of industrial processing of boron minerals. The isotopic composition of potential contaminants, which spans over a wide range, helps in identifying boron contamination sources and geochemical processes undergone in natural waters. Data on natural waters collected

in ISOBORDAT show variations on 11B/10B ratio of almost 60‰ in categories Rainwaters, Rivers, Lakes, that reach 90‰ in category Groundwater. The observed span is huge for an element not undergoing redox reaction in nature. The variations on 11B/10B ratio observed for the category "Contaminants" is also wide, and span about 25‰ for inorganic products and 110‰ for organic products. A simple statistical elaboration of more than hundred boron isotopic data on Italian groundwaters from disparate geological settings is presented.

The $\delta^{11}B$ values scan from -30 ‰ to +50 ‰, i.e. over a 80 ‰ range. All data have been obtained by positive thermal ionization mass spectrometry (PTIMS) in our institute in the last two decades and are perfectly comparable.

Compilation of a database is by nature a permanent "work in progress". In order to have a database as complete as possible, the collaboration of the whole boron isotope community is necessary. We believe that such a database will be of great help to boron isotope hydrologists and geochemists by speeding up the research of, and the comparison with, data already existing in the scientific literature.

Key terms: ground water flow; connectivity; alluvial aquifers; tracer transport; mathematical modeling

The heterogeneity of alluvial sediments at fine scales has a direct impact on water flow and contaminant transport in the subsurface at larger scale. In particular the spatial distribution of hydrofacies controls the spatial variation of hydraulic conductivity (K), which in turn controls, together with the hydraulic gradient and the stresses on the aquifer system, groundwater flow and the fate of contaminants in the subsurface. However, the connectivity of permeable materials could be more important than the local K values to determine the behaviour of solute transport. In fact it controls the existence of preferential flow paths or of hydraulic barriers and induces local distortions of the flow field. In order to reach a deeper insight on this topic, several aquifer analogues, namely alluvial sediments exposed along vertical faces, e.g. in sand and gravel quarries, have been examined in the last years. The sedimentological and hydrostratigraphical analysis of the sediments and of their architecture, together with laboratory tests on samples (grain size distribution, conductivity of fine-grained almost undisturbed samples, etc.), has been the basis for the classification of hydrofacies, the reconstruction of hydrofacies distribution at scale lengths from centimetres to decimetres on the exposed faces and the identification of K for each hydrofacies. The 3D spatial distribution of hydrofacies, and therefore of K, has been obtained with the application of stochastic simulations tools (SISIM, T-ProGS, MPS). Then the equivalent conductivity tensor has been computed at larger scales, by 3D groundwater flow modelling. Moreover, numerical experiments of convective transport of conservative solutes have been conducted and have been interpreted with single and dual domain models, thus obtaining equivalent hydrodispersive parameters. The values of the equivalent hydrodynamic and hydrodispersive parameters and the general behaviour of the breakthrough curves have been compared with several connectivity indicators, which are related either to the spatial distribution of hydrofacies or to flow and transport statistics. This evaluation has provided an important confirmation of the role of connectivity to characterize transport processes in alluvial saturated sediments. Moreover the results have shown similarities and differences of connectivity and transport characteristics among various kinds of sedimentary facies with variable hierarchy and scales.

Key terms: Stratigraphic reconstruction; Hydrogeology; Subsoil; Po Plain; Piedmont

The research regards the stratigraphic reconstruction of a wide area surrounding the well field of Cascina Giarrea, situated in the central Piedmont plain, near the confluence of the Dora Baltea River in the Po River. The well field (groundwater mean discharge of about 1 m³/s) constitutes the main water supply for the inhabitants of the Monferrato Hills (developed South of the plain area), through a supply network around 2000 km long.

Nine detailed stratigraphic cross sections has been elaborated, interpolating well and piezometer data logs. Despite the large number of stratigraphies, difficulties have been encountered during the subsurface reconstruction owing to the inaccuracy of some technical and lithological data.

The top of the examined plain area is represented by the Middle Pleistocene-Holocene glaciofluvial and fluvial sediments: a complex of highly permeable sandy gravel, 30-60 m thick, constituting a superficial unconfined aquifer.

The underlying sediments are essentially constituted by the Middle Pliocene-Lower Pleistocene deltaic and fluvial Villafranchian Succession. This complex consists essentially of alternating layers of silt (rich in vegetable rests) and sand, 50-100 m thick, hydraulically interpretable as a multilayered aquifer.

Locally, the Lower Pliocene littoral clayey sand and deep sea clayey silt (Sabbie di Asti and Argille Azzurre, respectively) occur at the bottom of the examined succession. These heteropic sediments (rich in marine fossils) show a general low permeability constituting an aquitard from a hydrogeologic point of view.

In the Monferrato Hills, South of the investigated plain sector, pre-Pliocene deep sea sediments (marl and silty clay) outcrop. Their low permeability characterizes such complex as an aquiclude.

The geo-structural setting is complicated by a lot of faults and thrusts that divide the subsiding Po Plain from the uplifting Monferrato Hills.

In the subsoil of the intermediate area, developed between the subsiding plain and the Monferrato Hills, a remarkable buried erosion surface named "platea", separates the pre-Pliocene and Pliocene marine sediments and the Pliocene Villafranchian Succession, below this unconformity, from a thin cover of Pleistocene glaciofluvial and fluvial sediments above.

The groundwater flow of both superficial unconfined and deep multilayered aquifers is southeastward, as well as the general trend of the topography and the flow of the Dora Baltea River.

The new collected data report a particularly thick Villafranchian Succession in the Cascina Giarrea site, connected with the filling of a wide depression. This depression consists both in a foredeep basin, connected with the Padane Thrust Front that border the Monferrato Hills, and in the ancient incision of the Aosta Valley. This context creates a favorable condition for the occurrence of the well field, main supply of the aqueduct of the hilly Piedmont central sector.

Key terms: alluvial sediments; aquifer analogues; hydrostratigraphy; interpolation techniques; geostatistical simulations

Realistic representations of the sedimentary heterogeneity of alluvial aquifers are necessary to solve flow and transport problems. The improvements of mathematical tools to simulate the heterogeneity distribution in these sediments permit to handle 3D fields at fine scales. At this purpose, the textural and geometrical components of heterogeneity must be reproduced efficiently. Nevertheless, the current mathematical methods are still far from yielding satisfactory results concerning complex geometries and facies distributions (i.e. textures and the related porosity/permeability properties). This is the case of alluvial aquifers that are characterized by: i) complex curve and oblique geometries of the sedimentary bodies bounded by complex truncation surfaces, ii) highly variable and non-stationary facies associations and iii) complex nesting of sedimentary units with contrasting permeability (scour pools, accreting bars, channel fills, terraced valleys and flood plains). Modeling this complexity in the real subsurface aquifer stratigraphy is difficult when fine-scale models are required. The study of exposed aquifer analogues permits to try and improve the geostatistical techniques for simulation of aquifer stratigraphy (pixel or object based methods), using complete sedimentological data-sets. Aiming to combine the best possible reproduction of complex geometries with the accurate simulation of the textural distribution, we investigated a sediment block (7 m x 4 m x 1.5 m) dug into a gravel-sand quarry that is open into the Upper Pleistocene sandur of the Verbano glacier amphitheater. The block shows a complex network of scour-pool fills, made of curve and planar cross-bedded gravel and sand (Trough Gravel Unit, TGU), cut into overbank very fine silt and sand (Sandy Unit, SU). The complexity of this setting includes also deformation structures due to undermining and failure of the pool banks, with gravel fills pinched in between projecting limbs of the silty-sands. A preliminary geophysical investigation and the subsequent progressive dissection permitted full inspection of the block volume, so that the data-set includes: geoelectrical and GPR surveys on the top of the block; sedimentological logs, photomosaics and facies maps at cm-scale accuracy along vertical and horizontal intersecting planes; infiltration tests with a spacing of about 50 cm; grain-size distribution measurements on samples; estimates and measurements of hydraulic conductivity on samples of the sandy gravel, sand and silty-sand facies to work out an hydrofacies classification from the facies association. This approach permitted to check the geostatistical model of the volume, that was obtained combining the interpolation of the boundaries of the individual scour pools with the geostatistical simulation of their sedimentary fill. At the scale of the highest order elements (TGU and SU units) the comparison of our results with the real block shows that the simulated model respects both the geometry of sedimentary units and the vertical vs. horizontal association of facies. At the scale of the individual scour pools, a good result was obtained concerning proportions and juxtaposition of (hydro)-facies, i.e. the permeability contrasts were reproduced in their correct locations, respecting the shape of these minor units. Differently, the curve geometry of the boundaries and of the internal fill of the pools were partly lost. In spite of its small size, the studied volume represents a realistic analogue both for comparable sediments in real aquifers and for the large-scale basin fills that are formed by concave-up channel fills cut into low-permeable fines, hence the results can be used to critically analyze and improve the simulation techniques even at this scale.

THE ROLE OF 3D LITHOSTRATIGRAPHICAL MODEL AS A TOOL IN GROUNDWATER VULNERABILITY MAPPING

DUCCI Daniela¹, SELLERINO Mariangela²

1 - Department of Hydraulic, Geotechnical and Environmental Engineering, University of Naples "Federico II"

2 - Consulting engineer

Presenter e-mail: daniela@unina.it

Key terms: Aquifer Vulnerability to Pollution; 3D models; GIS

The aim of this paper is to apply a computer based methodology in order to reconstruct a lithostratigraphical 3D model of an aquifer so as to define some parameters involved in the evaluation of the aquifer contamination vulnerability.

The last twenty years have seen the widespread use of point count system methods in the evaluation of 'Aquifer Vulnerability to Pollution', such as DRASTIC (Aller et al. 1987), widely used in the USA, and SINTACS (Civita & De Maio 2000), based on the same seven parameters, but with some modifications due to the most commonly found Italian hydrogeologic settings.

Moreover, the advent of GIS, permitting the inventory, archiving, retrieval and display of spatial data and the link to numerical rating systems, made the use of point count system methods easier and encouraged the development of new specific methods as the AVI method (Van Stempvoort et al. 1993).

The SINTACS method has been applied to an alluvial coastal aquifer of the Southern Italy (Corniello et al. 2011). The stratigraphical reconstruction has been obtained by interpolating stratigraphical data from more than one borehole per 2 square kilometres. The software used for the lithostratigraphical model creation is Rockworks 2006, which allows the reconstruction of a 3D model for tridimensional or bidimensional representation. The reconstruction allowed to identify the main aquifer in the thick alluvial and marine clastic sediments. The piezometric pattern (defined by the piezometric surface monitoring) shows the groundwater flow direction toward the sea.

In the studied river plain, the layers of depth to water, impact of the vadose zone and hydrogeological characteristics of the aquifer media have been evaluated not by the interpolation of the single boreholes and piezometers, but by the 3D model, assigning the scores of the parameters of each layer of the 3D model. The comparison between the hydrogeological characteristics of the aquifer media constructed from the weighted values in each borehole and from the attribution of the aquifer media value of each layer of the 3D model, highlights that the second representation avoids or minimizes the plume effect linked to the presence of boreholes with higher or lower values.

In the same alluvial plain also the AVI method (Van Stempvoort et al. 1993) has been applied. This method uses only two variables to formulate a vulnerability index, these being: the thickness of each sedimentary layer above the uppermost saturated aquifer (d) and the estimated hydraulic conductivity of each of these layers (k). The "hydraulic resistance" (c) of each layer is then calculated as the quotient of thickness and conductivity ($c = d/h$). The total hydraulic resistance for several sedimentary layers is established by summing the values for each layer. Authors suggest to make this calculation for each borehole, and then to interpolate the c values (inversely proportional to the Vulnerability). In this study the c values have been easily assigned to each layer of the 3D model. The Vulnerability map thus calculated is as effective as applying SINTACS, but here the evaluation is speedier and suitable also at a regional scale.

The resulting vulnerability maps demonstrate that parameter layers prepared using the 3D model generate gradually changing boundaries between vulnerability classes. Sudden changes caused by data points are avoided. The main stratigraphical variations are along vertical paths, as expected in the sedimentation phenomena.

3D MODELLING HYDROSTRATIGRAPHIC GEOMETRIES FROM REGIONAL TO LOCAL SCALE

CAVALLI Emmanuele¹

1 - Università degli Studi di Milano, Dipartimento di Scienze della Terra "A. Desio"

Presenter e-mail: emmanuele.cavalli@unimi.it

Key terms: alluvial sediments; hydrostratigraphy; 3D modelling; quantitative geology

Realistic hydrostratigraphic models are necessary to compute the hydrological balance of surface vs. ground waters. In this perspective a key-sector of the Lombardy alluvial plain NE of Milan was selected to study the relations between Adda river and the phreatic nappe. The study focuses on a 10x10 km area close to Cassano d'Adda, that includes the local uppermost alluvial terraces (Middle Pleistocene glacio-fluvial sediments), the intermediate "Livello Fondamentale della Pianura" (Late Pleistocene sandur) and the lowermost post-glacial terraces within the Adda valley. In the subsurface, the transition between the northern glacio-fluvial alluvial fans and incised valleys, and the southern braided river deposits, occurs. This hinge corresponds to the transition from a single phreatic aquifer (North) to a stack of partly confined aquifer complexes (South), that is accompanied by emergence of the phreatic nappe along a belt of plain springs ("fontanili"). In this area many canals derive up to 95% of the discharge of the Adda river. In this work, the new geological and hydrostratigraphic model of the area is presented. The work is based on surface geology and subsurface stratigraphy, in a GIS environment linked with a 3-D modelling software, that allowed for a "try and error" procedure of stratigraphic correlation.

The results show the architecture of a large T-R sequence, from the marine Early Pleistocene to the present-day fluvial setting, punctuated by low-order cycles. The lowermost Geological Unit (GU-O, Early Pleistocene) is formed by gently tilted marine shales with sporadic gravel and sand lenses. Three complex channelized sequences, with erosion relationships (GU-1a, GU-1b, GU-1c) are incised into, and stacked above the marine deposits. These sequences are interpreted as the local effect of Middle Pleistocene eustatic cycles and uplift of the Alpine substratum. In this time the coastline moved at least three times from N to S, temporarily exposing the previous coast and shelf environments. The resulting incised valleys were filled by the three GU-1 sub-units. The subsequent regional regressive pulse is witnessed by the glacio-fluvial sandur of GU-2 (Middle Pleistocene), which buries the GU-1 sequences, after a large south-eastward shift of the coastline. GU-2 and the overlying GU-3 (Middle p.p. - Upper Pleistocene amalgamated gravels and sands) are separated by a very Pleistocene red paleosol throughout the entire study area. During latest Pleistocene (LGM) decametric silt layers cover the ancient fluvio-glacial gravely sediments. The Postglacial (PG) to recent sediments are confined within the Adda valley.

This geological reconstruction leads to a hydrostratigraphic scheme that includes: 1) Basal Aquiclude (GU-0), laterally continuous at regional scale with local, small, confined and partitioned Aquifer systems; 2) Intermediate Aquifer Group (GU-1a, GU-1b, GU-1c) with a complex alternation of fining upwards sequences and juxtaposed gravel and fine-grained bodies due to erosion; 3) Uppermost Aquifer Group (GU-3, GU-4), decametric amalgamated gravel and sandy gravel units, locally separated fine-grained layers (preserved palaeosols); 4) Shallow Aquitard (GU-5) forming a discontinuous sandy silt cover above the underlying aquifers.

The geological and the hydrostratigraphic units have been modeled in 3-D, obtaining the maps of their boundaries, the location of their pinch-outs and the distribution of the internal genetic units (fining and coarsening upwards sequences). A descriptive statistic approach was used to characterize the sediments of these units. Multivariate analysis permitted to quantify the vertical and lateral variation trends of lithofacies and poro-perm properties.

The quantitative geological model yields the shape of the highest-order stratigraphic units within which the internal architecture and the permeability, porosity and electrical field gradients can be interpolated and/or simulated.

Key terms: Carbonate aquifer; groundwater circulation; Conceptual hydrogeological model

In this speech a scheme of groundwater flow circulation between the structures of Lepini Mountains, Albani Hill and Pontine Plain is offered, developed through a research program sponsored by Roffredo Caetani Foundation and funded by the Province of Latina and the Latium Region. In this analysis great importance is given to the geological and structural setting because these elements give an invaluable support to the conceptual scheme of groundwater circulation between aquifers belonging to the domains of carbonate, volcanic and fluvial-lacustrine geological facies.

The authors, following the surveys and original interpretations, have produced a 1:50,000 scale geological map and several cross sections referring to entire study area.

The map highlights that the structural setting is more complex than noted in the past by other authors.

The geological study has identified areas where the groundwater flow is blocked by subdivision due to compressive and distensive tectonic movements that affected the chain of Lepini Mountains.

As the carbonate structure dips below the Pontine Plain, the groundwater flow appears partially at the contact with fill deposits of the plain and on the other end flows through calcium deposits submerged that are upperly confined by lithological complex with low permeability.

The cross sections of the Pontine Plain were constructed on the basis of geophysical, gravimetric and geoelectrical surveys and on the basis of stratigraphy obtained from geomechanical surveys.

For the entire study area, the geological map and cross sections has been read with hydrogeological approach obtaining complex with similar groundwater circulation behavior

Of particular interest is the cross section parallel to Via Appia (SS 7), it provides important information on the carbonate bedrock trend and on the volcanic complex trend towards SE, which is going to leap with the silty sand complex of fluvial-lacustrine facies.

These results provide the 3D hydrogeological model which allows us to formulate the hydrogeological kind of boundaries existing between the units concerned.

From the hydrogeological model carried out as stated aquifers behavior numerical model implementations and distributed hydrogeological balance assessments are derived by a method not contained in this presentation.

Key terms: Hydrogeophysics; Aquifer characterization; Vertical Electrical Soundings; Electrostratigraphy; Lodi plain

Hydrogeophysical imaging is an approach to efficient representation of alluvial aquifer heterogeneity. The integration of hydrostratigraphy with ground-based Direct Current resistivity methods can be effectively used to fill the gap between borehole data and to obtain valid representations of sedimentary heterogeneity from the scale of depositional systems to the scale of basin fills.

Such an approach was applied to the Quaternary aquifers of the southernmost Lodi plain (Lombardy, Italy) where syn-depositional tectonics acted by shaping the depocentral areas and the hydrogeological divides between the uplifted and folded Pliocene-Lower Pleistocene marine-transitional sequence, composed by clays and sand to gravel/conglomerate lenses, and the Middle to Upper Pleistocene alluvial sequence, composed by gravely-sands to sands and sandy-silty clays. 35 Direct Current (DC) Schlumberger Vertical Electrical Soundings (VES) and 7 Time-Domain Electromagnetic Soundings (TDEM) were collected over a 37 km² area across the Casalpusterleno and Zorlesco relic reliefs. Here, the weathered alluvial units are exposed due to the structural culmination of Apenninic two ramp anticlines.

Electrostratigraphic interpretation of 1D VES resistivity models, calibrated with deep subsurface data (water wells) including groundwater chemistry, and supported by TDEM models, yielded the identification of the

electrostratigraphic sequence and of the local geoelectrical heterogeneities.

N-S and W-E oriented electrostratigraphic sections, more than 50 km long, enabled to detail the aquifer compartmentalization. Electrical resistivity was used as a "proxy" of the hydrofacies association at depth, thus identifying the electrostratigraphic units (EsUs) in the subsurface, i.e. the geophysical signature of hydrostratigraphic units. These units are meters to tens-of-meters high and thousands of meters long, defined as sedimentary volumes identified by resistivity contrasts that spatially preserve the vertical polarity by i) the horizontal variation of the electrostratigraphic sequence, and ii) the increasing thickness at increasing depth, according to the equivalence principle.

Lithology logs near the Casalpusterleno and Zorlesco reliefs enabled to integrate electrostratigraphy and hydrostratigraphy through the identification of the resistivity contrasts produced by the vertical stacking of the Middle to Upper Pleistocene alluvial sequence above the uplifted and folded Pliocene-Lower Pleistocene marine-transitional sequence.

From top to bottom, an association (T1) of N-dipping, alternating resistive and conductive EsUs association, up to 140 m thick, corresponds to Middle to Upper Pleistocene freshwater aquifers. The major resistivity contrast bounding the base of T1 reach the shallowest depth in correspondence of the Casalpusterleno and Zorlesco reliefs, where T1 wedges out and partially covers the top of an association (T2) formed by a widespread, high-conductive EsU which contains resistive, lens-shaped EsUs, tens of meters thick, corresponding to the freshwater aquitards and aquifers hosted in the Pliocene-Lower Pleistocene sequence. The inferred geometry and the hydrostratigraphic interpretation are well supported by the exposition of the weathered, low-resistive alluvial units, which smooth the fold hinge.

To the South, the deepest detectable resistivity contrast at the base of T2 association marks the presence of a widespread, very high-conductive EsUs (association S). The low values of electrical resistivity at depth are well constrained by electrical logs in deep wells drilled for hydrocarbon exploration and by a deep dipole-dipole DC survey across the San Colombano anticline and can be correlated to the presence the fresh-saltwater interface.

THREE - DIMENSIONAL NUMERICAL MODEL OF GROUNDWATER FLOW IN THE LOMBARDY PLAIN (NORTHERN ITALY): GROUNDWATER BUDGET ANALYSIS

CANEPA Paola¹, BONOMI Tullia¹, FEINSTEIN Daniel Timothy²

1 - DISAT - Università degli Studi di Milano - Bicocca

2 - United States Geological Survey

Presenter e-mail: paola.canepa@unimib.it

Key terms: 3D numerical model; Groundwater budget; Lombardy plain

Groundwater sustainability must be based on a detailed knowledge of the aquifer system and the groundwater budget. Computer science and numerical models allow scientists to integrate and process a large amount of different data regarding hydrogeological settings and groundwater budget sources and sinks. Consequently, numerical models can be useful to support decision makers in water management.

This report describes the development and first results of a 3D numerical model that reproduces groundwater flow and budget in the Lombardy plain (Northern Italy) which extends from eastward from the Ticino river to the Oglio river. The study area is about 6,900 Km². The aquifer system consists of Quaternary alluvial sediments; its geometry is defined according to the depositional surfaces as described in "Geologia degli acquiferi Padani della Regione Lombardia" (Regione Lombardia, Eni Divisione AGIP, 2002). Furthermore, a complex network of surface water (streams, canals and "fontanili") characterizes the study area and influences the piezometric levels.

The model was developed using MODFLOW - 2005. It integrates 8,429 stratigraphic logs (stored in a customized well database, TANGRAM) and monitoring data of groundwater budget inflows and outflows. A specific method was used to calculate the spatial distribution and temporal fluctuations of aquifer recharge: Soil Water Balance code (SWB). SWB calculates recharge on a rectangular grid congruent with the MODFLOW grid. It uses commonly available land-surface data (land use, flow direction, hydrologic soil groups and AWC) and climatological information (chiefly, precipitation and temperatures). It easy to manage these data in a Geographic Information System.

The aquifer was discretized into 207 rows, 333 columns and 107 layers of non-uniform thickness. Cells are 500 x 500 m. 3D geostatistical reconstructions of aquifer heterogeneity, based on georeferenced stratigraphic logs, were used to define the distribution of aquifer hydrologic properties (hydraulic conductivity and effective porosity). In this way, properties values vary cell to cell. Model boundary conditions represent natural and anthropic elements that affect the groundwater budget such as streams (head-dependent flux boundary), recharge from infiltration of precipitation (specified-flux boundary) and pumping wells (specified-flux boundary).

The model was calibrated to steady-state conditions by using average heads (2001-2005) from the Lombardy Regional Monitoring Network. The calibrated model simulation adequately reproduces the elevations and trends of the regional water table, but the results also suggest that more information about withdrawals and rates of stream loss or gain would appreciably improve the fit in some places. Rates of stream loss or gain could be used as flux targets to also calibrate the model strictly. In this way, simulated volumetric budget would compare better with measured inflows and outflows.

NUMERICAL FLOW MODELLING OF THE POROUS AQUIFER FOUND IN THE ALLUVIAL SEDIMENTS OF THE RIVER ROJA IN VENTIMIGLIA (LIGURIA, ITALY)

CAPACCI Fausto¹, MIGLIORINI Jenny¹, BARAZZUOLI Piero¹, RIGATI Roberto¹

1 - UNIVERSITA' DEGLI STUDI DI SIENA

Presenter e-mail: capacci10@unisi.it

Key terms: Aquifer; Hydrogeology; Roja; Flow

The part of the aquifer studied is contained within the Quaternary alluvial and detrital sediments that crop out to the north of the city of Ventimiglia (Liguria, Italy) and extends for around 2 km² in the area of confluence

between the rivers Bevera and Roja.

The geometrical/structural reconstruction of the subsurface was carried out on the basis of the lithostratigraphic data obtained from geostatic drilling and of the geophysical surveys performed in the ambit of the "Eurobasin" and "Risknat" European Community Projects. The presence was thus revealed of a single unconfined aquifer, mainly composed of sandy gravel with pebbles, with an average thickness of 32 m and characterized by a high degree of permeability. This aquifer is confined below by a substratum with low permeability, composed of Ventimiglia Flysch.

The hydrodynamic characterization of the aquifer was carried out by means of a piezometric survey of 20 measurement points (wells and piezometers) which made it possible to represent the groundwater flow field in the period between June 2010 and June 2011.

Thanks to this background knowledge (appropriately integrated with data regarding anthropic impacts), it was possible to develop a conceptual model of the aquifer that allowed us to determine the inflows (river Roja, river Bevera and infiltration) and outflows of the system (pumping and river Roja), from which, despite the strong impact water pumping, a positive hydrogeological balance was seen.

Moreover, it emerges that the majority of the aquifer is very susceptible to waterborne pollution, which gives rise to the necessity for suitable measures for its safeguard, also because of its great importance to both the Italian and French communities as a strategic source of drinking water.

In order to reach the objective of a correct and integrated management (quality/quantity) of this water resource, in both space and time, once the conceptual model had been elaborated we proceeded with the construction of a numerical model which, by means of a process of iteration, made it possible to verify the hypotheses formulated regarding the aquifer's hydrogeological and hydrodynamic properties.

The aquifer system was represented by means of a three-dimensional numerical model with finite elements (FEM), with the use of the FEFLOW 6 numerical code (Finite Element subsurface FLOW system), capable of combining powerful and versatile calculus algorithms that interface with GIS systems.

3D GEOLOGICAL MODELLING AND GROUNDWATER MANAGEMENT IN THE CAMPANIAN PLAIN (SOUTH ITALY)

FABBROCINO Silvia¹, FORTE Giovanni²

1 - Department of Earth Science; University of Naples Federico II

2 - University of Naples Federico II

Presenter e-mail: forteu@hotmail.it

Key terms: 3D geological modeling; Groundwater management; Flow model

Three-dimensional geological modelling is a key topic in hydrogeological studies and has significantly developed in last decade. Despite the constant improvement of knowledge and technologies in 3-D mapping, the predictive function of groundwater models is often constrained by the lack and dishomogeneity of competent existing data.

The present paper points out an integrated approach, combining sedimentological, stratigraphical and hydrogeological analyses, to construct a better and more reliable groundwater flow model in complex geological areas, such as the coastal campanian plains.

The sample area is a sector of Campanian Plain, located between the Sarno River Plain and the southwestern extremity of the low Solofrana River Valley, wide approximately 10 km².

The site is an area of intense exploitation of groundwater resources, because of many industrial and agricultural activities.

The existing boreholes data, integrated with geomorphological and structural information, have been used to build and bind an hydrogeological block diagram. The subsurface model has been used to better define the complexity of this plane sector and to identify the most accurate boundary conditions for the flow model.

The setting up of groundwater mathematical model has been calibrated using an iterative approach based on a try and error procedure.

As a result the simulation of a specific pumping scenario follows a real observed state (recorded in July 2006) and shows the great control of anthropic activities on the groundwater flow conditions of plain aquifer systems.

So an optimized approach to perform an integration between geological and hydrogeological issues is discussed with reference to a real case.

HYDROGEOLOGY OF THE VIVERONE LAKE AREA (PIEDMONT, NW ITALY).

DE LUCA Domenico Antonio¹, BARBERO Erica¹, FORNO M. Gabriella¹,

GIANOTTI Franco¹

1 - Department of Earth Sciences, Turin University

Presenter e-mail: domenico.deluca@unito.it

Key terms: hydrogeology; Ivrea Morainic Amphitheatre; Viverone Lake; Pleistocene

The research regards the hydrogeological reconstruction of the left frontal sector of the Ivrea Morainic Amphitheatre (IMA). In detail the studied area includes the internal depression in which the Viverone Lake develops, the frontal morainic relief that borders the lake and the proximal sector of the external glaciofluvial plain. The local stratigraphy was reconstructed based on the interpretation of the water well logs. The pre-glacial succession consists in ancient Dora Baltea fluvial sediments (Lower Pleistocene). The overlying glacial succession includes the Dora Baltea Glacier subglacial and marginal sediments (Middle-Upper Pleistocene), forming the morainic hills. At the top of the sequence different glaciofluvial covers form the external plain (Middle Pleistocene) and the internal depression (Middle-Upper Pleistocene).

Some hydrogeological complexes are defined according to their textural features and stratigraphic position.

The Hydrogeological Complex A consists of the pre-glacial fluvial sandy-gravel with high permeability and hydraulic conductivity estimated greater than 10-5 m/s. A layer of reddish silty clay is probably referable to a buried paleosol developed at the top of the unit. This complex constitutes a deep confined aquifer.

The hydrogeological Complex B consists in numerous overlapped lenticular bodies of prevalently matrix supported deposits, belonging to the IMA

glacial succession. Coarse gravel with blocks in a sandy-silty matrix are referable to marginal deposits, with hydraulic conductivity greater than 10-5 m/s. Laminated silty sand and clayey silt correspond to glaciolacustrine fine sediments with low permeability (conductivity 10-5÷10-7 m/s). Finally, over-consolidated massive silty sand with gravel corresponds to subglacial till with low permeability (conductivity 10-7 m/s). This complex constitutes a multilayer aquifer.

The Hydrogeological Complex C is represented by sand and gravel, with hydraulic conductivity greater than 10-5 m/s. In detail it includes sandy gravel glaciolacustrine deposits of the external plain, constituting a shallow aquifer, and a sandy fan-delta glaciolacustrine lower body filling the internal depression, constituting a semi-confined aquifer.

The Hydrogeological Complex D consists of a fan-delta glaciolacustrine and glaciolacustrine upper body of the internal depression, and of the recent lacustrine deposits at the floor of the Viverone Lake. This complex, with hydraulic conductivity between 10-7 and 10-9 m/s, constitutes an aquitard.

The collected hydrogeological data were obtained by two piezometric surveys (October 2009 and August 2010). Three flow systems (surficial, intermediate and deep) have been recognized. The deep flow system develops below 180 m a.s.l., the intermediate one between 230 (Viverone Lake surface) and 180 m a.s.l. (Viverone Lake floor) and the surficial flow system higher than 230 m a.s.l.

The surficial flow system (contained in the B and C complexes) flows generally from the morainic reliefs to the Viverone basin, feeding the lake. The intermediated aquifer (contained in the B and C complexes) feeds the lake, except at the lake floor (180 m a.s.l.) where the flow is directed from the lake towards the aquifer.

The deep flow system, contained in Complex A, is directed from the lake floor to East, while a westward flow is impeded by the presence of Complex D deposits. A drainage axis into the Complex A develops with NNW-SSE direction at the East of the Viverone Lake, from Roppolo to Alice Castello.

The lake and well waters belong to a bicarbonate-Ca Mg hydrochemical facies. Both surficial and deep waters result of the same type with different compositional maturity, owing to a connection between the lake and the aquifers.

The hydrogeological balance of Viverone Lake is highly influenced from groundwater, with an input of 6.21 Mm³/y and output of 0.86 Mm³/y.

ELECTROMAGNETIC EFFECTS GENERATED BY FILTRATION OF FLUID IN PERMEABLE POROUS LAYERS

FEDORYSHYN Oleksandr¹

1 - Carpatian Branch of Subbotin Institute of Geophysics of National Academy of Ukraine

Presenter e-mail: ofedoryshyn@mail.lviv.ua

Key terms: porous layers; filtration theory; magnetic field

In this work the theoretical study of electromagnetic effects associated with the movement of liquid in saturated porous media is presented. There are enough examples of occurrence of such effects in real rocks. Anomalous magnetic field always appears around working artesian and oil wells. The nature of this field is not fully understood, but there is reason to believe that it arises as a result of electrokinetic effects in the saturated rocks. For describing the motion of viscous fluids in porous media it is necessary to use the filter equations. These equations can be obtained from the equations of motion in viscous-elastic inhomogeneous solids by statistical averaging. As a result we obtain the dependence between fluid flow and pressure gradient, so-called the Darcy's law

$$\text{grad } p = -\frac{\eta}{k} \bar{q}$$

and the filter equation

$$\Delta p - \frac{\eta}{kk} \frac{\partial p}{\partial t} = 0.$$

The coefficient k is a permeability of medium, it does not depend on fluid

properties, but only on the geometrical structure of pore space, η is the viscosity of fluid. Based on these equations we can be obtained pore fluid pressure distribution in the layer $p(r, t)$, and fluid flow $q(r, t)$. At the separation surface between solid and liquid phases of rock electric charges always appear. Liquid moving in consequence of filtration captures these charged particles generating thereby current which is not generated by an external electric field. This phenomenon was called seismo-electric effect of the second kind. Seismo-electric current generates a magnetic field. This field on the order of magnitude is much smaller than the natural magnetic field of the Earth, but modern high-precision measurement methods allow you to fix it.

Saturated rocks under certain conditions can generate electromagnetic radiation under mechanical actions (electromagnetic emission). The nature of this radiation is the same as the nature of the magnetic field caused by fluid filtration i.e. it represents a capture of charged particles moving fluid. Based on Biot model for saturated porous media can be found fluctuations of velocity inside of the medium. If the pores are interconnected i.e. the medium is permeable, these fluctuations represent the relative velocity of movement between liquid and solid phases, i.e. that velocity of the particles of the body that is responsible for the appearance of

electromagnetic emissions. We introduce the dimensionless parameter ξ tortuosity of the pores, which represents the ratio of surface area of porous medium with random porosity to the surface area of porous

medium with spherical porosity, this will be $1 \leq \xi < \infty$. This parameter depends only on the geometrical structure of pore space. Theoretical estimates show that the fluctuation rate is proportional to the amplitude of excitation wave. The coefficient of proportionality depends on both

frequency as Ω^2 and the tortuosity $(\xi^2-1)/\xi^2$. From electrodynamics it is known that the intensity of the moving charge is proportional to the square of its acceleration,

$$P = \frac{2e^2}{3c^3} \dot{v}_c^2.$$

Thus we can be concluded that the intensity of electromagnetic emissions

will depend on the amplitude of excitation wave in proportion to Ω^4 . The given mathematical model gives us the qualitative description of the seismic-electric effect in saturated porous media. Based on this model we can plan doing laboratory experiments on real samples of rocks.

ANALYTICAL SOLUTIONS OF THE RICHARDS EQUATION FOR A FINITE-THICKNESS DOMAIN

MENZIANI Marilena¹, PUGNAGHI Sergio¹, VINCENZI Sergio¹

1 - Dip. Ing. Materiali e Ambiente Università di Modena e Reggio Emilia

Presenter e-mail: sergio.pugnaghi@unimore.it

Key terms: Richards equation; Finite thickness domain; Porous aquifer; Aquifer recharge; Soil water content

Numerical methods are very powerful in solving complex nonlinear problems but, in contrast, analytical solutions of differential equation, well describe the physical mechanisms of the involved phenomena. For this reason the analytical solutions of the linearized Richards equation are searched and compared with the numerical ones. The linearization of the nonlinear differential Richards equation simplifies the model but the solutions are related to the considered domain. The authors determined a procedure computing the solutions of the linearized one-dimensional Richards equation for a half-space domain for any discrete soil volumetric water content initial vertical profile and any discrete flux boundary condition. Here it is shown a method to solve the same linearized Richards equation, but for a finite-layer. Both the initial condition (vertical profile) and the two boundary conditions (at the top and at the bottom) are any discrete step functions; that is the measured soil water content at a hydrological station. These solutions represent the time evolution of the profile of the soil water content reading measured in the first two meters surface layer (Parma-Taro area) better than the solutions obtained using the half-space domain procedure.

INFLUENCE OF THE GEOLOGICAL SETTING ON THE RESPONSE TO CLIMATIC CHANGE AND TO INCREASING PROLONGED DROUGHT PERIODS OF FRACTURED LIMESTONES SYSTEMS

CAMBI Costanza¹, DI MATTEO Lucio¹, VALIGI Daniela¹

1 - Dipartimento di Scienze della Terra - Università degli Studi di Perugia

Presenter e-mail: coscambi@unipg.it

Key terms: Climatic change; Drought; Fractured aquifer; Spring; Recharge area

It is widely known that, in Southern Europe and the Mediterranean area, in the last hundred years, the temperature has risen by about 1°C, and the average annual precipitation has increased. The analysis at different time scales of historical thermo-pluviometric series recorded in South/Central Italy shows a higher frequency and duration of droughts in the last few decades: the number of three years lasting dry periods recorded since 1990 are as many as those recorded in the interval 1921-1989. The hydrogeological processes regulating both ground and surface water availability are greatly influenced by climate change. If the present trend should continue, a reduction of total yield of 10-20% with respect to present should be expected in the next 50 years. This work shows that the response of a specific hydrogeological system to climate change closely depends on the geological and lithological characteristics of the system. The aquifers hosted in the karst/fractured limestones extensively outcropping in the mountain areas of Central Italy, which supply several mountain springs with high-quality water, are taken as examples. The recharge areas of the springs fed by these aquifers are unaffected by human activity: the analysis of spring discharges is therefore useful to understand the effect of climate change on groundwater regimes. Some of the springs of the Umbria-Marche Apennines, (e.g., Bagnara, Scirca, Pescara di Arquata del Tronto) have long, continuous discharge data sets which show statistically significant negative trends of mean annual and monthly discharges. The Bagnara spring, which is of great importance on the water supplying point of view, is an example of "local system" representing the "overflow" of a deeper regional groundwater circulation, connected with larger "base springs", the quality of which is often poor due to interactions with evaporitic sediments of Triassic age. Springs of this kind are quite frequent in the Umbria-Marche region. A dynamic groundwater divide, the position of which depends on the amount of recharge, separates the recharge areas of the regional flow from those of local springs as Bagnara: low recharge periods correspond to a low level of the piezometric surface, with the piezometric divide shifted towards the systems located at higher elevations and a consequent reduction of their recharge areas. On the contrary, the other system taken as an example in this work, the Lupa spring, although similar to Bagnara for lithological, topographical and climate characteristics and for mean annual discharge (about 120 l/s), has a geologically defined recharge area the extension of which does not depend on the recharge. The analysis of the recession curves of these two springs showed that the response to prolonged drought periods is more severe for the Bagnara than for the Lupa spring; this result can be extrapolated to all the springs connected to a deep regional groundwater circulation, which are more vulnerable to climate change than those with invariable geologically defined recharge areas.

A LABORATORY PHYSICAL MODEL TO ANALYSE FLOW AND TRANSPORT PROCESSES IN POROUS AND FRACTURED ROCK SAMPLES AT BENCH SCALE LEVEL

CHERUBINI Claudia¹; GIASI Concetta¹; PASTORE Nicola¹
1 - Politecnico di Bari

Presenter e-mail: claudia.cherubini@gmail.com

Key terms: experiments; bench scale; drainage/recharge; tracer tests; numerical modeling

The knowledge of flow and transport phenomena in porous media and fractured rocks is very important in hydrogeologic engineering in order to optimize clean up and monitoring strategies, to carry out risk assessment and to manage interventions in aquifers.

Recently, understanding, characterizing and modelling physical and chemical interactions within fractured aquifers has acquired increasing importance, especially with regard to the question of water resources development and groundwater contamination. Sometimes the equivalent porous medium approach fails to reproduce flow and transport patterns in such complex geological formations.

In this paper are presented different experimental studies carried out at bench scale in both porous and fractured rock samples having different shapes and covered in different ways.

Mainly these laboratory activities focus on the role of solution features within the media on flow and transport processes. High permeability non consolidated media with low permeability discontinuities and fractured rock samples have been analyzed.

The porous medium is located inside a watertight pond of 0.76x0.18x0.50 m dimensions with two ports located at the northstream and southstream sides at different heights while the fractured rock samples of parallelepiped (0.60x0.40x0.8 m) and cylindrical (0.25x0.25 m) shape have different ports in correspondence of the fractures and are submitted to different boundary conditions configurations by changing the entry and exit ports.

Hydraulic loss for drainage/recharge tests and breakthrough curves for saline tracer pulse are measured in transient and steady state flow field through the covered samples.

The above experiments are aimed at understanding the relations existing between the applied boundary conditions, the geometry of the system and the occurring flow and transport phenomena. Even the effects of non linearity have been investigated both for porous and fractured media. The observed data have been compared with numerical model results in order to show the divergence between experimental evidence and conventional models.

A comparative analysis of measured and simulated results has given information about the properties of the investigated sample on the one hand, and about the possibilities and limitations of the chosen model concept on the other.

10.1474/Epitome.04.0074.Geoitalia2011

WATER MIXING IN KARST SYSTEMS TRACED BY DISSOLVED NOBLE GASES

MAGRO Gabriella¹, GHERARDI Fabrizio¹, BELLANI Stefano¹
1 - CNR-Istituto di Geoscienze e Georisorse, Pisa

Presenter e-mail: g.magro@igg.cnr.it

Key terms: Helium isotopes; dissolved inert gases; karst; hydrology

The complex hydrodynamics of three selected karst systems in Europe (Baget and Larzac in France, Drama in Greece) was investigated by means of dissolved noble gases (He, Ne, and Ar) and N₂ in spring waters. The molar ratios and isotopic composition of these conservative compounds help to trace mixing processes in karst systems and to identify the occurrence of air excess and deep He excess in spring waters.

The dissolved gases were extracted from sampled water by means of the space head method and the measured concentrations were recalculated to spring water conditions using Henry's law.

N₂ and Ar were analyzed by gaschromatography, He and Ne by a quadrupole mass spectrometer after separation in an all metal high-vacuum line. The He isotopic composition (expressed as R/Ra = (3He/4He)_{sample}/(3He/4He)_{air}) was obtained by means of a magnetic mass spectrometer for rare gases.

Most of the spring water samples show N₂/Ar and He/Ne ratios higher than those expected for water equilibrated to air (ASW) in the temperature interval of cold springs (0° to 15°C). The presence of excess of air in water is a common event, mainly due to small bubbles of air entrapped by recharge water at the undersaturated-saturated interface. For all of the samples the shift of N₂/Ar from theoretical values is well explained by addition of air. The presence of N₂ excess derived from sources different of air cannot however be excluded.

The presence of air excess by itself does not explain the He/Ne ratios higher than asw/air typical ratios in a few Larzac and Baget samples and in most of the Drama samples.

Three main conclusions can be drawn on the basis of the He isotopic composition. Samples from Baget show a dominant air and air saturated water origin; Larzac samples have a slight mantle-derived He excess, while a crustal He excess is evident for Drama.

The Larzac samples result from the mixing of a dominant air/asw end-member with a deeper 3He-enriched component, as it occurs in the nearby thermal spring of Auvergne, along the Rhone Graben, marked by R/Ra up to 2.5.

The Drama samples result from the mixing of an air/asw end member with 4He crustal-derived enriched fluids.

The influence of deep waters enriched in He was more evident during the dry season. Karst waters are the result of a complex hydrologic circulation of several reservoirs with different water residence times that exchange water mainly during floods.

ISOTOPIC RATIOS AS FUNDAMENTAL TOOL IN KARST AQUIFER STUDIES: SOME RESULTS FROM ISOTOPIC APPLICATIONS IN THE APUAN ALPS CARBONATIC COMPLEXES

DE FILIPPO Simona¹, DOVERI Marco², MENICHINI Matia¹
1 - Dipartimento di Scienze della Terra, Università di Pisa
2 - Istituto di Geoscienze e Georisorse, CNR, Pisa

Presenter e-mail: m.menichini@igg.cnr.it

Key terms: karst aquifers; isotopic ratios; Apuan Alps

Karst rocks may be considered among the most important aquifer complexes, but their vulnerability and wide variability in flow rate pose some problems to the water resources management. An useful tool to

know karst aquifers and their hydrodynamic behaviour is represented by isotopic ratios, like as 18O/16O and 2H/1H of H₂O and 13C/12C of TDIC. In mountain environment, where karst aquifer systems are often located and conventional hydrogeological surveys are not easily carried out, the isotopic approach allows to provide information related to the whole basin drained by the analysed springs. An isotopic screening can also constitute a valid basic working for specific surveys such as tracer tests, showing the areas from which the tracer will likely reach the springs under study. Water-stable isotopes contents in groundwater are linked to meteoric precipitations ones, which are characterized by variability with altitude and seasonal periods, although their annual weighed average value is rather constant in a determinate site; the 13C/12C ratio depends chiefly on biogenic CO₂ input and on water-rock interaction. Consequently, isotopic analyses can be helpful to define the feeding area and the hydrodynamic response to the rainwater infiltration. To achieve the best results by means of the isotopic techniques is important to know the vertical isotopic gradient of the studied area, as well as to compare the isotopic results with the hydrostructural features.

Major results of isotopic applications in hydrogeological studies carried out on the Apuan Alps carbonatic complexes are here discussed. The aquifers taken into account are chiefly developed in the metamorphic carbonate rocks of the Apuan Unit and secondary in the equivalent not metamorphic ones belonging to the Tuscan Nappe Unit. Karst springs with average flow rate in the range 30-100 L/s were sampled in the River Carrione basin (NW Apuan Alps) in low, high and transitional flow conditions, in any case after a sufficient time from storm events. Similar springs in the same flow regime conditions were sampled in the River Versilia basin (S Apuan Alps) in 2003 and recently, in graduate and Phd programs. Sampling was also carried out during storm events for both karst springs and rainfall, in order to evaluate the short-term effect of the infiltration. From an isotopic point of view the ratio 18O/16O, 2H/1H of H₂O and 13C/12C were determined.

In both areas also several low flow rate springs (1 L/s or slighter) flowing out from less important aquifers were analysed. These are widespread on large altitude intervals and are representative of short groundwater circuits with average feeding altitudes close to outflow ones. In this way, altitude vs. 18O/16O regression lines were obtained, allowing us to evaluate the average feeding altitudes of the high flow karst springs, for which 18O/16O was analysed. This information, together with 13C/12C data, hydrostructural features, flow rate regime and chemical data, allowed to delimitate the feeding areas of several karst springs, in some cases identifying hydrogeological basins wider than hydrographic ones. Isotopic data highlighted other important aspects: i) karst springs very close to each other, and showing the same chemical features, are characterized by important differences in average isotopic contents, which point out the presence of different circulation systems substantially separated; ii) some karst springs show a constant isotopic composition during the year, despite their high variability in discharge (high flow rate up to 200% greater than the low flow rate), thus highlighting a peculiar hydrodynamic behaviour of the aquifer, which is linkable to local hydrostructural features; iii) the kind of isotopic variations registered for some springs during storm events indicated the principal area from which quickly water circuits occur, reaching in a short time the same springs and altering their flow-base.

ANALYSIS OF THE TANK-RESERVOIR DRAINAGE AND SIMULATION OF KARST AQUIFERS

FIORILLO Francesco¹
1 - University of Sannio

Presenter e-mail: francesco.fiorillo@unisannio.it

Key terms: spring hydrograph; drainage; recession coefficient; karst

Drainage of a cylindrical water-filled tank- reservoir has been analysed by different physical models, providing relative discharge-time equations. The process has been simulated (1) in a condition of free-flow discharge, where no energy is lost during the process, and (2) where friction forces and water viscosity take effect. Simulation (1) is considered to be a Torricelli reservoir, characterised by a linear decrease of discharge; (2) is based on Darcy's law or on Poiseuille's law, where discharge decreases exponentially with time, giving a straight line in the semilogarithm plot. For the Darcy's law simulation, the tank tube was filled with sand. The cylindrical water-filled tank-reservoir drainage analysis has been applied to simulation of the actual shape of karst spring hydrographs. It has been determined that the recession coefficient, α , is proportional to a hydraulic constant, c , which represents the hydraulic characteristics during the baseflow recession, and α is inversely proportional to the product of the water-table area with the effective porosity. This product expresses the area of the aquifer filled by free-flowing water along the water table and can vary during the aquifer drainage.

VIGOLANA MASSIF (TRENTO - NORTH OF ITALY): WATER CIRCULATION IN A KARST AND FRACTURED AQUIFER

TERRANA Silvia¹, GAMBILLARA Roberto¹
1 - Università degli Studi dell'Insubria

Presenter e-mail: roberto.gambillara@uninsubria.it

Key terms: Vigolana; hydrogeology; water circulation; fractured rock; dual porosity

The Vigolana massif is located at South-East of the city of Trento, North of Besenello. This massif is delimited by four valleys: Valsorda to the North, the valley of the Centa river to the East, the Adige Valley to the West and the Gola Valley to the South.

The study area covers the South-West of the massif, where a tunnel, having a W-E direction was excavated.

This massif is characterized by the presence of numerous springs, including seven in the western sector. The spring, located inside the tunnel in Murazzi area (200 m a.s.l.), arises from the rock (dolomite) and it would seem, by the continuous monitoring since February 2009, with such perennial average flow of 80 l/s. The maximum flow rates (about 140 l/s) were found in May and minimum (50 l/s) in November and in March. The Vigolana massif is characterized by both highly fractured rocks and karst conduits that developed in the limestone and dolomite. The difficulties that have occurred in the study of this area were: the high

vegetative cover, the inaccessibility of many areas inaccessible and steep, a problem typical of mountain areas, and complexity in the reconstruction of the conceptual model for the presence of an extensive network of karst conduits within the rock mass.

The calculation of water balance showed a surplus of precipitation equal to $8.18E+07$ m³/year; this indicates that in the basin, delimited by the structural analysis, enters more water than what flows from the springs. By the characteristics of the Vigolana massif it was considered a rock mass, to scale the catchment area of the spring in a tunnel, as a medium of dual-permeability. In this massif the two media with different permeability are the portion of the fractured rock around the spring conduit and the karst conduit where the spring in the tunnel arises. The fact of considering the contribution by fractured rock mass and by the karst conduit, allowed a better quantification of phenomena and showed that the integration between different models, with a careful choice of the scales of analysis brings to good results applicable to management of water resources.

The estimation of the changing flows between the portion of the fractured rock around the conduit and the conduit gives indications on the possible exploitation of water resources and maintaining a base level, which derives from the fractured rock.

It was calculated a rate of exchange of $1.03E-05$ m/s per meter of variation in hydraulic load and per unit of area: this flow will be in favor of conduit when the load on the matrix will be greater than the conduit (Hm major than Hc), during periods when you have less rainfall, in the depletion phase of the flow curve; on the contrary, during charging period, you will find that this flow will be in favor of the fractured rock mass (Hm minor than Hc); no exchange takes place in the case of equilibrium (Hm equal Hc).

GEOTHERMAL ANOMALIES OF ITALIAN ALPINE CHAIN REGIONS: FEATURES OF THERMAL SPRINGS AND WELLS

MENEGON Alan¹, DE LUCA Domenico Antonio¹, GUGLIELMETTI Luca¹, MANDRONE Giuseppe¹

¹ - Dipartimento di Scienze della Terra, Università di Torino

Presenter e-mail: alan.menegon@unito.it

Key terms: THERMAE; SPRINGS; GIS-DATABASE

Volcanoes and hydrothermal phenomenon are evidence of the Earth inner heat flowing outside. In particular, hot water springs highlight deep thermal anomalies. Every study concerning geothermal phenomenon begins from the mapping of these evidences.

This study is part of a research project concerning thermal claims in northern Italy. The aim of this study is to create an updated database of northern Italy thermal springs and wells, gathering bibliographic and technical information from universities and authorities. All data collected in the database are displayed in a GIS project that provides a global view of all data, and are exported in a GoogleEarth® application. This application allows to have a sudden overview of all the objects of study, displayed with their main features (location, physical, chemical and isotopic features), in a way easy to be read by everyone.

The Alps do not host particular thermal anomalies or abnormal heat flow, but show many examples of thermal springs. Thermal rate, discharge and chemistry of thermal waters are rather different. Since roman times (2000 years B.P.) thermal springs were exploited for their curative properties all over Italian territory but, thanks to recent technologies, hydrothermal resources aren't important only for body wellness but also to produce electricity. Binary cycle can produce electricity using temperature from about 75 °C and discharges of at least 30 l/s.

The database counts over 350 springs and wells with a temperature over 20 °C, including 137 deep petroleum probe drilling in Po Plain. In particular, 7 thermal springs, 28 thermal wells and 40 petroleum probe drillings show a temperature over 60 °C, a parameter that is important to evaluate if the geothermal resources has a potential also for power generation. Most of these wells and springs are include in six main geothermal areas. In these main anomalies, peculiar geological assessment brings hot waters to the surface or at low depths, so thermal water can be exploited by wells.

Even if it is not possible to find similar geological origin alpine thermal springs, many recurrent items can be recognized. The greater number of Italian alpine thermal springs are not related to particular thermal anomalies, according to chemical, isotopic and geo-structural data. In presence of approximately normal geothermal gradient, the geological assessment is a decisive factor in water heating. Meteoric waters leak in the underground, until they reach temperatures of 20 ÷ 90 °C; then, due to favourable structural conditions, hot waters rise quickly to the surface to create thermal springs.

Thermal resources, in northern Italy, are nowadays very well exploited but a possible development of this study is to identify past thermal places, now forgotten or abandoned, and to identify possible new favourable conditions: for example, in Veneto region, the drilling of some wells (deep up to 300 meters) brought to the development of some new thermal activities.

10.1474/Epitome.04.0079.Geoitalia2011

FIRST RESULTS OF AN HYDROGEOLOGICAL STUDY IN THE VAIONT AREA

ORTOMBINA Mirta¹, FABBRI Paolo¹

¹ - Università degli Studi di Padova, Dipartimento di Geoscienze

Presenter e-mail: mirta.ortombina@unipd.it

Key terms: Vaiont; springs; karst; cross correlation

The aim of this research is the hydrogeological characterization of the Vaiont area, especially that of the M. Toc, and the development of an hydrogeological conceptual model.

The analysed area is located in Erto e Casso (Friuli Venezia Giulia Region) and Longarone (Veneto Region), in the south-eastern part of the Dolomites area. The zone is bounded by M. Salta (2039 m a.s.l.) and M. Borgà (2215 m a.s.l.) to the North, by Gallina valley to the South, by the Piave river to the West and by Zemola and Mesazzo Valleys to the East. In this area crops out mainly Mesozoic carbonate formations, while the quaternary deposits consist chiefly by slope and alluvial deposits. The Zemola valley shows several significant springs, while the M. Toc area is characterized by surface water scarcity and few springs, most of which

with a small-discharge. This situation should be due to a karstic groundwater circulation. This hypothesis come from field observation and the presence of dolines in the area above the Vaiont landslide; in this zone most of rainwater infiltrate without producing a significant surface water flow. Any way the presence of karst phenomena and the surface hydrography scarcity is already mentioned in literature (Handron & Patton, 1985).

In the studied area twenty springs were identified. Most of them have very low discharge (<1 l/s) and similar physico-chemical parameters. Chemical analyses were carried out on eight springs (Na, K, Ca, Mg, total hardness, TDS, Fe, Mn, methyl orange alkalinity, Cl, sulphates, carbonates), and they could be classified as oligomineral (135 < TDS < 210 mg/l), cold (6.7 < T < 10 °C) and calcium magnesium bicarbonate-type waters; furthermore all the springs have a slightly basic pH ranging between 8 and 8.4, an Eh ranging between 182 and 274 mV and an electrical conductivity

ranging between 162 and 281 µS/cm, this last information roughly indicates young waters with short circuits.

After the first field analyses two springs with monitoring appropriate features were chosen; since July and September 2010 two data loggers (Diver) were installed monitoring hourly discharge, electrical conductivity and temperature of spring waters. "Ega Nass", on the West of M. Toc (Dogna, Longarone), and "Le Spesse", on the opposite side of the Vaiont landslide (Le Spesse, Erto e Casso) were the chosen springs. Monitoring data were compared with rainfall from two different weather stations (ARPAV, Servizio Idrografico Regione FVG), in order to have an idea of the spring behaviour after rainy events and comparing rainfall discharge, temperature and electrical conductivity between them. A cross-correlation analysis was carried out to estimate linkage between rainfall and spring water discharge, conductivity, temperature and so on. All data analysis were made by the R code (R development Core Team, 2011), which is a free software environment for statistical computing and graphics. The first results show a clearly karst behaviour of the springs with a recharge circuit very short, indeed the time delay from the rainy event to the increase of the spring discharge is very small. Four cross-sections (two N-S and two E-W) through the two observed springs were carried out, improving the hydrogeological conceptual model of the area. The outcropping formations were also divided into five groups, according to their permeability (from very high to very low permeability) to identify subsequently the possible groundwater flow paths (Aa.Vv., 2002).

ASSESSMENT OF THE CONCEPTUAL MODEL OF GROUNDWATER FLOW SYSTEMS IN FRACTURED TURBIDITE AQUIFERS: THE CASE OF MOUNT ANTOLA LIMESTONE (NORTHERN APPENNINES-ITALY)

PILLA Giorgio¹, ZORNETTA Alberto¹

¹ - Dip. Scienze della terra e dell'Ambiente - Università di Pavia

Presenter e-mail: giorgio.pilla@unipv.it

Key terms: Fractured rocks; Turbidites; Spring monitoring; Vulnerability; Northern Appennines

Even though different studies about the groundwater resources are available for karst systems that are affected by relevant discharge springs, few studies have been carried out on fractured media systems, as the turbidites formations of the Northern Appennines, affected by low discharge springs. Nevertheless, these springs represent the primary resource for drinking and domestic water supplies for little villages. Furthermore, the quality of these groundwaters is generally excellent. In fractured media systems studies, it is fundamental to carry out a detailed analysis of the hydrogeological frame to define suitable methods, aim at protecting the groundwater resources.

In order to achieve this objective, we tested some investigation methods applied on the Gaggina spring system, located in the south of Oltrepò Pavese region, on the eastern slope of Mount Lesima. We selected this spring as a representative model of the great amount of small springs related to fractured turbidites aquifers in the Appennines. The key element is the working out of a hydrogeological conceptual groundwater-flow model to assess the spring vulnerability.

The first step was a detailed field survey to reveal the geological structure of the spring catchment area and to understand the emergency setting. Through geological and structural survey we defined the aquifer properties of the Mount Antola Limestone.

In particular, these surveys established the shallow hydraulic conductivity, by two different approaches. We also carried out a hydrochemical characterization of surface waters and groundwaters of the area.

Then, the study focused on Gaggina spring. Important parameters, such as the discharge, the water temperature and the specific electric conductivity, have been monitored by means of an automatic gauge, acquiring measures every two hours, during a hydrological year. This step was fundamental to characterize the groundwater hydrodynamic system and the behavior of springs during recharge events. We found out two different kind of hydraulic circulation during recharge events. The "piston flow" occurs as a clear response to each significant meteoric event, while the "prevailing replacement" phenomenon, that represent the quick arrival at the spring of freshly infiltrating waters takes generally place during the spring and autumnal groundwater renewal. We got, however, some clues about the arrival at the spring of freshly infiltrating waters even during secondary rainy events. These two phenomena could therefore occur simultaneously in some occasions.

The different kind of surveys carried out in this study have allowed to estimate the aquifer and spring vulnerability, with the aim of planning suitable groundwater protection strategies.

HYDROCHEMICAL CHARACTERIZATION OF THE METAMORPHIC-SERPENTINITIC ACQUIFER OF THE CORECA BASIN (CALABRIA, SOUTH ITALY)

VESPASIANO Giovanni¹, APOLLARO Carmine¹, MUTO Francesco¹, CRITELLI Teresa¹, DE ROSA Rosanna¹

1 - Dipartimento di Scienze della Terra, Università della Calabria
Presenter e-mail: giovanni.vespasiano@gmail.com

Key terms: hydrogeochemistry; aquifer; metamorphic-serpentinitic

A preliminary study of the metamorphic-serpentinitic aquifer of the Coreca Basin (Calabria, south Italy) is carrying out. In the studied area rocks belonging to metamorphic and sedimentary units outcrop in tectonic window. Basal unit is constituted of Triassic dolostone and limestone overthrust by ophiolitic sequence of Gimigliano and Frido units. The latter mainly consists of metapelites and slates. Metamorphic units are sealed by Late Miocene sedimentary sequences consisting in calcarenites, clays, marls, Messenia limestones on the upper part. Pleistocene terraced deposits rest on the top. The main aquifer of the Coreca area consists of serpentinites, metabasalts, phyllites and carbonates. The structural assemblage of the area suggests the presence of a perched metamorphic aquifer represented by the ophiolitic rocks, suspended by slates of the Frido Unit. A second aquifer consists of Miocene mainly carbonate rocks and results separated from the metamorphic aquifer by high angle faults. The study has been carried out following the classic techniques of the hydrogeological prospecting, which have specifically concerned: 1) a preliminary mapping study; 2) the characterization, in terms of hydrogeology, of the outcropping rocks; 3) the sampling and analysis of 24 springs and wells. Preliminary results allowed to identify the groundwaters and water table characteristics in the basin and to reconstruct the hydrogeochemical model of the area. Two groups of waters can be identified: the first one falling in the Ca²⁺ field, suggests that the chemical composition of these springs is controlled by the dissolution of Ca-rich phases present in metabasalts; while an interaction of meteoric water with serpentinitic rocks may explain the second group of Mg-HCO₃ groundwaters. Geological, hydrogeological and geochemical data confirm the existence of two distinct aquifer in the Coreca Basin.

SUSTAINABLE GROUNDWATER DEVELOPMENT IN A NATURALLY ARSENIC-CONTAMINATED AQUIFER: THE CASE OF THE CIMINO-VICO VOLCANIC AREA (CENTRAL ITALY)

BAIOCCHI Antonella¹, COLETTA Attilio¹, LOTTI Francesca¹, PISCOPO Vincenzo¹

1 - Università della Tuscia, Viterbo, Italy

Presenter e-mail: piscopo@unitus.it

Key terms: Arsenic; Volcanic aquifer; Sustainability; Cimino-Vico volcanic area

In the volcanic areas of central and southern Italy the presence of arsenic in groundwater has been documented for about thirty years. After the recent revision of legislation concerning the drinking water standard, i.e. lowering of the MCL from 50 to 10 µg/L, arsenic is now not only a health problem but also a socioeconomic issue. As a consequence, water management companies and authorities must invest in water management to ensure drinking standards in line with the new regulatory context.

This study concerns the occurrence of arsenic in groundwater of the Cimino-Vico volcanic area (Central Italy), widely used for the local drinking water supply and irrigation. The purpose is to provide a hydrogeological support for addressing the groundwater resource management.

From current knowledge on the hydrostratigraphic and structural setting, potential recharge and discharge rates of the system, groundwater quality, type and nature of the aquifers, the arsenic content in groundwater has been examined. Afterwards, the local response of aquifers has been analysed to evaluate the present systems of groundwater abstractions. A complex groundwater system results, including several perched aquifers and a continuous, unconfined or leaky basal aquifer in the volcanites. In some areas a relatively deep aquifer in the volcanites, or in its fractured sedimentary substratum, is characterized by thermal waters. Interactions between shallow and deep groundwater flow were frequently found. The occurrence of arsenic in groundwater is mainly connected with the deep-rising fluids that characterize the active hydrothermal system. The highest arsenic concentrations (from 180 to 370 µg/L) were found in the thermal springs and wells fed from relatively deep groundwater flow. In the shallow volcanic aquifer, the arsenic concentrations in groundwater (from 2 to 100 µg/L) are related to the local hydrostratigraphy, structural setting, hydraulic parameters and nature of the different overlapped aquifers. Where the volcanic aquifer is open to the upward flow through the fractured, semiconfining substratum, relatively high arsenic concentrations (from 20 to 100 µg/L) were found. Where the volcanic aquifer is recharged only by infiltration and the aquifer base is sealed by a high thickness of low-permeability sedimentary rocks, arsenic concentrations less than 20 µg/L were found. The lowest concentrations (less than 10 µg/L) were found in the wells and springs of the perched aquifers. For the continuous basal aquifer arsenic concentration seems also to be related to the type of volcanic products which differ from one another in composition, age, porosity, and hydraulic conductivity. At present, the groundwater resources of the volcanic aquifers supply the local demand of drinking water (about 150,000 inhabitants) through numerous wells and springs, whose location is based on proximity to the users and on rate of flow. A new approach to groundwater management should be implemented to contain the impact on human health. Specifically, the nature and structure of the substratum of the volcanic aquifer must be included among the criteria to identify the location and manner of the groundwater withdrawals. Hydrothermal areas and faulted zones in the units underlying the volcanic aquifer represent the more vulnerable situations for the pumping of drinking water. Around these more vulnerable zones, it should always be verified that the pumping effects on the horizontal and vertical flow contain the mixing between the relatively shallow and deeper groundwater units. From a simulation conducted in one of the areas where the arsenic concentrations in the present tapped groundwater are between 15 and 40 µg/L, it results that the costs of water treatment are decidedly higher than those necessary to building of new wells according to the previous above criteria.

Key terms: hydrogeology; springs; climatic change; modeling

Analysis of the most reliable meteorological datasets for Central Italy reveal that most of the series have trends. Their presence and intensity vary according to statistical technique, to quality of data and geographical location, but the general picture is quite clear: in practice, all stations showing significant trends report a decrease in rainfall and an increase in temperature. Temperature increase and rainfall decrease inevitably reduce the water yield of hydrological systems: indeed, analyses of discharge data series of some hydrogeological systems in Central Italy show negative trends. Although in some systems it is not easy to define in which proportions this trend is to be related to climatic variations or to exploitation or land use, there are some systems - particularly mountain catchments and springs - which can be considered as not influenced by human activity and which show a decrease in yield over the last 40-50 years. One of these systems is Bagnara Spring which has been studied in order to obtain some reasonable scenario about the discharges during the next 30 years, assuming that the climatic trend of the last decades will persist. Bagnara spring is fed by the Monte Pennino anticline, which is a typical Apenninic structure, an east-vergent asymmetric anticline, with a main thrust structure and some secondary thrusts on the eastern slope, and back thrust structures on the western slope. The rocks outcropping in the area belong to the Umbria-Marche geological sequence, which is mainly made of limestone formations within which some marl formations occur. According to the geological setup, the potential recharge area of the spring is about 7.5 km² wide. In spite of their poor quality, the analysis of the meteorological data in the area indicates that during the period 1982-2009 the water surplus (defined as the difference between rainfall and evapotranspiration) decreased of about 15 - 20 % compared to the 1954 - 1981 period. In order to have an idea about the future discharges of the spring, a set of lumped models of the rain-discharge process transformation was applied. All the models were on a monthly basis. Under the assumption that the present trend will continue and in spite of their different performance, the models indicate a decrease of the discharges higher than the decrease of the water surplus. This should be taken in account in the future water management plans. Sounder results and better modeling could be obtained if the meteorological data were more reliable: it is imperative that a reliable data net for the measurement of evaporation, piezometric heads, rain, snow and temperature is established.

IMPLEMENTATION OF GROUNDWATER NUMERICAL MODELS IN URBAN AREAS: THE CASE OF ROME

DI SALVO Cristina¹, FEINSTEIN Daniel Timothy², MAZZA Roberto³, CAPELLI Giuseppe³, CAVINATO Gian Paolo¹

1 - Igag (Istituto di Geologia Ambientale e Geoingegneria)-CNR

2 - University of Wisconsin-Milwaukee, U.S. Geological Survey - Water

Resources Division. Wisconsin District

3 - LINQ, Laboratorio di Idrogeologia Numerica e Quantitativa, Università degli Studi Roma Tre

Presenter e-mail: cridisalvo@hotmail.it

Key terms: Hydrogeology; numerical models; Rome; urban areas

This study is part of the Urbisit project, led by Igag-CNR and Roma Tre University and funded by the National Civil Protection, which purpose is to investigate the geological risks in urban areas. This research represents the first attempt to modeling the roman aquifer system at a regional scale; a hydrogeological numerical model in an urbanized area can be fundamental to check the impact of subterranean works on the geological and groundwater system. The study was developed in several phases:

- Data collecting (from Roma Tre - the LINQ database and the IGAG-CNR database) and archiving in the URBISIT project database; the total number of collected data in the study area is 2950.
- Data elaboration; building cross sections.
- Translating the geological setting into hydrogeological setting and conceptualization of the aquifer system.
- Elaboration of the top surfaces of the main hydrogeological complexes by mean of ArcGis@ tools.
- Implementation of a numerical model by mean of the finite-difference code MODFLOW2000@

The "ROMA" numerical model is a basin-scale, steady state model; it is made by 8 layers with uniform cell dimension of 50 x 50 meters, over an area of about 237 km². Hydraulic conductivity values were derived by about 130 field data and by laboratory test, already archived in the LINQ database. Because of the small number of tests respect to such heterogeneous complexes, k values from literature), from numerical models previously developed by the LINQ and from technical reports were also considered. To calculate the recharge, two different cases were distinguished, "natural" and urbanized areas. In natural areas, the average recharge for years 1997-2007 calculated by the distributed water budget method (Capelli et alii, 2005, updated with rainfall data up to year 2007). In strongly urbanized areas, as in the historical center of Rome, the recharge was calculated taking into account both the sealed surfaces (reducing the rainfall infiltration and increasing the runoff) and artificial recharge sources (coming from over irrigation in municipal gardens and water leakage from mains. The rivers and streams stage were simulated by using RIVER and DRAIN cells; rivers stages are taken from the SIMN (Servizio Idrografico e Mareografico Nazionale). In some areas of the historical center, the streams are nearly-completely hidden by urbanization and partially substituted by artificial mains (as in the case of ancient cloacae), which were simulated as DRAIN cells. In the city of Rome, withdrawals are mainly due to: industrial uses, irrigation of municipal gardens, car washing plants, domestic uses in not-strongly urbanized areas, agricultural and zootechnical uses, fire hydrant. Withdrawals were quantified by mean of three databases collecting data from Rome municipality. The total estimated withdrawal is 29097.5 m³/d. The boundary conditions were implemented on the model border in order

to simulate inflows and outflows which are compatible with the estimated water budget within an established tolerance threshold. The model has been calibrated by a trial-and-error method based on the target residuals statistic, which is the discrepancy between observed and simulated values. Five "Autosensitivity" analyses were performed in order to establish which parameters would give a better solution in a calibrated model; the most sensitive variables were identified and subjected to calibration. Then, the calibrated model was verified by a comparison with observed water levels (for year 2008) and water budget for years 1997/2001. At the current stage of development, the model "ROMA" can be used for quantitative evaluations of the groundwater resource at basin scale; it is possible to simulate different steady-state scenarios, by varying rivers stage, withdrawals and recharge. Moreover, the model can be used to derive boundary conditions for local-scale models, that can be obtained by a "grid refinement" starting from the regional model.

APPLICATION OF THE MODFLOW GROUNDWATER NUMERICAL MODEL TO BRACCIANO HYDROGEOLOGICAL VOLCANIC UNIT

TAVIANI Sara¹, HENRIKSEN Hans Jorgen², MAZZA Roberto¹, CAPELLI Giuseppe¹

1 - Università Roma Tre

2 - Geological Survey of Denmark and Greenland

Presenter e-mail: staviani@uniroma3.it

Key terms: groundwater model; volcanic deposits; lake

The hydrogeologic system studied is located in the north of Rome (Sabatini area) and is characterized by volcanic deposits. There is a main aquifer inside volcanic deposits and Bracciano lake has a direct exchange with the aquifer.

Bracciano hydrogeologic basin includes: four volcanic calderas, two of these still occupied by lakes (Lake Bracciano and Lake Martignano), there are two big water abstraction sites: one from lake (Paolo aqueduct) and the other fed by drains on the northwest side of the Lake Bracciano (Traiano aqueduct). At the same time the area is exposed to a continuous exploitation and dewatering from effect of the several public and private pumping wells from the groundwater aquifer put in action in the last twenty years.

It was built a conceptual model: geological and hydrogeological framework has been investigated, a volumetric reconstruction of the aquifer has been made, were areas with different hydraulic behaviour were identified and media type defined (porous media and fractured). Then the identification of the sources and sinks were summarised in the elaborated water budget.

It was applied a methodology, suggested by Sonnenborg & Henriksen (2005), to determine the uncertainty of observational head data in relation to the model. The purpose of quantifying the uncertainty of

observational head data (σ_{obs}) is to achieve a measure of how accurately the model can reproduce the data. This should in principle be an objective criterion for how data weighted approximation and more importantly, how data of different types must be relatively weighted (important when using objective functions).

Volcanic deposits are characterized by a high heterogeneity which conditions groundwater flow patterns, so it was considered the effect of the heterogeneity on the uncertainty estimation.

It was revealed that the component due to geologic heterogeneity on the whole observational head uncertainty value, played a major role for such performance assessments and that the lack of experimental data suggested that this aspect should be further analyzed in more depth when doing future model analysis of volcanic aquifers.

From the conceptual model a numerical groundwater flow model (mathematical model) was set up using a finite-difference code MODFLOW2000; using the graphical interface of Groundwater Vistas@5.41 (ESI), which allowed incorporation of the implemented lake package, thus it was possible explicitly to include Lake Bracciano and its interaction with the underlying volcanic aquifer within this package.

Calibration tests were carried out, PEST was used for the inverse calibration, with head and flux targets. During calibration process, the water budget values were constantly compared with the volumes estimation coming out from simulations to evaluate the results. The management of a complex system is challenging, and could surely benefit of the predictive capacities that a calibrated and validated model would enable and provide. It should be an interest and preference of the public administration to implement a stronger tool as a groundwater model, since a quantitative understanding of the whole system and its interactions are needed in order to exploit the groundwater aquifer in a sustainable way. Also for the different water users it is important to manage their own wells based on a better understanding of the whole system, and how their groundwater abstraction and land use affects the recharge, water balance of the aquifer, interaction with lake, wetlands near the lake and runoff from the area.

HYDROGEOLOGICAL BUDGET OF THE MONTE AMIATA VOLCANIC AQUIFER

PRANZINI Giovanni¹, CINTI Lorenzi¹

1 - Università di Firenze

Presenter e-mail: giovanni.pranzini@unifi.it

Key terms: Volcanic aquifer; resource depletion; hydrogeological budget

The Monte Amiata aquifer holds the most important water resource of Southern Tuscany, exploited for the civil water supply of Southern Tuscany and Northern Latium. In the last decades a remarkable reduction of the springs flow rate has been observed, as well as a dramatic lowering of the water table, as resulted by a recent geomagnetic survey. It has been put forward the hypothesis that such resource reduction would be caused by the geothermal cultivation by ENEL: the pressure reducing in the below carbonate reservoir would cause a water recall from the volcanic aquifer. Instead, some others believe that the impoverishment of the resource is only due to the reduction of the aquifer recharging, due to climatic change, owing that the geothermal reservoir is isolated from the volcanic one by clayey units of the Ligurian Units.

To give a contribution to the solution of this problem, the groundwater budget relative to three sub-periods of the interval 1939-2008 was drawn up, as well as that of the entire period 1939-2008:

1. the period 1939-1956, preceding the geothermal exploitation;

2. the period 1957-1980, with geothermal cultivation and characterized by an artificial exploitation of the aquifer (boring of draining tunnels);

3. the period 1981-2008, characterized by a dramatic reduction of the sources flow rate.

Due to the lack of measures of the superficial outflow, the water budget was limited to the comparison between the infiltration in the volcanic outcrop (I) and the total flow of springs and wells (Qs).

The infiltration rate of each volcanic unit outcropping was calculated, by means of GIS processing, with the formula $I = (P - E) * C_{ie}$. The actual infiltration coefficients C_{ie} was preliminarily assumed high (80-90%) according to previous budgets of the aquifer.

Most of the springs have only few measures of flow rate. The completion of the time series of all the springs was made through correlations mostly based on the only source monitored with continuity, the Ermicciolo spring. With the values of I and Qs calculated, the first two budgets show a fairly good accordance between infiltration and outflow from underground.

Instead, the flow of the sources in the third period results greater than meteoric recharging, putting forward the hypothesis that the drainage of the tunnels is still reducing the geological reserve. Considering that in the same period the geothermal cultivation has increased, we can conclude that the feared impact of the exploitation by ENEL on the groundwater resource is null or negligible. In this context, the drop of the water table highlighted by the recent geophysical campaign (drop significantly overestimated) would be caused by the drainage of the tunnels above mentioned and not by the losses to the geothermal reservoir.

Apart for this conclusion, it must be said that our budget, as well as those made by others, is clearly inaccurate: in fact, the runoff would be only 2% of precipitation, which conflicts with the direct observation of the stream's flow during heavy rainfall. The reason is that the meteoric inflows do not take account of the snow, as there are no stations equipped to register the snow; and the M. Amiata is a ski resort! Assuming that the height of snow accumulated in each winter of the period 1939-2008 is equal to the average of the 20 winters from 1986-1987 to 2005-2006 - this is the only data available on the snow -, we estimate an increase in infiltration of 102 mm/year. This leads to a reduction in C_{ie} to 0.81-0.82, leaving room for a runoff close to 10% of rainfall.

3D NUMERICAL MODELING OF THE PISA COASTAL PLAIN (NORTH-WESTERN TUSCANY)

CURCIO Chiara¹, AMBROSIO Michele², FAGIOLI Maria Teresa², GIANNECCHINI Roberto¹

1 - Università di Pisa

2 - AF Geoscience and Technology Consulting srl

Presenter e-mail: chiaraec84@aliceposta.it

Key terms: hydrogeology; seawater intrusion; numerical modelling; Pisa coastal plain; Tuscany

Since prehistoric times, the Pisa coastal plain, lowest portion of the Arno and Serchio Rivers basins, was the preferred site for human settlements. It was therefore involved in important drainage and hydraulic reclamation works. They began before Roman Empire and produced an almost entirely artificial hydrographic network, including significant modifications to large part of the main river courses. In the last two centuries, population quick rise, urban centers, tourist and industrial activities growth raised both water and dry land demand. Irrational water pumping near the coast produced severe seawater intrusion in the coastal aquifers.

3D finite differences numerical simulations (Visual Modflow 4.2) were applied to the phreatic aquifer of the Pisa coastal plain (Wide Area Model - WAM), with dedicated zooms on the densely inhabited areas of Marina di Pisa and Tirrenia. In particular, the WAM has its boundary at the Arno River to the North, the Navicelli Canal to the East, the Scolmatore Canal to the South and the seashore to the West. The WAM output was used as boundary condition to implement the zoomed models of Marina di Pisa and Tirrenia (Visual Modflow Seawater code).

The work required a first step of acquisition, systematization and processing of bibliographic and field data, in order to build the geological and hydrogeological conceptual model; the conceptual model was then translated into numerical input.

The implementation of the numerical model based on the hydrostratigraphic structure, rainfall pattern, thermometric and piezometric data collected from October 2007 to December 2009 (calibration stage), as well as on the unconfined and first confined aquifer salinity data logs, and on the main hydraulic parameters (hydraulic conductivity, porosity, storage coefficient) of the studied aquifer. The unconfined aquifer, 10-15 m thick, is hosted in sandy coastal dunes, characterized by medium-high hydraulic conductivity ($K \approx 10-2$ cm/s) and overlies an aquiclude ($K \approx 10^{-7}$ cm/s) generally constituted by clay and silty clay.

Besides numerical modeling the correlation between rainfall and piezometric level data was analyzed in order to identify the phreatic aquifer recharge time. For almost all the monitored piezometers, a high correlation coefficient ($0.75 < R_2 < 0.85$) between rainfall and water table data was detected for a span of 75 days. The identified correlation helped the model simulations interpretation.

The WAM was implemented and calibrated in order to analyze the water flow system, while the zoomed models of Tirrenia and Marina di Pisa were carried out and calibrated to calculate the extent and saline content of the seawater intrusion. The results reached a significant statistical correspondence to observed data sets. Regarding Marina di Pisa and Tirrenia models, simulation was also performed to forecast possible future scenarios relating the water table trends and seawater intrusion.

Both models show a modest degree of seawater intrusion near the shoreline. In particular, in the Marina di Pisa area, close to the dune system, the seawater intrusion is just a thin level below a thick freshwater body. On the other hand, in the Tirrenia area the salt water completely saturated the unconfined aquifer. In the internal portion of the study area, between the dune system and the Navicelli Canal, in ancient times characterized by lagoons, marshes and swamps, the salt content raises, from high to very high for the whole thickness of the aquifer.

In conclusion, the simulation models show the important role of the natural dune system as freshwater pseudo-hydrostatic barrier, effectively contrasting the seawater intrusion in the unconfined coastal aquifer.

Moreover, simulations identified the main cause of the seawater intrusion in massive pump driven dewatering by the artificial drainage network, which causes a significant lowering of the water table, from 1.70 to 2.50 below the sea level.

MODELING GROUNDWATER RESOURCES IN AN ALLUVIAL AQUIFER OF SOMALILAND

CATTANEO Laura¹, GIUDICI Mauro¹, PETRUCCI Bruno², LOZEJ Alfredo¹
 1 - Università degli studi di Milano
 2 - Africa '70

Presenter e-mail: laura.cattaneo1@unimi.it

Key terms: water resources; alluvial aquifer; mathematical modeling; dry land

Water for the city of Hargeisa (Somaliland) is supplied by wells drilled in the alluvial aquifer of the Ged Deebale (GD) basin. The well fields were started in the 1970's by the Chinese cooperation and some new wells were drilled later. The water production, after the drop due to the civil war, raised again to the pre-war levels (around 6000 m³/day) in the first years of the millennium, and up to 10.400 m³/day at the beginning of 2010. This trend reflects in the variation of the water table depth with time. An EU project allowed to perform some exploration activities from 2003 to 2007, including: a detailed geological survey, a geoelectrical campaign, a series of pumping tests, a continuous monitoring activity prolonged for two years. The data permit a first reconstruction of the basin shape, of the hydrological structure and of the mechanisms of the aquifer recharge. The aquifer consists of unconsolidated sediments deposited in lacustrine or fluvial environments and is bounded by a Precambrian crystalline bedrock. From a structural point of view, the basin is the result of the intense tectonic thrusts that gave birth to the Gulf of Aden rift: it probably formed by two major tectonic trenches, E-W oriented, connected by a long fracture with N-S alignment. A wide outlet was found at the N-E edge which connects the GD basin to the Laas Dhuurre-Damal (LDD) basin. The available data were used to apply a FORTRAN90 original code for the simulation of 2D groundwater flow. The mathematical model considers a 2D hydraulic flow approximation, pseudo-steady conditions corresponding to the average annual flow, no-flow boundary conditions in correspondence of the crystalline bedrock and fixed head at the edge with the widespread and thick LDD basin. The calibration of the mathematical model was quite difficult for the uncertainties on the old data, but showed some results that improved the knowledge of the physical system and gave some practical answers to the questions posed by the water management agency. From the hydrogeological point of view, there is a division of the basin in two sections, separated by an area of low permeability; the recharge in the upstream (southern) section probably comes from an underground fracture-fault network, whereas in the downstream (northern) section comes from the LDD basin. From the point of view of resource management it appears that the GD basin alone cannot satisfy the future water demand of the city without a further, more dramatic depletion. However, a shift of the production from the wells in the southern section to those located in the northern one or even to the much wider LDD basin could support the growth of the city water demand.

 3 - Istituto ISTI - CNR Pisa

Presenter e-mail: borsi@math.unifi.it

Key terms: unsaturated zone; surface/subsurface water interactions; modelling and coding

This work is part of the research project SID&GRID, started April 2010 and funded by Regione Toscana (Italy) under the POR FSE 2007-2013 program.

Our focus deals with the modification of the well-known code MODFLOW-2005, in order to extend its capability of the unsaturated zone investigation. The better understanding of the vadose zone is very important for practical applications (the study of agricultural fields, for instance), but also in any general picture in which the modeler aims at investigating the coupling between surface and subsurface water: indeed, the unsaturated zone is the main interface between groundwater and surface water.

We addressed the problem of using MODFLOW-2005 to this purpose by modifying or extending some part of the code. In particular:

1. We updated the packages of MODFLOW2000-VSF, Variably Saturated Flow (Thoms et al., 2006), in order to be used within MODFLOW-2005 endowed with the LGR capability, known as Local Grid Refinement (Mehl and Hill, 2005). This modification allows to describe the unsaturated zone in a deeper way only in those regions of the domain where this investigation is really important; in the other regions, the vadose zone is simulated by means of the package UZF, Unsaturated Zone Flow, (Niswonger et al., 2006).
2. A new algorithm to route the overland flow inside the domain had been developed: whenever in a cell of the model top is saturated, the excess flow, representing the sum of Hortonian and Dunniann runoff, is routed according to the slope end the exposure of the cells and, eventually, it is added as input to rivers and/or lake. This method results in a slight modification to the UZF package, and the implementation of the same concept within the VSF packages PND (ponding) and SPF (seepage flow), (Thoms et al., 2006).
3. The stream package SFR2 (Niswonger and Prudic, 2005) had been updated to compute the transient routing and the leakage to/from the aquifer in a semi-couple way, using a method already developed in other codes like PARFLOW-CLM (Maxwell and Miller, 2005).

The main features of the new model definitions will be presented, along with the results of preliminary tests.

To be updated about code development, please, follow our work at the website: <http://sidgrid.isti.cnr.it>

EVALUATION OF GROUNDWATER RECHARGE IN HIGHLY URBANIZED AREAS

FUMAGALLI Letizia¹, BONOMI Tullia¹

1 - Università Milano-Bicocca

Presenter e-mail: tullia.bonomi@unimib.it

Key terms: Groundwater recharge; Runoff; MACRO; Curve Number

The evaluation of groundwater balance is an indispensable goal in the hydrogeological studies aimed to correctly manage groundwater exploitation, in a particular way in urbanized areas, for which groundwater is the only drinkable water source. In these cases the water pumping rate from wells should be controlled and planned in such a way that groundwater abstraction doesn't exceed groundwater recharge, which depends on many variables among which precipitations and soil permeability.

This study analyzes groundwater recharge in the River Seveso watershed, located in the northern lombardian plain, over the period 1985-2010. It is an attempt to evaluate the influence of the factors that contribute to the infiltration towards groundwater and/or to the runoff towards rivers, which give rise to frequent floods in some urbanized areas during high intensity rain.

A double (numerical and empirical) approach has been used for this purpose, which includes the use of the numerical MACRO code (Jarvis, 1994) to evaluate the soil hydrological balance, and the Curve Number method to evaluate the soil runoff, which is considered as a lost recharge rate.

This approach allows to consider how multiple variables such as climate change, soil and subsoil hydrological characteristics and land use influence the recharge rate.

The results, on a daily scale, allow to define the variability of the hydrological balance on the watershed over a 25 years period, and to analyze the changes driven from both climate and land use planning on the soil hydrology, and on the hydrological balance as a consequence. The recharge rate in the area, 60% of which is urbanized, is up to 400 mm/year, with respect to an average precipitation rate of 1108 mm/year. The average runoff rate, in the same period, is up to 400 mm/year in intensively urbanized areas, and up to 800 mm/year on the paved streets and roads, as a function of their different permeability.

Concerning the groundwater reservoir, the water table variations in the considered period are consistent with the model results.

The proposed methodology could support water management studies, such as groundwater reservoir evaluations, hydrogeological model implementations aimed at groundwater managing, land use planning aimed at preventing both a runoff increase and a groundwater recharge decrease.

DEVELOPMENT OF A REGIONAL GROUNDWATER FLOW MODEL FOR A PUBLIC WATER COMPANY IN BERGAMO PROVINCE, ITALY

REMONTI Michele¹

1 - Free lance hydrogeologist

Presenter e-mail: michele.remonti@gmail.com

Key terms: MODFLOW; Groundwater modelling; Water resources; Bergamo

The territory between Rivers Adda and Serio, in the Bergamo province plain - Northern Italy, have one of the highest population density in Italy and is characterised by intensive industrial and agricultural activities.

Water resources, both superficial and groundwater, historically have been, and still are, strategic for the development of the area: natural streams and irrigation channels are abundant and the alluvial aquifers have high productivity. Particularly the latter are extensively exploited, through more than 1.000 water wells that abstract about 20 m³/s of water.

In the last decades, several severe groundwater contaminations occurred in the area, determining relevant social and economical effects for the resident population. Moreover, water abstraction from the numerous wells raised the attention of Public Authorities and water managing companies to the needs of a more efficient quantitative and qualitative control of the aquifers.

In 2010, a regional groundwater flow model has been realised for the water managing company Cogei S.p.A., serving 16 municipalities and more than 90.000 inhabitants in Western Lombardy. The model has been developed with the finite difference code MODFLOW 2005, is quasi-3D and represents the unconfined aquifer between the ground elevation and 30-45 m b.g.l., the semiconfined aquifer, until 45-75 m b.g.l. and the deep confined aquifer, that reaches the depth of 300 m b.g.l., in an area 2.400 kmq wide.

The hydrogeology of the area is complex, due to the presence of tectonic buried structures of regional importance, which conditioned the sediment deposition, the aquifer thickness and the distribution of the lithologies within the aquifer. This factors affects the groundwater direction and hydraulic gradient, resulting in a complex groundwater flow net. The realisation of the model required a wide data collection and interpretation, which allowed a deeper understanding of the hydrogeological conceptual model of the area. The calibrated model represents a quantitative tool that will help the water managers to optimise the distribution of the well pumping rates and will allow estimating the environmental fate of the groundwater contaminations.

POTENTIALITIES AND ACHIEVEMENTS OF EVOLUTIONARY MODELING AS AN INNOVATIVE APPROACH TO GROUNDWATER

DYNAMICS ANALYSISDOGLIONI Angelo¹, SIMEONE Vincenzo¹

1 - Politecnico di Bari

Presenter e-mail: a.doglion@poliba.it

Key terms: Data-Driven; groundwater; evolutionary modeling; hydrogeology

Data-driven techniques are commonly considered among the most powerful approaches to the modeling of environmental phenomena. Their popularity can also be attributed to the increasing availability of monitoring information. These provide a reliable mathematical description of the relationship between the physical variables of the systems. Among the evolutionary modeling technique, Multi-Objective Evolutionary Polynomial Regression, EPR-MOGA proved particularly effective at modeling the dynamics of groundwater, in terms of response to rainfall. Evolutionary Polynomial Regression (EPR) is an evolutionary modeling technique (Giustolisi and Šavic, 2009) successfully applied to multiple problems related to natural systems (Doglioni et al., 2010; Giustolisi et al. 2008). It proved effective at modeling the dynamic relationship between groundwater levels and rainfall heights for specific cases, related both to porous and karst aquifers (Doglioni et al., 2011; Giustolisi et al. 2008, Mancarella and Simeone, 2008). Although, EPR-MOGA is a data-driven model based on a regressive approach, the returned models are explicit polynomial equations, and this allows for conjecturing on the relationship between the main variables of the investigated phenomena. This allows for highlighting some unclear or unknown relations and to indirectly get information about the physics of the phenomenon at stake. EPR-MOGA already proved to be particularly fit to those cases where the input to the process and the boundary conditions are not easily accessible, as for the case-study. EPR-MOGA identified simple and significant models, which provides knowledge on the aquifer behavior, based on simple variables used to study the dynamic response of the aquifer.

The aquifers investigated by the authors are representative both of karst and porous scenarios. In both the cases, EPR-MOGA identified models, which were consistent with past studies and with the physical knowledge of the system, allowing for explicating the main rainfall components influencing the water table and the lag between rainfall and water table oscillations. These show that EPR-MOGA can be a really powerful and reliable for the study of the dynamics of aquifers, also in complex scenarios.

Specifically, EPR-MOGA was applied to three aquifers located in south Italy: the deep karst aquifer of Lecce (Doglioni et al., 2011a), the shallow porous aquifer of Brindisi (Doglioni et al., 2010; Giustolisi et al. 2008, Mancarella and Simeone, 2008) and the shallow porous aquifer of Metaponto plateau (Doglioni et al., 2011b). Brindisi and Lecce are located in Salento Peninsula, south of Puglia region, extreme southeast of Italy. The investigated aquifer of Metaponto is located on the south coast of Basilicata, south Italy, between the rivers Basento and Cavone. GENERATING SYNTHETIC TIME SERIES OF SPRINGS DISCHARGE IN RELATION TO STANDARDIZED PRECIPITATION INDICES. CASE STUDIES IN UMBRIA (CENTRAL ITALY)ROMANO Emanuele¹, DEL BON Andrea¹, PETRANGELI Anna Bruna¹, PREZIOSI Elisabetta¹

1 - ISTITUTO DI RICERCA SULLE ACQUE - CNR

Presenter e-mail: romano@irsa.cnr.it

Key terms: CARBONATIC SPRINGS; STANDARDIZED PRECIPITATION INDEX; WATER RESOURCES MANAGEMENT; CLIMATE CHANGE

In the Umbria region (Central Italy) water for human, agricultural and industrial uses arises from different kind of resources: surface water (streams, lakes and reservoirs) and groundwater (karstic and volcanic springs and wells tapping mainly alluvial aquifers). As a consequence, the water system integrates a number of sources different in size, recharge time and storage capacity. In this context it is fundamental for management purposes to study the relations between the evolution of the rainfall input overall the basin and the distribution in time and space of the stored resources, in relation to the present or future basin climatic conditions. This information, combined with data concerning the water demand evolution by means of suitable management models, permits to foresee possible conditions of water scarcity. Additionally, modeling the water availability necessitates of real or realistic surface and groundwater time series as an input to management models. However, especially for springs, the lack of sound and representatively long time series represents an obstacle, as very often only few information on their flow regimen is available. Hence one of the problem that the modeler has to face concerns the reconstruction of reliable spring discharge time series consistent with the observed rainfall regimen.

In this communication, we focus our attention to the relation in time and space between the precipitation and the springs discharge, that currently constitutes about 75% of drinking water consumption in the study region. The final aim is to determine suitable parameters for generating realistic weekly hydrograms for the main springs, consistent with the observed precipitation evolution.

For this goal, the available data for the outflow of 15 carbonatic springs located in the Umbria Region have been analyzed for the period 1998-2010 (except one of them, whose data are available from 1971). These springs share the same hydrological behavior: a recharge period (approximately winter and spring) characterized by a steep quasi-linear increase and a discharge period characterized by a decrease of the outflow

which can be approximated by an exponential function. The statistical relation between the seasonal and annual Standardized Precipitation Index (SPI, McKee et al., 1993) computed at local and basin scale and the main parameters of the springs hydrogram at the annual scale (minimum, maximum and mean outflow, recharge and discharge duration), has been analyzed.

The comparison between precipitation index and spring discharge indicates that: 1. basin scale values of SPI are better related to actual minimum and annual mean discharge than local values. 2. Minimum and mean annual discharges are more conveniently related to a precipitation index, that takes into account only the autumn, winter and spring. 3. The recharge duration is deterministically related to the winter SPI. The statistical relations between SPI and spring discharge parameters have been used in an algorithm able to generate the weekly outflow of the springs consistent with the time evolution of precipitation at the basin scale. Such synthetic hydrograms are the input for a management model that simulates the hydraulic behavior of the whole water system of the Umbria Region (Preziosi et al., 2011). Finally, precipitation time series from climate change scenarios A2 and B2 of the GCM HadCM3 of the Hadley Centre (Brocca et al., 2010; Camici et al., 2011) have been considered for generating synthetic hydrograms of springs for the period 2010-2070.

POTENTIAL CONTRIBUTION OF NATURAL ZEOLITE TO QUALITATIVE PROTECTION OF THE HYDROLOGIC SYSTEMPASSAGLIA Elio¹

1 - UNIVERSITY OF MODENA AND REGGIO EMILIA

Presenter e-mail: elio@unimo.it

Key terms: NITRATE POLLUTION; SOIL AMENDANT; WASTEWATER TREATMENT; ZEOLITE; ZEOLITITE

Pyroclastic rocks (tuffs, ignimbrites), diagenized with dominant (> 50%) zeolite content (clinoptilolite, mordenite, chabasite, phillipsite) and defined as "zeolitites", show peculiar chemical-physical features (reversible dehydration, high cation exchange capacity distinctly selective for ions with low energy of solvation such as NH₄⁺, high water retention, low apparent density, lithic nature, permeability). These properties, along with a large and widespread availability in nature, especially in Italy, as deposits of great potential and low extraction cost, justify their increasing use in application areas that require large amounts of material (building; separation, purification and dehydration of natural gases; purification of industrial, civil, and zootechnical sewage; animal feeding and fish farming; agriculture and flower growing; as alternative to pesticides in the fight against crop micropathogens; antiparasitic action on food). The results of laboratory and full field studies, subject of an extensive and qualified literature, widely demonstrated the key role of zeolitites in qualitative protection of surface and subsurface water resources, at high risk in the Po Plain mainly because of the disposal of sewage from livestock farms and the increasing intake of synthetic fertilizers in current agricultural practices.

Also in accordance with the recent EU directive on nitrates that provides a maximum limit of 170 kg / ha / year of nitrogen for the disposal of livestock manure in zones vulnerable to nitrate pollution, the use of 2-3% of zeolite in swine diet produced a significant reduction (20-30%) of NH₄⁺ content in sewage and, as a result, in the emission of smells; the NH₄⁺ content of sewage is further reduced (20-25%) by means of static treatments with a moderate (25 g/l) amount of low cost zeolite (quarry semi-finished material).

In the agronomic field, the addition to soils of zeolite characterized by low Na content, high selectivity for the NH₄⁺ ion, and high water retention, allows a drastic decrease of irrigation water, and above all of synthetic fertilizers, with a consequent remarkable reduction of the leaching of their nitrogen component, and thus of the current increasing and worrisome nitrate transfer in the aquifer.

Besides these relevant environmental advantages, the results of several experiments on greenhouse and full field cultivations of cereals and vegetables (rice, corn, sorghum, spinach, chard, lettuce, basil, celery, radish, tomato, pepper, courgette, melon, watermelon, strawberry, kiwi), as well as of turf on soils and substrates amended with natural zeolite (5-10 Kg/m²) and concomitant reduction (30-40%) of ferti-irrigation, evidenced either an increase or a quasi-quantitative maintenance of the agricultural production.

It is of economic and strategic importance that once zeolitites are added to the soil, they become an integral and indestructible part of it, thus being always able to perform their specific positive effects; furthermore, fertilizer saving and consequent reduction of the environmental impact are possible by adding as amendment NH₄⁺-charged zeolite, which can be obtained either artificially or, even better, by means of a previous use in the treatment of urban, industrial, and zootechnical wastewater.

ENVIRONMENTAL STATUS OF GROUNDWATER RESOURCES IN THE SOLOFRANA RIVER VALLEYFABBROCINO Silvia¹, PADUANO Pasquale¹

1 - Università degli Studi di Napoli, Federico II

Presenter e-mail: pasquale.paduano@unina.it

Key terms: groundwater pollution; aquifer; water systems

Heterogeneity of natural systems governs the pathway of pollutant in the environment, mostly in groundwater resources. A large number of hydrogeological research aims to parametrize and model these processes. The spatial variability of the hydrogeological properties of the rock can be defined from geologic observation and local measurements.

The Solofrana River Valley is a real natural laboratory to improve understanding of the behaviour and transfer of pollutants on large scale, because of its geological and structural complexity combined with a strong

industrial and agricultural activities.

A multidisciplinary approach has been employed to delineate aquifer/aquard unit and characterize scale-dependent heterogeneity using geological, hydrogeological and geochemical techniques. The paper describes firstly the experience carried out in an area characterized by a high anthropic impact. Besides, it reports about relevant geological and hydrogeological aspects of the Solofrana River Valley and presents some interesting aspects related to field operations and quantitative evaluation of pollution flow and transport.

NITRATE CONTAMINATION RISK FROM AGRICULTURE AND HOUSEHOLD DISCHARGES IN THE MIDDLE VALDARNO (TUSCANY, ITALY)

PRANZINI Giovanni¹, FRULLINI Riccardo¹

1 - Università di Firenze

Presenter e-mail: giovanni.pranzini@unifi.it

Key terms: Groundwater; Contamination risk; Nitrate; Agriculture; Household discharge

The study, conducted with the contribution PRIN 2007, concerns the risk assessment of nitrate pollution to groundwater in a plain with high density of population and productive activities. In the alluvial plain of Florence-Prato-Pistoia farming is subordinate with respect to industrial, with the exception of the Pistoia territory, where nursery is the main productive activity. Groundwater is used for all purposes: civil supply, agriculture, industry.

As for nitrate from agriculture and livestock, the risk was assessed by combining the vulnerability SINTACS (Civita and De Maio, 2000), with the IPNOA (Agricultural Nitrate Hazard Index, Capri et al, 1999). About half of the plain has a vulnerability to "high" to "extremely high". The IPNOA map shows, for the agricultural areas, a prevalence of the "low" and "medium low" indexes. The Risk Map, however, indicates a prevalence of areas with risk "high" or "very high": clearly, the vulnerability weighs more than the hazard index.

For nitrate from household discharges, the vulnerability was combined with the IPNOA (index of hazard by nitrates from household origin, Frullini and Pranzini, 2008). The SINTACS map has been revised to reflect the fact that the pollutants are dispersed directly underground: we considered the depth of one meter for the discharge of scattered houses, two meters for the loss of the sewer.

The calculation of the hazard by nitrates from household discharge was done with the methodology developed in the coastal plain between Rosignano and San Vincenzo (Frullini and Pranzini, 2008).

For discharges not connected to sewerage systems, the Index was calculated considering, for each area unit of one hectare, the number of inhabitants and its production of nitrogen (5.5 kg / year per inhabitant). For leakage of sewers, the index is derived from the combination of the nitrogen load carried by any duct (risk factor) with a coefficient of wear and breaking, depending on the material they are made and their age (controlling factor).

The average IPNOA index in the plain is "low." Nevertheless, the risk of nitrate pollution is "high" to "very high" in most of the plain, apparently because of the high vulnerability.

424 water samples from wells were analyzed in the country for the determination of ammonia, nitrites and nitrates. The maximum admissible concentration for drinking water was exceeded by 18% of the samples for Ammonium (CMA 0.5 mg/L), by 6% for Nitrites (CMA 0.5 mg / L), and 8% for Nitrates (CMA 50 mg / L). The contaminated wells are found mainly in urban areas, which means that the losses of the sewer are the major risk in the plain studied. In particular, in the urban area of Pistoia most of the wells exceed the CMA for both the Ammonium and Nitrates. This depends on the age of the sewer system, and the presence of groundwater at shallow depth, so that the sewer pipes are often flooded.

On the contrary, a fairly good water quality was found beneath the city of Florence, where almost all the samples were classified as "low concentration". The fact is surprising when one considers that in the years between 1975 and 1990, all the wells for civil water supply were abandoned because of contamination from nitrogen compounds. Clearly, the improvement of the sewerage system of Florence has paid off.

Key terms: Deep aquifer; Lateral heterogeneity; Unconfined aquifer; Seismic survey; Time-Domain Electromagnetic Method

The Friuli plain is crossed by a complex river system which is closely linked to the hydrogeological and geomorphological characteristics of the area where the river flows. In the high plain, the high permeability of the sediments is the cause of the disappearance of the surface water, which flows in depth. The area of Torrate di Chions, located on the Tagliamento megafan between Pordenone and Portogruaro, is covered by a sequence of mostly incoherent Quaternary deposits at least 700 m thick. The hydrogeological structure of this area poses the area of Torrate in the range of the medium plain, characterized by a progressive decrease in gravel which alternates with impermeable clay horizons. In this area, the

water table crops-out, creating a characteristics belt of springs, which crosses the park of Torrate di Chions (PN).

This report illustrates the geophysical part of a more complex research project, aiming to characterize the hydrogeological, geophysical and petrographic setting of two deep aquifers, located at 270 and 480 meters below the ground, as they were considered strategic reservoir for the quality and abundance of their waters.

The architecture of these aquifers was reconstructed through a combination of seismic and geo-electric investigations, taking into consideration the available geological and stratigraphic information. Two 1.5 km-long, SW-NE-trending seismic reflection lines were recorded, with a DMT-SUMMIT registration system and 10 Hz single geophones, deployed with a 10 m interval. A Time-Domain Electromagnetic Method (TDEM) survey was also performed with the execution of a loop transmitter located at the end of seismic line with a loop of size 100x200. The equipment used to energize the transmitter coil is the TEM 47 Geonics Ltd. Only two surveys have provided the best data (best signal-to-noise ratio) where the interpretation of the data inversion (obtained through parallel-plane mode) has allowed to identify three resistivity strata at different depths. Seismic processing revealed the presence of two strong reflectors, which showed that the aquifers A2 and A4 have good lateral continuity to the south-western part of the Friuli plain according with the results from the electromagnetic model.

Our results show that both methods, properly combined, offer the best results for the characterization of these deep aquifers in alluvial powerful blankets, and for the indirect estimation of petrophysical parameters (e.g., porosity, saturation, etc.).

HYDRODYNAMIC OF WEST LOW FRIULI PLAIN DEEP AQUIFERS: A MANAGEMENT TOOL FOR STRATEGICAL GROUNDWATER RESOURCES

MARTELLI Grazia¹, GRANATI Cristina¹

1 - Università di Udine

Presenter e-mail: grazia.martelli@uniud.it

Key terms: West Friuli plain; multilayered aquifer system; monitoring network; lithostratigraphic data; geochemical facies

The Friuli Plain on the right side of the Tagliamento River is characterised by the presence of a relevant detrital sedimentary body of Quaternary age, whose thickness increases from E (about 100 m at the foot of the Carnic Prealps) to W (more than 900 m at the border with the Veneto region). Such area is divided into two distinct sectors:

- the High Plain (AP), formed by coarse-grained and hence highly pervious sediments, prevalently gravels, as a consequence of the progradation, union and partial coalescence of the Cellina, Meduna and Tagliamento Rivers' alluvial fan system;

- the Low Plain (BP), characterised by sand and gravel lenticular bodies intercalated with impervious, wide and continuous silty-clay layers; such structure gives the reason for a multistrata aquifer system to be present. Along the transitional stretch between the BP unconfined aquifer and the AP multilayered system, part of the High Plain groundwater surfaces, giving rise to the springs' area that feeds the Low Plain's hydrographical network.

Owing to the PRIN 2008 financing for the BP multilayered system survey, a census of the BP water-wells has been taken in order both to outline the underground hydrogeological structure and to plan a quali-quantitative monitoring network for the groundwater characterisation.

The lithostratigraphic data coming from 120 water-wells formed the basis of a hydrogeological cross-sections set, that allowed to single out 12 aquifer levels ranging between 37,4 and over -371 m of depth; the deepest level has been recognised between 528,5 and 564,2 m bsl.

The monitoring network has been arranged relying on 124 water-wells suitable for pressure and qualitative measurements of all the recognised aquifer levels. Water samples coming from 18 springs and the main rivers have also been collected.

The preliminary results of the first series of measurements show pressures ranging between 0,1 and 2,8 bar (increasing with the aquifer levels' depth), a prevailing Ca-bicarbonate geochemical facies (with bromine characterising some levels) and high sulphate concentration values in the BP eastern sector aquifers. The radiocarbon isotope contents and the isotope composition of hydrogen ($\delta^2\text{D}$) and oxygen ($\delta^{18}\text{O}$) have not yet attained.

Key terms: salt water intrusion; groundwater; Venice lagoon; geophysic; geochemistry

The investigations carried out since the early '970 showed that salt water intrusion affected most of the Venetian coastal area. However, at that time, phenomena such as land subsidence and flooding (known as "acqua alta") had the priority in relation to the city protection, thus the study of the salt water intrusion process assumed a secondary role.

During '990, the salinization process became the subject of a research project performed by the Institute of Marine Science (ISMAR CNR-National Research Council). The results revealed a severe hydrological situation, particularly critical in the southern region. Aware of saline contamination effects on the environment and the agricultural activities, mainly horticultural crops well developed around Chioggia, the Venice Province started in 1998 the "Saline Wedge Project" to understand the consequences of the salt water intrusion in the subsol, in connection also to land subsidence, at the southern part of its territory.

The knowledge acquired by the two institutions (Venice Province Authority, ISMAR-CNR) constituted the common basis for new research and monitoring projects. Several meetings were promoted to involve all

the authorities and institutions responsible for land management to raise awareness of the saline contamination and its environmental and socio-economic impact, and to highlight the need of establishing appropriate monitoring networks in critical areas.

In the southern sector, where the possible damages for the agricultural-horticultural activities could be economically relevant, two projects (Saline Wedge 1998-2000; ISES Project 1999-2002) were initiated in the late '90, involving all the authorities managing the territory. The aims of these projects were a) to increase the knowledge on the factors enhancing the salt water intrusion; b) determine the areal extent of the saline contamination; c) assess the critical conditions in relation to the economic activities, mainly of agricultural and tourist type. Once obtained a detailed hydrogeological representation, specific actions to limit the process have been planned (Brenta Project, 2003-2004). Preliminary investigations were performed to realize a mobile gate at the mouth of the Brenta-Bacchiglione river to prevent the encroachment of sea water into the river bed during high tides. More recently, scientific efforts have been devoted to better understand the process dynamics. Mathematical models have used to investigate the effects of other possible mitigation strategies (CORILA Project 3.10 2004-2007; VECTOR-Cliven Project 2007-2010).

In the northern sector of the Venice territory, between the Piave river and the lagoon margin, researches aimed at improving the comprehension on the salt water intrusion phenomenon started in 2004, through the cooperation between the University Ca' Foscari of Venice and the University of Padua (PRIN Project "The deep aquifers of the Po Valley as regional resource: aquitard in hydrodynamics, generating of water chemically and thermally anomalous, a suitable place for the CO₂ atmospheric trapping").

The combined use of adequately validated geophysical and geochemical tools conferred a multidisciplinary character to the research and allowed for the definition of the phenomenon's superficial extension. Geophysical analysis based on Vertical Electrical Sounding (VES) and conductivity logs have been performed together with water table measurements and geochemical analysis on samples collected from selected wells. Moreover, a critical review of old geophysical data allowed for the verification of a possible saline contamination changes in time. Interesting results have been obtained specifically within territory of Jesolo. In this case, considering the influence of the Piave and Sile rivers and the presence of a coastal sand dune, a map of salt water contamination was created to evaluate the agricultural use of superficial water. The effective origin of salt water found in the aquifers, its distribution, extension and its preferential way of movement within the territory were defined relating all the information acquired to the geological, geomorphological and stratigraphic characteristics of the area.

In addition, the presence of salt water contamination in the shallow aquifers below the city of Venice has been highlighted by recent studies developed at the IUAV University.

Key terms: un-manage aquifer recharge; salt water intrusion; shallow coastal aquifer; irrigation; infiltration

In the coastal aquifer of Ravenna, high rates of anthropogenic (gas extraction) and natural (sediment compaction) subsidence and artificial drainage (land reclamation canal system and pumping machines) have caused groundwater salinization.

We have studied a 10km-long transect extending, normal to coast, from the shoreline using 10 fully penetrating piezometers. This transect is one of the most representative for the coastal aquifer of Ravenna. Different land uses are represented along the transect: beach dunes, pineforests, irrigated and rain-fed agricultural land, and gravel quarries. The maximum elevation is 5m in the most recent dune belts, whereas the areas around the quarries are at 2m below sea level. In addition to the transect normal to coast, we have recently focused our attention on a small area (6ha), behind the coastal pineforest (500m from sea), where there is an irrigation channel which, during the growing season, is filled with freshwater from the Po river to irrigate the nearby fields. In February 2011 we drilled other 2 fully penetrating piezometers one to the west and one to the east of the irrigation channel. In order to obtain thickness and dimensions of the freshwater lens in the aquifer, we performed 3 series of 16 Vertical Electrical Sounding (VES) aligned along a cross section normal to the irrigation canal, in different season. In this way, we can compare the state of the salinization of the aquifer where only natural recharge is present and where there is also a contribution to recharge from irrigation in different season.

A quarterly aquifer monitoring along entire transect, was conducted with Straddle Packer to collect geochemical parameters of the water: pH, Eh, Temperature, Electrical Conductivity (EC) and Dissolved Oxygen. We also measured monthly rainfall and infiltration rates, by four pluviometers and drain gauges placed along the transect.

The lithological 3D aquifer model shows that the aquifer is unconfined only below the pineforest and in a few adjacent areas.

Here we report the results of year 2010-11 monitoring of the evolution and dimension of the freshwater lenses floating on top of the saltwater in the coastal phreatic aquifer along the whole transect studied.

The EC data show, along the transect, a dynamic fluctuation of the freshwater lenses in every season. In the well, inside the coastal pineforest and closer to sea, the aquifer is salty and there is only 0.5m of freshwater lens at the top of the water table. In a second well localized within irrigated agricultural land at 2km from sea, EC data indicate a counter-intuitive trend: in summer we measure lower EC value than in the winter probably because of the high irrigation rate during the growing season. Inside the historical Classe Pineforest, at 4km from the coast, the groundwater is mostly saline (10g/l) with 1m of freshwater lens at the top. Fresh groundwater lenses within the quarry belt at 7km from sea, have a large thickness (2m) but at the bottom saltwater is still present. At 10km from the coast, in our last monitored well, groundwater EC values were under 1g/l along the entire depth-profile of the well indicating almost exclusively the presence of freshwater.

The rainfall distribution shows, during the summer, 50% of differences between one pluviometric station and the next at a small scale (2km);

accordingly, the infiltration rate was dissimilar and also groundwater recharge was not homogeneous along the whole section. During the Summer, the EC data measured in the wells around the irrigation canal and VES profile shows a rather thick freshwater lens of 5m. In this same area the amount of Summer rainfall and irrigation measured was 4 times as much as that measured in other pluviometers far away from irrigated land. During the winter, VES records show different results from the summer situation: a freshwater lens 300m wide and 2m thick in the eastern part of the canal and a completely saline aquifer in the western part.

SEASONAL VARIATIONS IN SALINIZATION WITHIN THE COASTAL PHREATIC AQUIFER OF RAVENNA (ITALY): GEOPHYSICAL CHARACTERIZATION

CAPO Donato¹, ANTONELLINI Marco¹, MARCONI Valentina², MARCHESSELI Giuseppina², LAGHI Mario², GREGGIO Nicolas², CIBIEN Monica², GABBIANELLI Giovanni¹

1 - Univerità di Bologna

2 - Univerità di Bologna - Polo di Ravenna

Presenter e-mail: donato.capo2@unibo.it

Key terms: Adriatic coast; Salinization; Geophysical characterization; Seasonal variations; Coastal aquifer

The coastal phreatic aquifer of the Ravenna province is salinized up to several kilometers inland. In order to characterize and assess the extent of the salinization, we have monitored the presence of fresh-water at the top of the watertable and the depth of the interfaces between fresh and brackish water and between brackish and salt water with particular attention to the seasonal changes and the variations in recharge. The study area is located between the Reno river estuary in the north and the Savio river mouth in the south; the investigated area extends landwards (west) up to 5 Km from the coast. A large part of the study area is below sea level. Several land uses and a complex morphology are present in this coastal zone: urban area, agricultural land, forests, quarries, and tourist establishments. There are also rivers, drainage canals, wetlands, lagoons and surface water bodies. The aquifer is mostly made up of sand and overlies a clay substrate at 25 m depth. Some pro-delta fine-grained deposits are found between 5 and 20 m depth. The study area has an average annual rainfall of 625 mm and an average temperature of 14.4 °C. The field work was carried out by means of Vertical Electric Soundings (V.E.S.) in a Wenner array configuration; the sampling points have been taken at a distance of 200-500 m on transects perpendicular to the coastline. The VES penetration depth varies, from case to case, between 8-9 m and 10-15 m. In order to avoid interpretation mistakes, we have calibrated the apparent resistivity with detailed stratigraphy logs obtained from several boreholes in the study area. Our work has shown, that where the top of the aquifer has a large hydraulic conductivity (sand) there is a freshwater lens (between 0.1 and 2.25 m in thickness) floating on saltwater and a thick mixing zone (between 1.00 and 12 m in thickness) whereas if the top of the aquifer has low hydraulic conductivity (silty sand, clayish sand) the freshwater lens is absent and the mixing zone is thin. The freshwater lens in the aquifer is promoted by the presence of a well-developed coastal dunes system and by the lack of drainage canals or surface water bodies. The VES were repeated in different periods of the year with different rainfall and they were compared to the precipitation data published in the DEXTER system of the ARPA Emilia-Romagna. The comparison of these data shows a strong seasonality in freshwater and mixing zone thickness. In particular it is observed that in the dry periods of the year (monthly average 30 mm) the freshwater thickness decrease (up to 0.1 m), whereas in the wet periods of the year (monthly average 80 mm) the freshwater thickness grows (up to 2.25 m). The thickness of the mixing zone has a similar behavior. This seasonality is observed almost exclusively where there are sandy deposits outcrop at the surface.

Presenter e-mail: mmarcaccio@arpa.emr.it

Key terms: Groundwater Bodies; Po River Alluvial Plain; Natural Background Levels; Threshold Values; Arsenic

Providing a robust estimate of natural background concentrations of heavy metals and inorganic compounds in groundwater bodies has become increasingly important in Europe after the adoption of the EU WFD (Water Framework Directive) 2000/60/CE and the GWDD (Groundwater Daughter Directive) 2006/118/CE. These directives have been implemented in Italy by the D.Lgs. 30/2009, which requires the identification of natural background levels (NBLs). Thus should then lead to provide an estimate of the threshold values (TVs) of the concentrations of chemical species that might compromise the good chemical status of the system. The choice of the proper methodology to estimate the natural background level depends on the type of available data and the objectives to be achieved. Amongst different existing methodological approaches, we select a framework which is based on the statistical analysis of the distribution of concentrations monitored over time. We analyze and compare the preliminary results associated with two different methodologies, i.e., Component Separation and Pre-Selection. Both frameworks make use of monitored information within a given water body to provide (a) estimates of the level of natural background concentration, and (b) the threshold values of target chemical species. Component Separation evaluates NBLs by discriminating a natural and an anthropogenic component, jointly contributing to the monitored concentration values. This is achieved by modeling the observed concentration frequency distribution as a mixture of Gaussian and/or Log-normal distributions. Pre-selection estimates the NBL by excluding a priori from the available data-set the samples that

could be considered as subject to human influence. These are assessed from indicator species associated with concentrations which are above a given value. We applied these methods to the 91 groundwater bodies delineated within the Emilia-Romagna region (Italy) in compliance with the EU WFD and D.Lgs 30/2009. The analysis is based on concentration time series recorded at several monitoring locations included in the extensive network of observation wells managed by the ARPA - Regional Agency for Environmental Protection. The groundwater bodies analyzed are located within the following porous aquifer complexes: the Apennine rivers alluvial fans, the floodplains Apennine, Po Valley and coastline. Free surface and confined groundwater bodies have been distinguished. The monitored distributions of Arsenic, Boron, Ammonium and Chlorides were then analyzed within the delineated groundwater bodies. The estimated values of NBLs and TVs indicate that in the cases examined the two methodologies provide comparable results, rendering background concentrations and, consequently, threshold values of the same order of magnitude. Both methodologies lead to estimates of Arsenic NBLs which, in this preliminary study, are not consistent with the observation that the largest arsenic concentrations are found in the deep groundwater bodies and only to a minor extent in the upper aquifers. We conclude that the results of these statistical methodologies should be jointly considered with a profound understanding and quantitative modeling of the physical processes that dominate the (hydro-geo-chemical) space-time evolution of the species analyzed in the groundwater system.

GROUNDWATER QUALITY CHARACTERIZATION OF CREMONA AREA (NORTHERN ITALY) AFFECTED BY AS, FE AND MN CONTAMINATION, COMBINING HYDROCHEMICAL ANALYSIS AND AQUIFER TEXTURE MODELING

Presenter e-mail: m.rotiroti@campus.unimib.it

Key terms: Arsenic; Iron; Manganese; Groundwater contamination; Aquifer texture modeling

This study was developed within the framework of a scientific collaboration between the University of Milano-Bicocca and the Province of Cremona. The main aim is to identify the quality of the groundwater hosted by the multi-layer aquifer of the Cremona area, affected by As, Fe and Mn contamination.

The specific study area is situated near the confluence between the Adda and Po rivers. It covers a 50 km² area around the urban territory of Cremona. The considered depth is around 200-250 m, corresponding to Aquifer Group A (Regione Lombardia & ENI, 2002), which hosts in this area both shallow and confined aquifers.

The applied methodology involves the (a) collection of historical data related to water quality, water levels and well logs, (b) storage of collected data in specific databases, (c) construction of a 3D model of the aquifer structure, (d) design and execution of a field survey of water levels and water quality, (e) analysis of the hydrodynamic properties of the system, (f) spatial and time analysis of water quality data considering the hydrodynamic properties and the lithological and textural structure of the aquifer, (g) elaboration of a general hydrogeochemical conceptual model, incorporating some hypothesis about the mechanism and the origin of the contamination.

The 3D hydrogeologic model simulates the textural distribution of the aquifer deposits. It was built by means of kriging interpolation of the percentages of fine (clays, silts, peats), medium (sands) and coarse (gravels, pebbles) deposits, derived from the numerical coding of well data logs. The resulting model underlines the abundance of fine deposits and puts in evidence the significant presence of peat lenses. The water quality measurements, executed in July 2010, indicate that the groundwater is characterized mainly by a calcium-bicarbonate facies, with higher chloride and sulfate in the shallow aquifer. pH increases with the depth of sampling, ranging from 7.0 to 7.5 in the shallow aquifer and from 7.5 to 8.5 in the deeper aquifers. Redox potential assumes positive values only in the shallow aquifer while in the confined aquifers it has negative

values (-100/-200 mV). Conductivity ranges from 300 to 1000 μ S and it increases with the depth of sampling. These values indicate a medium/medium-high level of water mineralization.

With respect to the most important chemical parameters, bicarbonates ranges from 200 to 600 mg/L and they increase with depth. The highest bicarbonate values could be generated by the equilibration of the CO₂ derived by the degradation of the organic matter of the aquifer. Nitrates and sulfates increases with the depth of sampling, with higher concentrations of the former than the latter. Ammonia has been detected with low concentrations in the shallow aquifer and generally with high levels (1-5 mg/L) in the underlying aquifers. Iron and manganese has been measured at high levels: they range

respectively from 100 to 6000 μ g/L and from 10 to 1200 μ g/L. Generally the higher levels has been found in the surficial aquifers. It is possible to identify a decrease of concentration with depth, probably connected to the pH increase.

Arsenic has also been measured at high levels (it ranges from 1 to 180 μ g/L) especially in the range of depth of 30-100 m. Consideration of the textural model and water quality data yield hypotheses regarding the processes which control on the degradation of natural organic matter and its relation to general groundwater quality. Degradation of peat, that can explain the high ammonia levels, is associated with the progressive reduction of O₂, NO₃⁻, Mn(IV), Fe(III), SO₄²⁻, CO₂. These processes could explain the measured high levels of Fe and Mn, but also the high levels of As, which is generally sorbed on the surface of iron and manganese oxides, subject to release during their reductive dissolution.

INTERACTION BETWEEN ROCK MOUNTAIN AND ALLUVIAL PLAIN AQUIFERS IN THE SERIO RIVER BASIN (BERGAMO - ITALY)

CREMONESI Daniele¹, GATTINONI Paola², SCESI Laura²
 1 - Università degli Studi - Milano Bicocca - Dipartimento di Scienze dell'Ambiente e del Territorio

2 - Politecnico di Milano - DIAR

Presenter e-mail: danielecremonesi@libero.it

Key terms: Hydrogeological balance; recharge; Serio River

Lombardy is one of the most important Italian Regions for availability of water resources, both on surface and underground. However, urban growth, industrial and agricultural spread caused a change in these resources, both in terms of quality and quantity, especially in the alluvial aquifer.

Therefore a correct management of water resources in the plain area assumes a correct comprehension of the recharge processes, in particular the relationship with Prealpine aquifers.

This study purposes to improve the knowledge about the groundwater circulation in mountain and piedmont areas of Lombardy, in order to define the recharge of hydrogeological plain system. To purpose this aim a hydrogeological balance-based method was utilized and applied to the Serio River basin (Bergamo District). The studied area has an extension of about 450 km² and it is characterized by great difference in altitude (from 361 m a.s.l. in Cene to about 2900 m a.s.l.). The Serio River basin mainly consists of carbonate rocks, where large fractured-karst aquifers have developed. The presence of a well developed epikarst layer on surface bring about an important infiltration capacity in all the basin. A number of springs are supplied by this hydrogeological system, among them the most important one is the Nossana Spring, having an average discharge of about 3 m³/s. The waters coming from the Serio River basin supply the plain area enclosed between the Adda and Oglio rivers.

The results obtained by the hydrogeological balance underline that the contribution to recharge of alluvial plain area arising from mountain rock masses is consistent, approximately about 6.5 m³/s, corresponding to 5% of total rainfall. Considering that the amount of water pumped from the alluvial aquifer of the Adda-Oglio basin (90 km²) is about 5.78 m³/s, the recharge coming from mountain aquifer is quite significant. At regional scale, the contribution of recharge from mountain rock aquifer is more consistent (about 48.5 m³/s), corresponding to the 15% of rainfall and to the 142% of the groundwater drawings.

This result confirms that at the regional scale, the recharge is important to maintain and preserve the plain aquifer.

The hydrogeological balance presented in this study can be the first important step to implement numerical models capable of simulating the water exchanges between the plain and the mountain areas, in order to obtain quantitative information on outflows and relationship between surface and groundwater aquifers. Another possible improvement is to use these models like provisional instruments.

Furthermore, in order to quantify the availability of water resource related to climate change scenarios, neural networks architectures have been built and trained. They are capable to relate the rainfall data (the input to the mountain system) to outputs, separating them in springs flows (for the mountain zone) and water table levels (for the plain area). Operating in this direction, it has been possible to evaluate the effects of climate change on water availability both in mountain and in plain area.

AQUIFER VULNERABILITY: AN ANALYTICAL PERSPECTIVE

CAMERON Enrico¹

1 - GeoStudio/Università di Pavia - Dipartimento di Scienze della Terra e dell'Ambiente

Presenter e-mail: geostd@teletu.it

Key terms: aquifer vulnerability; impact; transport equations

Theoretically it should be possible to predict the impact of a polluting event on an aquifer from the knowledge of the aquifer vulnerability and of the features of such event (i.e. chemicals involved, volumes released etc.); the most common vulnerability assessment methods, however, does not allow such a prediction to be made.

Starting from the examination of analytical solutions to transport equations it will be discussed under what conditions and to what extent it is possible at all to properly speak of aquifer vulnerability and how a class of reference vulnerability measures may be constructed.

GEOPHYSICAL AND HYDROCHEMICAL SURVEYS WITHIN THE STUDY OF THE SALTWATER UPSISING OCCURRING IN THE OLTREPÒ PAVESE PLAIN AQUIFER (NORTHERN ITALY)

TORRESE Patrizio¹, PILLA Giorgio¹, BERSAN Marica¹

1 - DEPARTMENT OF EARTH AND ENVIRONMENTAL SCIENCES - UNIVERSITY OF PAVIA

Presenter e-mail: patrizio.torrese@unipv.it

Key terms: saltwater uprisings; Vogherese Fault; geophysical survey; VLF-EM; electrical tomography

The alluvial aquifer of the Oltrepò Pavese plain sector (Po Valley, Northern Italy) is characterized by a natural pollution by Na-Cl rich paleowaters (Messinian) that up-rise from the tertiary marine bedrock and mix with the shallow groundwater. This phenomenon is associated to the presence of the "Vogherese Fault", a buried tectonic discontinuity along which the saline waters are mainly distributed. Mapping of these chemically anomalous groundwater is greatly useful. Indeed, extreme mineralization is often a barrier to its use, not only for drinking water supply but also for industrial and agricultural use. Given that saltwaters mapping cannot be undertaken on the sole basis of wells hydro-chemical monitoring as these are often insufficient or absent in some areas, a geophysical survey was carried out. VLF-EM technique was tested to achieve an expeditive mapping of the conductive bodies over the entire area, involving 35 lines for a total length of 71 kilometers. Seventeen resistivity depth soundings were undertaken along a cross section of the "Vogherese Fault" to reconstruct the bedrock geometry and the different hydrogeological units. These were undertaken in a sub-area that is considered representative of the entire study area and were necessary for the different geophysical techniques calibration. The geometrical complexity of the contaminated areas located in proximity to the fault, was also studied at the local scale within a selected experimental site, during a more detailed phase of investigations: a resistivity profile, 5 resistivity depth soundings, 5 long spread and 1 short spread 2D-ERT (Electrical Resistivity Tomography) surveys, two 3D-ERT surveys and a closely spaced grid VLF-EM survey were undertaken along an approximately 3000 m long profile crossing the fault zone with a N-S direction and overlapping a significant length of the

VLF-EM surveys. The geophysical survey revealed that the morphology of the bedrock, the spatial distribution of the structural discontinuities and the hydraulic conductivity of alluvial deposits are likely to be controlling the areal distribution and in depth geometry of salty groundwater within the alluvial aquifer. Hydro-chemical investigations were carried out as well. These involved a 4 years water level monitoring of groundwater and sampling from contaminated water wells in order to determine chlorides concentration and its variation in time. This allowed to detect the 3 areas where the phenomenon is more intense and diffused, that are located along the "Vogherese Fault", even if evidence of the phenomenon was found also in other zones, placed near the Apennine margin. This fact could be explained by the presence of the "Marginal Fault" that intersect the marine substratum and probably contribute to vehicle the saltwater to the shallow aquifer. The distribution of saltwater into the aquifer is very complex as geophysical surveys revealed and varies not only horizontally, but also vertically, being conditioned by the aquifer's different times of recharge, with the arrival of new fresh water. The saline water-fresh water interface and its variation were detected by means of electrical conductivity and temperature logs over some wells. To assess the instant aquifer's reaction to the recharge events, a continuous monitoring system on some significant wells was undertaken using a multiparametric probe. This kind of investigation pointed out an increase of water's mineralization simultaneous with alluvial water level maxima. We interpreted this apparently anomalous behavior as a consequence of an intense recharge that affected the near Apennine fractured aquifers, connected to the deep circuits that controls saltwater uprising into the plain aquifer, on which a "pressure transfert" acted to determine a "mass transfert" of the deep mineralized waters and a salinity increasing of the shallow aquifer.

THE TRANSPORT MODEL OF PESTICIDE IN SOIL AND GROUNDWATER IN VERCELLI PLANE, ITALY

ZHAO Ye¹, DE MAIO Marina¹
1 - Politecnico di Torino

Presenter e-mail: sunnyzhao2007@hotmail.com

Key terms: pesticide; groundwater contamination; model

As a result of agricultural practices, pesticides have been detected in many aquifers and surface waters. Contamination of groundwater by agrichemicals (pesticides and fertilizers) is now widely recognized as an extremely important environmental problem. Despite the extensive scientific attention paid to this contamination, the fate and transport of pesticides in the area is not well understood. In particular, little is known about how, despite their low solubility, significant quantities of these chemicals have been transported to groundwater. Various attempts to evaluate groundwater vulnerability to surface contaminants have been made over the past two decades. Generally, they can be classified as (1) direct observations of pesticides or other agricultural contaminants in groundwater, (2) simulation methods, or (3) index methods.

Index methods are usually used to make groundwater vulnerability maps, which delineate the land surface according to the potential for pollutants to reach groundwater resources, have been generated using a variety of ranking or scoring methods to produce qualitative or semi qualitative output. These maps usually assess the overall potential for chemical contamination of aquifers and are not specific to individual compounds or classes of. Although these maps are useful for supporting policies with regard to the general protection of water resources, they are not suitable for driving detailed monitoring programs for pollutants. The mathematical models help to understand the mechanism of pesticide leaching in soils towards groundwater, which are useful tools for assessing the risk of groundwater contamination resulting from the agricultural use of pesticides. These models are cost-effective methods as compared to field sampling studies.

Pesticides applied at or near the soil surface can leach to considerable depths. Pesticide fate models account for a variety of processes including soil water flow, solute transport, heat transport, pesticide sorption, transformation and degradation, volatilization, crop uptake, and surface runoff. A particular modeling challenge is to predict pesticide transport at very low leaching levels important for pesticide registration. Groundwater is widely used for drinking, agriculture, industry, urban development, wetlands and recreation. Due to high crop productivity in this region, there is extensive use of pesticides including insecticides, herbicides, fungicides and defoliant. The wide use of pesticides contributes to the groundwater contamination. Several pesticides including bentazon, molinate, atrazine, propanil and quinclorac have been detected in wells, rice field and surface water in this region, although some of them are forbidden to use for many years. The purpose of the groundwater module is to predict the concentrations of agricultural pesticides reaching the water table of any groundwater unit Vercelli likely to be abstracted by small, locally used, wells. The objective of this study is to investigate quantitatively the transport of pesticides in the Vercelli region. Data are presented on concentrations of pesticides in groundwater, river water, and farm field in the area. These data are utilized alongside the findings of past studies to develop numerical and analytical models of groundwater flow and transport, with the aim of evaluating the nature of contaminants and their distribution in groundwater. Hydraulic and chemical data were collected in the area, helping in defining the conceptual models of flow and transport, and serving as model calibration targets.

3D HYDROGEOLOGICAL MODEL OF THE PO PLAIN: A PROPOSAL

BONOMI Tullia¹, BERTOLO Beatrice², GIULIANO Giuseppe³, CAVALLIN Angelo⁴, PUMA Francesco², ZUPPI Giovanni Maria⁴

1 - DISAT- Università Milano Bicocca

2 - ADBPO - Parma

3 - DTA - CNR Roma

4 - IGAG - CNR Roma

Presenter e-mail: ANGELO.CAVALLIN@UNIMIB.IT

Key terms: 3D; hydrogeology; Po plain

Last year the Po River Basin Authority (ADBPO) requested the national scientific community to formulate comments on the draft of the River Basin Management Plan as well as to propose integrative actions aiming to

increase the efficiency of open problems solving solutions.

The Department of Environmental and Territory Science (DISAT) of the University of Milan Bicocca (UNIMIB) proposed the realization of a unitary 3D hydro-geologic model of the full Po plain as an integrative measure.

The model rationale is to build a homogeneous shared knowledge of the plain subsoil as a unitary basis for evaluating the groundwater resource, identifying critical areas, protecting its quality, planning its strategic development in front of change of precipitation regime and water demand increase. It has to be considered as a tool to harmonize, coordinate and integrate the information patrimony on the subsoil presently distributed among scientific community, river Authority, and various territorial institutions.

The measure was included by the Authority in the list of those judged as urgent and of high priority for the Management Plan implementation, with specific reference to the water balance Plan.

An ad hoc Memorandum of Intent has been recently signed by the three Institutions (CNR; ADBPO and UNIMIB) to operationally manage the measure realization.

Fundamental element of the knowledge is the 3D reconstruction of underground reservoir features, made up of alluvial deposits with lithofacies and textures (gravels, sands, clays) highly heterogeneous in space. The aim is the definition of the groundwater bodies geometry, of the permeability limits, of boundary conditions.

A specific database of water wells (TANGRAM), with special regard to their stratigraphic features, has been developed and used for uploading data related to some pilot areas (e.g., more than 25,000 data already available for the Lombardy territory).

The physical model of plain underground is built from the wells stratigraphies by means of a methodology which integrates databases, GIS systems and GOCAD (Geologic Object Computer Aided Design).

The methodology, applicable in a multi-scaling context up to a regional level, allows to define the space basic knowledge which along with the hydrologic dynamic data, related to balance and flow, are used for the hydro-geological numerical modelling simulation (e.g. Modflow) as a supporting tool to groundwater resources management.

Under the coordination of ADBPO, an ICT node will manage, according remote standard procedures, information flows from/to the peripheral web services of territorial institutions. Information exchange will concern both processed data of the 3D subsoil model and evaluations derived from simulation models.

The measure will allow to upgrade the efficacy and efficiency of information released from monitoring networks by means of a progressively adaption to a unitary vision of the natural groundwater system operation and of the impacts related to human activities.

The measure is being developed by the three specialized research Institutes of CNR, namely Water Research Institute (IRSA), Environmental Processes Dynamics Institute (IDPA) Environmental Geology and Geo-Engineering Institute (IGAG), along with DISAT/UNIMIB.

Collaborations will be also established with the Universities localized in the Po basin. The measure is strategically managed by ADBPO and CNR, while scientific coordination is in charge of DTA- CNR.

A pilot realization of the measure is actually applied to a test area located in the Lombardy plain, in between the rivers Oglio and Adda, with a 3D model developed by DISAT/UNIMIB.

A7-18 Orale Fetisov, Vyacheslav

10.1474/Epitome.04.0109.Geoitalia2011

THE AOSTA PLAIN ZONING ON CONDITIONS OF INTERCONNECTION OF SURFACE WATER AND GROUNDWATER

FETISOV Vyacheslav¹, DE MAIO Marina¹, LODI Laura Pia¹
1 - Politecnico di Torino

Presenter e-mail: vyacheslav.fetisov@polito.it

Key terms: groundwater/surface-water relations; mountainous regions; Aosta plain

Alluvial deposits of mountain valley are characterized by considerable inhomogeneity which is reflected in their filtration properties. It is caused by features of alluvium formation and also by presence of sediments of various genesis in alluvial stratum at different depth (remains of ancient alluvial fans, dealluvial trails, rock fall, landslides and etc.). In some cases they carry out a role of local weak permeable or almost impermeable interlayers, in others cause worsening of filtration properties of alluvium. Sharp variability of mountain alluvium facies can lead to considerable errors, first of all at substantiation of the filtration scheme. If conclusions about filtration properties of alluvium are based only on results of the aquifer test analysis carried out in small volumes on local site, then it is possible to get any and casual results.

Therefore at the preliminary stage previous to modelling, performance of zoning of the plain on conditions of interconnection of surface water and groundwater which define filtration properties of alluvial deposits is expediently.

Taking into account the data of groundwater and surface water monitoring, there was executed the Aosta plain zoning between two morphological narrow sites of the Dora Baltea valley (commune Villeneuve in the west, commune Pontéy in the east).

The average slope of the Dora Baltea river between gauging-stations PF1 (Trépoint) and PF6 (Ponte vecchio Saint-Marcel) which restrict Aosta plain in the west and the east makes 6,4 0/00 (according to LiDAR survey of the Dora Baltea river). It is possible to mark out two sections with different slope surface and accordingly different speeds of the river: the first section is situated between stations PF1 and PF3 (Passerella Gressan) with an average slope 9,3 0/00; and second - between stations PF3 and PF6 with average slope 4,4 0/00. The first initial section of plain was raised during neotectonic development of the territory, the second section was exposed to depressing and widening.

Complexity of geomorphological conditions is expressed in the sharp variability of width of the alluvial aquifer and its thickness that finds direct reflexion in directivity and intensity of water exchange between the alluvial stratum and the river. The flow section of the groundwater stream of the Aosta plain, according to the accepted geologic model, changes on the average from 20 thousand M2 in narrow parts of the plain to 120 thousand M2 and more in its central widest part.

The initial narrow section of the valley between gauging-stations PF1 and approximately to the boundary of communes Aymavilles/Jovencan is characterised by alimentation of the Dora Baltea river by aquifer. Further downstream, the plain begins to widen and as a result of the sharp increase in the alluvial aquifer cross-sectional area is a constant alimentation of alluvium by river waters. Here it is possible to mark out a section with intensive alimentation of the alluvial aquifer from the river and a section with moderate alimentation located lower the Buthier alluvial fan. An intensive alimentation from the river is accompanied by

filling of pore spaces of coarse alluvium by fine-grained materials transferred by the river. That causes a worsening of filtration properties of the upper part of the alluvial aquifer. This is confirmed by the data of the granulometric analysis of alluvial sediments from the wells S3 drilled in this site (De Maio et al., 2010). The content of argillo-arenaceous fractions in diameter less than 2 mm in samples which have been taken above and below the groundwater level is increased from 43 to 62%. Approximately from the site of gauging-stations PF5 (Ponte Pollein), where there is narrowing of the groundwater flow cross-section area, the discharge occurs into the river, that prevents the entrance of argillo-arenaceous fractions into the alluvial stratum.

OXYGEN SUPERSATURATED WATER INJECTION SATURATED FOR MTBE AND HYDROCARBON BIOREMEDIATION

GRIGLIONE Michele¹, BOCCARDO Delia¹, DAVIT Jean Pierre¹, CALI' Angiolo¹
1 - Golder Associates Srl

Presenter e-mail: DBOCCARDO@GOLDER.IT

Key terms: Oxygen supersaturated water; injection; hydrocarbon; MTBE; bioremediation

In-situ enhanced biodegradation is a well established technique for the remediation of sites impacted by petroleum hydrocarbon. The majority of the remedial approaches used involve however a series of traditional technologies such as Pump and Treat, air sparging or use of oxygen-delivery compounds.

Due to historical leaks from underground storage tanks, soil and groundwater at the Site described in the study were impacted by light and heavy hydrocarbons and MtBE. Biodegradation was observed to be an important process at the Site, but with a kinetic too slow to allow for a remediation under an acceptable timeframe. Being oxygen, the limiting factor, air sparging was considered but abandoned due to the generally low hydraulic permeability and the high degree of vertical stratification of the soil. Based on a feasibility analysis, a mixed remediation technique was selected and comprising of injection of super-oxygenated water (SOW) and traditional P&T.

The system is composed of an oxygen source, a recirculation system (extraction/injection wells, pump), an hydraulic barrier for the protection of the sewer and an SOW generation system, which was developed by Golder in 2003 and constantly improved since then.

The injection of SOW offers significant advantages over conventional technologies for direct injection of air into the groundwater:

- ° the completely oxygen dissolved prevents the generation of gas bubbles and avoids the need to install a vapor recovery system;
- ° contact oxygen-ground water is not made in the form of bubbles in the soil, because oxygen is already being fully dissolved; the injected water, unlike air bubbles, follows the same path of groundwater and is therefore less influenced by different preferential pathways;
- ° high concentrations of oxygen in the injected water generate a high concentration gradient that allows the diffusion of oxygen even in areas with low permeability;
- ° injection may be continuous and controlled by traditional P&T, overcoming the difficulties represented by the emplacement of oxygen delivery chemicals in socks or injections.

Considering that, in these low permeability soils, the SOW injection creates a rising of the groundwater level and significantly modifies the groundwater direction, a P&T system was added in order to provide for groundwater flow control, limiting potential contaminant displacement and further mass reduction.

After 18 months of operation of the PAT, in conjunction with the plant P&T, a strong decreasing of contamination was measured and a considerable increase of the MtBE- and hydrocarbons-degrading bacteria in monitoring wells.

MtBE in the sampling conducted in September 2010 is lower than the remediation targets in all samples analyzed, while benzene and total hydrocarbons has shown respectively a very strong and a significant decrease. The increase of bacteria was detected in many monitoring wells, near the injection wells. This increase, compared to the low injection flow of supersaturated water (about 1 l/min well), confirms that the reduction of the contamination is not attributable to dilution/P&T removal. The results obtained have shown that the SOW injection, combined with P&T, can be effectively used for the remediation of groundwater contaminated with hydrocarbons and MtBE.

When compared with the traditional P&T addition, the acceleration of the biodegradation generated by the SOW injection has consequently increase in the duration of the activated carbon, due to lower contaminant mass load to the P&T filters.

The residual contamination of benzene and total hydrocarbons will be treated by the continued operation of SOW injection and P&T to achieve the objectives of remediation. The injection of oleophilic nutrients is currently also considered to further increase the biodegradation of the heavier hydrocarbons.

SCHEME MAP OF THE PROTECTION (UNSATURATED) ZONE OF THE UPPER KAMA SALTS DEPOSIT

FETISOVA Natalya¹, FETISOV Vyacheslav¹
1 - Politecnico di Torino

Presenter e-mail: vyacheslav.fetisov@polito.it

Key terms: groundwater; vulnerability; salt deposit

The Upper Kama potassium salts (sylvinitic, karnallit) deposit is situated within the bounds of the Perm Krai on the left bank of Kama river. The deposit is the largest in Russia and the second in the world. Sylvinitic is raw materials for production of potash fertilizer (contains about 75% of halite). Karnallit is raw materials for the magnesian industry.

The upper layer of the territory is presented by Quaternary deposit (consists in sand, sandy loams, loams, clay); next layer is the bedrock of the Perm system: presented by speckled stratum (sandstones, clay, aleurolites, argillite), terrigenous-carbonate stratum (limestones, marl), salt-marl stratum (marl, clay, gypsum). Under that the directly salt deposit is allocated. Development of the deposit is carried out by underground mining, depth of mine changes from 100 to 500 m.

After flotation the halite and clay are taken place above the ground surface as the waste products, in form of technogenic massifs from solid

halite waste (80-93 %) and clay-salt sludge (7-10 %). (The altitude makes 100 m and more.) They are the main source of salinization of ground and surface waters, soils and rocks in the zone of active water exchange.

On the observable territory there are available more than 20 large water supply point, they take groundwater from aquifers above salt stratum. Every day they pump out about 150 - 200 thousand m³ of groundwater. In this connection, the estimation of groundwater vulnerability is the actual problem.

The assessment of groundwater vulnerability is carried out in two stages. The quality assessment of groundwater vulnerability based on a complex of available map (soil map, map of the Quaternary deposits, geological map, the depth to water table, relief of the territory) is carried out at the first stage. That means, the map of the protection zone is made by superposition of these maps. The sites with identical characteristics are allocated on the map of the protection zone. And at the second stage the time required for particular contaminant to reach the aquifer is calculated for each of these concrete sites.

The typical sites which characterised the same structure of soils and rocks of the unsaturated zone are allocated on the schematic map of the protection zone.

Making of this map was carried out in ArcGIS by superposition of the next above-mentioned maps: a soil map, a map of Quaternary deposits and geological map.

In the investigated territory it is possible to mark out two category of the groundwater protection. The least favorable protection conditions are: the not deep groundwater level (from less 1 to 5), insignificant total thickness (0,5-3,5) of weak-permeable sediments in the aeration zone. Such conditions are developed in the western and northwest parts of the deposit where there are mainly sandy fluvio-glacial sediments with small of weak-permeable rocks.

PASSIVE VS. TRADITIONAL GROUNDWATER SAMPLING METHODS: A COMPARATIVE ANALYSIS

CAZZANIGA Alberto¹, BENTIVOGLIO Nicola¹, DAVIT Jean Pierre¹, CHIARONELLO Dario¹
1 - Golder Associates Srl

Presenter e-mail: jdavit@golder.it

Key terms: Hydrasleeve; Passive sampling; Chemical analysis results comparison; Sampling cost reduction

Groundwater passive sampling is a method which is becoming increasingly accepted by most of North American Environmental Agencies given its reliability, reduced waste generation as well as time and cost effectiveness. The method is still basically not applied in Italy because pre-sampling purging is required by the ISPPA guidance and local ARPAs are reluctant to rely on a no-purge sampling technique.

The aim of this study was to conduct a comparative analysis of two different groundwater sampling methods and provide a basis for a technical proposal for passive sampling applicability.

A passive groundwater sampler is defined by ITRC as one able to acquire a sample from a discrete position in a well without active media transport induced by pumping or purge techniques. The sampling device is exposed to media in ambient equilibrium during the designated sampler deployment period. In wells, the water is expected to be in natural exchange with the formation water (Robin and Gillham 1987).

Two different sampling practices were compared:

- ° No-purge passive sampling, using a Hydrasleeve sampler; and
- ° Traditional purge and sample, using a low-flow pump or a traditional subsurface pump.

The groundwater samples were collected in different Sites impacted by dissolved contaminants such as chlorinate solvents and hydrocarbons (diesel gas oil and gasoline).

The comparison of the two sampling methods dealt with the following aspects:

- ° comparison with concentration of contaminants detected;
- ° sampling operation cost-effective analysis;
- ° environmental compatibility; and
- ° compliance with the legislation.

Regarding the chlorinated solvents, the two sampling methods gave comparable results; both detected the same contaminants with similar concentrations, in almost all the wells.

Hydrasleeve and traditional sampling results showed a good linear correlation and an average Relative Percentage Differences values lower than 40%.

In the sites impacted by hydrocarbons contamination, the concentration values detected were:

- ° comparable for benzene, toluene, ethylbenzene xylenes and for MtBE; and
- ° higher for TPH in Hydrasleeve samples.

The main advantages related to Hydrasleeve sampling are:

- ° sampling cost reduction by 50%-80%, obtained by saving field time and material and additional costs for disposal of purged water;
- ° good environmental compatibility, by displacing a minimal amount of water;
- ° suitability of sampling for most physical and chemical parameters; and
- ° compliance with Italian legislation for low yield aquifers sampling.

The limitations of Hydrasleeve are:

- ° it requires a minimum water column above bottom of monitoring wells;
- ° it has limited sample volume and does not allow for field measurement of physico-chemical parameters; and
- ° in general it is not accepted by Italian Authorities in substitution of traditional sampling methods.

Although site-specific results comparative analysis is recommended prior to replace the traditional sampling methods, this comparative analysis showed the suitability of Hydrasleeve as a passive sampling method for monitoring of groundwater contamination.

3D STRESS-STRAIN ANALYSIS OF THE ETNA VOLCANO: A CONTRIBUTION TO DEFINE THE HAZARD ASSOCIATED WITH FLANK DYNAMICS

APUANI Tiziana¹, CORAZZATO Claudia², MERRI Andrea¹, TIBALDI Alessandro²

1 - Università degli Studi di Milano - Dip. Scienze della Terra
2 - Università di Milano-Bicocca - Dip. di Scienze Geologiche e Geotecnologie

Presenter e-mail: tiziana.apuani@unimi.it

Key terms: Etna Volcano; flank instability; numerical modelling; FLAC

As many active volcanoes, Mount Etna shows clear evidence of flank instability, and different mechanisms were suggested to explain this flank dynamics, based on the recorded deformation pattern and character. Shallow and deep deformations, mainly associated with both eruptive and seismic events, are concentrated along recognized fracture and fault systems, mobilising the eastern and south-eastern flank of the volcano. Several interacting causes were postulated to control the phenomenon, including gravity force, magma ascent along the feeding system, and a very complex local and/or regional tectonic activity. Nevertheless, the complexity of such dynamics is still an open subject of research. Being the volcano flanks heavily urbanized, the comprehension of its gravitative dynamics supports hazard and risk evaluations, and must guide the civil protection actions. The present work addresses the problem by integrating field data, laboratory tests and numerical modelling. A bi- and tri-dimensional stress-strain analysis was performed by a finite difference numerical code (FLAC and FLAC3D), mainly aimed at evaluating the relationship among geological features, volcano-tectonic structures and magmatic activity in controlling the deformation processes. The analysis is well supported by dedicated structural-mechanical field surveys, which allowed to estimate the rock mass strength and deformability parameters. To take into account the uncertainties which inevitably occur in such a complicated model, many efforts were done in performing a sensitivity analysis, devoted to evaluate the effect of topography, geometry and rheological behaviour of the structural units, along the WNW-ESE section crossing the volcano summit and the Valle del Bove depression. Then a 3D numerical model, extended 40x60 km, was implemented to simulate the volcano deformation pattern. First, the role of the Pleistocene subnean clays was investigated, then, two "structural weakness zones" - the Pernicana fault system and the NE rift - were introduced and their effects on the flank instability evaluated. Two extreme hydrogeological conditions, drained and undrained, were analyzed. The results are expressed in terms of stress-strain field, displacement pattern, plasticity states, shear strain increments. Two main instability mechanisms were identified: the first deep seated, and the second one at shallow depth, with the sliding surface located inside the subnean quaternary clay. Both mechanisms contribute to explain the present deformation pattern and some of the main structures of the Etna flank. The effect of magma pressure exerted on the active dyke walls during eruptions was then simulated, and relations between magmatic activity and flank instability were investigated.

A FUNCTIONAL ENTITIES APPROACH TO PREDICT SOIL EROSION PROCESSES IN SMALL PLIO-PLEISTOCENE MEDITERRANEAN CATCHMENTS

MAERKER Michael¹, SCHROEDER Boris²

1 - University of Florence DiPSA
2 - University of Potsdam

Presenter e-mail: mmaerker@unifi.it

Key terms: Erosion Processes; Land slides; spatially explicit prediction; Classification and regression trees; Chianti

In this paper we evaluate different methods to predict soil erosion and shallow landslide processes. We derived different layers of predictor variables for the study area in the Northern Chianti, Italy, describing the soil-lithologic complex, land use, and topographic characteristics. We mapped erosion processes by interpretation of aerial photographs and field observations. These were classified as erosional response units (ERU), i.e. spatial areas of homogeneous erosion processes. The ERU were used as the response variable in the soil erosion modelling process. We applied two models i) bootstrap aggregation (Random Forest: RF), and ii) stochastic gradient boosting (TreeNet: TN) to predict the potential spatial distribution of erosion processes for the entire Orme River catchment. The models are statistically evaluated using training data and a set of performance parameters such as the area under the receiver operating characteristic curve (AUC), Cohen's Kappa, and pseudo R². Variable importance and response curves provided further insight into controlling factors of erosion. Both models provided good performance in terms of classification and calibration; however, TN outperformed RF. Similar classes such as active and inactive landslides can be discriminated and well interpreted by considering response curves and relative variable importance. The spatial distribution of the predicted erosion susceptibilities generally follows topographic constraints and is similar for both models. Hence, the model-based delineation of ERU on the basis of soil and terrain information is a valuable tool in geomorphology; it provides insights into factors controlling erosion processes and may allow the extrapolation and prediction of erosion processes in unsurveyed areas.

AN INNOVATIVE APPROACH FOR THE IDENTIFICATION OF GEOMORPHOLOGICAL ANOMALIES BASED ON WAVELET TRANSFORM

DOGLIONI Angelo¹, SIMEONE Vincenzo¹

1 - Politecnico di Bari

Presenter e-mail: a.doglioni@poliba.it

Key terms: DTM; wavelet; engineering geomorphology; quantitative geomorphic analysis

Landform analysis for detection of terrain anomalies constitutes a hot topic, which is often faced by exploiting digital models of the surface topography, which are usually quite accurate as well as geographically exhaustive. Digital Terrain Models (DTM) embody representations of the earth surface as rectangular grids or as mesh of triangles. However, these representations can be seen as matrixes of real numbers, which can be processed according to the approaches of signal processing.

Numerical geomorphic analyses of DTMs represent an interesting approach to these kind of studies, allowing for a detailed and pretty accurate identification of hidden topographic anomalies that may be related for instance to large landslides. The hierarchical analysis of DTMs permits a multi level identification of geomorphic entities, which constitute an inventory of landforms and natural resources.

Applications to 1D topographic data show useful results, including the identification of changes in topographic structure with scale. Extension to 2D analysis allows for the quantification of characteristic shapes, scales and orientations in the landscape.

Wavelet analysis of DTM was undergone for the identification of anomalies of unique features of the surficial topography. Application of wavelet analysis to morphotectonic lineament investigation, i.e. tectonic faults, associated with characteristic geomorphological features such as linear valleys, ridgelines and slope breaks are known from literature. In particular, these are used for the delineating the characteristic spatial frequencies of deep-seated landslide morphologic features such as ridges, scarps, and displaced blocks of material. In fact, spectral power shows characteristic frequency bands of spatial patterns, thus highlighting past slope instabilities and allowing the delineation of landslide terrain.

An approach for geomorphic numerical analyses is herein presented. The hierarchical representation of the DTM, can provide evidences of anomalies or singularities of the land surface, which are not directly evident from the DTM as it is, or from a simple slope and curvature analysis. In particular, 2D wavelet transform preserves the average values of the elevation at different scales, and this is particularly suitable for grid-based DTM. The grid-based DTM can be assumed as a matrix, where a discrete wavelet transform is performed columnwise and likewise, which basically represent horizontal and vertical directions. The significant outcomes of this analysis are low-frequency approximation coefficients and high-frequency detail coefficients. The detail coefficients in particular are analyzed, whereas sudden and wide variations of these coefficients are related to the variations and discontinuities of the DTM. Detailed coefficients are therefore 2D-plotted both on the horizontal and vertical direction, thus allowing to visualize and quantify potential anomalies of the land surface. Moreover, a further level wavelet analysis can be performed on the matrix of the approximation coefficients, which represent a smoothed representation of the land surface. This allows for the construction of a further level detail coefficients matrix, which can provide further information about the land surface. In this kind of approach, the choice of a proper wavelet is a tricky point, since it conditions the analysis and then their outcomes. Therefore multiple levels as well as multiple wavelet analyses are guessed.

Here the introduced approach is applied to some interesting cases study of south Italy for which detailed DTMs are available. These analyses show the performance of results in terms of different wavelets and different DTM resolutions. Moreover, the wavelet transforms are performed on multiple levels, thus trying to address the problem of which is the level extent for an accurate analysis fit to a specific problem.

THE TERRESTRIAL LASER SCANNER (TLS) SURVEY OF VIGNANOTICA'S BAY (GARGANO, APULIA, SOUTHERN ITALY): DETAILED MODEL OF A CLIFF

MARSICO Antonella¹, INFANTE Marco¹

1 - università degli studi di Bari

Presenter e-mail: infante.marco@unibari.net

Key terms: laser scanner; survey; model; cliff; apulia

The Terrestrial Laser Scanner (TLS) allows, at a distance of several hundreds metres from the stationing position, the acquisition of points belonging to a surface of inaccessible area.

In order to study the geomorphological and the mechanical features, the TLS is used to survey the sea cliff sited at the foot of Vignanotica valley, in southern coast of Gargano peninsula.

The main characteristic of the slope is its uprightness, up over 100 meters, with a front, divided by the valley mouth, which spreads for about 900 meters on the Adriatic coast.

The great interest in this site is due to its geological setting and to the effects of tectonic uplift that causes visible structural changes.

Since the sea cliff rises up to great altitude with a vertical slope, an high accurate, georeferenced digital model provided by TLS surveys is used in order to approach a qualitative and not interpretive study of discontinuities in rock.

Despite the cliff height, which rises over 120 meters in the eastern side, the lack of data acquisition was never counterchecked as consequence of the instrument space range. Instead, the digital model is not complete for shadows (i.e. areas invisible to the laser) due to brushes or morphological features noise. In order to minimize shadows during the later combination, straight scans overlap of about 50% according to the complicated geometry of the exposed rock face.

The generated virtual surface model is then queried to gain detailed measures up to 2 centimeters, precision chosen during the scans combination. The 3D model clearly shows all geomorphological and sedimentary evidences of the cliff, which are visible in place only in the lower part, and it allows appreciating these features at a height in the whole rock face. Herein, the Calcarei a Maiolica formation outcrops (limestone with chert beds and nodules) characterized by the presence of syndimentary deformations (slumps). The effects of tectonic uplift, as fractures and faults, are visible along the whole outcrop and they often mark the entire slope. The karst features are noticeable as carvings, which may overlap the pre-existing structural lineaments, and as vertical caves that widespread along the cliff notch; these last features let's hypothesize the superimposition of waves action on the chemical solution of the limestone.

The model depicts the real distances on the rock face and then it allows to measuring the void and caves in order to assess the amount of missing rock material.

Moreover, the DGPS georeferencing of collected data let's detect the fractures orientation in order to identify the main discontinuity groups and to pick out boulders that could move down to the slope.

MIARIA is a project funded as part of the Italy/Switzerland Operational Programme for Trans-frontier Cooperation 2007-2013 (INTERREG Italy/Switzerland).

The project aims to build innovative systems and technologies for the distributed acquisition of regional data and the communication of that data to second-generation operating control rooms; the aggregation of the information on a phenomenological basis, and the generation of dynamic integrated risk scenarios in trans-frontier Alpine environments, with particular regard to domino effects (Area Integrated Risk Plan-denominated scenarios).

Within this frame the Institute of Earth Sciences of the Applied University of the Southern Switzerland (IST-SUPSI) is responsible for the application of the project in the case study of the Canaria valley. This region is particularly susceptible to landslides and consequent domino effects that could cause severe damage to population and to infrastructures of North-South axis of San Gottardo.

Numerous active landslides are present in the valley involving both right and left slopes. In particular two phenomena are particularly active with measured displacements up to 20 cm/year: the Rutan di Sassi deep rotational slide in the left flank of the main river and the Ce complex rockslide in the right flank.

On October 2009 a rockfall has occurred in the front of Ce complex rockslide involving a volume of 350'000 m³. The accumulation has partially dammed the main river of the valley. A new similar event could be totally dam the river with heavy hazard of structures and infrastructures located at the toe of the valley. We present results of in situ geodetic lidar and ground based radar measurements to predict the potential scenarios and the results of run-out model applied on the Ce rockslide. The dam break modeling has recently conducted by damflood model (Cannata & Marzocchi, 2009), a 2D numerical model for the dam break flooding simulation.

2 - Dipartimento di Matematica, Università della Calabria, Via P. Bucci, 87036 Arcavacata di Rende (CS), Italy

Presenter e-mail: fedluca@unical.it

Key terms: Landslide susceptibility; Hazard; Cellular automata

The ultimate aim of many landslide studies is the assessment of the risk to population and/or infrastructures. To achieve this goal, information on landslide hazard is required; it involves the evaluation of the location and timing of occurrence of the events, and also the magnitude or intensity of the potentially hazardous phenomena.

These issues are addressed in our study, which highlights the preliminary results of a method for evaluating landslide invasion hazard on the basis of numerical simulation through Cellular Automata coupled with geological-morphological field survey and GIS techniques. The method has been tested on the northern sector of M. Pendolo (Sorrenro Peninsula) where proclastic covers, blanketing Mesozoic carbonate massifs, were affected by debris slides-rapid earth flows in the last decades.

By assuming that landslides will occur in the future because of the same conditions that produced them in the past, a logistic regression method was implemented to predict the geographical location of future landslides. The approach allowed to investigate the relation between landslide location and predisposing factors, adopting a stepwise procedure to select the optimal landslide susceptibility model.

Temporal probability of landslide occurrence was obtained from catalogues of historical landslide events occurred in the study area and by adopting a Poisson distribution model for the occurrence of the landslide events, while we used the thickness involved in the initial detachment as proxy for landslide magnitude or intensity.

For landslide invasion hazard purpose, several possible source areas have been hypothesized; for each of them, a simulation has been carried out by assuming the total entrainment of the cover thickness, whose distribution was drawn up in detail by field measurements. Simulations were performed by using the latest release of SCIDDICA, a Cellular Automata model previously calibrated on past events. Among other characteristics, the model is able to take into account phenomenological specifications such as energy dissipation, erosion and inertial effects. Ultimately, for each point affected by simulation, an overall hazard was calculated by overlapping the simulations and summing the product of relative probabilities of: (i) spatial occurrence (susceptibility), (ii) occurrence of slope failures in any give year (time), and (iii) landslide magnitude. Preliminary results clearly portray the most susceptible and hazardous sectors.

PRELIMINARY RESULTS OF LANDSLIDE SUSCEPTIBILITY ASSESSMENT IN THE SHEET N. 348 - ANTRODOCO (CARG PROJECT)

CHIESSI Vittorio¹, VITALE Valerio¹, TOTI Simona²

1 - Ispra
2 - Istat

Presenter e-mail: valerio.vitale@isprambiente.it

Key terms: landslide susceptibility assessment; logistic regression; rare

events

The aim of this work is to present the preliminary results of landslide susceptibility assessment performed by ISPRA (Institute for Environmental Protection and Research) in a test area represented by the sheet n. 348 - Antrodoco of the geological map of Italy at the 1:50.000 scale (CARG Project).

To carry out the analysis and make it more possible generalizable it was decided to use data available throughout the country such as the Digital Elevation Model (Istituto geografico Militare Italiano), the Corine Land Cover coverage and a landslides inventory produced by the IFFI Project. The work intends to focus attention on the statistical methods adopted, using two different type of spatial discretization representing by grid cells and unique condition units (UCU).

Because of their limited spatial occurrence, the landslides in the study area can be considered as "rare events". Then it was adopted the statistical methods able to keeping the rarity of the landslide events. In particular, it was used a logistic model for rare events. Finally it was compared the results with those obtained through "conventional" analysis such as discriminant analysis.

10.1474/Epitome.04.0120.Geoitalia2011

RAINFALL THRESHOLDS FOR THE INITIATION OF SHALLOW LANDSLIDES AND MUD-DEBRIS FLOWS IN LOMBARDY: FIRST RESULTS

PALLADINO Michela Rosa¹, D'ACQUARICA Riccardo¹, LUINO Fabio¹
1 - CNR - IRPI Torino, Strada delle Cacce 73, 10135 Torino

Presenter e-mail: michelapalladino@alice.it

Key terms: Shallow Landslides; Mud-debris flows; Hazard; Threshold; Lombardy

The Lombardy Region, like all Alpine regions, is highly susceptible to natural instability processes. In the last 25 years the great deal of geo-hydrological processes has resulted in severe economical and societal damages. A recent study has emphasized that 687 municipalities of Lombardy (44% of the total) have to be considered at medium-high geo-hydrological risk level.

Hazard mitigation and damages reduction require an accurate forecasting of phenomena, especially in relation to rapid processes such as shallow landslides and mud-debris flows. The role of rainfall for the initiation of such movements is pivotal, to the extent that many research groups worldwide from several decades are looking for a correlation between rainfall thresholds for the initiation of landslides. Nevertheless such a prediction is made difficult because of the multiple provoking factors and the lack of a complete knowledge of the triggering mechanisms.

The aim of the present study, carried out by CNR-IRPI of Turin on behalf of Lombardy Region, is to characterize the relationship between shallow landslides and mud-debris flows occurrence and rainfall, in order to determine the amount of rainfall needed to trigger this processes and to provide a forecasting tool. The considered area consists of the Lombard Provinces of Bergamo, Como, Lecco and Varese (a total area of 6030 km²).

A total number of 378 shallow landslides reports have been collected between 1950 and 2010. Nevertheless only 89 of them (24% of the total) have provided the rainfall quantities required for succeeding analysis.

Collected data have been gathered in a catalogue. Both reported phenomena and rain gauges location on the study area have been represented in a map using a GIS. This operation has allowed to define the relevant rain gauge stations for the triggering events and to obtain cumulative rainfall (P), duration (D) and intensity (I) for each of them. The I-D values associated to triggering rainfall appears to vary in a quite wide range, but they seem to balance one each other. Summer landslides appear to be more relied on event duration than the spring-autumn ones. The threshold curves, which delineate the minimum I-D values able to trigger shallow landslide, are obtained from the empirical rainfall data using a linear regression analysis. To cope with the climatic and hydrologic differences in the different catchments, the rainfall information has been normalized using MAP (Mean Annual Precipitation) as a climate index. Collected data shows that for the most of the listed processes (41% of cases) P/MAP ratio ranges between 10% and 15%. No cases of P/MAP exceeding 25% are reported. Two normalized Intensity-Duration thresholds have been proposed in order to take into account the different trends shown by triggering-precipitation with durations (D) minor or superior to 10 hours.

CHARACTERIZATION OF THE DETRITAL LAYERS USING GEOSTATISTICAL TECHNIQUES

BARBIERI Giulio¹, CAMBULI Paolo², MAZZELLA Alessandro¹, SECCI Romina², URAS Gabriele¹

1 - University of Cagliari
2 - Regione Sardegna - University of Cagliari

Presenter e-mail: romysecci@gmail.com

Key terms: detrital layers; principal component analysis; cluster analysis; depth of incoherent deposits; kriging

The problem of identifying areas having a higher propensity for the triggering of shallow landslides during extreme weather events is crucial in land use planning. The danger is defined as the probability that a particular landslide occurs in a given area and in a given period of time, is calculated and then graphed (using cards from the slope stability), through the use of different methodologies. In the last decade, the continuous progress of information technology has allowed the application of methods for assessing increasingly complex landslide hazard, although the possibility of a correct implementation is subject to a thorough knowledge of their limits of validity as well as a choice and effective representation of the spatial distribution and characteristics of the factors presumed to affect the processes of slope instability.

The possibility to implement a realistic and accurate representation of the depth and geomechanical properties of incoherent deposits would greatly improve the calibration of deterministic models for landslide hazard assessment.

This research aims to develop statistical models on the spatial distribution as well as the characteristics of the geomechanical slope deposits and layers of granite alteration on a fairly large area near the village of Capoterra (Cagliari); often subject to flooding and debris flow phenomena of great magnitude. These models have been developed through analysis

of correlations between the depth of the detrital layers, the their geotechnical, geo-mechanical, hydraulic, and several other variables (morphological, geological, structural, physiographic, vegetation, etc.). Following a classification of the areas previously affected by sediment transport and on the basis of Standard Penetration Tests (SPT) and field surveys have been analyzed the characteristics of stability and strength of the identified areas by building a geodatabase full of over 500 sample points.

Once normalized data was applied geostatistical technique of PCA (Principal Component Analysis). In combination with PCA was also used cluster analysis. The combination of these techniques have obtained some correlation between the data values calculated for each sample. At the end of the analysis is obtained as the dependent variable the thickness of the deposits was carried Kriging of the data obtained. The possibility to implement a realistic and accurate representation of the depth and geomechanical properties of incoherent deposits will greatly enhance the calibration of deterministic models for landslide hazard assessment. Through a better stratigraphic, pedological, hydraulic and mechanical characterization of the studied basin, the location and timing of initiation of the phenomena of sliding surface of the detrital layers are determined, in the context of a meteoric event of a certain intensity and duration.

MORPHOMETRIC EVOLUTION OF A LARGE EARTHFLOW: THE MONTAGUTO LANDSLIDE, SOUTHERN ITALY

GIORDAN Daniele¹, ALLASIA Paolo¹, BALDO Marco¹, LOLLINO Giorgio¹, GUZZETTI Fausto¹, CORAZZA Angelo², ALBANESE Vincenzo²

1 - CNR IRPI

2 - Dipartimento della Protezione Civile nazionale

Presenter e-mail: daniele.giordan@irpi.cnr.it

Key terms: landslide monitoring; LIDAR; Robotized total station; Montaguto landslide

In the spring 2006 a large earthflow moved in the Montaguto municipality (Campania region, southern Italy). This was a partial reactivation of an older mass movement occurred in the same general area. In April 2010, the earthflow reached the Cervaro valley advancing at a rate of up to 6 meters/day partially damaging the provincial road SP-90 connecting Naples to Foggia and covering about 300 m of the railroad track. Traffic along the railroad and the road was interrupted for about four months, causing severe problems chiefly to the local residents and the local economy, but also to the national railway system with consequences in southern and central Italy. To re-open the railway and to re-construct the provincial road, the Italian national Department of Civil Protection (DPC) organized a large-scale effort to mitigate the effects of the moving landslide on the road and the railroad.

In this study, we investigate the geomorphological and kinematical evolution of the Montaguto mass movement. Starting from the first phase of the emergency (April 2010) the IRPI GeoMonitoring Group supported the DPC activity studying the long-term evolution (2004-2010) of the landslide through a multi-temporal analysis based on high-resolution DEMs derived from a regional map and the results of four airborne LIDAR surveys. With LIDAR data, we estimated the volume of materials that have been transferred downwards the valley and we support the DPC for the planning of landslide mitigation activity. In addition, we considered the short-term evolution of the landslide by analysing the actual surface displacements measured via a network of three robotized total stations. This system provided near real time measurements of the surface displacements to the civil protection authorities responsible for the safety of the workers that operated on or near the active landslide. We show that the joint consideration of geodetic techniques allowing the long- and short-term observation of the surface deformation is a convenient approach for the interpretation of the morphometric and kinematic evolution of complex landslide phenomena.

DEEP GRAVITATIONAL PROCESSES IN THE MARATEA VALLEY (SOUTHERN ITALY): EVIDENCE FROM HIGH RESOLUTION REFLECTION SEISMIC PROFILING OF THE SURROUNDING OFFSHORE

AIELLO Gemma¹, MARSELLA Ennio¹, PELOSI Nicola¹

1 - Istituto per l'Ambiente Marino Costiero Consiglio Nazionale delle Ricerche Napoli

Presenter e-mail: gemma.aiello@iamc.cnr.it

Key terms: deep gravitational deformations; Maratea Valley; submarine landslides; morpho-bathymetry; Basilicata

Deep gravitational deformations (DGPV; sacking, gravitational spreadings, gleistung) are interpreted in terms of superficial landslides and gravitational tectonics. These movements have been singled out in many outcrops of Italy, mainly referring to their distribution on the territory and to geomorphological aspects (Dramis et al. 1983), in particular in the regional examples of the Central Alps, western Sicily and central and southern Apennines (Forcella et al. 1982; Agnesi et al. 1987; Calamita et al. 1982; Guerricchio and Melidoro 1979). Among their main characteristics there are the great volume of the involved masses, the very ancient age of the deformations, the slow evolution during geologic time (of a deep-seated creep type), the persistence of gravity instability conditions through time and the movement reactivations during seismic and meteoric events. The Maratea Valley (Basilicata) is characterized by deep gravitational movements involving the Meso-Cenozoic calcareous-dolomitic formations (tectonic units "Alburno-Cervati" and "Bulgheria-Verbicaro") interpreted as sacking-type phenomena. The complex morpho-structural setting of the area has been influenced by the Pleistocene extensional tectonics, probably still active. The tectonic dislocations, characterized by a strike-slip component at a regional scale, have caused the superimposition of the Bulgheria-Verbicaro Unit on the Crete Nere Formation and the tectonic contact of the last formation on the Alburno Cervati unit, cropping out on the right flank of the valley. Normal faulting, block rotations and structural widening of the valley are produced as an effect of differential velocity during strike-slip tectonics. The Crete Nere flysch (Liguride Units) takes on a plastic behaviour due to high water contents. It is affected by a flow-type, relatively deep process (30-50 m) within the valley and near the sea. High resolution multichannel seismic profiles, coupled to Subbottom Chirp sections have provided new insights

on offshore prolongation of the Maratea Valley and related landslides. Late Pleistocene-Holocene slope sequences deposited in an intra-slope basin and then appear to be tectonically uplifted in correspondence to complex morpho-structural highs controlled by normal faults. Three main seismo-stratigraphic units, representing the sedimentary cover overlies a rocky acoustic basement, characterized by two main acoustic facies and truncated by a wide erosional surface, referred to the isotopic substage 5e have been recognized (Aiello et al. 2010).

Key terms: Landslide; GPS Network; Geotechnical Network; DSGSD; Displacements

Multidisciplinary approach to study a deep-seated gravitational slope deformation (DSGSD) and a number of ancillary landslides of different types, affected the Greci slope (Lago, Calabria), have been performed since 1996 (SORRISO-VALVO et al., 1999; BONCI et al., 2010). The study case concerns a moderately urbanized area affected by mass movements, where lithological-structural and hydrogeological complex conditions favor slope instability. The geological settlement of the area is characterized by the presence of different thrust nappes forming an allochthonous tectonic building piled up in the Oligocene - Lower Miocene, upon which Quaternary alluvial and colluvial deposits lie. Metamorphic fissured deposits outcrop widely; in addition the scenario is complicated by the presence of deep-seated, medium deep, and superficial instability resting on the DSGSD.

The investigation of the kinematics of the slope was based on integrated monitoring network: the geotechnical network (2 inclinometric verticals and 6 piezometric verticals), the geodetic network (20 GPS vertices). Besides, the integrated network is completed by a rain gauge inside the instability area. With several campaigns carried out from 1996 to 2006, the Integrated Monitoring Network (IMN) has highlighted a complex situation characterized by different slope displacements (BONCI et al., 2010). The Greci slope is affected by a DSGSD moving with maximum velocity of 0.5 cm/y for thicknesses of about 100 meters. In the area affected by the DSGSD some medium (Piscopio) and deep (Acqua Fredda) mass movements have been detected, prevalently translational slide mechanism, with constant velocities of 1 cm/y and 10 cm/y respectively. Deep and medium depth landslides, sometimes occurring in areas affected by deep-seated slope deformations, may rapidly accelerate and significantly affect structures and infrastructures, as confirmed by recent instability phenomena which damaged some building works.

Based on the results achieved from 1996 to 2006 the INM of the Lago DSGSD was upgraded. Since 2007 the INM includes: 5 GPS permanent control stations inside the unstable area, and one permanent reference station external the unstable area; 4 inclinometric verticals; 2 piezometric verticals, with transducers; a meteorological station.

The GPS permanent stations are equipped with dual frequency GPS receivers with choke ring antenna in the reference station while geodetic antenna with groundplane is used in the monitoring points. The control centre, located in Rome (Geophysical Service of ISPRA), acquires the data via ADSL from the local centre, located in the Lago Town Hall, where the data are preliminary processed automatically. The GPS data have been acquired with different modality to test the system and to define the current configuration.

The displacements detected by the permanent GPS stations, that are in agreement with the inclinometric measurements, show a trend that seems to depend by cumulated rainfall in 2008-2009. The greatest superficial displacements are confirmed in the central portions of the slope studied (Acqua Fredda), where inclinometric data indicate displacements until a maximum depth of 60 m.

The preliminary results acquired by the upgraded Integrated Monitoring Network, enable a fine-tuning of geotechnical model for the Greci slope and show the improvement of the control performances of the monitoring system.

GEOLOGICAL STUDY OF THE SERRI LANDSLIDE (ACCEGLIO, NW ITALY) AIMED AT THE RISK MITIGATIONCASTAGNA Sara¹, BUGNANO Mauro¹
1 - Polithema S.I.

Presenter e-mail: castagna@polithema.net

Key terms: complex landslide; Acceglio; monitoring systems

This paper shows the results of a multi-disciplinary study concerning a deep landslide located near Acceglio (Cuneo, NW Italy), which aims to provide a more update knowledge about the local geological context and a geological - hydro-geological interpretation of the landslide movement: this study is preliminary with respect to the design choices aimed at the slope stabilization and the construction of weirs along the underlying Mollasco river.

As a consequence of heavy rainfalls, such as those on may 2008 and on april 2009, several landslides occurred within Acceglio territory, and among them also the reactivation of the Serri landslide, on the left side of Mollasco valley.

The Serri landslide, quite extensive and deep, covering a vertical drop of about 300 m, with an area of the main body of 0.22 km², is a complex type movement including soil slip and rotational slide types.

From the geological point of view, the outcropping rock formations belong to the two main tectonic domains of the Western Alps, the Piemontese Zone with green-stones and calcschist and the Permian-Triassic sequence of the so-called Brianzonese Zone.

The landslide hazard and the geological risk assessment are connected with the possibility of a collapse of the landslide main body or of a part of it, and a consequent mass-transport phenomena toward Acceglio, along the Mollasco river.

The current landslide is a reactivation of a previous and larger instability movement, including seemingly stable areas on the both sides of the lower portion of the active main body; in its lower portion, are observable several signs of movement (scarps, crowns, small trenches).

The landslide caused on spring 2010 the complete destruction of a weir and the damage of some of the others along the Mollasco river.

This paper shows the results of the following investigation methods employed to describe the local geological model with particular regard to the Serri landslide's triggering mechanisms:

- field survey focused on the identification of main rock types and their structural relationships, combined with GPS techniques.
- Data Processing in GIS
- Analysis and interpretation of geognostic available data (2001 and 2008-2009 surveys)
- Analysis and interpretation of inclinometer data
- aerial photographs interpretation technique
- Correlation between meteorological, hydrological and piezometric data in order to identify the triggering mechanism

Field surveys showed that the landslide is set at the main tectonic contact between the Piemonte Zone calcschist and the Brianzonese Zone rock formations, as a result of the high degree of deformation and of the local structural conditions.

The presence of water inside the landslide body is the main cause of the landslide triggering, as found on the basis of piezometric data. Monitoring data surveying carried out in June 2009 showed that compared to the past there was a sudden and sharp increase in movements, a phenomenon that appears to be related to snow melt process.

In fact, while there are not so obvious correlations between the rainfall data and the average groundwater level, a good correlation is observed between this one and snowfall.

The snow melt process seems to be the real responsible for the sudden increase in the water level within the main landslide body.

The inclinometer data confirmed the presence of a main surface of rupture, about 30 m deep; minor sliding surface are even located at shallower depths, due to differential movements within the main body.

On the basis of the study's results was finally possible to project and plan some engineering solutions aimed at the mitigation of geological risk along the slope involved in the landslide movement and the construction of some damage weirs along the Mollasco river, in order to consolidate the slope foot and to steady the riverbed itself.

Key terms: ICP; LS3D; deformation

Several methods are developed to allow accurate and automated measurements of landsliding slopes. Such a method is the terrestrial laser scanner (TLS), which offers notable advantages in terms of speed, accuracy and replication of the experiments.

In the present study, we used a TLS to study deformations and displacements of some parts of a hill in the area "Feo di Vito" at the Northeast side of the city of Reggio Calabria, which is specifically located between the Engineering and Agricultural campuses of the University of Reggio Calabria. We processed the data using two different approaches: i) with the first approach we measured deformations by subtracting two DEMs that correspond to a pair of observation time points of the area of interest, and ii) with the second approach we measured deformations through the global registration of the point clouds corresponding to the two time points of the area of interest, rendering DEMs unnecessary. The scans were performed over an area of around 24000m² in two time points t1 and t2 with the terrestrial laser scanner Riegl LMS-Z420i. The morphology of this area required the use of two instrumental stations and the monumentation of suitable supports for the placement of the targets used in the two epochs.

In the first method, the registration of the two scans required for the generation of the whole point cloud in each epoch was operated with the use of the algorithm ICP (Iterative Closest Point) that applies in an interactive way a rigid roto-translation in space for one of the two clouds considered mobile, so that it overlaps in the best possible way with the other stationary cloud. Once data registration, clearing and filtration with the purpose to circumscribe the areas of interest and to eliminate the present vegetation are done, the next step is to generate the DEM that segments the whole point cloud in small regions of 2.5D. Specifically, to generate the DEM we used the algorithm Ransac (RANdom Sample Consensus) in a voxel approach that generates a pyramid that allows the extraction of planar elements. Subsequently, these planes are aggregated through hierarchical clustering to build a plane of larger dimensions.

Finally, from the aggregated planes and with a further step of clustering we get more structurally compact portions. Therefore, turning the point clouds of every epoch into DEM under the form of a square grid lattice

with DEM resolution, we proceeded with the analysis of the differences between the two epochs t1 and t2.

In the second method, the registration of the point cloud for both instrumental stations in each epoch was performed using the algorithm "Least Square 3D surfaces matching" (LS3D) that does not need the use of targets even though they were there. This process is called "global matching". Once the registration of the scans for the generation of the whole point clouds for each epoch t1 and t2 was completed, we again applied global matching using parts of the point cloud assumed to be stable while eliminating parts of the point cloud characterized by possible deformations. The two whole clouds of the two epochs are therefore transformed in a common coordinate system. The final step is to estimate displacements of some parts of the hill using LS3D, but this time we applied "local matching." These parts are identified in the point cloud t1. For each part, the correspondence on the point cloud t2 is automatically searched by LS3D and the 7-parameter transformation (3 translations, 3 rotations and a scale factor planned unitary) is estimated, which is the deformation.

The use of TLS as already demonstrated has made a major contribution to the deformation analysis of landsliding slopes. The first method provided us a single value as the average of displacements observed, and a deformation map with the results of the significance analysis. The second method, LS3D, provided us with the 6 parameters of the deformation and thus the direction of displacements.

Key terms: cliff instability; coastal geomorphology; Slovenian coast

Coastal cliff stability is undermined by the sum of the sustained action of marine and continental factors. Therefore, their stability depends on the interrelations of the geological and environmental settings of the area. In particular, this work aims at evaluating the role of lithology and fracture pattern and at creating a map of instability of the coastal area. A detailed characterization of the geomechanical properties, the quality of rock masses and the susceptibility to rock falls have been used to study the area.

The characterization of geomechanical features of rock masses, using the GSI method, has been carried out in 15 stations along the Slovenian coasts, in the Northeastern Adriatic Sea. The Slovenian cliffs are cut in the Eocene Flysch, a turbiditic succession composed by centimetric-metric sandstones with millimetric-centimetric interbedded silty marlstones, almost horizontal in the study area. The low resistance of the rock mass allows the rapid retreat of the cliffs and the development of wide shore platforms.

The results of the GSI analysis in the studied stations show that the quality of rock masses is little influenced by the properties of the discontinuities, that are fairly constant, while the number of joints (Jv) is probably the dominant parameter for slope failure.

2 - Environmental Protection Agency of Piemonte, Department of Geology and Geohazards, Torino, Italy

Presenter e-mail: davide.tiranti@arpa.piemonte.it

Key terms: early warning system; nowcasting; GIS technique; Piemonte; North-western Italian Alps

Channelized debris flows affect alpine valleys, causing casualties and monetary losses. A recent classification proposal groups the alpine basins into three main catchment lithology classes: (1) massive and/or crudely stratified/foliated carbonate rocks (i.e., dolostones, limestones, marbles); (2) fine-grained sheared finely-foliated metamorphic rocks (i.e., calc-schists, shales, phyllades); (3) massive or coarse-grained crystalline rocks (i.e., granitoids, gneiss, serpentinites). The basin bedrock nature influences the rheology, the sedimentary processes, the depositional styles and the alluvial fan architecture, the triggering frequency and the triggering seasonality of debris flows that originate in the basins themselves. In particular, this classification includes triggering causes as classifier parameter and distinguishes the rainfall type causing a debris flow in each basin class. The basins of group 2 are more easily triggered by storm of moderate intensity; this behaviour is clearly underlined by the average triggering recurrence of debris flows and increased incidence during the summer, where the storms are much more frequent than the extended and prolonged rainfall events.

Traditional warning systems are usually based on rainfall rate thresholds derived by rain gauges, but ground networks are often inadequate to properly monitor rain field in mountain areas. Operational polarimetric C-band radar can provide reliable real-time rainfall estimation with high spatial and temporal resolution. Recently, it has been implemented an algorithm for storm identification and tracking using TREC (Tracking Radar Echoes by Correlation) technique. In this pattern recognition procedure radar-echo data are stored in arrays, and on each iteration an array is compared to all other arrays of same size for the subsequent time step to determine which array exhibits the highest correlation with previous array. In this way cells are localized, characterized (i.e. maxima echo, storm area, VIL - Vertical Integrated Liquid) and tracked. Considering the overall path of the storm is possible to predict next position of the storm and, consequently, if the storm will involve a basin sensitive to that type of

rainfall.

A HYDROLOGICAL MODEL FOR PREDICTING LANDSLIDE MOBILIZATION: EXAMPLES OF APPLICATION FOR EARLY-WARNING PURPOSES

IOVINE Giulio G.R.¹, GARIANO Stefano L.¹, IAQUINTA Pasquale¹, TERRANOVA Oreste G.¹
1 - CNR-IRPI

Presenter e-mail: G.IOVINE@IRPI.CNR.IT

Key terms: landslide; hydrological model; early warning

Rainfall is the main causal factor of landslide activation in Italy, as in many parts of the world. In this study, a new hydrological model is applied to forecasting landslide activations, provided that a sufficiently long period of observation of rainfalls, and suitable series of dates of landslide mobilizations are available.

Concerning hydrologic models, several valuable methodological proposals can be found in literature, generally focused on thresholds for either single phenomena or specific types of slope movements within a homogeneous geo-environmental setting. Difficulties in modeling landslide activations, both in physical and economic terms, generally increase with dimensions of the considered slope movements.

In this study, the hydrological model SAKe (Self Adaptive Kernel) is applied. The model is based on the assumption of a linear and stationary response of slope stability to rainfall: such response can therefore be expressed in terms of a "mobility function", obtained as integral of convolution between the Kernel and rainfall data. Threshold values of the mobility function can finally be determined by considering past landslide occurrences.

As regards model calibration, different automated tools can be utilized, based on either iterative cluster modification or Genetic Algorithms. As a result, a family of optimal, discretized kernels can be obtained from initial standard analytical functions, whose values represent the probability of landslide activation, given that a critical threshold is overcome. The obtained family of mobilization functions can be constituted by similar individuals in case of high informative content of the considered historical cases of landslide activations.

Model application needs that the geological context, as well as the geomorphic characteristics of the considered phenomena, and their expected evolutive scenarios are properly understood. Effective calibration depends on quality of input information (slope and landslide characterization; dates of past landslide activations; representativeness and completeness of hydrological series).

By employing only a subset of available historical dates of activations for calibration, model validation can be performed against the remaining subset. In case of satisfactory results, the model can finally be adopted to support an early-warning system for civil protection purposes, even more when future rainfalls can be reliably predicted.

Examples of application of the model to case studies of various type and dimension in southern Italy are discussed, together with the first results of sensitivity analyses, and problems in determining the family of kernels.

3 - Consorzio LaMMA

Presenter e-mail: perna@lamma.rete.toscana.it

Key terms: landslides inventory; spatial-geological continuum; object oriented relational database

The Geological Service of Regione Toscana, in collaboration with Consorzio LaMMA (Laboratory for the Meteorology and Environmental Modelling for the Sustainable Development) and CGT (Geo Technologies Centre of Siena University), has started a research program to carrying out a landslides inventory concerning those events occurred in the regional territory and that have been surveyed by many planning tools and through previous regional projects. The Landslides Database comes out from the extraction from the Regional Geological database of all landslide bodies and their associated elements (main scarps, landslide scars), with the main objective to compare these elements with the landslides that have been surveyed by several planning tools such as General Development Plan, IFFI database, Autorità di Bacino Hydrological Plans, and with other maps coming from many other projects focused on the environmental knowledge and on the landslide risk evaluation (AVI, VEL, CARG, SCAI projects and other regional projects).

The landslides inventory is a basic part of the New Geological Database of the Regione Toscana (NBDGRIT) by Corongiu et alii (2004): an object oriented relational database where the 1:10.000 scale geological continuum is archived.

The different object classes are associated to other classes with different shapes (points, lines, polygons) depending on the features that have to be described and inherit their characteristics. This allows to store different objects depending on the more suitable geometry while maintaining the class information describing those specific objects at the conceptual level. Having used the geodatabase data model as a physical format of data storage, all classes of the schema are associated according to ESRI™ rules for object class generalization.

Editing tasks have been accomplished through commercial GIS software (ESRI™) such as ArcGIS/ArcInfo® 9.3, inside the shared architecture of ESRI™ ArcSDE® that allows different desktop client to interface to several enterprise DBMS, including PostgreSQL.

Therefore, the possibility to use proprietary tools/software together with the adoption of an open source DBMS, allows data to be accessible from users (both using open source or proprietary tools) for data visualization, data processing and data publication.

Data quality and interoperability, together with the production of metadata following ISO/TC 19139 - ISO19114 standard, allow the landslides database to be in accordance with the latest European

regulations concerning the production of spatial data, including the 2007 INSPIRE Directive.

Up today the landslides database collects information for 85.448 landslides: 35.780 complex, 12.691 mud flow, 33.593 sliding, 893 falls/topples, 2.491 not determined type of movement. In relation to the state of activity, landslides are classified as dormant: 62.435, active: 11.060, stabilized: 1.900 and with non-assigned status: 10.053. The Landslides Database is a decision tool useful for a responsible preliminary planning and a valid estimate of the susceptibility to slope instability, landslide hazard and geomorphologic risk in Tuscany.

Landslides affect many areas in Europe. They are characterised by a low probability of evolution as a very catastrophic event but may have very large direct and indirect impact on men, infrastructures and environment. This impact is becoming increasingly dangerous due to the rising anthropisation of the territory (continuous construction of new buildings, roads, railways, etc...). Methodologies for the identification and mitigation of risk are therefore a major issue.

Key terms: Rockfall; Geomechanical Survey; Photogrammetry

Rockfalls are frequent fast moving landslides, which constitute hazards and can damage infrastructures imposing frequent and additional maintenance, crash or bury vehicles and cause injuries or deaths. These type of landslide events are characterised by instantaneous triggering and fast evolution and therefore, even if typically triggered by intense rainfall, they occurs without any clear warning.

The first task to be accomplished is, in these cases, to understand both the intensity and areal distribution of these phenomena; this is normally done using computational instruments able to compute slope hazard and territory vulnerability. As a second task, consolidation works have to be designed and built following a time schedule that takes the risk distribution into account.

The hazard and vulnerability evaluation needs to be based on the knowledge of the surface morphology and on the geometry of the involved rock masses. The data can be inferred by photogrammetrical surveys, either terrestrial and aerial. The data duly treated, can be utilised to analyse both the triggering and the evolution phases for computing block stability and detachment, rock fall paths, energy etc.

This paper reports several application of methodologies that improve the rock fall risk assessment starting from the rock mass survey. These methodologies are described by means of some case histories. In particular an application of terrestrial photogrammetry survey in Chiavenna valley and another of aerial photogrammetry on the Garda lake shores are reported to outline advantages, limits and possible improvements in the applied procedures.

Presenter e-mail: g.fioraso@csg.to.cnr.it

Key terms: rock avalanche; landslide dam; Chisone Valley; Western Alps

In the central Western Alps post-glacial gravitational deformations have given rise to diffuse and impressive slope collapses, leading to the highest concentration of instability phenomena of the Alps: they includes rock slide, rock fall and sackung. The large number of landslides and deep-seated gravitational slope deformations is due to lithological composition of bedrock (mainly composed by ophiolite-bearing calcschists of the Piedmont Zone) and, secondly, to the structural set-up of the area. In many cases (12) landslide dams have been formed with remarkably different age, genesis and morphological characteristics.

In the upper Chisone Valley the most striking landslide dam is located between the villages of Pourrières and Fenestrelle, generated by the collapse of a huge rock avalanche originated at 2605 m a.s.l. on the southern slope of the Mount Ciantiplagna (2849 m), along the Susa-Chisone drainage divide. The landslide involved massive carbonatic calcschists of the Cerogne-Ciantiplagna Unit with subordinate intercalations of serpentinites, prasinites and amphibolites. The blocky accumulation covers an area of 3.56 km² with an estimated volume of 130 Mm³. The rock avalanche travelled a horizontal distance of 4.5 km with a vertical drop of 1.4 km and stopped at an elevation of 1415 m a.s.l. against a transversal moraine ridge situated at the mouth of the Rio del Laux Valley. The travel angle (fahrboschung) is equal to 17.3° with an

excessive travel distance of 2.3 km.

The landslide deposits created a cross-valley barrier with the development of a large fluvio-lacustrine basin extending 4 km upstream and with a maximum estimated depth of 120 m. Detailed fieldwork and deep-seated investigation (drillholes) highlighted that the rock avalanche deposits rests above an earlier rock slide that involved a huge ophiolitic mass (serpentinites with minor metabasites). The original surface accumulation is not preserved because the widespread presence of numerous low-gradient benches suspended 15-120 m above the present river level: these surfaces have been interpreted as a product of erosion by the Chisone river and tributary stream network at the expense of the blocky deposit.

The seismic activity that affects the central sector of the Western Alps, with few strong historical earthquakes up to intensity VIII of the MCS (e.g., the 1808 event), can be regarded as a potential triggering factor of the landslide. The precise age of the rock avalanche is not known; nevertheless i) the overlapping of the distal portion of the landslide over the glacial moraine, ii) the presence of some late Copper Age archaeological sites (Roc del Col and Balm'Chanto) close to the area, and iii) the deep erosion of the blocky accumulation are in agreement with an early post-glacial age of the Mount Ciampagnina rock avalanche.

GEOMATICS AND DISTINCT ELEMENTS NUMERICAL METHODS FOR ANALYZING THE STABILITY OF A ROCK SLOPE IN THE APUAN ALPS MARBLE DISTRICT (ITALY)

FRANCIONI Mirko¹, SALVINI Riccardo¹, RICCUCCI Silvia¹, LITRICO Sebastien¹

1 - UNIVERSITY OF SIENA - EARTH SCIENCES DEPARTMENT AND CENTRE FOR GEOTECHNOLOGIES

Presenter e-mail: francioni4@unisi.it

Key terms: Engineering-geological survey; UDEC; Rockfall; Photogrammetry; Laser Scanning

The present paper describes the stability analysis of a quarry front and the simulation of a tunnel excavation carried out through the use of distinct elements numerical methods. The research derives from a project focused on the marble exploitation in the Altissimo Mountain (Apuan Alps, Italy) and carried out thanks to the contribution of the Tuscany Region and the HENRAUX Spa.

The stability analysis of fronts, for rock exploitation planning, bases on the knowledge of both the structural setting and the physical-mechanical properties of intact material and its discontinuities.

Information about the geometrical-structural setting of slopes and joints were achieved in this work by integrating geological, engineering - geological surveys with Digital Terrestrial Photogrammetry and Laser Scanning.

Geological and engineering - geological surveys allowed to get the knowledge of the area structural setting, to characterize the main discontinuities sets and to classify the rock mass as "mediocre" (IV class) according to the Romana (1985) method. Results from these analyses were compared with ones coming from the kinematic stability study in order to find out the most dangerous joints systems.

Afterward, a deterministic study of the fronts stability was performed integrating geological data with geomatics deliverables. Laser Scanning allowed the creation of the digital elevation model of the area from which analysis the joints attitude, persistence and spacing were measured even in inaccessible zones. Moreover, Digital Terrestrial Photogrammetry was used for the photo-interpretation of joints and most dangerous blocks and wedges visible in the fronts and for the processing of topographic profiles in areas characterized by points cloud shadows. In order to achieve the complete stereoscopic viewing of the slopes at any height (up to 200m), the photogrammetric equipment was arranged on an aerostatic balloon and the acquisition of stereo pairs was performed through vertical strips. The integration of data coming from traditional geological and geomatics surveys allowed to carry out the slope stability analysis by distinct elements numerical methods (Itasca UDEC code). This analysis was performed both in static and dynamic conditions considering the historical seismic events occurred in the study area and recorded by local stations. In order to verify the stability even in the case of the proposed tunnel excavation, a further simulation was carried out; starting from previous analyses, several excavation steps were modeled and bolts insertion considered. Mechanical characteristics of bolts and their insertion ways during the expected excavation phase were chosen in agree with the Viareggio ASL 12 PISLL (responsible for the workplace health and safety) and the HENRAUX Spa.

Results from the study highlighted conditions of stability for the whole slope with some exceptions: if the simulation considers a few meters persistence of fractures into the rock mass and consequently, from them, a low attenuation of the seismic wave, the selected seismic event could bring to instability.

With respect to such a result, with the aim to reduce the uncertainty of joints persistence within the rock mass, further investigations by the use of Ground Penetration Radar, drilling and log technologies are in progress. Finally, from the position and volume value of unstable blocks recognized on the slope, possible trajectories of rock falls have been calculated on the DEM. The probabilistic distribution of rock fall end points, together with the kinetic energy along the falling path resulted from this activity. The spatial distribution of trajectories has been analyzed in terms of rock fall transit density and kinetic energy, making possible the creation of the hazard map.

Key terms: Debris flow; intensity; risk; peru

A practical methodology to landslide risk assessment has been applied in

two Peruvian areas: the village of Aguas Calientes, in the Urubamba valley, close to the historical site of Machu Picchu, and the villages of Maca and Lari, in the Colca valley. Both the areas play an important and strategic role in the Peruvian tourist circuit and in the national economy. The study has been carried out in the framework of a capacity building project (FORGEO), focused on improve quantitative approach in landslide risk assessment.

The Urubamba Valley, or Sacred Valley of the Incas, is a narrow, winding valley, close to the Inca capital of Cusco and below the ancient sacred city of Machu Picchu. Being the heartland of the Inca Empire, it contains numerous archaeological remains and villages. Colca Valley is famous because of its deepness and beauty of the landscape and for historical and cultural traits which hold up recent request to be included in UNESCO World Heritage. High slope energy and specific geological characteristics of these valleys cause the widely presence of different typologies of landslides and, more than other, of several debris flows.

Failure surfaces of these phenomena are developed especially at the contact between soil and bedrock. An inventory focused on identifying predisposing parameters contributes to the quantification of slope susceptibility. Each factor has been mapped and implemented as a layer in a GIS project. Overlay of all layers generates a subdivision of the area into Homogeneous Land Units, which a degree of susceptibility is assigned through a susceptibility function. On the basis of a detailed DEM (5x5m), specially realized from air photos, areas with different potentials to be affected by debris flow run-out were mapped. Run out distance and velocity of potential events triggered in high susceptibility sample areas were estimated using the Johnson & Rondine (1984) method. Exposure maps were developed assigning a relative value index to different structures and infrastructures. GIS overlay of run out susceptibility and exposure maps results in risk maps.

The village of Aguas Calientes is located on an alluvial fan and is regularly hit by floods and debris flows that come from upstream creeks. The southern part of the alluvial fan is characterized by four former drainage lines that have a direct hydraulic or morphological relationship with the Alcamayo creek. Under the centrifugal force effect, water and debris can overflow and overrun old sewer lines. All shallow areas of the alluvial fan show an high hazard level of run-out susceptibility and the railway station is characterized by the highest risk. These critical conditions have been further worsened by the rapid urban growth. Moreover, incipient landslide processes recognized on a ridge close to the Phuyupatamarca historical site, increase the hazard in the Urubamba Valley in the proximity of historical sites of Chachabamba and Choq'susuy. In fact, given the volumes involved, the estimated speed and the distance between potential source area and downstream areas, it seems likely that a landslide could dam the Urubamba river at the mouth of the Santa Rita creek, and potentially damage the hydroelectric plant of Machupicchu and the Aguas Calientes village.

Maca and Lari are two villages, facing each other on opposite banks of the Colca river. The area is affected by large rotational landslides that have repeatedly damaged the main road between Chivay and Cabanaconde. However debris flows developing in loose deposits hanged on the steeper slopes are triggered by the concentrated rainfalls between January and March. An assessment of volumes and velocities of potential events shows that debris flow run out could reach the urban areas of both the villages.

ANALYSIS OF RAINFALL INFILTRATION IN UNSATURATED, FINE TEXTURED AND FRACTURED SOILS AS TRIGGERING FACTOR OF SHALLOW LANDSLIDES

GALEANDRO Annalisa¹, DOGLIONI Angelo¹, SIMEONE Vincenzo¹

1 - Technical University of Bari - Engineering Faculty of Taranto

Presenter e-mail: annalisa.galeandro@poliba.it

Key terms: rainfall-induced landslide; infiltration; rainfall threshold; shallow landslides

Rainfall-induced landslides are widely discussed in scientific literature, with particular interest to the evaluation of the rainfall thresholds triggering the slope failure.

The equilibrium of potentially instable masses along a slope is often related to soil suction: in unsaturated soils, rainfall infiltration induces significant changes on pressure heads distribution, causing a decrease of suction and then of shear strength triggering slope instability.

In unsaturated conditions, the presence of fractures at the topsoil accelerates infiltration and can condition pore pressure variation in relation to rainfall intensity and soil properties. Swelling materials cause a progressive closure of cracks and hold water flow. The presence of a permeable layer underlying the top unsaturated soil can create a capillary barrier which could affect infiltration and pore pressure distribution. So the combined effect of cracks, swelling materials and capillary barrier can seriously condition the pressure heads regime and the stability of slopes of unsaturated soil. In spite of their relevance, these features are poorly investigated by the existing models. For this purpose, it has been pointed out an evolving dual-permeability model for the simulation of water flow through fractured swelling soils. The model has been applied to the case of a fractured loamy soil (thickness of 2 m) superimposed to a coarse sand layer, in order to investigate the influence of different rainfall intensities on infiltration process, on pore pressure distribution and then on slope stability.

Results show how, for weak and prolonged rains (2-5 mm/h for 4-10 hours) in the fractured soil matrix it is possible to reach low values of suction close to zero, while in the case of intense and brief precipitations (20-50 mm/h for 0.4-1 hours) there could be small variations of pressure heads. Then, a prolonged weak rain could be more dangerous than an intense one in triggering soil slip in the surficial strata.

Without fractures, the pressure head variation is limited to really surficial strata, while the presence of fractures can facilitate infiltration and diffusion phenomena, leading to fast pressure head variations and consequent fast strength decrease in the whole mass, till the failure. This could mean that slope failure would happen in smaller times in fractured deposits, while without considering cracks the triggering rainfall threshold could be underestimated.

In addition, fractures accelerates the break out of the capillary barrier, which happens in very short times (few minutes for weak rains, seconds for intense precipitation), while for homogeneous soils without cracks the break is delayed.

Finally, cracks closure due to soil swelling holds vertical flow in fractures and stops water diffusion process in matrix. Then, after the closure there is only vertical flow in matrix: the decrease of pressure heads delays and the rainfall amount which triggers the landslide could be greater. The model is a really interesting tool to better understand how rainfall

intensity and duration, fractures and swelling materials condition the infiltration process and the evaluation of rainfall thresholds for soil landslide activation. The implementation of a more specific model can contribute to build up more realistic approach to landslide risk analysis, supporting the identification of more reliable rainfall thresholds for landslide alert.

Key terms: SPH; 2D numerical modelling; landslides in fast motion

The modeling of slopes subject to incipient instability and the eventual onset of fast fluxes, using the same computer code, poses serious numerical problems, particularly with regard to the significant distortions of the numerical grid, as it is usually applied in common practice, due to the soil material desegregation. Both Eulerian and Lagrangian approaches, based on structured or unstructured mesh gridding, show heavy drawbacks. In alternative meshless type approaches have been explored by different authors (i.e. Ha H. Bui et al. 2008, Int. Journal for numerical and analytical methods in Geomechanics). Two of the most common methods of this type are PFEM (Particle Finite Element Method) and SPH (Smoothed Particle Hydrodynamics). The first method, actually, has the advantages of a purely meshless method and the advantages of a method based on finite elements. Nevertheless, for the study of landslides in fast motion, we initiated an exploratory study of the SPH technique, to be followed by a subsequent implementation of PFEM techniques. The SPH method, originally developed during the 70's to solve astrophysical problems, is a particle mesh-free Lagrangian method, well suitable for computing highly transitory free surface flows of complex fluids in complex geometries. Thus it has shown many attractive features that have led many authors to try to use it to solve fluid flows problems. Its free surfaces tracking capabilities and its straightforward implementation of multi-materials interactions make him well suited for complex flows modelling. At this early stage of our research program, a virtual landslide in fast motion has been simulated using a 2D flow of a mixture composed of fluid and solid material. The two set of equations related to fluid and solid phase, has been simplified in only one set of equations, considering just one equivalent material. Both mass and densities have been considered constant. Then the Bingham or "Herschel-Bulkley", non Newtonian constitutive equations, describing a viscoplastic material suitable to simulate the rheological behaviour of mudflows, has been selected. The final mathematical model, a divergence free set of Navier-Stokes equations, has been solved by a numerical approach using a 2D numerical model based on the specificity of the SPH method. Essentially, the following are the SPH discretized equations related to conservation of mass and momentum:

$$\frac{D\rho_j}{Dt} = \sum_{j=1}^n m_j \cdot v_{ij} \cdot \nabla_i W_{ij} \quad \text{mass conservation}$$

$$\frac{Dv_i}{Dt} = f_i - \sum_{j=1}^n m_j \cdot \left(\frac{p_i}{\rho_i} + \frac{p_j}{\rho_j} \right) \cdot \nabla_i W_{ij} + \sum_{j=1}^n m_j \cdot \frac{\delta \eta_{ij}}{\rho_i \rho_j} \cdot \frac{v_i - v_j}{|x_i - x_j|} \cdot \nabla_i W_{ij} \quad \text{momentum conservation}$$

Where: ρ_j is the mass density, f_i is the external force, m_j represents the j th particle mass; $v_{ij} = (v_i - v_j)$ represents the difference between the interacting particles velocity; W_{ij} is a particular influence bell shaped function, characteristic of the SPH method, c is the artificial equation of state from which the pressure of each particle is calculated, where c is the

artificial speed of sound and ρ_0 is the reference density of the fluid at zero pressure, $r_{ij} = r_i - r_j$ represents the difference between the interacting particle position; η_{ij} is a symmetrised dynamic viscosity between

interacting particles, such that $\eta_{ij} = \eta_{ji}$.
Finally a laboratory experimental test has been selected for comparison. Satisfactory results have been achieved. Nevertheless, further parametric analysis will be carried out and further considerations about both constitutive equations and numerical improvements will be employed and discussed in future papers.

Key terms: debris avalanche; numerical modelling; Southern Italy

Pyroclastic deposits covering most of the carbonate relief of the Campanian Apennine are prone to develop recurrent high-velocity flow instabilities. The present study investigates the debris avalanche occurred at Nocera Inferiore (Campania Region, Southern Italy) on March 4, 2005, following heavy and intense rainfall, which claimed three casualties. The landslide event is representative of a series of catastrophic failures which taken place in Campania during the last decades and induced loss of human lives and considerable damage to the economy and building

heritage of several sectors of the Region.

Detailed geological-geomorphological surveys, supported by site and laboratory tests and investigations, led us to define the main features of the studied phenomenon and identify the mechanisms and triggering factors. The landslide involved the 1.5 to 2 m thick layered pyroclastic mantle which overlies the carbonate hill slopes. The early stages of the movement consists in a debris slide, then evolving in a debris avalanche on the 45°-dipping open slope. Landslide initiation is linked to the change in the morphological settings due to the building of a carriage path to be used as access for the nearby open quarry.

The debris avalanche has involved a specific slope portion never affected by landslide of the same type of the one occurred. Reconstructions carried out on aerial photographs and photos of different time highlighted that the route construction can be supposed around the 1998, increasing the landslide susceptibility of this section and demonstrating that cut slope is the main cause for the occurrence of the Nocera Inferiore landslide.

Comparison among similar landslide events of the recent past (e.g. Sarno, Quindici, Siano and Bracigliano in 1998 and Cervinara in 1999) shows that such a predisposing cause is a common element in triggering landslide in the pyroclastic mantle of Campania. Road cut and the consequent interruption of the lito-stratigraphical continuity of the pyroclastic layers change the surficial and underground water circulation, modifying the natural equilibrium and inducing pore-pressure increase.

The propagation characteristics of the landslide were modelled by using a 2D and 3D dynamic models (DAN). These analyses are well comparable with those implemented by the same authors on debris avalanches and debris flows happened in different sector of the Campania Region, confirming the similar behaviour and character above mentioned.

10.1474/Epitome.04.0139.Geoitalia2011

A GIS-AIDED METHOD FOR THE ASSESSMENT OF VOLCANICLASTIC SOIL SLIDING SUSCEPTIBILITY ON CARBONATE SLOPES OF A PART OF CAMPANIA (SOUTHERN ITALY)

PERRIELLO ZAMPELLI Sebastiano¹, BELLUCCI SESSA Eliana², CAVALLARO Marco¹

1 - Dipartimento di Scienze della Terra, Università di Napoli Federico II
2 - Istituto Nazionale di Geofisica e Vulcanologia - Osservatorio Vesuviano

Presenter e-mail: perriell@unina.it

Key terms: debris-slide susceptibility; volcaniclastic soil cover; soil cover discontinuities; planform curvature

A significant part of Campania is extensively covered by volcaniclastic soils, deriving from the alteration of airfall-sedimented formations of layered ashes and pumices that were ejected by Campi Flegrei and Mt.Somma-Vesuvius during explosive eruptions. Where such soils cover steep slopes cut in carbonate bedrock, landforms depend essentially on the morpho-evolution of the slopes prior to the deposition of the volcaniclastic soils, because they are generally present only as thin veneers, up to a few meters of total thickness. In this part of Campania, landslides that originate within the volcaniclastic soil veneer "sandwich" lying on carbonate slopes and terminate at their foot or at gully outlets are frequent and often destructive, following critical rainfall events. Such landslides can be classified as complex, occurring initially as debris slides, but rapidly evolving into debris avalanches and/or debris flows. The localization of the initial sliding areas (i.e. "sources") on the slopes depends on both the spatial distribution of characters of the soil cover and the spatial distribution of the triggering rainfall events. It therefore appeared reasonable to separate the two aspects of the problem, and focus on the former one, in order to attempt an assessment of soil sliding susceptibility in the event of landslide-triggering rainfall.

Some results of the application of a method aimed at such an assessment are going to be presented. The method, called S.L.I.D.E. (from SLiding Initiation areas DETection), is based on the assumption that, in case of spatially homogeneous slide-triggering rainfall sequences and volcaniclastic soil cover, different slope gradient threshold values for sliding failure exist, depending on soil cover continuity and planform curvature. Such threshold values are considered as higher on planar slopes than on slopes with discontinuities within the soil cover, as well as on slopes that display upwards concavity in planform (hollows).

The method is indeed geomorphological, but it is also essentially quantitative, as in its workflow only the delineation of soil cover existence, and of discontinuities within it, are subjective. Comparison between past landslides' source areas localization (although available with variable reliability) and S.L.I.D.E. method susceptibility provided encouraging results, especially regarding soil-covered sloping hollows.

Where such a localization was available with adequate accuracy and the number of nearby landslides was large, the method appeared as capable of recognizing most of the actual landslides' source areas. At the same time, the method reasonably overestimated areas considered as susceptible to sliding with respect to actual source areas. Overestimation, however, should be considered as such only with respect to past landslides: areas deemed as susceptible to sliding, but not interested by past landslides, should also be carefully evaluated with respect to the possibility of future landslides.

Developments of the method are being pursued, by analyzing slope areas that fall into more than one susceptibility categories. In practical terms, for instance, opening new slope tracks within volcaniclastic soils covering slope hollows at angles > 30° appears inappropriate with respect to rainfall-triggered potential local instability.

Assessment of soil sliding susceptibility, while only a subset of the related hazard and risk assessments, can certainly be considered worth investigating, as planners and communities could certainly take advantage from knowledge regarding where landslides can originate in case of critical rainfall. This, together with analyses of potential paths and run-out of debris avalanches/flows, could suggest including also the feasibility of slope stabilization work within evaluations of risk-reduction cost-benefit options, as techniques for the stabilization of soil covers on the slopes are nowadays indeed available.

Key terms: Bagnara Calabria; debris flow; Analisi piogge

Il tratto di costa tra Bagnara Calabria e Scilla (provincia di Reggio Calabria, Calabria meridionale), ricadente al piede di versanti molto acclivi in rocce cristalline frantumate ed alterate, costituisce una singolarità morfologica in un lungo tratto di costa alta, sovrastato da ripidi versanti degradanti verso la costa con dislivelli di circa 500m nello spazio di 1km e solcati da numerosi corsi d'acqua a carattere torrentizio altrettanto ripidi.

Esso è soggetto a diffusi fenomeni franosi, ad alluvionamenti ed a debris-flow da parte dei ripidi fossi incombenti sugli abitati e sulle infrastrutture, in particolare sulla ferrovia, a mareggiate per l'esiguità della fascia costiera sede delle espansioni urbanistiche e ad un'elevata sismicità. La presenza di numerosi conii di deiezione alla base dei ripidi versanti dell'area costiera in esame rappresenta la testimonianza geomorfologica di eventi multipli da antichi debris-flow sempre, però, interpretati come fenomeni alluvionali delle fasi di erosione-trasporto-sedimentazione.

Dagli anni '70 nell'area in esame si è verificata una serie di eventi determinati dalle condizioni idrometeorologiche, ma favoriti dall'incuria umana. Nella presente nota vengono presi in esame cinque distinti episodi da debris-flow, innescati da particolari condizioni idro-meteorologiche, verificatisi nell'area in studio nel 1970, 1988, 1989, 2001 e nel 2005, che hanno investito le infrastrutture, provocando, negli ultimi due casi, il deragliamento di treni in transito sulla sottostante linea ferroviaria, che corre alla base del versante costiero, generando una condizione di allarme nella popolazione e richiamando per il loro interesse scientifico l'intervento degli studiosi.

Per tali due casi è stato svolto anche uno studio idrologico finalizzato alla valutazione delle condizioni di innesco.

ROCK-FALL HAZARD ASSESSMENT AND NUMERICAL PREDICTION OF THE ROCK-MASS BEHAVIOUR FOR A SEA ARCH (THE NATURAL ARCH OF PALINURO, CAMPANIA)BUDETTA Paolo¹, DE LUCA Claudio¹

1 - UNIVERSITY OF NAPLES "FEDERICO II"

Presenter e-mail: budetta@unina.it

Key terms: Sea arch; Rock-fall hazard; Geo-mechanical characterization; FE method

The presence of embayment, caves or arches along the coast, attests a heavy marine erosion developing near structural weaknesses in stiff rocks, such as joints or faults. Even though the strongest wave impacts are episodic, the wave erosion is undoubtedly the most important factor in causing coastal retreat, in more resistant rock-masses. Generally, sea cliffs stand seaward as headlands, or persist offshore as sea arches or stacks, where the waves attack planes of weakness affecting headlands. Over time, caves produced on both sides of a promontory may join, to model a tunnel and, finally, an arch. Successively the supporting roof of the arch may collapse, depending on the rock-mass strength and wave action. Consequently, arches are ephemeral geomorphological structures tending to survive over periods of just few centuries. Therefore, one might ask whether it is worthwhile to protect these structures using adequate, active or passive countermeasures. For purposes of coastal planning and engineering mitigation, these natural "sculptures" must be preserved if they are enclosed in a very attractive landscape or if possible damages, resulting from rockfalls, are intolerable for people and infrastructures. This paper deals with rock-fall hazard and the assessment of stress and displacement distribution affecting the opening of the Natural Arch of Palinuro, developed as a result of "excavation" by wave action. The study area is placed along the Cilento coast (Campania - Southern Italy), and the Arch represents an important geotope inserted in a very attractive landscape. In the last 50 years, this structure has been affected by several rockfalls mainly due to wave erosion as well as gravity. The sea level rise, partially induced by human activities, is the main reason for these phenomena which seriously are threatening the stability of the structure which could completely disappear in a few years. About 15 years ago, in an attempt to protect it, provisional countermeasures were executed consisting in a submerged reef and in a wire netting added to the supporting roof. Nevertheless these works proved to be insufficient, because a new rockfall happened in 2007, affecting the northern facade of the arch.

In order to localize the arch portions which are in urgent need of reinforcements, the rock-mass behavior was studied, by means of a preliminary geo-structural and geo-mechanical characterization. Afterwards, a finite elements approach was implemented using a

two-dimensional elasto-plastic stress analysis program. Stress, strain, and displacements were calculated for an idealized model including four stages. In the first stage, application of the natural in situ stress distribution (gravity loading), in which the vertical stress is assumed to vary linearly with depth, was examined. In the following three stages, simulations of the progressive enlargement of the arch opening, beginning from the last 10,000 years ago (coinciding with the initial post-Glacial sea level rise) were analyzed. This approach was applied by analogy to man-made cavity collapses (such as tunnels, caverns, etc.), bearing in mind a number of problems that are less significant or not considered in man-made excavations. These problems concern: (i) the different excavating modalities distinguishing wave erosion, respect to man-made action; (ii) the shallow rock-mass forming the arch, is subject to concentrated weathering and marine corrosion playing an important role in determining the overall strength and deformation characteristics. In spite of these remarks, the employed 2D approach, assuming a plain-strain behavior largely simplified respect to the in-situ strain pattern, must be considered as a first-order investigation of the arch stability.

Key terms: Rock-slope instability; Hazard assessment; Sorrento-Amalfi coast

The natural predisposition to recession of rocky cliffs represents a typical environmental hazard in densely urbanized coastal areas especially where lifelines and settlements are located along the coast because of orographic and economic factors. Along the coastal sectors of the Campania region (southern Italy) characterized by high rocky slopes, several municipalities, densely populated and highly touristic attractive for the worldwide famous landscapes, are exposed to risk due to rock-slope instability. Particularly, the municipalities belonging to the Sorrento and Amalfi coast, such as Sorrento, Vico Equense and Furore, can be considered among the most representative case-studies being prone to the recurrent instability of rock blocks, which in many cases caused the interruption of roads and railways and their isolation from the other parts of the region.

Rocky cliffs and slopes of Sorrento and Amalfi coast are mainly constituted of sedimentary rock-masses, mostly belonging to Mesozoic carbonates, and subordinately, to Quaternary pyroclastic tuffs. Due to the common location of settlements and roads in the vicinity of carbonate high cliffs and slopes, here a diffuse condition of high risk does exist, which makes difficult to identify priority in addressing financial resources for the construction of suitable mitigation works.

In order to find an appropriate method for assessing and classifying the susceptibility to rock-slope instability as well as to map zones with higher values, the combined application of standard methods was tested, such as the Romana's Slope Mass Rating (SMR) and the Matheson's tests, in two test sites of the Sorrento and Amalfi coast.

Results were respectively balanced and weighted both by means of the number of fundamental instability mechanisms (plane sliding, wedge sliding and toppling), recognized for intervals of slope aspect, and by means of the persistence of each discontinuity set. The implementation of the geometric and mechanical constraints, found out as critical for slope stability, in a GIS environment allowed to map susceptibility to rock-slope instability and to identify conditions of higher susceptibility.

Key terms: Landslides; Hyperconcentrated flow; Runout and propagation assessment

On September 9, 2010 the Amalfi coast has been struck by a rainfall event of short duration and relatively high intensity. The focus of the event coincided with the hydrographic basin of the Dragone torrent, where a variety of instabilities occurred, ranging from linear and areal erosion to debris flows. The downvalley transfer of the debris mobilized from the slopes and eroded along the hydrographic network soon assumed the characters typical of an hyperconcentrated flow, as well shown by some videos. The flow invaded the small town of Atrani, located along the final stretch of the Dragone torrent, causing the loss of a young girl, huge damage and a pronounced progradation of the fan delta.

The Atrani event has been simulated by means of two well-known codes, DAN-W and FLO-2D, with the aim of verifying the overall features of the complex phenomenon, especially as regards its runout and propagation potential. Thanks to the availability of excellent field data, it has been possible to carry out a back-analysis of the event, which, in turn, allowed to assess the reliability of the required parameters, usually adopted under similar conditions. In conclusion, the obtained results have been critically examined, also by their comparison with previous experiences, in light of a wider assessment of the landslide and hydraulic hazard impending upon the study area.

FIELD CHARACTERISATIONS OF SHEAR STRENGTH AND TRIGGERING MECHANISMS OF DEBRIS FLOWS IN PYROCLASTIC

SOIL MANTLED SLOPES OF CAMPANIA (SOUTHERN ITALY)

Key terms: ash-fall pyroclastic soils; shear strength; Borehole Shear Tester; root strength; debris flows initiation

Despite the shallowness, the triggering mechanisms of debris flows involving ash-fall pyroclastic soils mantling mountains that surround volcanic centers of the Campania region (southern Italy) are complex to be modeled. A number of factors have to be taken in account for a correct slope stability modeling, each of them characterized by a high spatial variability and heterogeneity. Among these factors, stratigraphic, hydrogeologic, morphological, pedological and mechanical characteristics of the pyroclastic soil horizons, as well as land use, have to be evaluated. At the detailed scale, debris flows are triggered by initial small landslides, which mainly involve the pedogenised pyroclastic soil horizons partly constituted of pumiceous pyroclasts, with grain size varying from coarse sand to gravel. Consequently, the modeling of the initial slope instability presents a high complexity just for the accurate characterization of the shear strength of pyroclastic soils due to their difficult mechanical testing and to the not negligible contribution of root strength. The first aspect regards the problematic undisturbed sampling of pyroclastic soils due to their high looseness and high porosity as well as the difficult testing of specimens with standard laboratory tests at very low levels of stress, as typical of shallow landslides (1 - 2 m depth), which determine dilatancy effects on coarse granular soils. The second aspect is the contribution to the shear strength given by the dense net of root apparatuses characterizing landuse classes typically occurring in source areas of debris flows that vary from the broad-leaved forest to the sclerophyllous vegetation.

In order to carry out a research focused on these two aspects, we carried out field characterisations of shear strength by means of both the Borehole Shear Tester (BST) and the measurements of root apparatuses in selected test pits of different source areas. The application of the Borehole Shear Tester at various depths in boreholes allowed obtaining a vertical log of the effective friction angle and cohesion. The results for the effective friction angle were determined as ranging from 36° to 38°, instead the effective cohesion was always estimated as lower than 1 kPa. The contribution to shear strength due to the root strength, acting as an apparent cohesion, was estimated by means of density, diameter and tensile strength measurements of root apparatuses and through the application of the Wu's model (1979). The apparent cohesion due to the root strength resulted as very variable along the depth, being highest in the shallower horizon (median value of 22 kPa) and lower in the deeper horizons (median value 9 kPa). The combination of results derived both from the application of the Borehole Shear Tester and from the estimation of apparent cohesion due to the root strength, as well as the results derived from the unsaturated and saturated characterisation of hydraulic properties, allowed formulating a comprehensive mechanical and hydraulic model of the pyroclastic mantle. Starting from this improved characterization, a slope stability modeling was carried out permitting a deeper understanding of the triggering mechanisms.

RAINFALL INITIATION OF DEBRIS AVALANCHE-FLOWS IN CAMPANIA (ITALY)

FIORILLO Francesco¹
 1 - University of Sannio

Presenter e-mail: francesco.fiorillo@unisannio.it

Key terms: debris flow; rainfall; Campania

Debris flows in Campania begin as soil slides within the pyroclastic mantle that blankets the steep local hill slopes, which are, in turn, composed largely of carbonate bedrock. The historical pattern appears to be that clusters of debris avalanche-flows occur after intense rainstorms that follow an accumulation of a certain amount of pre-storm seasonal rainfall. The physical analysis of the interaction of rainfall with the pyroclastic mantle requires two-phase approach. Phase 1, early in the rainfall season, concerns the accumulation of the capillary and hygroscopic water in the soils, up to field capacity. During this phase, the soil moisture content has been modelled as hydrological balance between precipitation and evapotranspiration, on a daily scale. The amount of rainfall required to reach the field capacity depend on the pyroclastic mantle thickness. After the soil moisture in the pyroclastic mantle reaches field capacity, the second phase of the analysis examines the accumulation of surplus moisture from intense rainfall, leading to the development of positive pore pressures and debris flow initiation.

In this study we analyse hydrological data up to December 2008, providing further 10 years of records respect to previous analyses (Fiorillo & Wilson, 2004), which allow us to verify a previous hypothesis on the soil moisture accumulation into the soil. In particular, we focused the analyses in the Sarno area (P.zzo d'Alvano), where a high-elevation rain-gauge is available since May 1998, which allows also to compare data with low-elevation rain gauges. The topic assumes particular significance in this case, because the storm of May 1998 didn't show exceptional rainfall at any of the rain gauge stations, to justify the high number of debris flows produced.

Finally, the spatial distribution of different values of the soil moisture storage capacity can have a strong control on the location of the landslide initiation, indicating that landslide initiation in Campania is also controlled by the characteristics of the storm and by antecedent hydrological conditions, as well as geomorphological and stratigraphical features of the slopes.

Key terms: Debris flow; GIS; Volcanic areas

The volcanoclastic flows are among the most recurrent and dangerous natural hazards in volcanic areas characterized by pyroclastic deposits. They can originate not only during or shortly after an eruption (syn-eruptive) but also during a period of volcanic quiescence (inter-eruptive), when heavy and/or persistent rains remobilize loose pyroclastic deposits. Damage and casualties relate to these events are common in the history of recent (AD 1631-1944) activity of Vesuvius, both near the volcanic complex and in the sub-Apeninne basins affected by pyroclastic fallout. Major historic flows occurred (Migale and Milone 1998) in 1954 at Villaggio di Vettica (30 deaths), in 1924 at Amalfi (30 deaths), in 1910 at Regina Major and Catara (60 and 110 deaths, respectively), in 1841 at Molino delle Capre (120 deaths), in 1823 at Salerno-Positano-Siano-Tramonti (120 deaths), in 1764 at Gragnano (43 deaths) and in 1640 at Sarno (40 deaths). In addition, 40 debris flow episodes occurred in the Sarno area in the two centuries prior to 1998 (Migale and Milone 1998). With the aim to mitigate and prevent the volcanoclastic flow hazard, we propose an GIS based application in Peninsula Sorrentina to individuate the drainage basins more prone to triggering debris flows. This application combines several morphometric parameters derived from the analysis of Digital Elevation Model of study area (Bisson, 2010) with information of territory the are considered very useful and necessary for our purpose (i.e occurrence of events in the past, lithology, joint systems, soil and landuse). As result we propose a map that distinguishes and classifies the areas with different degree of susceptibility for triggering debris flow (low, moderate, high).

FLOW-TYPE LANDSLIDES MAGNITUDE ESTIMATION IN CAMPANIA (SOUTHERN ITALY)

DE FALCO Melania¹, DI CRESCENZO Giuseppe¹, SANTO Antonio¹
 1 - Università di Napoli Federico II

Presenter e-mail: santo@unina.it

Key terms: Flow-type landslides; Landslide magnitude or intensity; Southern Italy

Flow type landslides represent one of the most severe natural hazards in Campania (Southern Italy) as shown by the large number of victims and the huge economic damage caused in recent years. These mass movements involve thin cohesionless, unsaturated pyroclastic soils widely found over a large area around Somma-Vesuvio and Phlegrean district. Studies on flow-type landslides in pyroclastic deposits have been performed to identify potential source areas and the main depositional mechanisms. Interesting methods for mapping landslide triggering susceptibility and potential invasion have also been proposed. Since the potential volume of flow-type landslides is a measure of event magnitude, hence of considerable use in hazard assessment, we propose to estimate the potential volume at the scale of slope or basin for about 130 municipalities which cover an area of 2,300 square kilometers. A simple method to estimate the potential flow-type landslide volumes use an empirical approach, recently proposed in literature (De Falco et al., 2011), derived from the interpretation of numerous geological and geomorphological data gathered from a vast amount of case histories on landslides in volcanic and carbonatic contexts.

The method is based on determining the thickness of the pyroclastic cover and the width of the detachment and erosion-transport zone. Thickness can be evaluated with a good degree of approximation since, in these landslides, the failure surface is always very superficial (from 0.3 to 2 m) and positioned in pyroclastic covers resting on a generally rigid bedrock (calcareous rocks, lava or tuffs). The area of the detachment and erosion-transport zone (Af) is calculated by a mathematical function (statistical correlation) which link this factor with the difference in height (H) between a point on the slope with the highest susceptibility and a point, the first break at the foot of the slope, where the deposition starts to take place and the landslide loses velocity. Finally, potential volumes are calculated by using Af and a constant thickness of the pyroclastic cover for the whole slope.

The study showed:

- a variability of the volume potentially mobilized ranging from 500 to 200,000 cubic meters;
- a non-random distribution of volumes mobilized that allows to show different macro-areas with several degrees of hazard ;
- a distribution of the volumes mobilized at a municipal scale that allows to identify the most dangerous landslides scenario.

The result could represent a useful tool to define the most critical area in the Civil Protection and to detect the main areas where risk mitigation works are required.

HISTORICAL INVESTIGATIONS AS A TOOL FOR A CORRECT LAND-USE PLANNING

AGNESE Claudio¹, CASILLO Filippo¹, LUINO Fabio¹, NIGRELLI Guido¹
 1 - CNR IRPI TORINO

Presenter e-mail: filippo.casillo@irpi.cnr.it

Key terms: Historical investigation; Land-use planning; Geo-hydrological processes; Piedmont

Geo-hydrological risk is one of the most important risks scouring Italy. It is widespread and differs according to the geomorphological characteristics of the territory. Landslides, mud-debris flows and floods are the most frequent geo-hydrological processes. Piedmont region has been violently hit many times in the last 20 years

(September 1993, November 1994, October 1996, October 2000 and May 2008): geo-hydrological processes have caused casualties and damage for millions of euro.

The aim of this research is to evaluate the spatial-temporal distribution of the instability's processes over the past two centuries and to relate it to the urban development occurred since the postwar period.

The study area (1,100km²), located in the north-western part of the Turin's Province, includes the upper part of the Orco Valley, until to the confluence with the Soana stream, and the Stura di Lanzo Valley, upstream the confluence with the Stura di Viù stream.

The methodology has been carried out by the following steps:

- analysis and interpretation of historical documents gathered in the IRPI Archive of Turin;
- drafting of descriptive records into a geodatabase, where are collected all the information about the rainfall event and the consequent natural instability processes;
- localization of the instability processes using Geographical Information System (ArcGIS 9.2);
- evaluation of the urban increase by the comparison between historical maps (1800-1900) and the present situation using the regional technical map (CTR);
- synthesis and data processing.

The documents of 24 municipalities were deeply analyzed and about 800 records were filled and georeferenced. They have permitted to have a more detailed picture of the main instability phenomena which affected the examined area and the relative damage.

This study highlighted how a correct land-use planning for the prevention and mitigation of geo-hydrological risk, cannot ignore a careful historical analysis from which to obtain a wealth of information that, properly developed and compared to the urban growth, can permit to identify the hazard-prone areas that can become risk when it involves urbanized areas.

Presenter e-mail: vincenzo.dagostino@unipd.it

Key terms: debris flow; flooding; historical documentation; event back-analysis; hazard mapping scenarios

Hazard and risk mapping related to debris-flow events is a key step in order to manage urban areas located in mountains regions. Within this mapping activity the assessment of depositional processes is the main task in producing consistent flooding scenarios.

Past events back-analysis allows a direct calibration of numerical models and frequently it offers the almost unique way to assess the flow dynamics at the field scale (e.g. flow rheology and interaction between the debris flow and the surface of the river bed and of the fan).

The study presents the hydrological reconstruction of the historical event occurred in the town of Chiusa (Bolzano, Italy) on 9th August 1921. An intense and composite rainstorm affected the upper part of the Rio Tinne basin and triggered a debris flow which stopped at the confluence with the Isarco river. The natural dam caused - due to a large backwater profile - a lake formation along the Isarco valley stretching as far as the Bressanone city. By the consequence Chiusa was flooded twice: by the Tinne debris flow and by the Isarco river flow.

An hydrological analysis was carried out in order to simulate erosion and transport processes causing the evolution of the historical flash flood into a debris flow. The congruence between sediment volumes which were observed after the event (800.000 cubic meters mobilized and 500.000 cubic meters deposited on the fan and at the junction) and those volumes assessed by a deterministic way using the reconstructed hydro/debris graph was verified. This comparison provided the interpretation of the actual dynamics of an extreme alluvial event, whose return period was estimated about 500 years. The numerical simulation of the event (debris flow propagation and deposition starting from the fan apex) was also conducted by means of a numerical 2-D model. Through the model results hazard maps have been proposed both for the 1921 event and for some possible scenarios related to current catchment disposition. Without the re-reading of the 1921 event the hazard and risk mapping would not be so defensible with respect to local authorities and resident population, thus confirming the key importance of deeply analyzing extreme alluvial events occurred in the past.

SETTLEMENTS AND INFRASTRUCTURE EXPOSED TO LANDSLIDE RISK IN LOMBARDY - ITALY

CERIANI Massimo¹, CANTONE Giovanni¹, CARELLI Massimo¹, TOFFALONI Carlo¹, ZACCONI Andrea¹

1 - REGIONE LOMBARDIA - PROTEZIONE CIVILE

Presenter e-mail: massimo.ceriani@regione.lombardia.it

Key terms: LANDSLIDE; RISK; SETTLEMENTS; INFRASTRUCTURE

Studies and analysis of hydrogeological instability (landslides, avalanches, floods) conducted in Lombardia region over the last 10 years, on both local and regional basis, have produced a quite significant framework of knowledge: over one hundred thousand landslides were mapped, more than eight thousand avalanches recorded, 2200 square kilometers of flooded areas identified in plain areas and alpine valleys. Standards of protection were defined and critical areas mapped, also planning choices and major works of prevention and mitigation of risks were made or planned. It would seem we are close to solving every problem and close to avoid any possible risk! Actually, the geomorphologic evolution of mountain areas inevitably implies landslides, even large ones (over 1 million cubic meters) that might cause enormous damage and permanently change the shape of a valley. These extreme events, although rare, have occurred in the past and may recur in the future. The Piuro landslide of September 4, 1618 that destroyed a city (over 1,200 victims) and major roads, the Sernio - Tirano landslide, happened in 1807 (3 victims and temporary lake), the Val Rabbia (Val Camonica) landslide in 1860 with the formation of a temporary lake larger than 2 km, the Gero

and Barcone landslide (Valsassina) in 1762 with the destruction of entire villages (115 victims), are examples of what has happened. Recent events, instead, are the Val Pola rock avalanche (35 victims and settlements destroyed), the debris flows of the Val Tartano (21 victims) and the Torreggio landslides (July 1987), the Bindo Cortenova (LC) landslide and the Brembilla - Camorone (BG) landslide (November 2002), all of which had a great impact on our regional territory and beyond. It is now well known that the evolution of an alpine land as majestic and grand as that of Lombardy, normally happens in a subtle way, but every few centuries, every few decades, the slope instability manifests itself in a devastating way. Works on soil protection, monitoring systems and land use policies may significantly reduce the risk level, especially for people, but real estate cannot be fully protected or relocated: for example the rock falls in Gallivaggio village in Valchiavenna, on Via Mala in Val di Scalve and major roads adjacent to large Alpine lakes, the huge landslides of Ruoin in Valfurva and La Pruna in Valtellina, Val Rabbia and Val Saviore in Valcamonica, Idro Lake in Val Sabbia and large sliding phenomena that could affect some hydroelectric reservoirs in high mountains. If we take into account the phenomena of deep seated gravitational slope deformation (DSGSD), we notice how whole villages like Fuipiano (BG) and Garzeno (CO) are interested by extremely slow continuous movements that usually involve even whole slopes (eg Mount Legnoncino above the lake of Como, Mount Padrio-Varadega, enclosed between Valtellina and Val Camonica). Roads, settlements, infrastructures and major projects related to water use are or may be affected by these extreme landslides (rare... but not so much!). Studies conducted to update the inventory of landslides by Lombardy Region, and summarized in the hundred sheets of the Atlas "Landslides of Lombardy", are meant to focus on events already occurred and on possible events in upland areas, not to scare people living in or crossing these areas, but to make them aware of being exposed to a certain level of risk with which people can and inevitably have to live. For centuries, even millennia, those who venture and settle in piedmont or mountain environments, undertake a certain level of risk, though rewarded by the beauty of the place. In the mountain environment, given the vastness of the areas that humans tend to live on, move and enjoy, a certain degree of risk for landslides will always exist and while it can be reduced, sometimes even predicted, it will never be completely cancelled.

LANDSLIDE HAZARD IN ROMAN URBAN AREA: CRITICAL ANALYSIS OF A FEW CASE STUDIES

AMANTI Marco¹, CHIESSI Vittorio¹, TROCCOLI Alessandro¹, VITALE Valerio¹

1 - ISPRA, Geological Survey of Italy

Presenter e-mail: alessandro.troccoli@isprambiente.it

Key terms: landslide; hazard; urban area; risk; dataset

The continuous and fast growth of the Roman urban area suggests to improve existing landslide hazard studies in that territory. Land planning and management has not always been correct in the last years, often owing to an incomplete knowledge of the morphological features of the area or of the slope failures occurred in the past, so the number and the value of the elements at risk increased.

Geomorphological evolution processes are the predisposing factors of instability. Anthropogenic processes act both positively or negatively on hazard, interfering with natural processes. Many historical news about landslides are often available for the Italian cities. They are very useful both to remember "forgotten" landslides and as elements of a statistical dataset to prepare or validate hazard models.

In particular the second issue is very important, because it allows to insert in the right way anthropic features in the model. In this context the Roman urban area is quite interesting both for its extension (geological and geomorphological variability, long and complex urbanization growth) and for the number of case studies.

The Geological Survey of Italy (ISPRA) has recently studied the landslides distribution of the territory of the Municipality of Rome (Amanti et alii, 2008). In this paper the analysis of a few case studies is proposed, to investigate the relationship between natural (geolithological, geomorphological, topographic) and anthropic factors. The aim is to improve the knowledge about landslide susceptibility in urban areas, obtaining as a final result, a support to risk mitigation in the same territory.

DEBRIS FLOW RISK EVALUATION ON URBANISED AREAS IN THE WESTERN ALPS: VAL VIGEZZO CASE STUDY (VERBANIA, PIEMONTE REGION)

PETREA Catalin Costel¹, TURCONI Laura¹, LUINO Fabio¹

1 - Consiglio Nazionale delle Ricerche, Istituto di Ricerca per la Protezione Idrogeologica (IRPI) - Torino

Presenter e-mail: catalin.petrea@irpi.cnr.it

Key terms: debris flow; alluvial fan; urbanised area; risk; Piedmont Region

Debris flows are amongst the most hazardous geo-hydrological processes that occur in the mountain basins, usually as consequence of short and intense rainfalls, especially in the summer. Such processes take place in a large variety of morphoclimatic environments all over the world. In the European Alps, due to wet climate, lithology and steep slopes, the alpine mud-debris flows are very common and can involve hundreds of villages located on the alluvial fans at the mouths of mountain creeks. For this reason, in the last decades, these kinds of phenomena have attracted the attention of the scientific community and concern of general public due to the death toll and damages to settlements and infrastructures by flooding, erosion, direct impact or sediment deposition. Adopting a well established methodology, frequently used at CNR-IRPI (Turin), the study focuses on: a) reconstruct the frequency and behavior of the flow processes; b) calculate the magnitude of the past events; c) identify the debris-prone areas; d) gather information about the type of damages; and e) evaluate the urban development on the alluvial fan. This methodology can make easier the assessment of hazard and afterwards the debris flow risk evaluation, providing design parameters for risk mitigation. In Piedmont Region, below 2000 m a.s.l., more than 2,900 alluvial fans have been identified with a total area of 1,560 km², which represents 4.8% of regional territory. Must be pointed out that a large heterogeneity exists at geographic and administrative level: e.g. the Verbania province with 18%

of its territory occupied by alluvial fans, has the highest potential hazard linked to debris flow processes in Piedmont. The case study concerns four creeks (Val Vigizzo), which have built up their coalescent alluvial fans onto the nearly level plain of the Vigizzo stream. These alluvial fans, that cover a total area of 8.1 km², were selected by taking into consideration the following criteria: 1) high rate of urbanization; 2) recently-occurred events and potential risk for residential areas located on the alluvial fan; 3) natural events well documented by historical data, aerial/satellite imagery and GIS metadata; 4) long-lasting rainfall records. One of the most important debris flows has occurred on 7-8 August 1978. All four above mentioned creeks have transported huge volumes of coarse-grained sediment that covered the fans with 5.5 km² of debris (with thickness between 0.5 m and up to 6 m). As consequence, several houses and bridges have been totally destroyed and other tens of buildings, road, rail network and many hectares of terrains have suffered considerable damages. In the subsequent years the local authorities have realized sediment control dams and canalization systems in order to mitigate future debris flows. Considering a series of data excerpted from written documents, historical maps and air photographs it was possible to reconstruct the timing and manner of urban development, in the last hundred years. It is comes out that the fastest grow rate occurred between 1950-1970. After the 1978 catastrophic event, urbanization rate has decreased especially within those areas severely affected by debris flow (i.e. apex zone and active channel). The 2006 up-to-date situation shows that alluvial fans represent 4.4% of the study area, but being the most suitable terrain for human settlements, an important percentage of residential areas and infrastructures are located on them. Currently in force, national and regional laws have included the Val Vigizzo debris-flow prone areas into elevate or moderate risk classes. It must be precised that after 1978 event till now no other debris flows have reached the same magnitude, so is hard to evaluate if the retention dams and laws provisions will successfully mitigate the risk for a potential high magnitude flow event with a several decades-long recurrence interval.

GEOMORPHOLOGICAL APPROACH TO INTENSITY AND RUN OUT EVALUATION OF POTENTIAL MUD-DEBRIS FLOW IN THE MESSINA MUNICIPALITY AREA (PELORITANI MOUNTAINS, SICILY)

FALCONI Luca Maria¹, CAMPELO Danilo², LEONI Gabriele³, LUMACA Silvia², PUGLISI Claudio¹

1 - ENEA - Italian National Agency for new technologies, energy and sustainable economic development

2 - Consultant geologist

3 - Roma Tre University, Department of Geological Sciences

Presenter e-mail: luca.falconi@enea.it

Key terms: Debris flow; hazard; peloritani; sicilia

Peloritani Mountains (Messina province, Sicily) are a costal ridge along the Ionian coast, characterized by narrow and steep catchments of small size (5-10 km²) with a high relief energy (up to 1000 meters drop in about 5 km) and a short concentration time (few minutes). The morphology of the Peloritani has been especially influenced by metamorphic lithology, complex geotectonic conditions related to the orogenic tectonics and recent tectonic uplift, active in the area since the late Miocene. All the steep slopes are covered by a few decimetres layer of debris, colluvium and soil.

During the night between 1 and 2 October 2009, this area has been affected by a sudden downpour, accompanied by strong winds and lightning. Sicilian Agrometeorological Informative Service estimated that more than 200 mm of rain fell in seven hours.

Lithological, morphological and hydrological conditions have meant that more than one thousand of mud-debris flows have been produced.

Triggered by heavy rainfall, the flows have reached valley's bottom and alluvial fans in few minutes and with high energy. Urban areas located along the Ionian coast were overrun and affected by heavy damage and casualties. Giampileri Superiore, Briga Superiore and Scaletta Zanclea, small villages 10 kilometres southward from the city of Messina, were the most injured areas.

An empirical geomorphological approach to evaluate run out and energy of potential mud-debris flows that affect the Peloritani Mountains is proposed in this paper.

An inventory map of more than 1000 mud-debris flows was the first task of the study, produced through geomorphological and morphometric survey and aerial photos analysis. The inventory was focused on identifying landslides parameters to obtain a susceptibility map of the area, following Enea-Roma Tre methodology.

Once localized source, transportation and run out areas of past mud-debris flows, velocity and intensity have been assessed. Velocity measurements with Johnson & Rindine (1984) method were realized in different points of occurred phenomena in order to determine the specific deceleration curves of the area. In the same points the kinetic energy released was calculated.

Subsequently source areas, run out, velocity and intensity of potential events have been investigated.

Comparing volume, run out and height difference between triggering areas and the toe of accumulation fan of past events, site specific formulas were obtained in accordance with Rickemann (1999) methodology. Two formulas have been carried out separately for the channelized (L1) and non-channelized (L2) flows due to the different length of run out:

$$L1 = 6,4126(V*He) 0,3078;$$

$$L2 = 3,2666(V*He) 0,3148.$$

Where:

L: length of run out;

V: volume;

He: height difference between triggering area and the toe of accumulation fan.

These results were then applied to some high and very high susceptibility areas in order to determine the expected kinetic energy in each morphological part of potential flows and the impact on the anthropic structures of the Messina municipality area involved by the potential flows. The morphology of Messina territory, the town and villages development above the creek outlet, the transformation of riverbed in street and the abandonment of terracing, contributed to increase geomorphological risk of urban areas.

Complementary to the definition of return times and rainfall thresholds, this study is therefore a necessary basis for an efficient assessment of debris flow's hazard. Moreover, knowledge of potential landslides energy is preparatory for subsequent phases of vulnerability of exposed elements assessment. Ultimately, this study promotes the definition of reliable risk

scenarios for mountain source and transit areas as well as for urban areas prone to deposit of mud debris flows, indispensable basis for predisposing sustainable land planning actions and identify efficient risk mitigation measures.

EVALUATION OF HYDRAULIC RISK IN MOUNTAIN BASINS AND ALLUVIAL FAN: THE CASE OF T.BUTHIER, VALPELLINE (AO)

QUARANTA Nicola¹, MARENCO Luigi¹, COGO Elena¹, MAGLIANO Marco², CRETON Joel²

1 - GEO engineering s.r.l.. Turin

2 - engineering consultant

Presenter e-mail: quaranta@geoengineering.torino.it

Key terms: Debris potential; Hydrology hydraulic models; Alluvial fan risk

The basin of T.Buthier di Valpelline is placed in the central Aosta valley, with an extension of about 60 square km, and due to high elevation it includes several glaciers and one small artificial reservoir.

According to standard methodological guidelines edited by Regione Valle d'Aosta, the approach of the study is dedicated to evaluation of current debris-flood risk analysis and design of mitigation solutions at a preliminary stage.

Geological analysis took place from aerial photointerpretation, field survey and data sampling and organization in a pre-defined GIS format. Historical analysis based on archive research has been performed.

Specific care has been dedicated to evaluation of debris potential along minor steep torrents and in the mountain slope, especially in the recent morain loose formations and from landslides, referring to different methods (Agostino, 2006 and Hungr et alii, 1984).

The available volume of debris were distributed referring to a discretization of the main basin in sub-catchments, taking in account the local slope reduction effects allowing intermediate deposition of the solid transport.

Detailed hydrological analysis, considering snowmelt contribution to flood formation, was developed throughout intensive rain analysis and referring to Curve Number (U.S Soil Conservation Service) into HEC-HMS 3.3 environment.

Clark Unit Hydrograph and SCS Unit Hydrograph methods have been applied in order to transform inflow into flows.

Keeping into account the results of Hydrological analysis, the evaluation of the channel functionality in the alluvial fan has been computed with HEC-RAS 4.0, assigning solid transport as a component of the liquid discharge from Smart - Jaeggy formula.

Assessment of risk flood on the alluvial fan considered intrinsic hazard and return-time of the flood as a probability and a parametric attribution of values to the exposed human activities.

Design of mitigation structures along the channel was supported by scenarios simulation with HEC-RAS 4.0, performing the reduction of the risk stage on the alluvial fan.

Key terms: historical investigations; geomorphological analysis; flood-prone areas; town planning; Italian Alps

This study has examined more than 30 municipal areas of three different valley bottoms in Lombardy (Northern Italy). The research was carried out from historical and geomorphological points of view, and was aimed at identifying flood-prone areas. The result has been used to verify the present land-use planning, and to start a review process of the existing urban plans and/or their general changes.

The study was developed in three steps: a) collection of historical flooding data from several public bodies; b) geomorphological analysis by field surveys and aerial photographs; c) analysis of urban planning.

The historical investigation included the identification of the information sources, the collection of the historical report and old maps, and the selection and validation of the data. The aim of this investigation was to map the damaged sites in the past.

The geomorphological analysis was developed with aerial photographs and field surveys, and was aimed at verifying the reliability of the historical data, verifying the planform changes of the river-beds, collecting information from inhabitants and identifying the most critical morphological-hydraulic stretches.

By overlaying the historical and geomorphological maps, maps of flood-prone areas were obtained, and two hazardous strip-like areas along the rivers were identified. The first flood-prone area corresponds to the ordinary flood and the second one to extraordinary flood. The urban planning of 34 municipalities was verified and up-dated by aerophotogrammetric and cadastral maps, mapping of recent buildings by field surveys. The zoning of all urban plans was subdivided into eight main classes: a "risk matrix" was created by combining fluvial hazard and the different urban hazard levels. A final flood hazard map of each valley bottom was obtained by overlaying the flood-prone area map and the urban planning mosaic map, which allowed the most critical hydraulic sites to be highlighted.

A STRATEGY FOR THE LANDSLIDE PREVENTION, THE CHOICE OF ALBA MUNICIPALITY

CAMPIGOTTO Laura¹

1 - comune di alba (CN)

Presenter e-mail: protezione.civile@comune.alba.cn.it

Key terms: deep gravitational movements; warning; monitoring

This work shows the prevention strategy in a hydrogeological high-risk

municipality, about deep landslides which can directly involve houses.

INTRODUCTION:

In the municipality of Alba, in which some deep gravitational movements were triggered after the flood in 1994, some inclinometer and piezometer pipes for surveys were installed. These are monitored by ARPA Piedmont which periodically sends the report to Alba municipality. In April 2009 there was a high intensity rainfall event on Piedmont, which made worse a situation already fragile due to rain and snow accumulated in the previous year. The event caused the reactivation of movements, mainly rotational and planar/composite translational.

Although the instrumental registration, during the survey, of a modest increase of the movement, action for public safety were not considered necessary, but the high depth of the potential sliding surfaces and the uncertainty coming from the actual early phase of the breaking mechanism, make the evaluation of the developmental stage unsure, both for displacements and for correlation between rainfall-trigger of the displacement. In other words the aim of the periodical manual monitoring is to verify the general evolution of the phenomenon and not to provide warnings in real time when the alarm thresholds are overcome.

THE CHOICES OF PREVENTION

Alba municipality has been wondering about prevention for the responsibility of the Major, Authority of civil protection to the people of his municipality, and also for the limitations to public expenses introduced in recently in Italy by the specific regulation "Fatto di stabilità". With the aim to intervene for the "Common good" of the city, making choices aimed priority to optimize the expenses obtaining at the same time the best performances, it is clear that investing in prevention means also the determination of instrumental and experimental data allowing an early warning of population, before the event.

Indeed the alarm thresholds defined by the designers of the mitigation works, based on regional data, were not effective for the aim, causing an excessive number of alarms and a lowering of the threshold of perception of risk by the population.

TECHNICAL DATA

For these reasons it was decided to make a system which, thanks to technological evolution developed in the last years, allowed an effective warning to population by the continuous monitoring of the phenomena. Three important sites were chosen: loc. Case Toino, loc. Strada Serre - Villa Fantina e loc. Cascina Villa - Commenda-Salera

A first borehole was made in loc. Case Toino on the upper side of a slope, up to a depth of 30 meters, for the 2D/3D remote monitoring of the landslides.

In the area, placed south of Alba and on the right bank of Cherasca Torrent, there are some houses built in the upper part of the slope (one of these repeatedly evacuated) and a municipal road with some houses in the lower part of the slope, next to the Cherasca torrent.

In particular in April 2009 the municipal road was interrupted by a landslide, which can be correlated to the deep movement mentioned before.

First remote monitoring data (since 20.04.2011) shows already some interesting information, like micro movements at depths of 16 meters and 26 meters in North direction, which are supported by the previous data.

GEOLOGICAL AND HYDRAULIC RISK ASSESSMENT IN URBAN AREAS: THE ANCONA CASE STUDY

SPIZZICHINO Daniele¹, IADANZA Carla¹, TRIGILA Alessandro¹
1 - ISPRA

Presenter e-mail: d.spizzichino@gmail.com

Key terms: Landslide; Risk; Adaptation

Geological and hydraulic risk in Italy is particularly high since the geological, geomorphological, climatic, seismic and structural settings render Italian territory susceptible to frequent and widespread geological and hydraulic phenomena. Italy is also densely populated and highly urbanized. In terms of landslide hazard, more than 485,000 landslides occurred between A.D. 1116 and 2006 within Italy, with a landslide area of 20,721 km² equal to 6.9% of the national territory. 5,708 municipal districts are affected by landslides (70.5% of the total), of which 2,940 with extremely high levels of criticality due to landslides affecting urban settlements. This data emerges from the IFFI Project (Italian Landslide Inventory) set up by ISPRA - Italian National Institute for Environmental Protection and Research/Geological Survey of Italy and the Regions and self-governing Provinces. With regard to exposure and vulnerability, urban areas in Italy account for 17,929 km², equal to 5.9% of the national territory. In the past 50 years, urban areas in Italy underwent a dramatic increase, whose surface has more than doubled. Often urban sprawl did not benefit from any form of proper land use planning and management or detailed landslide hazard assessment. Scope of the present study is to present a methodology for a preliminary geological and hydraulic risk assessment at municipal scale. The work is being carried out within the framework of the Life Project ACT (Adapting to Climate change in Time) aiming at the development of Local Adaptation Plans and funded by the European Commission. The area chosen for the implementation of the analysis is the municipality of Ancona in the Marche region. The assessment has been implemented within a GIS platform by overlapping landslide data derived by the IFFI Project, hydraulic risk area derived by River Basin Authority, jointly with urban area derived by Land Cover Corine 2006, populations census data and main transportation network at municipal level. The total area of Ancona municipality is equal to 124,4 km² of which 26,9 km² (21,62 %) affected by landslides. The urbanized area is equal to 19,67 km² and the related area affected by landslide is equal to 2,37 square kilometers (1,92 %). For the Ancona municipality area landslides have been classified in two main categories: rapid and slow movements. The rapid phenomena are correlated to the people safety, while the slow one concern mainly losses and usability of goods and infrastructures. Consequently different strategies for planning and emergency management must be adopted and implemented. The people exposed to landslide risk at municipal level and critical points along highways, railways and road network has been also estimated. Related to population, the analysis permitted to estimate the number and age of people exposed to landslide risk in terms of safety of human life and also for social and economic losses. In order to reduce the impact of landslides and hydraulic events within urban areas and along linear infrastructures, different measures should be adopted and implemented by the developing of adaptation plan. In addition to engineering works and delocalization, the instrumental monitoring networks and emergency plans assume a fundamental role for the risk management. The main outcome of the proposed methodology is a rapid and useful tool for land use planning and management at local level in order to reduce and minimize the impact of

geological and hydraulic hazard in urban area.

Presenter e-mail: mauro.palomba@unito.it

Key terms: debris flows; GIS; geomorphological mapping; hazard assessment

A classical approach to debris flow risk assessment includes: 1) identification of affected area, event's magnitude and return time; 2) estimation of territorial risk and vulnerability; 3) evaluation of social consequences. The three components have been analyzed in the Aosta Valley (NW-Italy), a small alpine Region (area = 3262 km²) where debris flows frequently occur, often interacting with human activities and structures. Results have been addressed to support activities for reducing human and property losses caused by debris flows potential hazard.

For a best debris flow hazard assessment, the joint research team University of Torino-Regione Autonoma Valle d'Aosta realized a debris flows inventory at a regional scale, combining historical data (1900 to present), technical maps and geomorphological analysis. Data collection and analysis have been organized in two different stages. As a first step, aerial photointerpretation and Digital Elevation Models (DEMs) analysis were conducted over the Aosta Valley Region to obtain a complete fans inventory and to identify the most affected sectors by debris flows. As a second step, data on debris flow events occurred in the Region has been collected from different sources, such as bibliographic and historical data, municipality hazard maps for land planning restriction and drainage basin technical studies. For each inventoried debris flow, aerial photointerpretations have been performed to validate geomorphological and historical data, mostly collected during major regional flood events. Finally, the selected debris flow events has been formally organized in a GIS to perform spatial and statistical analysis.

The preliminary analysis of the debris flow selection led to the identification of about 200 single phenomena, thus successfully upgrading a Regional database for management of natural instabilities ("Catasto Dissesti"). Knowledge on natural hazards related to debris flow has been improved at a regional scale by the production of a 1:100.000 geotematic map.

Most vulnerable areas are located where tributary drainage paths intersect major valley bottoms: here debris flows represent a risk for structures and infrastructures located on the slopes or along the valley bottoms, especially on the alluvial fans. Because urbanization on fans has strongly increased in the last decades, the debris flows risk has also been enlarged: these instability phenomena often interfere with man-made structures causing damages to settlements and roads and also, in some cases, people injury and casualties.

Most of the records acquired are connected to the 13th - 16th October 2000 flood event, one of the most severe flood episode of the last century in North western Italy, with 270 different debris flow phenomena occurred on the fans involving a total area of about 4,3 km². Prolonged rainfalls affected large areas of the region, leading to widespread flooding with large-scale sediment transport and several debris flow along the stream network; rainfall-induced phenomena developed both from soil slips and torrential floods, often affecting buildings on alluvial fans at the foot of the steep slopes, causing serious damages to man-made structures in several areas of the middle Aosta valley and also 18 victims in the neighbourhoods of the town of Aosta, almost all killed by a single debris flow event.

Among activities undertaken to reduce human and property losses caused by debris flows, collected data also allowed important improvements to local knowledge on debris flows, through the recognition of multiple occurrences in the same alluvial fan: estimation of their magnitude and temporal occurrence led to more precise hazard and risk assessment, useful for proper land planning. Finally, geological, geomorphological and climate factors have been recognized, responsible for controlling typical activation thresholds and debris flow characteristics in different sectors of the Aosta Valley Region.

Presenter e-mail: laura.turconi@irpi.cnr.it

Key terms: early warning; historical flood events; risk-alluvial fans; Mallerio stream (Sondrio)

Almost every year and often several times in a year landslides, debris flows and stream floods events are impacting on settled areas and infrastructures, causing deaths, economic and social damages; due to a growing soil occupancy even in high-altitude areas, often accompanied by unsuitable land use practices, the exposure to risk increases, while the events per se should be regarded as usual and cyclical processes in nature. Early warning strategies must take into account the usually very short time span between the initial occurrence of some rapidly-evolving natural processes and the gathering of information in order to cope with risk and organize rescue operations. A purposely-made search and elaboration of historical data concerning natural instability processes and land use evolution is of primary importance in order to draft ready-for-use and up-to-date risk scenarios. The basin of T. Mallerio in the Sondrio

province (Adda Valley) represents a good case-study; it extends for 300 km² and its drainage network accounts for more than 650 km. In such basin landslide and torrential flood processes often occurred in the last five hundred years and the city of Sondrio has once more, dramatically, experienced destructive flood on 18-19 July 1987. A large landslide, which in extreme conditions could act as a dam barrier along the most important tributaries of Mallerio stream, are well-known since Centuries; the last one, involving Quaternary deposits and metamorphic rocks (gneiss, quartzite and marble) accounting for 20-106 m³ of materials, is usually quiescent but could re-set in motion in case of intense and long-lasting rainfall, as did in fact happened several times in the past. A method of analysis is illustrated, based upon research, selection, interpretation and processing of historical data, combined with a comparative analysis of aerial imagery taken at quite regular time intervals, and applied to the Mallerio basin with respect to the urban setup of the city of Sondrio, which has growth untidily when referred to the critical geomorphological conditions characterizing the large alluvial fan where the city is built. The effects of natural events, in case of extraordinarily huge floodwaters, may thus result in damages and danger to inhabitants. Some 170 documents have been used in the study, concerning reports on flood and landslide events as well restoration and protective works realized in the basin, which refer to a lapse of time as long as 500 years, with a fair good continuity over the period dating back to 1800 up to the present. The natural hazard conditions have been thus evidenced, connected to the geographical and geomorphological features of the area with special regard to the built-up alluvial fan. The result goes beyond the procedure usually followed in developing hydraulic models of recurrent floods, because there are not always available useful data inputs at local scale; the method here applied enhances the need for landscape analysis through the use of data objective and sound. The historic datum, appropriately balanced through a careful critical reading, may be regarded as a direct witness handed down through years, often bearing detail and precision required at a small-scale. It must be supported by a methodical investigation through interpretation of the catchment-system as it looks presently; to do it field recognitions are needed, supported by aerial and terrestrial images. In most part of mountain areas the co-existence between natural processes and man life and industry is a mere postulate. That is a good reason by which, independently from structural interventions and protective artifacts, the development inside the small communities of the culture of prevention, is a urgent need. Such knowledge mostly depends upon the historic information which could provide to landscape owners and especially the land planning Bodies the tools to re-act to extraordinary events through suitable rules and in right way

 Presenter e-mail: nicsanta@unina.it

Key terms: alluvial fan; flooding susceptibility; southern Italy

The great urban expansion which has occurred in the foothill areas of southern Italy in recent decades makes the problem of defining flooding susceptibility increasingly urgent. These areas have been prime spots for urban development because were generally considered to be safer than the valley floors. Entire towns (Sala Consilina, S. Maria a Vico, Arienzo, Piedimonte Matese, Volturara Irpina) often dating back to Roman or Medieval times have developed on alluvial fan surfaces. It should be pointed out that due to the relatively long time lags between floods and the consequent loss of historical memory, urban expansion in recent decades has not taken into account the presence of alluvial fans. In many cases the apical areas of the active fans have experienced significant urbanization and the feeder channel has either been completely buried or converted into a road. Extensive observation made during field surveys shows that in many cases hydraulic works are completely lacking and, when present, they are planned for ordinary rains, with small sections that are generally unfit to contain high discharges and/ or high debris loads. The sum of these conditions obviously increases regional vulnerability. In such contexts the difficulty in carrying out investigations and the lack of data or field evidence of past debris flows cause real problems in producing detailed and exhaustive studies. Risk management planning is generally tackled by local and area administrations (such as watershed basin authorities) in an approximate way and at an inadequate scale (1:25,000 or 1:10,000).

In the case of wide and extensively urbanized alluvial fans the real hazard conditions should be checked on a more detailed scale (1:2,000 - 1:1,000), taking into account the hydraulic sections, the topographic and morphological variations of the fan and the interactions between water flows and local infrastructures.

This paper describe some cases study for which the flooding susceptibility zoning was assessed at a very detailed scale (1:2000). The adopted procedure bases on a painstaking field survey both in the watershed basin and in the fan areas, associated with in-depth historical research of past events. Starting from 1581 up to now, we collected evidence of more than 50 alluvial events which often caused severe damage to property and infrastructures, and in many cases also loss of life.

The reconstructed flooding scenarios, showing the fan portions potentially affected by different alluvial processes, may represent a useful tool for subsequent studies aimed at land hazard mapping. In particular, the proposed procedure, allowing precise susceptibility zoning within an urbanized area, may contribute significantly to defining intervention priorities and planning risk mitigation works.

THE TERRITORIAL DIMENSION OF WATERSHED MANAGEMENT: A SUBURBAN CASE STUDY

VALENTINELLI Alessandra¹, ZUMAGLINI Marco¹
 1 - Freelance Consultant

Presenter e-mail: marcozuma@gmail.com

Key terms: land use; watershed; flood; mudflow; forest

Leading to a "territorial dimension" for the environmental policies, in order to more effectively meet the Climate Change adaptation challenges, the incoming EU Common Agricultural Policy will address the ecological connectivity of rural landscape as well as the implementation of the Water Framework Directive. Watershed integrated management is thus supposed to become a crucial matter, focusing on both biodiversity and land use management that are to be improved with a view to flood and landslide risk mitigation.

In order to provide scientifically sound figures and relevant criteria to land planners, the case study of the small Pollena watershed, located in the south-eastern suburbs of Naples but including a small section of Vesuvius National Park, has been analyzed owing to its being well representative of a variety of land use patterns, environmental concerns and human pressures. The research has been carried out by an interdisciplinary team in cooperation with the technical staff of the Napoli-Volla "Consorzio di Bonifica" (Land Reclamation Agency).

With the aim to study the effects of land use in the prevention/mitigation of floods or landslides affecting urban settlements, a computer model (Topkapi by Todini et al.) has been applied to simulate the rainfall-runoff transformation process: a physically-based grid-cell scale modeling of the hydrological processes has allowed detailed understanding of the influence of land cover changes on stream flow.

Alternative land use scenarios have been tested, featuring different land protection practices and/or land use types and patterns, such as the afforestation of buffer areas strategically located either along riparian strips or across the Vesuvius lower slopes.

The contrasting effects have been investigated of urban sprawl and afforestation.

The identified scenarios have served a double purpose: i) Peak flow analysis; the flood hydrographs have been calculated by the model starting from input rainfall of known probability (the two recurrence intervals of 5 and 50 years have been considered adequate); ii) Soil moisture analysis; among the model outputs, soil moisture at grid-cell level is paramount when mudflow hazard is to be assessed: the geology of the area, featuring a volcanic ash layer overlying a volcanic bedrock, makes it dangerously prone to such hazards (the well known Sarno disaster involved quite a similar geology).

The following major issues have then been highlighted:

- Soil moisture prior to precipitation plays an important role in runoff generation (the effects of this parameter have been investigated as well, by applying the same precipitation to two different soil moisture conditions, a "dry" one and a "wet" one);
- Mixed and multi-layered (i.e., close to climax) forests assure high performance in soil protection and stream flow control: they can extend to up to 2m the depth of the underlying topsoil (it corresponds to the plants' root system and is crucial to soil moisture and runoff generation control); when located along watercourses, they prove most effective in mitigating floods featuring low antecedent soil moisture content; conversely, when spread across the lower slopes, they tend to be more effective against high antecedent soil moisture content floods;
- When urban areas sprawl up to 60% of watershed area, parallel watershed afforestation together with revegetation of urban riparian strips allow no substantial changes in major floods, whereas minor floods will noticeably increase in frequency and magnitude;
- Concerning mudflow hazard, climax forests located where mudflows are likely to generate (i.e., spread across Vesuvius's - or rather, mount Somma's - steepest slopes) prove beneficial in keeping soil moisture levels comparatively low, thus counteracting soil liquefaction phenomena; additionally, buffer forests located at the foot of the mountain can contribute to protection of downhill urban areas by damping mudflow destructive energy.

COUPLED DECADAL VARIABILITY OF THE NORTH ATLANTIC OSCILLATION, REGIONAL RAINFALLS AND SPRING DISCHARGES IN THE CAMPANIA REGION (SOUTHERN ITALY)

DE VITA Pantaleone¹, ALLOCCA Vincenzo¹, FABBROCINO Silvia¹, MANNA Ferdinando²

1 - Department of Earth Science - University of Naples "Federico II"
 2 - External collaborator

Presenter e-mail: padevita@unina.it

Key terms: climatic variability; North Atlantic Oscillation; regional rainfall; groundwater recharge; southern Italy

The climate change is one of the issues most debated by the scientific community with a special focus to the combined effects of anthropogenic modifications of the atmosphere and the natural climatic cycles. Various scenarios were been formulated in order to forecast the global atmospheric circulation and consequently the global distribution of air temperature and rainfall. The effects of the climate change were been analysed respect to the risks of desertification, droughts and floods, remaining mainly limited to the atmospheric and surface components of the hydrologic cycle. Consequently the effects of the climate change on the recharge of regional aquifers and on the groundwater circulation is still a challenging topic especially in those areas whose aqueduct systems depend basically by springs or wells, such as the Campania region (southern Italy).

In order to analyse the long-term climatic variability and its influence on groundwater circulation, we analysed decadal patterns of precipitations, air temperature and spring discharges in Campania region (southern Italy), coupled with the North Atlantic Oscillation (NAO).

The time series of precipitations and air temperature were gathered for 90 years, in the period from 1921 to 2010, choosing 18 rain gauges and 9 air temperature gauges among those with the most continuous functioning as well as resulting in a homogeneous spatial distribution. Moreover, for the same period, we gathered the time series of the winter NAO index and of the discharges of the Sanità spring, belonging to a fractured carbonate aquifer (Cervialto Mount) located in the central-eastern area of Campania region. The hydrogeological features of such extended carbonate aquifer, its relevance due to the feeding of an important regional aqueduct system, as well as the unique availability of a long time series of spring discharges, allowed us to consider it as an ideal test site, well representative of the

other carbonate aquifers in the Campania region.

The time series of normalised indexes of mean annual precipitation, mean annual air temperature and mean annual effective precipitations, as well as the time series of the normalised annual discharge index were calculated. Different methods were applied to analyse the time series: trend analysis, trough moving-averages and numerical filters, cross-correlation analyses, Fourier analysis and statistical tests. The analysis of the indexes has highlighted a long-term complex periodicity, strongly correlated with the winter NAO index. Moreover, we also found robust correlations among precipitations indexes and the annual discharge index as well as between the latter and the NAO index itself.

Although the effects of the North Atlantic Oscillation had already been proved on long-term precipitations and stream flows patterns of different European countries and Mediterranean areas, the obtained results appear original because they establish a link between a large-scale atmospheric cycle and the groundwater circulation. Therefore, we demonstrated that the winter NAO index can be considered as an effective indicator to forecast the decadal variability of groundwater circulation in Mediterranean areas and to prospect critical scenarios for the feeding of aqueduct systems.

HYDROLOGICAL ANALYSIS OF THE RAINFALL ANTECEDENT TO THE LARGE LANDSLIDE OF MAIERATO (SOUTHERN ITALY)

DOGLIONI Angelo¹, GALEANDRO Annalisa¹, GUERRICCHIO Alessandro², SIMEONE Vincenzo¹

1 - Technical University of Bari - Engineering Faculty of Taranto

2 - University of Calabria - Engineering Faculty

Presenter e-mail: annalisa.galeandro@poliba.it

Key terms: rainfall and landslide; hydrological analysis; Maierato landslide

Rainfall-induced landslides is an hot topic in scientific literature, with particular interest to the evaluation of the influence of rainfall on landslide triggering to obtain a pre-alert information on landslide risk.

On the 15 of February 2010 a really large deep seated landslide activate in Maierato Southern Italy after a rainfall period of several months. General characters of the landslide area described in Guerricchio et Al. 2010. These work presents the analysis of the antecedent rainfall events developed using different hydrological technique to show the singularity of the rainfall. The analysis has been developed on the base of the data of Vibo Valentia rain gauge station where daily rainfall data were available since 1920 (ARPA CAL).

The time series analysis showed that both the 2009 and 2010 winters were really rainy, in particular the last three months before the landslide. During this period, there were long and well distributed rain precipitations easy to infiltrate into the soil and denoted by large volumes of water than by high peaks of intensity.

The classic hydrological analysis has developed for cumulative rainfall of 5, 10, 15, 20, 30, 60 for the whole studied period (1920-2010). For each duration, the maximum values of each year were analyzed using the gamma probability distribution to evaluate the return period of the rainfall. The return period of the 20 and 60 day rainfall preceding the landslide is the maximum of the last 20 years, despite being lower than 10 years. This is due to the fact that Maierato area is subject to really severe storms, e.g. in the cases of Vibo Valentia floods (2006 and 1938). These singular events condition the evaluation of rainfall exceptionality, even if they are not particularly important for the activation of deep seated landslide. In fact these events generate intense run-off and poor infiltration.

The analysis has been pursued also according to the approach of Cotecchia & Simeone (1996), who propose to consider a time series of rainfall with a threshold of 25 mm/d. Each daily rainfall value exceeding 25 mm was assumed as 25 mm. So it was obtained a modified rainfall series that considers only the rainfall that can potentially originate a quite high infiltration. The cumulative rainfall analysis has been repeated obtaining really different results. In this kind of analysis the cumulative rainfall to 20 years has a return period of more than 100 years.

In fact, in the 20 days before the landslide there were continuous rainfall, also if the amount of rainfall for each day is not very high. Therefore, a condition favoring deep infiltration occurred, thus implying pore pressure variation at deep levels and triggering deep large landslide.

The study confirmed that hydrological analysis is a really useful tool for estimating the landslide hazard. However, the hydrological exceptionality of single events does not immediately relates to the exceptionality of the landslide hazard pertaining to rainfall.

ANALYSIS OF THE POTENTIAL EFFECTS OF DAM BREAK FLOODING USING A GIS-TOOL FOR RISK ASSESSMENT IN MOUNTAIN REGIONS. AN EXPLORATORY STUDY ON A HYPOTHETICAL EVENT: THE VAL CANARIA FLOOD

BARUFFINI Mirko¹, POZZONI Maurizio¹, MARZOCCHI Roberto¹

1 - Institute of Earth Sciences, University of Applied Sciences of Southern Switzerland, IST-SUPSI

Presenter e-mail: mirko.baruffini@supsi.ch

Key terms: risk-assessment; floodplain mapping study; natural debris dams

Several percent of the Canton Ticino (Southern Switzerland) is prone to slope instability. The climate of southern Switzerland favors slope failure. In particular, landslides and accelerated creep are commonly triggered by major storms associated with warm humid air flowing from southwest towards the Alps.

These storms can be particularly severe in the Ticino region. The storms of 1993 and 2000 caused extensive flooding, triggered debris flows and landslides, and induced higher rates of creep in some existing large

landslides.

Some of these landslides are located near Airolo in the upper Leventina valley (Val Canaria). They consist of failed rock masses on both sides of the valley with a total volume of about 80 million m³. The area is historically known for its instability (Seno and Thüning, 2006). In particular, the channel of the Canaria stream at the slope's toe is filled with unvegetated landslide debris. A natural dam could form after a landslide event with a possible subsequent disastrous failure and destructive consequences on the important traffic lines passing in the Leventina valley.

This scenario, although characterized by a very low probability of occurrence, is nevertheless possible and could have effects that would certainly be devastating for a big part of the Swiss economic system. A damaged infrastructure would cause serious material damage that would require extraordinary repairs or restorations. The services inactivity, as a result of a malfunction, would generate important financial losses and problems in essential services supply in the region (Maggi R. et al, 2009). All these elements justify a risk analysis of this region. With a Geographical Information System adapted to run with a tool developed to manage risk analysis, it is possible to survey the data in time and space, obtaining an important system for managing natural risks. The aim is to join and organize the various data currently available to carry out a qualitative and semi-quantitative analysis giving an overview of the risk (BUWAL, 1999).

In this work we present few scenarios of flooding in the upper Leventina valley that are obtained applying two different 2D computational model:

(i) FLO-2D, a hydraulic model distributed by FLO-2D Software Inc and (ii) a numerical GIS embedded model appositely implemented for dam break flooding (Marzocchi & Cannata, 2011).

Evaluation of the models was performed by comparing simulation results against each other and finally a risk analysis is performed using a specific tool appositely developed in a GIS (Baruffini, 2010).

The outcomes can provide an answer to the questions: "what can happen?" and "how achieve maximum safety with a minimum of effort?" or, depending on the desired depth, they can represent also input to start an increasing order of analytical analysis (i.e a cost-benefit analysis or so on).

Key terms: Earthquake hydrology; Groundwater level changes; Dynamic stress

Using groundwater level data recorded in seven wells in the Tivoli quarry area and in the Cornicolani Mts (Central Italy), the intermediate-field response to the 6th April 2009 L'Aquila earthquake (Mw 6.3) has been studied. The hydrological setting of the Tivoli area is characterized by two superimposed aquifers, the deep one is in carbonate rocks, the shallow one is in travertine rocks. Has been observed that in five wells located in the travertine quarry area the groundwater level contemporary decreased exactly at the time of the L'Aquila earthquake occurrence, one of this wells reported also a decrease in water temperature at the same time, while there is a slight increase of level in the natural shaft of the Pozzo del Merro karst lake located in the carbonate deep aquifer.

A conceptual model to explain those variations has been proposed, assuming that the variations in groundwater level and in water temperature are given by an enhanced permeability in the shallow travertine aquifer caused by the dynamic stress, from the seismic waves.

TREND AND FLUCTUATIONS IN THE LONG KARST SPRING DISCHARGE SERIES

FIORILLO Francesco¹, GUADAGNO Francesco Maria¹

1 - Dip. di Scienze per la Biologia, la Geologia e l'Ambiente

Presenter e-mail: guadagno@unisannio.it

Key terms: spring discharge; karst; time series; Campania region

The recent tendency of temperature increasing and rainfall decreasing in many region of the world, enclosing the Italian peninsula, favours a reduction of infiltration, and thus the reduction of the spring discharges of many karst aquifers.

Karst springs are very important climate indicator, being controlled directly by the rainfall and temperature regime, and are very sensitive to poor rainfall during drought.

This study analyses long hydrological time series of spring discharge, to find the effect of the climate change on the karst systems analysed. Data refer to the Picentini mountain and Matese massifs, which are the

most important karst systems of Campania region (Southern Italy), characterised by a typical Mediterranean climate. These massifs are constituted by a limestone sequence of Mesozoic, deeply fractured and faulted, and supply the main aqueducts of Southern Italy, providing water for several millions of people.

Analyses have been particularly focused on the drought periods, analysing the effect of poor recharge on the aquifer response. Prolonged periods of poor rainfall can reduce the response of the spring discharge, with spring characterised by a predominant quick flow component showing a diminished frequency and/or peak-values of impulses, and spring characterised by a predominant slow flow component showing a reduced annual maximum value. During intense droughts, spring hydrographs present a continuous decreasing trend, which can occur also for two or more consecutive years (multi-years drought). The effect of the temperature increasing and rainfall drop appear well recorded in the spring discharge series, which show a very similar trend inside a wide area of Southern Italy.

Despite a different hydrological regime can be found for different karst springs, a general similar trend can be ascertained, characterised by a general drop of spring discharge since last two decades.

STUDY ON WATER LOSSES EVALUATION FROM IRRIGATION CANALS

CLEMENTE Paolo¹, DE LUCA Domenico Antonio¹, DINO Giovanna Antonella¹, LASAGNA Manuela¹, MARZANO Francesco¹

¹ - UNIVERSITA' DEGLI STUDI DI TORINO

Presenter e-mail: paolo.clemente@unito.it

Key terms: canals; losses; seepage; water

Considering regional scale, several tens of thousands km of irrigation canals are present in Piedmont network.

The loss of water due to seepage from irrigation canals constitutes a substantial part of the usable water. Irrigation canals placed in native soil or lined with earth can have seepage water losses varying from 20 % to more than 50 %. Providing perfect lining can prevent seepage loss from canals, but cracks in lining develop and performance of canal lining deteriorates with time. These losses have economic, hydrogeological and environmental consequences. So quantifying irrigation water losses is required for good water management.

The aim of the research is to find an expeditious, fast and reliable method to identify and evaluate losses.

The seepage loss from canals is governed by hydraulic conductivity of the subsoil, canal geometry, difference between the canal water level and the aquifer one. One way to evaluate water losses is using hydraulic laws for porous medium. But, most of times, numerical models does not reflect real conditions because they do not consider many variables, which depend on the specific context. The purpose is to start from numerical models, for a more detailed assessment, by direct measures.

For the purpose, five sections were selected from five different canals, choosed on the basis of the variability in hydraulic, morphological, geological and hydrogeological contexts.

For every investigated canal, hydrogeological and hydrological characterisation have been leaded, in order to understand the relationship between groundwater and stream water (eg. piezometric and hydrogeochemical survey campaigns). Moreover different soil characterization (eg. size distribution) have been carried out on soil sampled from the bottom of investigated canals. Different infiltration tests have also realized in order to evaluate water losses, both for the canals nearby and for the river bed, in the case of drainage during canal maintenance.

In order to reconstruct the local geological setting different penetrometric tests and electrical tomographies (parallel and transverse to the investigated canals) have been carried out.

In a first phase of the project three different methods have been tested in order to evaluate the stream discharge and its variations, by means of measures along different sections of the selected canals.

The first one, represented by the use of floats, gave us first data about stream flow in the canals, after an appropriate correction of the recorded flow velocity.

Mechanical and digital flow meters have been employed also. This method, even if expeditious and practical, is not totally effective and able to assess the real water loss, because of the high instrumental error (order of magnitude).

Finally lots of tracks (slug and continuous injection) have been realized in order to evaluate the stream discharge in canals. In order to reduce the error of this method, driven by the punctual measurement in the streambed, it has been applied a multistage sampling in different points of the cross section, by means of the contemporary water picking up. The results, obtained with the samples mixing and homogenization, guarantee an error decrease. The multistage sampling, in fact, takes into account the irregular blending of the tracer along the considered cross section. It also guarantees, after water mixing into the pump, a more representative value of the whole section.

Because of some unavoidable lack of accuracy, we are testing the application of more rigorous methods based on quantification of artificial tracers mass loss through exfiltration, by means tracers as well as NaCl, Uranine (Fluorescein) and Rhodamine WT. The first results of such tests seem to be more accurate and in accordance with the aim of the research.

Key terms: Advanced InSAR; geological processes; Piemonte

In the last years the use of persistent scatterers (PS) SAR data in the studies of some geological slow processes like subsidence (Herrera et al., 2007), landslides (Colesanti and Wasowski, 2006) tectonics (Bürgmann et al., 2006) or building deformations (Gernhar et al., 2009) has shown a rapid growth.

Many national or local authorities decided to use PS on large scale as one of the instruments of natural hazard mapping. We have studied the from regional to detailed scale the potentiality and limitation of this techniques in Piedmont.

In this work are discussed the results of the interpretation of the Radarsat data (2003- 2010) elaborated with SqueeSAR™ methodology compared with the older ERS data interpretation that we made in the last years. In particular we tested some improvement of the data like the time series quality or the higher density in order to check if the mapping and the description of some geological process are really improved.

The Piedmont region is one of largest areas (25'000 km²) covered by PS data. This wide area, required the development of procedure to manage and to interpret so large amount of data. The "anomalous areas" methodology (Meisina et al., 2008) was set up to solve this problem. The interpretation of ERS (1992-2001) data processed with PSInSAR methodology in Piedmont region produced a database of about 2'300 interpreted "anomalous area".

This work allowed us to describe some advantages and disadvantages of PS techniques:

- The interpretation allowed us to detect a lot of ground displacement related to different geological processes in different geological environments (Alps, Langhe Hills, Apennines,...). For instance with PS data we updated the information of some landslides of IFFI inventory.
- The disadvantages showed by the regional interpretation are also a lot: the data available are good only in descending geometry some many slope in alpine region cannot be investigated; in many areas the lack scatterers related to land use reduced a lot the number of process suitable; the time series are not useful because processed with linear algorithm.

Now on the western sector of Piedmont Region we have the possibility to analyse the data (radarast sensors) processed with the more advanced SqueeSAR™ processing (Novali et al., 2009). This processing allow to obtain ground information displacement information not only from traditional scatterers like rock or buildings but also from the distributed scatterers (DS) represented at ground by sparse vegetation areas. The first results showed that this technique joined with the use of both geometries of acquisition and the RADARSAT sensors with low incidence angle allow an increase in the number of processes mapped. The availability of two geometries allowed us to resolve the velocity in the East-West and vertical components and the time series processed with non-linear algorithm allowed a better analysis of the processes. The classical limitations of PS techniques however still to exist: only slow process can be studied; the time-series even better still have some ambiguity related to phase-unwrapping.

It is possible to describes some interesting case histories representative of different geological processes:

- in the Po Plain we tried to compare the PS Time Series with groundwater level and we find a good correspondence with up-lift and subsidence registered by SAR sensors;

- Over a landslide in the Alps the correlation between PS data, field surveys, and other geomorphological observations has allowed us to well know the kinematic, the state of activity and the geometry of the process.

- In the Langhe hills the time series, in spite of some problems, seems match quite well the inclinometers data.

- Another case is represented by some peri-glacial processes in the Alps. With PS data was possible to detect movement of some geofoms formerly considered as non-active.

MEASURING SUB - MILLIMETER TERRAIN MOTIONS FROM SPACE WITH PRESENT AND FUTURE RADAR SATELLITES.

ROCCA Fabio¹

¹ - Politecnico di Milano

Presenter e-mail: rocca@elet.polimi.it

Key terms: DInSAR; PSInSAR; Carbon Dioxide; Oil exploration

Optical leveling campaigns, tiltmeters, GPS and InSAR are geodetic techniques used to detect and monitor surface deformation phenomena. In particular, InSAR data from satellite radar sensors are gaining increasing attention for their cost-effectiveness and unique technical features, making it possible the monitoring of large areas, even revisiting the past. Moreover, more advanced InSAR techniques (PSInSAR, SqueeSAR) developed in the last decade are capable of providing millimeter precision, comparable to optical leveling, and a high spatial density of displacement measurements, over long periods of time without need of installing equipment or otherwise accessing the study area.

Thanks to the high density and quality of the measurements the PSInSAR data can be successfully used in geophysical inversion, to measure the permeability of oil reservoirs and/or to evaluate the possibilities and risks due to seismic faulting in the sequestration of CO₂. In these cases, the precision, the sub weekly frequency of the measurements and the time required for the data to be available are the most important aspects, more relevant than the spatial resolution.

Until recently, the main limitation to the application of InSAR was the relatively long revisiting time (24 or 35 days) and the quite long waiting period for the delivery of the acquired data. The new Sentinel-1 mission, based on a constellation of two satellites, is expected to reduce such limitations guaranteeing a revisit cycle of 6 days over Europe and Canada and providing a high level of service reliability with near-real-time delivery of data within 24 hours, important for risk management applications. Results from ground based radar show that this improved precision is indeed achievable from C to Ku band, provided that an accurate model of the delay due to atmospheric water vapor is available or that precise reference points are close by.

Permanent Scatterer SAR Interferometry (PSInSAR™) is today one of the most advanced technologies for surface deformation monitoring capable of overcoming most of the limitations of conventional differential radar interferometry. It exploits long temporal series of satellite radar data, acquired over the same area of interest at different times, to identify "natural radar targets" (i.e. the so-called Permanent Scatterers) where very precise displacement information can be retrieved. Recently, some significant advances have been reported in InSAR data processing that can further increase the quality and the effectiveness of this data source: (a) the availability of new processing algorithms: at the end of last year TRE developed a new algorithm (SqueeSAR™) which allows a significant increase in the spatial density of measurement points by exploiting signal returns from both Permanent and Distributed Scatterers (PS and DS); (b) the availability of an increased number of satellite radar sensors characterized by higher spatial resolution (down to 1 m), as well as higher temporal frequency of acquisition (down to a few days, rather than a monthly update). Thanks to its capability to detect small displacements over long periods and large areas, PSInSAR™ analysis can be considered complementary to conventional geological and geomorphological studies in performing landslides inventories at regional scale and supporting the design of early monitoring systems at local scale. The Italian Ministry of the Environment has recently awarded a contract for the processing of more than 12,000 SAR scenes acquired over Italy aimed at creating the first database of interferometric information on a national level for mapping unstable areas. This is somewhat an evidence of the fact that, in less than ten years from its development, this technology has become a standard monitoring tool. Surface deformation monitoring can provide valuable constraints on the dynamic behavior of a hydrocarbon reservoir enabling the evaluation of volumetric changes in the reservoir through time. Depending on depth and reservoir/overburden rheology, volumetric changes in reservoirs due to fluid extraction and injection can induce either subsidence or uplift which could trigger fault reactivation and threaten well integrity. Examples regarding the use of SqueeSAR™ for monitoring hydrocarbon fields and calibrating reservoir models in case of EOR (Enhanced Oil Recovery), CCS (Carbon Dioxide Capture and Sequestration) and UGS (Underground Gas Storage) will be presented. The availability of surface deformation data can be helpful during site characterization in infrastructure design, as well as during the construction and the operation phase. An overview of applications in the railway field, with particular reference to case studies involving underground works, will be provided.

Presenter e-mail: m.morelli@arpa.piemonte.it

Key terms: Permanent Scatterers; spatial statistic techniques; active tectonics; Piemonte (Italy)

SAR interferometry based on Permanent Scatterers (PS-InSAR™) is used here to study the present crustal mobility of a large area of NW Italy, in the Piemonte region. Thirty-eight satellite scenes (ERS SAR), taken from May 1992 to January 2001, were analysed for detecting more than 2 million PS on the study area. Continuous velocity surface maps (Iso-Kinematic Maps: IKM) were obtained from geo-statistical and spatial cluster techniques (Hot Spot analysis) of PS "short-period" data, to identify relative ground motions and to compare them with "long-period" tectonic mobility trends, i.e. those inferred at regional scale over geological times (some million years). The comparison was made by individuation of homogeneous kinematic areas, represented in the IKM, and characterization of the boundaries between them (Iso-Kinematic Boundaries: IKB). The IKB were used as tools to assess if the PS-InSAR data on present-day crustal mobility could fit with the distribution of real tectonic structures or field geological elements. IKM were drawn for uplifting geological sectors of Piemonte (Maritime Alps, Gran Paradiso, Langhe) where moderate to very low seismicity is recorded, and gravitational instabilities of rock mass on mountain slopes are widespread. The land sectors have been chosen in order to test the suitability of IKM in very different geomorphological conditions. Different types of correspondence between the IKM and the geological kinematic trend were found:
- a first type in which the kinematic trend of short-period (a decade of years, i.e. the PS-InSAR detection time span) is in agreement with a long-period tectonic trend (some million years) and seem to be driven by well known faults subparallel to the IKB. These kinematic trends can be hidden by the slope movement due to gravitational instabilities;
- a second type in which the kinematic trend of short-period does not strictly correspond to the long period trend, but can be considered as minor-order, uplifting-subsidence cycles, even if in contrast with the long-period kinematic trend. Alternatively, the short-period kinematic trends could reflect the action of deep-seated geological forces or structures, not yet known or inferable (at least with the recorded PSInSAR velocities) on the basis of the available geological data and models.

Key terms: Sea level change; DinSAR data; Morpho-stratigraphy; Uplift/Subsidence; Campania

The predicted sea level rise caused by ongoing climatic changes is one of the main problems for the management of the coastal areas, in particular for the low coasts. It's the case of many Italian coastal plain generated by delta and lagoonal-barrier trasgressive/progradational systems during Late Quaternary sea level rise. In the Campania region, the Sele river coastal plain. It is confined seaward by a straight sandy coast formed during the Last Interglacial and the Holocene, and represents the evolution of a barrier-lagoon system shifted alternatively landward and seaward as a result of the eustatic sea level changes. The back-barrier depressions, only recently reclaimed by drainage channels, located an altitude from 0,5 m to 2,5 m a.s.l., could be subject to flood risks by future sea level rise. In order to model possible future scenarios to the sea level rise, it's very important to understand the vertical movements of the coastal area, was interested by local or semi-local vertical ground movements. In order to evaluate subsidence and uplift phenomena with a good approximation in all the sectors of the plain, we compared morpho-stratigraphical data with available ground deformation rates derived by DinSAR data (Settore Difesa Suolo-Regione Campania, 2008).

In this work we present the preliminary results of our integrated approach. The morpho-stratigraphical approach used data by the geological literature and by new boreholes, drilled in different locations of the coastal area. The stratigraphical analysis was integrated by chronological data (14C absolute datings and archeo-tephro-stratigraphical relative datings), by palaeo-ecological data (ostracoda, benthic foraminifera and mollusks assemblage) and by pollen data. This approach also allowed the identification of some palaeo-sea levels of the Upper Pleistocene Age and in particular of the Holocene Age (Amato et al, 2011). Comparing the paleo-sea level data with those of the tectonically stable areas (Antonoli et al, 2008; Lambeck et al, 2004) we can notice some altitudinal discrepancies. In particular, in the SE sector of the coastal plain, near Paestum, the Holocene paleo-sea levels are slightly more high (1-2 m). These values show the area gently uplifting during Holocene times (< 0,5 mm/yr). In the central sector of the plain, near the Sele River, and in the outer NW sector, between the Sele and Tusciano river mouths, the altitude of the Late Quaternary coastal and lagoonal deposits are slightly more low (2-3 m). These values show the area gently subsiding during Holocene times (< 0,7 mm/yr).

On the basis of Din-SAR data, the coastal sector of the Sele plain is characterized by a complex vertical velocity pattern during 1992-2000 time period (Vilardo et al., 2009a). Northward Sele river, a 2 km-wide strip coast-line backward area is clearly characterized by a relative subsidence rate of about 5-7 mm/yr and a relative uplift rate of 1-2 mm/yr occur westward Battipaglia town. The differential vertical rate is of about 6-9 mm/yr along a distance of 6-7 km. A localized area of strong subsidence (up to 8 mm/yr) develops along the river Sele course from 2 to 7 km from the coast in the surroundings of Hera Argiva sanctuary ruins. Southward Sele River, localised subsidence areas are present nearby Capaccio Scalo town only with a relative subsidence rate of about 1-3 mm/yr.

The more recent relative vertical movements derived from Din-SAR data seem to agree with the morpho-stratigraphic data, showing trends of movements that are more durable and will probably cover a consistent part of the Upper Pleistocene and Holocene. As preliminary hypothesis, the vertical movements could be induced by NW-SE and NE-SW trending faults dissecting the plain. In particular the NW sector could be interested by NW-SE fault, lowering the outer part of the plain; the central sector could be interested by two NE-SW faults, lowering the actual Sele river valley, as a like-graben area.

On September 2010 a Mw 7.1 earthquake took place along a previously unrecognized east-west fault line, the strike slip Greendale fault, close to Darfield (Canterbury). About five months later, on February 2011, another seismic event of Mw 6.3, hit the city of Christchurch. It was generated by a blind thrust fault, occurred approximately 6 km south-east of city centre. This second event is located at the easternmost limit of the Darfield aftershocks distribution. In the present work we investigated the possible causal relationship between these two earthquakes. For this purpose, two pairs of ALOS PALSAR images acquired along two adjacent tracks have been exploited to retrieve the deformation fields of the two earthquakes. The pre-seismic images have been acquired on August 13, 2010, and January 1, 2011, respectively, while the post-seismic data were on September 28, 2010, and February 25, 2011. The displacement fields from both shocks have been derived by means of Differential SAR Interferometry (DinSAR) technique. In particular, the September 2010 earthquake generated a complex pattern due to the activation of the Greendale fault and other secondary buried thrusts. A linear inversion algorithm has then been applied in order to calculate the fault's features, exploiting the DinSAR results. By evaluating the Coulomb Failure Function, the connection between the first earthquake in promoting the rupture of the second has been analyzed. The outcomes of such analysis, shows that the more shallow part of the Christchurch fault has been unloaded by the Darfield earthquake, whereas, at the same time, the deeper part of the fault has been brought closer to the rupture.

Key terms: SBAS; subsidence; active tectonics; aquifer-system compaction; South-eastern Sicily

Advanced DInSAR technique represents the most innovative geodetic technique developed in the last decade, allowing the analysis of the spatio-temporal progression of typically seasonal or evolving deformations phenomena. The wide spectrum of investigated phenomena includes subsidence induced by fluid extraction, mining, sink-holes, as well as landslides, tectonic, volcanic and urban area deformations. We applied the Small Baseline Subset (SBAS) DInSAR algorithm by Berardino et al. (2001) to a dataset composed of ERS 1-2 SAR data, spanning from 1992 to 2000 and covering part of the Hyblean Foreland, in SE Sicily. The SBAS algorithm, unlike most of the DInSAR techniques, does not rely on point-like targets unaffected by temporal and spatial decorrelation (Persistent or Permanent Scatterers; PS) to calculate displacement time-series. This technique detects even distributed scatterers, maximizing the coherent pixels density. This is obtained using an appropriate combination of SAR image pairs grouped in several independent interferometric Small Baseline Subset (SBAS), linked using the Singular Value Decomposition (SVD) method. We computed 200 and 136 interferograms, from descending and ascending data, and we inverted them retrieving the ascending and descending mean velocity maps. These maps show the deformation along the Line of Sight (LoS) of the satellite (23° with respect to the vertical for ERS 1-2). Displacement time series are available for each of such coherent pixels. The East and Vertical deformation components of the deformation were successively estimated for each pixel common to both the velocity maps.

We compared and validated SAR deformation rates with permanent and campaigns GPS data, morphotectonic and geoarchaeological analyses. The residual values we found fall within the standard deviations (1 mm/a for the Up and 2 mm/a for the East component) reported in literature for East and Up mean deformation velocity maps obtained with the SBAS algorithm and similar ERS dataset.

The tabular morphology of the Hyblean Plateau prevented perspective distortion (shading, foreshortening or layover), resulting in a high coherence all over the area. The scarcity of vegetation, plenty of outcrops and developed sites along the Ionian coast as well favored a striking density of the data.

Using velocity profiles, time series and geostatistical analysis we detected: 1. previously undetected subsidence patterns, in particular the Augusta, Villasmundo, Priolo and Siracusa subsiding areas. Deformation rates reach values up to -18 mm/a, and are mainly attributed to subsidence induced by fluid extraction.

2. a slight uplift (1 mm/a) of the Hyblean Plateau s.s. with respect to the Ionian area, which is quasi-stable, in good agreement with morphotectonic and geoarchaeological data (residuals well below 1 mm/a). In details, morphotectonic rates deriving by paleontological dating and geoarchaeological sites showed the best correlation.

3. the East velocity field points out a major subdivision of the Hyblean foreland in two tectonic domains; the almost stable Hyblean Plateau s.s. and the Ionian area, moving westward. These two domains are separated by a NNW-SSE striking and well constrained deformation belt, showing a deformation gradient much higher than the rest of the study area. We called this feature the Florida-Cassibile Weakness Zone (FCWZ). The FCWZ is parallel to the submerged Malta escarpment and it is located in correspondence of a retreat of this morphological escarpment towards SW; we interpret it as an inherited extensional fault system presently undergoing tectonic inversion. The integrated use of SAR and GPS suggests that the FCWZ works as a left-lateral deformation belt, accompanied by a secondary compressional component, under the current stress field caused by the NW-SE oriented Africa-Eurasia convergence.

Presenter e-mail: marco.moro@ingv.it

Key terms: Differential SAR Interferometry; Large gravitational deformations; L'Aquila earthquake

We have studied large gravitational deformations triggered by the Mw = 6.3 L'Aquila earthquake, which occurred in the Abruzzi region of central Italy on April 6, 2009. Indeed it is common knowledge that the strong ground motions caused by large earthquakes can induce gravitational collapses. By means of the Differential SAR Interferometry technique and using a couple of high resolution COSMO-SkyMed (Constellation of Small Satellites for the Mediterranean Basin Observation) X-Band synthetic aperture radar (SAR) data acquired on April 4, 2009, and April 12, 2009, respectively, we have obtained an accurate and spatially continuous measure of the co-seismic ground displacement at 5m resolution. Within the classical low frequency fringe pattern belonging to surface co-seismic deformation caused by the normal fault dislocation, we have observed higher spatial frequency fringe patterns suggesting localized deformation not related to the fault displacement field. In particular, we show two examples of subtle (4-5 cm) deformation patterns associated with long-term gravitational mass movements recognized through geological and geomorphological interpretation. We give an interpretation of the deformation mechanisms by integrating geological analysis and simple analytical modeling of the Differential SAR Interferometry (DInSAR) observations.

Key terms: DInSAR; Deformation; SBAS

Differential Synthetic Aperture Radar Interferometry (DInSAR) is a remote sensing technique that allows us to produce spatially dense deformation maps with centimeter to millimeter accuracy. An effective way to detect and follow the temporal evolution of deformation is via the generation of time-series; to do this, the information available from each interferometric SAR data pair must be properly related to those included in the other ones, via the generation of an appropriate sequence of DInSAR interferograms. In this context, several approaches have been already proposed. Among these procedures, we consider the one referred to as Small Baseline Subset (SBAS) approach that implements an appropriate combination of DInSAR interferograms generated from SAR images pairs characterized by a small spatial and temporal separation (baseline) between the acquisition orbits.

In this work we perform a full exploitation of SBAS technique to investigate long and short term surface deformation occurring in some selected volcanic and seismogenic areas. To this aim we benefit of the SBAS technique capability to work in multi-frame and multi-sensor scenarios in order to improve the spatial and temporal coverage, as well as to employ new generation SAR sensors to increase the temporal sampling of the retrieved time series. In this work we apply the SBAS algorithm to analyze the temporal evolution of the detected displacements affecting different deformative scenarios by means of deformation time series retrieved through data acquired by European (ERS-1/2, ENVISAT) and Italian (COSMO-SkyMed) satellites. In particular, as a first step we focus on the analysis of the deformation patterns associated with the activity of the North Anatolian (NAF, Turkey) and the Lazufre volcanic area (Chile) retrieved by the ERS-1/2, ENVISAT sensors. Then, as a final issue, we show the benefit that may derive from the shortened revisit time of the new generation SAR sensors if compared to that of the C-band systems. Accordingly, we present the results we achieved by applying the SBAS approach to a set of COSMOSkyMed SAR data over Abruzzo region, Neapolitan volcanic area and Etna volcano; accordingly, we show the strong impact that the new generation sensor data (such as the COSMO-SkyMed ones) may have in seismic and volcano deformation analysis, particularly in terms of spatial coverage and temporal sampling of the retrieved measurements.

2 - Gamma Remote Sensing

Presenter e-mail: christian.ambrosi@supsi.ch

Key terms: landslide; inventory; SAR; interferometry; photogrammetry

The landslide inventory of the alpine areas of Cantone Ticino (about 1000 km², southern Switzerland) is a large database with more than 2000 phenomena. The inventory is aimed to provide a support tool for landslide hazard assessment.

Inventory was done by means of aerial photo-interpretation. The interpretation of optical images is commonly applied in support of landslide inventories. Based on aerial photography interpretation complemented by field surveys and historical records, landslide inventory maps were produced. The aerial photographs (Swisstopo) are available at 1:20'000 scale and were taken in the last 50 years. Using stereoscopic images landslides were distinguished by typology, depth and activity. The high resolution of aerial digital photographs has also permitted to recognize the geomorphological features associated by mass movements, such as scarps, counterscarps, trenches, debris flows, debris fans and rockfalls. The state of activity was performed by means of available monitoring data, satellite and ground based SAR measurements and morphological features.

A statistical analysis was performed on the landslide dataset and it enhances the relationships between landsliding and several geological and environmental factors. Lithology exerts a strong control on landslide distribution.

Key terms: DInSAR; Source Modelling; Tohoku-oki; Earthquake

On March 11th, 2011 (at 05:46:23 UTC) a Mw 9.0 earthquake occurred offshore the coast of Honshu island (Japan).

It was generated along the subduction plate boundary between the Pacific and the North America plates and was followed by a destructive tsunami of rare power, which cause wide and heavy damage along the coast of Honshu island. The epicenter was located at about 130 km East of Sendai city at a depth of about 32 km. All the data related to location, geometric parameters, and focal mechanism agree with the occurrence of the seism along the subduction plate boundary.

The mainshock ruptured about 300 km x 150 km along the fault plane, and a maximum slip was estimated up to 30-40 m. Soon after the seism some of the most important Space Agencies, JAXA (Japanese Space Agency), ESA (European Space Agency), DLR (German Space Agency), NASA (National AeroSpace Agency) and CNES (French Space Agency) provided a large number of SAR and Optical data, covering the whole epicentral area.

We applied the Differential SAR Interferometry (DInSAR) technique to a dataset composed of 27 Envisat - C band SAR - IS6 frames along three adjacent tracks and to a set of ALOS PALSAR - L-band SAR - Fine Beam Single polarization (FBS) and Fine Beam Dual polarization (FBD) along ascending and descending paths.

The obtained interferograms have been unwrapped over each track and a maximum displacement of about 2.5 m has been measured along the

Envisat IS6 LOS. Parallely, we applied the same approach to the ALOS PALSAR dataset. Inm order to calculate the displacement along North, East and Up directions, we applied the SISTEM approach that simultaneously integrate DInSAR and GPS vectors. Finally, we used the output from SISTEM for the inversion of seismic moment release. During this cruise event, ESA made available data from the ERS2 satellite, too. ERS2 platform was previously moved on a new three days revisiting time orbit. Precise orbit files, based on Laser Range data, were also delivered with only two days delay. The optimal ERS2 orbital control allowed getting very short baseline values that with the three days revisiting time gave a chance to get an almost continuous monitoring system, allowing a near-real-time data processing. Besides that we had the possibility to extract just the coseismic deformation field with the postseismic deformation filtered out. The choice of the ERS2 processed interferograms, has been done based on the occurrence of some strong aftershocks (April 7th, M7.4 and May 5th, M6.3) after the mainshock of March 11th.

Key terms: geology of volcanoes; DInSAR; remote sensing; ground deformation; geomorphology

Calderas are roughly circular depressions and are distinctive features in volcanic areas. These structures are some of the most studied volcanic features, particularly for their possible implications for hazard assessment and mitigation. In this work we process optical and microwaves remotely sensed data in order to study geological features of Cerro Blanco/Roblede volcanic complex, located in northwest Argentina. Ground deformations associated with the present-day volcanic activity are measured using DInSAR techniques, in particular by means of time series analysis. The Cerro Blanco/Roblede caldera, is unusual among the actively deforming volcanoes because it is subsiding. An ENVISAT-ASAR dataset has been processed on a descending track spanning from 29/04/2004 to 23/01/2007 using StampS/MTI software. In a previous study, the measured rate of subsidence seems to decrease with time from a maximum of more than 2.5 cm/yr in the radar LOS (interferograms spanning 1996/7-1992) to less than 1.8 cm/yr (2000-1996). In this work we obtain a velocity map of the area showing a rate of subsidence of 11 mm/yr in the radar LOS, confirming the deformative trend. Terra-ASTER data will be used in order to depict the surface distribution of erupted products and their evolution with respect to time. The surface classification will be performed by using both the L1B Terra-ASTER data and L1B atmospherically corrected data set. A comparison among the results obtained by means of different atmospheric correction tool will be done. All the results will be compared with the available geo-lithological map also by using DTM understanding the role of the morphology on the recent volcanic evolution.

SOME CONSIDERATIONS ABOUT THE ROLE OF PUBLIC AGENCIES IN COPING WITH THE GEOLOGIC HAZARD

TROISI Carlo¹
 1 - Regione Piemonte

Presenter e-mail: carlo.troisi@regione.piemonte.it

Key terms: public agencies; geologic hazard; risk perception

If confronted with other types of natural or human-generated hazards, the geologic hazard (s.l.) poses some peculiar types of problems. The geologic hazard is (usually, at least) not human-generated and nobody can therefore be taken as responsible for generating it or for not conforming to given security standards. Geologic hazard and the deriving risk, is almost universally coped by public agencies and, almost universally, a number of such agencies are involved each one with its own mission, hierarchy, political mandate, budget, legal basis, technical and administrative structure. Moreover some of the involved agencies may have conflicting interests, such as the case of a Development Agency and a Geologic Survey posing some kind of restrictions over a new industrial area. The result is that, in many cases, procedures and competences are unclear and many actions may therefore be ineffective. Another point to be considered is the perception of geologic hazard and risk by the populations and by the local representatives (in Italy, at least). Unlike other hazards (such as the car accidents-related hazard) the geologic one is often very poorly understood and it is perceived in a variety of biasing modes, last but not least the diffused belief that "if what should be done was done" no heavy rains (or other natural phenomena) could produce negative effects, giving almost no allowance for any residual risk. This attitude often results in a strong demand, by local councils, for actions which may be of little effectiveness or even be counter-productive.

Giovanni², TOFFOLON Giovanni²

1 - Accademia delle Scienze di Torino
 2 - LTS Padova

Presenter e-mail: giorgio.dalpiazz@unipd.it

Key terms: gravitational deformation; mass movement; DSGSD; Aosta valley; Western Alps

Gravitational slope and ridge deformations extensively developed in the Aosta valley from the retreat of Olocene glaciers. Most of them are active, at least partly, and may be a relevant risk factor. Numerous deep-seated deformations (DSGSD; Terzaghi, 1962; Dramis 1984; Mortara & Sorzana 1987; Bertolo, 1990; Bistacchi & Massironi 2001) have been recognized and mapped by the CARG Project (e.g., sheets Chatillon, 2010, Aosta and Courmayeur, in press). Here we focus on other gravitational deformations along the left side of the Aosta valley, from the Valtournanche (Motta di Pletè, Cime Bianche, Petites Murailles-Bobba, Punta Fontanafredda), Ayas (Piure-Ruine, Tantanè-Portola) and Gressoney (Seehorn-Gabiet) valleys to the Challant-Mt Jovet watershed (Arbaz-Arlaz). They occur within the sheets Monte Cervino, Monte Rosa and Verrès we have mapped in the last decade. These DSGSD are poorly influenced by lithological setting, since they are mainly developed in calcschists and/or ophiolitic units of the Combin zone (Motta di Pletè, Cime Bianche, Punta Fontanafredda, Piure-Ruine, Seehorn), but also in the ophiolitic Zermatt-Saas zone (Arbaz-Arlaz), Dent Blanche nappe (Petites Murailles), Pilonnet-Combin contact (Tantanè-Portola eastern side), and glacial deposits (Valtournanche village). Low-angle thrusts, regional schistosity and lithological bedding are influential factors in the Cime-Bianche case and probably also in the Motta di Pletè, along staircase deformed segments of the Pancherot-Cime Bianche decollement cover unit. Other DSGSD are characterized by high angle out-off-sequence cuts, slow spreading and various amount of lateral displacement. Striking features are crest doubling, open trenches, block rotation along gravitational listric faults with normal displacement and antithetic uphill-facing scarps, boulders or chaotic land-slides in the frontal part. Maximum downslope and lateral displacements are hectometric and kilometric in size, respectively. Bilateral ridge deformations characterize the Piure-Ruine and Seehorn crests, even if the most relevant processes developed in the western slope, favoured by the westward merging regional schistosity and metamorphic bedding. Doubling occurs also in east-west-trending crests (Punta Fontanafredda, between Chamois and Cheneil). The Motta di Pletè DSGSD shows various systems of open trenches that mark the active gravitational stress-field in the mountain range over Cervinia. As a whole, the Motta di Pletè morphostructure may be envisaged as a small-scale natural homologue of continental rifting. Regional brittle tectonics in the study area is dominated by the Aosta-Ranzola line and other Oligocene-Neogene fault systems (Bistacchi et al., 2001), but the main causes of the concerned gravitational processes are post-glacial unloading and high relief-energy of slopes which display a vertical development up to 1.000 m, facilitated by NNE- and N-trending joints. In the Arbaz-Arlaz case, pervasive fracturing and alteration are also related to the emplacement of gold-quartz veins within a ridge of metabasalt and some serpentine slivers, later erased by the Ayas and Aosta glacial confluence. The Petites Murailles sackung (Swiss sheet Matterhorn, 2003) can be better regarded as a huge and fast land-slide, since this basement slice displays a high-angle gliding surface with black cataclasis (Rifugio Bobba prong). The relatively smaller Valtournanche case is equally noticeable because the DSGSD involves the glacial deposits on which the chief town is built up, and their slow flow is induced by fluvial erosion.

10.1474/Epitome.04.0183.Geoitalia2011

RAPID LANDSLIDE RUNOUT SIMULATION: A THOROUGH USE OF NUMERICAL MODELS

PIRULLI Marina¹
 1 - Politecnico di Torino

Presenter e-mail: marina.pirulli@polito.it

Key terms: rapid landslide; numerical modeling; runout; continuum mechanics

Rapid landslide runout analysis, the prediction of landslide motion and its effect, is an essential component of landslide risk assessment. Numerical simulation can provide a useful tool for investigating the propagation phase of phenomena involving granular material, like debris flows, debris- and rock-avalanches. In the attempt of modeling landslide dynamics, methods based on discontinuum mechanics and continuum mechanics have nowadays emerged as promising approaches. Discontinuum methods model the run out mass as an assembly of particles moving down a surface. Each particle is followed as it moves and interacts with the stationary bedrock and with its neighboring particles. Continuum methods resort to an "equivalent fluid", that is a hypothetical material, whose properties do not correspond to those of any of the slide components but are intended to be able to simulate the bulk behavior of the moving mass. The use of these two approaches have advanced incrementally over the past three decades to the point where, when used in combination with careful engineering and geological judgment, first-order runout prediction appears to be possible. However, there is still considerable room for improvement.

It is here evidenced that whatever the applied numerical model, results of a simulation depend on many aspects that have to be critically considered and not neglected when reliability of both runout results and numerical models are considered.

In this regard, three key aspects for a numerical simulation are discussed in the following:

1) Digital Terrain Model (DTM) resolution; 2) Morphology and substrate influence on rheology; and 3) Entrainment process. The role of each of the above aspects is here analyzed through the application of RASH3D, that is a numerical code based on a continuum mechanics approach and on the St. Venant hypothesis for shallow flows. Similar considerations are valid if a discontinuum model is applied.

The importance of onsite surveys and DTM resolution is here discussed with reference to the 2000 Nora debris flow which had place in the Italian Alps and where the mass split in two branches during the runout process. Comparison of numerical results obtained with the two available pre-event DTMs, which have a 10m and a 5m resolution, respectively, has evidenced that for this case only the high resolution DTM allowed to properly reproduce the runout process. Moving to the second aspect, it can be evidenced how the failure of soil and rock slopes under natural conditions involves a variety of mechanical processes that can produce several kinematically and structurally distinct types of landslide phenomena. As to this, the 2004 Thurwieser rock avalanche (Italian Alps) whose runout path was partially covered by a glacier was analysed with different rheologies.

Whatever the rheology is, it emerges that a correct simulation is possible only if a change in rheological properties is considered in the glacier area. Finally, it is observed that the entrainment of channel path material plays an important role during run-out of many rapid landslides. Such mechanism is able to change significantly the mobility of a flow, through rapid changes of the flow volume and rheology. The case of the 2000 Tsing Shan event (Hong Kong), which was characterized by an important increment of volume during the runout process (from 150 m³ up to 1620 m³) was correctly simulated only if the entrainment was considered in the carried out numerical modeling. In conclusion, the findings of analyses have showed that the selection of an appropriate DTM resolution depends on the type of event to analyze. Furthermore, a detailed knowledge of geological and morphological feature and of the entrainment process, that are fundamental characteristics of the flow dynamics, cannot be neglected when a case is studied.

COMPARISON OF RESULTS FROM A TRANSLATIONAL-SLIDES PREDICTION MODEL WITH DATA RECORDED BY THE REGIONAL LANDSLIDES MONITORING NETWORK OF PIEMONTE (NORTH-WESTERN ITALY)

TIRANTI Davide¹, TARARBRA Mauro¹

1 - Environmental Protection Agency of Piemonte (Arpa Piemonte)

Presenter e-mail: davide.tiranti@arpa.piemonte.it

Key terms: warning system; antecedent precipitations; Langa hills; South Piemonte; North-western Italy

Several studies were made on landslides of Piemonte (North-western Italy) in order to improve the evaluation of slope instability in this region. In detail, this study outlined the relationship between antecedent precipitations and activation of a particular type of landslide that occur mainly in a southern hilly sector of the Tertiary Piemonte Basin called Langa. The studied landslide type corresponds to a translational rock-block slide involving wide sectors of sedimentary bedrock. The Langa hills are particularly renowned for the cultivation of valuable vines, therefore, constitute a place of important economic and tourist interest. Furthermore, the high density of structures and infrastructure in this area exposes a number of elements to the activity of these large landslides. In order to minimize human and economic losses, it is particularly important to establish a warning system capable of providing sufficient advance announcement for activation of translational rock-block slides. In this direction, the Environmental Protection Agency of Piemonte (Arpa Piemonte) developed a precipitation-thresholds based model, also considering the contribution of snowmelt, according to previous studies and to an extensive collection of historical data on landslides movements since 1926, related to a complete meteorological dataset. The regional meteorological gauges network and the forecasting service of severe weather provide input data to the model. Moreover, the output model results can be tested by the observations from the regional landslides monitoring network consists of inclinometers and piezometers, managed by Arpa Piemonte.

B9-5 Invitato Marchisio, Claudio

10.1474/Epitome.04.0185.Geoitalia2011

GEOLOGICAL DATABASES FOR RISK PREVENTION: NEW PERSPECTIVES

MARCHISIO Claudio¹, PISPICO Rocco²

1 - Regione Piemonte - Opere pubbliche, difesa del suolo, economia montana e foreste

2 - Arpa Piemonte - Geologia e dissesto

Presenter e-mail: claudio.marchisio@regione.piemonte.it

Key terms: geological databases; geological data production processes; geological staff competence; open source software

Over the past twenty years software used to support the management of geological data has undergone a substantial evolution: in the geological departments of Regione Piemonte and Arpa Piemonte we have evolved from software developed ad hoc, to proprietary software, and from the first databases available on personal computers to relational databases and to complex geographic information systems.

At each step, functional enhancements have been made to meet the growing technical demands of daily use to manage a significant amount of descriptive data, iconographic and geographic information.

But this evolution has changed both the processes of production of databases and the skills of the staff involved. The time in which we can plan to use in a systematic and not just experimental way information technology throughout the process of making of databases, from the measurement to the delivery of the final services is approaching.

Starting from these assumptions Regione Piemonte and Arpa Piemonte have launched initiatives to evolve both the tools and the knowledge of the technicians involved, growing their awareness of knowing how to manage these tools. Both organizations have therefore begun jointly to migrate some data sets used in domestic production processes from outsourced platforms, implemented and managed by external suppliers but not maintained any longer, to platforms managed directly by technicians inside the organizations.

This development is influenced by the dramatic scarcity of resources available to support the software development. In this context open source software combined with the increased staff competence plays a leading role. This particular combination makes it possible to overcome the shortage of resources necessary to purchase new software or to adapt existing ones, while the increased staff competence allows the improvement of the production capacity so that it is not so affected by staff shortages. Moreover reusable software and interchangeable experience make it easier collaboration between public authorities than solutions that use only proprietary software.

Regione Piemonte and Arpa Piemonte have started the process of conversion of both technical geological databases (geotechnics, inclinometers, sources and documentation, SIFRAP, alluvial fans, Damage) and administrative ones, using open source or otherwise free of license costs software.

B9-6 Invitato Lanteri, Luca

10.1474/Epitome.04.0186.Geoitalia2011

THE UPDATE OF ARPA PIEMONTE LANDSLIDE INVENTORY IN THE RISK-NAT PROJECT

LANTERI Luca¹, SARA Di Priolo¹

1 - Arpa Piemonte

Presenter e-mail: l.lanteri@arpa.piemonte.it

Key terms: landslide inventory; Risknat; SAR; geodatabase

One of the main goals of the strategic Project RISK-NAT, a programme for Italian-France cooperation (Objective 3 ALCOCTRA) is to develop operative tools that can be helpful for land planning and risk management. Especially the B2/C2 working package is aimed to improve the knowledge of the hydrogeological risks in the alpine region and to make available an easy to use and updated framework about natural risks both to common people and administrations.

Starting from the end of '70, the Geological Survey of Regione Piemonte collects information concerning flooding, landslides, geomorphological characteristics of earths and rocks; now the Thematic Department "Geologia e Dissesto" of ARPA Piemonte (Regional Agency for Environmental Protection) is in charge of maintaining this valuable resource and to keep it up to date. From 2000 to 2004 the IFFI project (The Italian landslide Inventory) contributes to the production of a national homogeneous landslide information system: a first level of knowledge, that defines a basic landslide classification (shape, location, state of activity and typology) was reached on the whole region. Now the activity of the RISK-NAT Project is focused to improve the knowledge on the more serious phenomena where detailed examination is needed. Different kind of data are integrated together in order to obtain an effective knowledge of phenomena: detailed morphological analysis, carried out mainly by air-photo interpretation and some aimed field survey, are coupled with the outcome of the monitoring system of Arpa Piemonte. The Agency manage several devices installed all over Piemonte to monitor landslides that occur close to facilities or built-up areas. The network includes about 300 monitored sites, up to now. The monitoring network includes many sites with few, mostly conventional instruments (inclinometers, piezometers, extensometers, and topographic benchmarks).

Another important instrumental data is provided by PSInSARTM analysis technique: indeed, space borne radars are able to increase the potentialities of the monitoring network because it integrates the punctual and accurate information of monitoring system with a superficial but extensive data for the whole region. In 2007, a PSInSARTM analysis was made over the entire region (~25'000 km²) using data sets from ERS-1 and ERS-2 radar satellites. The results identified about 2.5 millions covering the time span from 1992 to 2001. In 2010, thanks to the funding of Risknat project, an alpine area of about 13'000 km² was covered using data sets from Canadian RADARSAT satellite. The survey was made using a newly patented processing algorithm (the SqueasarTM) and identified more than 2 millions PS for the time span from 2002 to 2009.

The results of this integrated approach are particular positive: the comparison of data issued from different monitoring systems has allowed to obtain an important cross-validation, especially for the brand new SqueasarTM technique, where there are few case studied.

All the data are stored in a geographic PostGIS database and they can be accessed by different instruments. Furthermore, some tools was developed in order to allow data analysis and plotting data directly with an open source GIS.

Up to now about more detailed analysis, corresponding to the so called second level of in-depth examination, was made for about 180 landslides and it could be 300 at the end of the project. In order to spread the second level data in a standard format a specific report was made. The reports contain a detailed cartography, some iconographic enclosure, a set of standard information and some textual descriptions. For few landslides, when the knowledge are more detailed, a completely text-form are filled out.

All informations are spreading by a specific webGIS service, available from the website of Arpa Piemonte and now also from the RISK-NAT project geoportal (<http://www.risknat-alcotra.org/>).

10.1474/Epitome.04.0187.Geoitalia2011

A CENSUS OF LANDSLIDE DAMS IN A SECTOR OF CENTRAL-NORTHERN APENNINES: SOME CONSIDERATIONS AND ANALYSIS.

CENCETTI Corrado¹, DE ROSA Pierluigi¹, FREDDUZZI Andrea¹, MINELLI Annalisa¹, TACCONI Paolo¹

1 - Dipartimento di Ingegneria Civile e Ambientale, Università di Perugia

Presenter e-mail: corcen@unipg.it

Key terms: northern-central Apennines; landslide dams; threshold for triggering relations

Landslide dams are typical phenomena of hilly and mountainous environments. The aim of this work was make a census of landslide dams of the central-northern Apennines (central Italy), covering the regions of Umbria, Marche, Tuscany and Latium.

In order to manage all collected data, a landslide detection card and a linked database were implemented to record all informations.

The card and the database are splitted in several sections related to different topics (general informations, morphological and geological data, dam typology, predisposing cause, damages, etc.).

A specified graphical user interface was created to upload data into database.

All collected data was used to make some statistical correlations with the most important parameters of each landslide event.

The considered aspects were: spatial-temporal collocation; kind of slided material; landslide typology; natural dam characterization; volume of slided material; width of channel and alluvial plain.

Regarding the spatial-temporal collocation, almost all slides are located in the west side of Apenninic chain and involve sandstones and marls in facies of flysch outcropping.

The most common kind of landslide is sliding (rotational and traslative), while the most frequent type of dam is the type I (using the Costa & Schuster classification, i.e. dam having a width smaller than the width of the floodplain and where the slide does not reach the opposite slope of alluvial plain).

The analysis of all registered landslides shows that for 30% of all cases a dam-lake was not formed or because the stream flow has deviated his path bypassing the obstruction, or because the material was rapidly

removed by the water flow.

For rest 70% cases, the dam-lake evolved in different ways: from the natural drain out up to become a stable lake (5% of cases). Another important observation lies in the fact that alluvial plains wider than 300 m never were dammed by a landslide.

Several statistical correlations have been performed using some considered parameters. Especially it was searched a relation between the two following variables: volume of slid material vs upstream contributing area at the obstruction. Looking the obtained scatter plot it is possible to define the couples of values for which an obstruction of water flow occurred. In practice by the scatter plot we can define a threshold relation which can separate the couples of observed values (in Apenninic area) for which a natural dam was formed, from the couples of observed values where such phenomenon doesn't occurs.

APPLICATION OF THE CROSS CORRELATION TECHNIQUE TO MICROSEISMIC DATA ANALYSIS FOR THE IDENTIFICATION OF ROCK WEAKNESS ZONES.

OCCHIENA Cristina¹, PIRULLI Marina¹
1 - Politecnico di Torino

Presenter e-mail: cristina.occhiena@polito.it

Key terms: microseismic activity; hypocentral localization; monitoring systems

The formation, growth and propagation of microcracks in rock material, considered as prior factors to a collapse, give rise to elastic waves, that can be detected by a suitable monitoring system. As a consequence, the monitoring of the microseismic activity can be considered a useful investigation tool to measure and analyze the deformation and the potential instabilities of rock slopes.

The correct analysis and interpretation of the recorded signals can provide information about the size, the type and the spatial localization of the source mechanisms. Considering the aims of the present work, the main approaches to the analysis of microseismic data and to their correlation with rock fracturing processes can be classed in three categories, concerning 1) the simple count of the number of events prior to the failure, 2) the localization of the microseismic sources, 3) the whole waveform data analysis.

In the frame of the third type of analysis, it is possible to determine the fault plane solution of the microseismic source events from the first data motion, assessing the direction of the stresses that generated the elastic wave propagation. Another way concerns the grouping of the microseismic events on the base of their waveform similarity. This clustering is referred to as "multiplet" and the grouped events are considered to be related to identical or neighboring source mechanisms. The technique for the multiplet identification is based on the cross correlation theory and the similarity between the analyzed waveforms is quantified by the computation of the coherency for each possible pair of events, recorded by the same microseismic network.

In the present work the application of the above technique to analyze the data recorded by the microseismic monitoring system installed by the CNR-IRPI of Turin (Italy), in the frame of the Interreg Project IIIA Alcotra n.196, "PERMAdatROC", on the Italian side of the Matterhorn peak is described.

The first six months of microseismic recordings have been analyzed and the computation of the coherency for each pair of events has allowed the identification of a class of similar appearing signals, in which nine events are collected. The localization of the nine hypocenters, carried out using the software NonLinLoc (<http://alomax.free.fr/nlloc>), has evidenced the presence of a cloud of source mechanisms aligned along a planar surface. The attitude of this plane is very close to that of a set of discontinuities, measured during a morphostructural survey.

COMPARISON OF METHODS FOR THE SPEDITIVE ROCKFALL HAZARD ASSESSMENT: ACTIVITY 1 OF THE MASSA (MEDIUM AND SMALL SIZE ROCKFALL HAZARD ASSESSMENT) PROJECT

BORMIOLI Daniele¹, DAMATO Davide¹, LANTERI Luca¹, MORELLI Michele¹, PISPICO Rocco¹, TROISI Carlo²
1 - Arpa Piemonte
2 - Regione Piemonte

Presenter e-mail: d.damato@arpa.piemonte.it

Key terms: rockfall; landslide hazard; ALCOTRA project; mountain environment

France, Italy and Switzerland are the countries involved in the project Massa designed to standardize the assessment of the landslide hazard. In particular, the MASSA project (<http://massa.geoazur.eu>), is an operational programme for cross-border cooperation "Italy-France (Alps-ALCOTRA, 2007 - 2013)", it started in 2010 and it will end in 2013, aiming to identify rockfall and landslides hazard assessment along international road in the Alpine area. The project is composed by three actions, that consist of: compare speditive methods for rockfall hazard assessment (Action 1); monitoring (Action 2) and modelling (Action 3) of medium-volume landslides (between 1000 and 100000 m³).

This work describes the Action 1 performed during the first year. The Lombardia (It), Sempione (Ch) and Roya (Fr) valleys were chosen as common test-sites in order to compared different methods:

- Proviapl methods developed by Arpa Piemonte, couple a mechanical probabilistic approach used to define the probability of rock fall, with a specific software (Rotomap software) for the three-dimensional run-out evaluation. The rock falls source areas and the geological and structural data of rock mass were collected by speditive field surveys (Arpa-Cemagref, 2008). In this project, in order to improve the Proviapl method new input data were used:

- * the density of the intersection fractures, derived from multiscale images analysis, was used to refine the evaluation of the probability of rock fall. Landsat ETM and Aster images were used to detect the main regional lineaments whilst the photo aerial were used to detect detailed fractures systems. To derived the density map of fractures intersection the geostatistical analysis of the fractures intersection were applied.

- * the empirical method of shadow angle (Evans and Hungry, 1993), that is used to define a maximum run-out distance zone for block propagation, it was improved in order to consider also the frequency of blocks transit and the maximum and medium height of the block starting points.

- Matterock light methods calculates the probability of rock face failure based on a detailed stability analysis using geomechanical parameters and considering external influences. Trajectories are used to establish the boundaries of the areas subject to rock falls in relation to the speed of the boulders (Rouiller et al., 1998, Crealp et al., 2006).

- BRGM methods allows to hazard assessment resulting to rockfall block trajectory with Bora software starting to field geological data. Bora, born to help hazard cartography allows to assessment downstream areas of detachment, likely invasion landslide (Sedan et al., 2006).

Although these methods are rather complementary, the comparison of the results (susceptibility maps, hazard maps etc.) obtained on common test-sites shows different results mainly due to:

- different set of field geological data collected are strongly related to experience of geologist especially during a speditive field surveys (ex. scales of geological survey, number of discontinuity systems, block sizes and volumes, probabilities of failure of the unstable rock mass, size and geometry of the homogeneous areas, etc.);
- most of the data collect in geologic database can not be used directly in model input;
- different graphical representation of the hazard and susceptibility maps (ex. representation of differing hazard levels, legends, color, symbology, etc.).

In the coming months many efforts being devoted on minimize these differences especially to joint collection of field geological data used as input model.

UNDERSTANDING GEENVIRONMENTAL DYNAMICS AND RISKS: THE CASSAS LANDSLIDE AND THE LARGE SLOPE INSTABILITIES OF THE MIDDLE SUSA VALLEY

GIARDINO Marco¹, BACENETTI Marco², PEROTTI Luigi¹, PIANA Fabrizio³, FRATTIANNI Simona², PIERVITTORI Rosanna³, FAVERO LONGO Sergio Enrico⁴

4 - Università degli studi di Torino, Dipartimento di Biologia Vegetale

Presenter e-mail: marco.bacenetti@gmail.com

Key terms: slope instabilities; hazards and risks communication; geological heritage; Piemonte

Mountain regions have geological and geomorphological features that make them attractive for leisure and tourism activities; land occupation and seasonal population in many mountain areas are consequently increasing, together with impacts on the natural environment and geomorphological risks for human activities and infrastructures. This happens also because of enhanced environmental dynamics of mountain areas, due both to climate change, seismotectonics activity and lithostructural conditions.

Sociological surveys have shown that "perceived risk", not "real risk", influences people's behavior towards natural hazards. Proper communication of hazard and risks studies can play an important role in raising awareness of tourists and residents in mountain areas of elevated risk and high geotouristic attraction. Based of this, we aim to: 1) contribute to the awareness-raising communication strategy of the RiskNat project (Interreg Alcotra 2007-2013, Action A.4.3) by synthesizing geoscience knowledge on slope instabilities of the Middle Susa Valley and information on models/prevention measures/warning systems of the Cassas landslide; and 2) achieve a new conceptual and operational discipline in the management of the geological heritage of the Middle Susa valley, by means of the development of techniques for recognizing and managing its rich geodiversity (ProGeoPiemonte Project, submitted to the "Progetti d'Ateneo" selection, operated by Università degli Studi di Torino and Compagnia di San Paolo Bank Foundation).

By analyzing natural risk components in the Middle Susa valley, we outlined an approach to slope instabilities including: (a) natural hazards identification; (b) estimation of risk and vulnerability, and (c) evaluation of social consequences. (a) A review of geoscience literature on geodiversity, climate and landscape evolutionary stages and natural hazards of the area delineated the local and regional components of environmental dynamics. Significant landforms, agents, processes and factors have been described and mapped for reconstructing the evolutionary stages of the mountain environment. The long-term geomorphological changes have been represented through virtual landscapes of the Pleistocene glacial phases, from LGM to cataglacial stages. Relationships between deglaciation and deep-seated gravitational deformation at the Susa-Chisone divide have been explored also by analysis of lichen colonization on rock surfaces. (b) By integration of multispectral satellite images and multitemporal aerial photographs, static and dynamic conditions to Cassas landslide risk and related territorial vulnerability have been outlined. (c) Since vulnerability is a function of population, settlement and infrastructures, images of historical events of instability and documentation of related local damages have been collected. Panoramic view-points have been selected for a didactic trail to show the risk that people face in various circumstances and to present mitigation strategies.

As a result of the systematic review of geoscience and natural hazards information, the Middle Susa valley became one of the 9 strategic geothematic areas have been selected by the ProGEO-Piemonte project to represent the geodiversity of our region, each characterized by high potential for enhancement of public understanding of science, and recreation activities supported by local communities. The visual representations and digital evolutionary models prepared for the RiskNat didactic trail and laboratory will contribute to the popularization of geological history, climate and environmental changes, natural hazards and related risk management practices in the Susa valley. A better recognition of the economic value of geodiversity and a stronger perception of natural risks will reduce local vulnerability to disasters and will support the territorial integrated quality management systems, suitable for tourism and sustainable development.

INFLUENCE OF THE TOPOGRAPHIC SURVEY ON TRAJECTORIES RECONSTRUCTION AND ROCK FALL SIMULATIONS: CASE STUDIES IN THE PROVINCE OF BOLZANO (ITALY)

BOCCALI Chiara¹, STRADA Claudia², ZINI Luca³, DEVOTO Stefano³

1 - Department of Geosciences, University of Trieste, Italy
2 - Autonomous Province of Bolzano, Italy
3 - Department of Earth Sciences, University of Modena and Reggio Emilia, Italy

Presenter e-mail: chiara.boccali@phd.units.it

Key terms: rock fall; topography; slope geometry; two-dimensional simulations

Rock falls, according to the high speed with which they occur, can lead to catastrophic consequences causing damage to infrastructure and threatening the safety of human lives. For this reason it is important to accurately assess the spatial diffusion of the phenomenon. The slope morphology and the direct surrounding of the potential falling rock are the most important factors determining whether a rock could fall. After the rock has been detached and starts to move, it descends the slope in different modes of motion, that strongly depend on the mean slope gradient.

For these reasons it is important the most likely reconstruction of the slope topography. The aim of this study is to compare different topographic methods, used to outline rock fall paths, and to identify which survey technique is the most suitable for the use of the simulation software RocFall (@RoScience).

The program requires a set of input parameters (geometry and properties of the slope, properties of the simulated rock) and provides, in the form of graphs, results on the location of the end-points, on the bounce heights, kinetic energy and rotational speed of the block.

This study seeks to understand which difference in results are achieved by choosing one or another topographic base, in order to determine which is the best for the purpose of forecasting phenomena of rock fall.

Three sites (Vadena, Vizzate Valley and Sinigo), located in the Autonomous Province of Bolzano (Italy), were chosen given the availability of topographic sections made using GPS, photogrammetry and laser scanner survey. All trajectories, 11 in total, were also reconstructed using the digital terrain model (DTM), with cells 2.5 to 2.5 meters, made available by the Province of Bolzano. A field survey was carried out in the study areas to detect in detail particular morphologies of the slope.

Basing only on the delineation of the topographic sections there is a distinct difference between GPS and photogrammetry, on the one hand, and DTM and laser scan, on the other. The profiles derived from GPS or photogrammetry are simplified and sometimes present morphological features, like stairs, not detected in the field survey. On the contrary, comparing the DTM and the laser scan, the highest density of points detected by laser scan allows a profiling of the rock wall thicker than the DTM and consequently seem that the DTM is missing some morphological characters.

All these morphological differences occur also in charts: in about half of the sections analyzed, comparing the specific topographic method with the DTM, was pointed out a difference of at least 10 meters in the location of the end-points of the boulders.

In all three areas the lack of significant morphological jumps causes, in the DTM profiles, bounce heights significantly lower than other topographic methods. On the contrary most gentle slope, with no evident gradient's changes, means higher angular velocity, linked to a preferential rotational motion, rather than free fall.

High kinetic energies correspond to significant bounce heights, but they cancel out on the impact with the ground. Also high velocities involve high energies, but they are spread over the entire length of the slope where the simulated block rolls.

This study shows that the most accurate method is the laser scan, as the high density of points, that can be detected, provides a good match with the real mountain side. Not to forget, however, are the limitations of this approach, particularly if portions of wooded slope were investigated. In most cases the laser scan data are not available and can be effectively replaced by the digital terrain model, taking care to maintain high resolution.

From these considerations can be infer that a most likely reconstruction of the slope, by topographic survey, combined with direct control on the field and a proper evaluation of land use, are the basis for the definition of rock fall hazard and for the design of mitigation works.

GEOMORPHOLOGICAL AND SEDIMENTOLOGICAL IMPRINTS OF HOLOCENE EXTREME EVENTS ON THE NORTH-WEST COAST OF EGYPT

AMR Saleem¹
1 - Ain Shams University, Egypt

Presenter e-mail: amr_saleem@art.asu.edu.eg

Key terms: Mediterranean Coast of Egypt; Paleotsunami; Marine Boulders; Holocene

The study deals with geomorphological and sedimentological phenomena which may have been accumulated by the extreme paleoevents. The presence of boulder fields and/or ridges is connected to coastal geomorphological types. Sedimentological phenomenon is equivalent to subsurface sedimentary sequences up to few meters. The term "extreme paleoevents" is used to describe both Holocene paleotsunamis and paleostorms.

The main purpose of the research is to examine some geomorphological and sedimentological findings along representative sites of the North West Coast of Egypt since mid-Holocene, and interpret them in the light of extreme paleoevents against the theory of sea level fluctuations.

Historical data and few sedimentological investigations reveal that many paleotsunamis and or paleostorms events occurred in Alexandria region since late Holocene. The most destructive one have been recorded approximately in (365 AD).

Field investigations of Holocene extreme events along the widespread North-West coast of Egypt are still rare. The precise study of fifteen explored mega boulders fields along the study area (explored by 2010) represents the core of the study. In addition, the study of subsurface sedimentary sequences along selective boreholes will be conducted. The sophisticated laboratory analysis such as geochemical characteristics of

sediments samples and carbon 14 dating are needed to complete the study successfully.

2 - Iranian National Institute for Oceanography (INIO)

Presenter e-mail: mhosseini@cerege.fr

Key terms: Makran; Coastal boulder; Storm; Tsunami; Hazard

Coastal boulder deposits attesting to large waves are found along the rocky coast of Makran from Chabahar to Lipar. Boulders are either scattered on the rocky coastal platform or accumulated in imbricated clusters. The boulders are mostly rectangular and composed of biogenic calcarenite originated from the present coastal platform. Significant morphologic features observed on the boulders include supratidal karstic pools, sharp broken edges and fractures. Some boulders contain boreholes and shells of marine bivalves suggesting detachment and transportation from the subtidal zone. The dimensions, elevation and distance from the coastline of 60 representative boulders are documented to estimate their volume, weight and inland displacement. The boulders, weighing up to 18 tons, are found up to 6 m above present mean sea level and up to 40 m from the shoreline. We applied hydrologic models to estimate and compare the wave height and inundation distance required to transport the boulders inland. Our results demonstrate that no known or probable storm event on the Makran coast is capable of detaching and transporting the boulders. Conversely, tsunami coastal wave height of 4 m is enough to detach all the boulders from the rocky coast and transport them inland. We conclude that a tsunamigenic origin for boulder deposits is most plausible. These data imply that the western part of the Makran coast has archived evidence of paleotsunami events probably generated by large earthquakes at the Makran subduction zone.

Presenter e-mail: a.marsico@geo.uniba.it

Key terms: extreme wave; tsunami; storm; Sardinia; Italy

Recent surveys performer by the team of Prof. Pascucci from Sassari University, highlighted the presence of boulders isolated, or organised in field, sometimes in berms, scattered inland along the western coast of the Sardinia, north to the village of Argentiera. Since the general features of the boulders (shape, size, weight, distribution) they have been considered as evidence of the impact of extreme waves, may be a tsunami. Up to the 2004, studies have been concentrated on boulders accumulation due to past event impact; the tragedy of the Ocean Indian Tsunami, the OIT 2004, evidenced the possibility that tsunamis are effectively able to detach, move and scatter inland several, hundred, boulders of large dimension. In the same time, the capability of exceptional storms to move boulders has been evidenced in several areas of the world.

Recent papers suggested a hydrodynamic approach to study the boulders accumulation. Actually, the scientific debate on the interpretation of past boulders accumulation is very intense; in spite of the numerous bibliography, the question on the methodology useful to discriminate between storm and tsunami boulders accumulation is still open. Generally, Nott's equation, although criticized, are at the base of the most recent hydrodynamic formulas. Some recent model underlined the necessity to perform accurate field surveys to improve the survey's methodology to obtain the correct data (a-, b-, c-axis length, shape and weight) useful to correctly apply the formulas. The use of terrestrial laser scanner methodology in the case of the boulders present along the western coast of Sardinia permitted to quantify these features and to apply the most recent formulas. Jointly to C14 age determination on bio concretions present on the boulders surfaces, the digital analysis and the computer simulation permitted to individuate the event responsible for their accumulation.

Presenter e-mail: cmonaco@unict.it

Key terms: tsunami; monitoring; southeastern Sicily

The recent tragic event, which occurred in the Indian Ocean on December 26, 2004, and in Japan on March 11, 2011 has drawn the attention of the international community to the natural phenomenon known as tsunami. As these natural events cannot be avoided, the study of the evidence of their destructive effects due to past event can be very useful in drawing up vulnerability maps for coastal area under Tsunami risk. These may help to estimate the recurrence time of future possible events and to calculate the

maximum inland penetration of impacting waves: these factors are very important for establishing evacuation/intervention plans and for locating appropriate shelter locations. South-eastern Sicily is one of the most seismically active areas of the central Mediterranean, marked by a high level of crustal seismicity producing earthquakes with MCS intensities of up to XI-XII and M~7, such as the 1169, 1693 and 1908 events. Several earthquake-generated tsunamis struck the Ionian coast of southeastern Sicily in historical times (AD 1169, 1329, 1693, 1818, 1908, 1990). According to most of published geological data and numerical modelling, the seismogenic source of these events should be located in the Messina Straits and in the Ionian offshore (the Malta Escarpment) between Catania and Siracusa. Geomorphological evidences of extreme waves impact are present all along the coast of southeastern Sicily between the town of Augusta and Capo Passero. Scicchitano et al. (2007) described boulder deposits related to tsunami and storm generated waves between Augusta and Siracusa. Hydrodynamic estimations and radiocarbon age determinations suggested that three distinct tsunami events (1169, 1693, 1908) were responsible for the deposition of the biggest isolated boulders and boulder fields. Scicchitano et al. (2011), using TLS and DGPS techniques, estimated the maximum inland penetration for the tsunami waves responsible for the deposition of the biggest boulders located in Maddalena Peninsula (Southeastern Sicily, Italy) applying the Pignatelli et al. (2009) method. Calculations provided results in good agreement with the morphological evidences of Tsunami impact and they highlighted the necessity to improve the topographical, morphological and infrastructural dataset in order to improve the accuracy of the estimations and to extend them to other area.

The aim of this work is to generate a geo-database for the area of Siracusa (Southeastern Sicily, Italy) including geomorphological evidence of past Tsunami and storm generated waves impact as well as: detailed topographical and morphological data (DEM 2x2, Orthophoto, TLS, DGPS), ondametric wave parameters dataset (RON, RMN), marine geophysical data (SBES, MBES, SSS, SPBP), infrastructural data (industrial areas, road, railway, shelters, etc...) together with the dataset provided from geoportale SITR (Sistema Informativo Territoriale Regionale - <http://www.sitr.regione.sicilia.it/>) to provide through GIS applications maps of vulnerability for the coasts of Southeastern Sicily to Tsunami and storm generated waves impact and to furnish the background of possible monitoring development.

MITIGATION OF TSUNAMI IMPACT: LESSONS FROM JAPAN 2011 TSUNAMI

MASTRONUZZI Giuseppe¹, KASUHISA Goto²

1 - Dipartimento di Scienze della Terra e geo-ambientali, Università "Aldo Moro", Bari, Italy

2 - Planetary Exploration Research Center, Chiba Institute of Technology, Chiba, Japan

Presenter e-mail: g.mastrozz@geo.uniba.it

Key terms: Tsunami; mitigation; Japan 2011 tsunami

On March 11, 2011 at 1446 local time (0546 GMT) a terrible earthquake which magnitude has been evaluated from 8.8 to 9.0 struck the bottom of Pacific Ocean about 250 miles northeast of Tokio. This earthquake was the fifth largest in the World since 1900.

The consequent tsunami was detected by the Pacific Tsunami Warning Center; it travelled in the open ocean not particularly large but with a speed evaluated in about 250-400 knots in function of the ocean depth. When these powerful waves approached shallow waters along the coast, their velocity slowed and their energy was dissipated; they consequently grown to a great height before smashing into the shore with a speed ranging from 40 to 80 knots and an incredible residual energy.

Japanese Tsunami hit essentially the coasts of Fukushima, Miyagi and Iwate Prefectures killing thousands of peoples and destroying cities and structures; 12 hour late waves reached the coast of California in USA. All the cited coasts were not unprepared; several tsunami hit these regions in different time. On 869 Jogan tsunami occurred devastating the Sendai coastal plain. A millennium after, on June 15, 1896 the Great Meiji Sanriku tsunami struck the coast of Sanriku few kilometres north to Sendai; the earthquake occurred about 150 km off the coast and waves reached about 38 m above mean sea level; about 22000 peoples were killed. More recently, on 1933 the city of Kamaishi - after to have been damaged by Meiji tsunami - was seriously damaged by the Showa tsunami. In the very recent past 1960, Chilean tsunami hit Matsushima, Kesennuma, Oofunato, Ryori Bay and Kamaishi again. The 2010 a new Chilean tsunami produced limited damages in Kesennuma city.

This long and incomplete list of tsunami that hit the northeast coasts of Japan induced the realisation of extensive operas in junction to early warning systems, evacuation plans and, at last but not least, the education of the population, all together devoted to the mitigation of the impact of tsunami. Breakwaters, seawalls, automatic tidal gates, evacuation areas, escape stairways, network of light, vertical and horizontal signs and acoustic alarms, wave buoys have been widely realised all along the coasts where human lives need to be protected. Notwithstanding the big number of human casualties and the immense economic damages, the effectiveness of the warning centre alarmed the peoples in the about 5 minutes following the earthquake and the identification of the approaching tsunami, saving numerous peoples. In some cases, like that of Arahama village, breakwaters and seawalls didn't produced any protection and the village was destroyed. The biggest lessons from the Japan 2011 tsunami is the necessity to predispose a correct planning in coastal use and urbanisation.

CRITICAL ISSUES CONTROLLING THE EFFECTIVENESS OF RESPONSE TO VOLCANIC CRISIS

ROSI Mauro¹

1 - Dipartimento di Scienze della Terra, Università di Pisa

Presenter e-mail: rosi@dst.unipi.it

Key terms: volcanic eruptions; signals monitoring; forecasting

There is a widespread perception that, in contrast to earthquakes, volcanic eruptions can be effectively forecasted (or will be soon successfully forecasted) thanks to the rapid technological advancements and expansion of instrumental networks. However, a revision of the volcanic events of the past four decades demonstrates that unrest volcanic signals are often difficult to separate from actual forecasting signals so that the risk of either false alarm or lack of alarm is still high. Moreover, the perception that expansion of technology represents the only effective way to fulfil eruption forecasting has often pushed geological studies of individual volcanoes to a second order rank of importance. The revision of some recent eruptive crisis actually indicates that solid knowledge of the structure and magmatic/eruptive behaviour of individual volcano provides invaluable elements for the reliable interpretation of pre-eruptive signals and for the definition of the expected scenarios. Perhaps the major challenge of third millennium relies on the capability to combine in a balanced way basic studies on active volcanoes and instrumental monitoring aimed at eruption forecasting also in view of cost/benefit analysis. The effectiveness of response to volcanic crisis finally requires the full integration of the scientific and civil protection functions.

EARTH OBSERVATION APPLICATIONS FOR CIVIL PROTECTION: THE EXPERIENCE OF ASI PILOT PROJECTS

CANDELA Laura¹, ZOFFOLI Simona¹

1 - Italian Space Agency

Presenter e-mail: laura.candela@asi.it

Key terms: Earth Observation applications; Multi-mission EO data; Civil Protection; Pilot projects

Earth Observation satellite systems provide key data to generate information that can be very useful to support decisions in all phases of the risk management; the research has already demonstrated technological capabilities and more national and international programs are working to prepare a sustainable and operational use of such innovative tools.

For hydro-geological and geophysical risks management, ASI pilot projects aim at demonstrating the performance improvement of state-of-art system for the civil protection from floods, landslides, seismic and volcanic risks when Earth Observation from space is used in conjunction with ground data.

Such systems covers various phases of the risk management, from the planning and preliminary vulnerability assessment to the prediction, the emergency management and the post-event damage assessment. Using specific data and models and a variety of satellites and sensors, the demonstrations build on the feeding of a large number of EO products and services to support decision, delivered to central and peripheral Functional Centers.

Joining the efforts of the Italian Space Agency in particular with the new COSMO-SkyMed mission and the Italian Civil Protection with the newly up-scaled Network of Functional and Competence Centers, the projects have been designed and implemented in order to produce such a kind of assessments within a three-year implementation and demonstration period.

The presentation illustrates also significant experiences made during real emergencies.

Key terms: Lava flows; Hazard; Cellular Automata; Mt. Etna

The use of thematic maps of volcanic hazard is of fundamental relevance to support policy managers and administrators in taking the most correct land use planning and proper actions that are required during an emergency phase. Typically, a volcanic hazard map divides the volcanic area into a certain number of zones that are differently classified on the basis of the probability of being interested by a specific volcanic event in future. Mapping both the physical threat and the exposure and vulnerability of people and material properties to volcanic hazards can help local authorities to guide decisions about where to locate critical infrastructures (e.g. hospitals, power plants, railroads, etc) and human settlements and to devise mitigation measures that might be appropriate. This could be useful for avoiding the development of inhabited areas in high risk areas, thus controlling land use planning decisions.

The methodology for defining high detailed hazard maps here presented is based on the simulation of an elevated number of events, by using the latest release of the SCIARA lava flows computational model. In particular, the methodology requires the analysis of the past behavior of the volcano, for the purpose of classifying the events that historically interested the region. In such a way, a meaningful database of plausible simulated lava flows can be obtained, by characterizing the study area both in terms of areal coverage, and lava flows typologies. Data is subsequently processed

by considering that different events can occur with different probabilities, which should be taken into account in evaluating the actual contribution of performed simulations with respect to the definition of the overall hazard of the study area. In most cases, such probabilities can be properly inferred from the statistical analysis of past eruptions, allowing for the definition of a more refined evaluation criterion. While this methodology permits the definition of general hazard maps, which can *per se* give valuable information to Civil Defense responsible authorities, more specialized applications can be devised by considering that the SCIARA simulation model is integrated in a GIS (Geographic Information System) application that permits, besides other features, to take also into account the effects of "virtual" embankments, channels, barriers, etc. In addition, the fact that a large number of lava flows of different eruption types, magnitudes and locations are stored in the database, a rapid extraction of various scenarios is possible. Civil Defense oriented applications can regard the possibility to identify all source areas of lava flows that are capable of affecting a given area of interest, such as a town or a major infrastructure (e.g., hospitals, power plants, etc.), while other specific category of simulation can regard the assessment of protective measures, such as earth barriers or channel digging, for mitigating lava invasion susceptibility. In this work, we present some applications to inhabited areas of Belpasso, Nicolosi, Zarrerana and Bronte located on Mt. Etna flanks, demonstrating the methodology's full suitability for land use planning and civil defense.

3 - Dipartimento di Chimica «Giacomo Ciamician», Alma Mater Studiorum Università di Bologna

4 - Laboratorio di Ingegneria Nucleare di Montecuccolino, DIENCA, Alma Mater Studiorum Università di Bologna

Presenter e-mail: giorgia.cinelli@unibo.it

Key terms: Vulsini Volcanic Products; Natural Radioactivity; Radiological Risk

The exposure of humans to ionizing radiation from natural sources is a continuing and inescapable feature of life on Earth. There are two main contributors to natural radiation exposure: high-energy cosmic ray particles incident on the Earth's atmosphere and radioactive nuclides present from the origin in the earth crust and ubiquitous in the environment, including the human body itself. Among the natural radionuclides (the so-called primordial radionuclides), only those having half-lives comparable to the age of the Earth, together with their decay products, exist in significant quantities on the planetary scale. Irradiation of the human body occurs both externally and internally. External irradiation is mainly due to gamma radiation from radionuclides in the 238U and 232Th series as well as from 40K, while internal irradiation arises from the intake of terrestrial radionuclides by inhalation and ingestion. Doses by inhalation result from the occurrence in air of dust particles containing radionuclides of the 238U and 232Th decay chains; the dominant component of inhalation exposure are the short-lived decay products of radon.

For most individuals, this exposure exceeds that from all man-made sources combined.

In nature some other terrestrial radionuclides, including those of the 235U-series, 87Rb, 138La, 147Sm, and 176Lu, exist but at such low levels that their contributions to the dose in humans is negligible.

In the quaternary potassic magmatism of the Vulsini Volcanic district, a large volcanic area located between northern Latium and southern Tuscany, processes of magma genesis and evolution produced a significant enrichment of radioactive isotopes, such as U and Th, 1-2 orders of magnitude higher than their average crustal concentration.

Samples from this area were collected and γ -spectrometry measurements of natural radionuclides conducted by means of two Hyper Pure germanium crystal detectors (HPGe).

In the Vulsini area volcanic products, such as lavas and tuffs, have been and still are widely used as building material, the origins of which date back to the Etruscan age. Because of their high concentrations of U, Th and K in this materials (up to 21 ppm, 78 ppm and 8 % respectively) the assessment of doses (both external and internal) is of fundamental importance: this is carried out in agreement with the two recommendations issued by the European Commission, dealing with indoor exposure to members of the public from natural radiation.

In addition to the dose assessment, the goal of this work is also the evaluation of the risk in a standard "house" followed by its comparison with the risk in other situations of average life conditions.

MARINE CARTOGRAPHY CONTRIBUTION TO GEOHAZARD ANALYSIS AND NEOGENE-QUATERNARY GEODYNAMICS IN LIGURIAN AND CALABRIAN MARGINS

FANUCCI Francesco¹, MORELLI Danilo¹

1 - DIGE - Università di Trieste

Presenter e-mail: fanucci@units.it

Key terms: Geohazards; Neotectonic; Sequence Stratigraphy; Marine geological Cartography

Marine geology data collected within various national and international research projects have been used for geohazard investigation and risk analysis in the Ligurian and Calabrian Margin.

In some areas, detailed 3D reconstructions of surficial and deep-seated morphostructural settings, allowed:

- the identification of the main geo-hazard elements;

- a better reconstruction of their characters;

- a better comprehension of the interaction processes responsible for their quick morphodynamic evolution.

The research has been focused to recent, surficial and deep-seated mass wasting and to their triggering mechanisms such as high sedimentary

input, seismo-tectonic activity and occurrence of gas-charged sediments. Most detailed analyses of some representative cases have confirmed the complexity of the geohazard evaluations and have arisen some, still open, crucial problems.

On the other hand, the geological marine cartography, began with the CARG Project, showed the structure, the recent evolution and the peculiar characters of some sectors of Italian margins.

In Ligurian region the Apennine margin (Sheets La Spezia and Massa), characterised by prevalent disjunctive tectonics, shows a system of thrust faults active in Upper Pliocene and Lower Pleistocene. The sequence stratigraphy of final Pleistocene and Holocene deposits put in evidence three main phases of post-glacial transgression and several testimonial of other eustatic cycles in the Middle and Upper Pleistocene formations. The alpine margin (Sheets Ventimiglia, San Remo and Imperia), very narrow and steep, is affected by a frequent and widespread seismic activity mainly at the base of the slope, where some tectonic lines, originated as transform faults during the opening of the Ligurian Basin, are reactivated as transpressive or thrust faults by a recent tectonic phase. The CARG, MAGIC and MALSAR projects highlighted the structural complexity of the continental slope whose peculiar morphology is determined by tectonics, retrogressive erosion and by several important landslides.

The pleistogeography during the last lowstanding of sea level and during the Younger Dryas has been reconstructed around the Elba Island. This work also clarified the nature of the thrust tectonics that characterizes the recent activity of Pianosa and Capraia Ridges.

NATURAL HAZARDS AND INDUSTRIAL SAFETY MANAGEMENT

CIUCCI Mariano¹, MARINO Alessandra¹

1 - INAIL ex ISPESL

Presenter e-mail: mariano.ciucci@ispesl.it

Key terms: Safety Management; Seismic Hazard; Hydrogeologic Hazard; Industrial Hazard

In the Italian territory about 1/3 of municipalities are located in areas exposed to seismic hazard. At the same time most of the Italian territory is subject to hydrogeologic events (i.e. landslides and floods). The area object of this study, Sulmona Basin and upper Pescara Valley, is characterized by potential exposition to these hazards, with a particular attention to seismic hazard and landslide hazard. Furthermore the area is characterized by the presence of major hazard industrial plants.

For this paper a dedicated GIS database has been built in order to evaluate the interactions between specific natural hazards and industrial hazard and the related vulnerability of territory and population. For this research MIVIS hyperspectral (at a 1500 and 3000 m elevation) images have been used. The obtained images have been georeferenced. From the processing and classification of these images some information layer have been obtained: thematic maps of land-use (industrial areas identification), vegetation conditions, thermal pollution, quality parameters (temperature, organic matter, chlorophyll, sediments) for river waters. Thematic maps obtained from remote sensing have been inserted in a GIS, that means a system to insert, store, integrate, extract, retrieve, manipulate and analyze georeferenced data layers in order to produce interpretable information. Then the data base has been integrated with further information inserted as continuous layers; thematic layers; vector layers; punctual data; attributes. Among inserted layers: location and information regarding industrial plants, seismic classification, local seismic amplification maps, landslides and landsliding hazard maps. Some specific operators (overlying, proximity analysis, recoding, matrix analysis) have been applied that allowed to integrate the information contents and therefore to obtain final thematic maps (hazard maps, vulnerability maps, events scenarios). The innovative technologies proposed facilitate and optimize the management of data and information obtained from different methodologies. Therefore it is useful to develop innovative methodologies in order to support industry and Competent Authorities in safety management and land use planning.

INSURANCE SOLUTION FOR NATURAL RISKS

ZACCONE Andrea¹, MELZI Carmela², TOFFALONI Carlo¹

1 - Regione Lombardia

2 - Regione Lombardia

Presenter e-mail: andrea_zaccone@regione.lombardia.it

Key terms: natural risks; cover; insurance; reinsurance; regional scale

As a commercial product for the covering of natural risks for private buildings still lacks, RL has developed a project for the exploration of the real chances of insurance solutions for purpose-built houses since 2006. During the first part of the project, RL, has tried to understand the practicality of the project. One of the hypothesis analyzed was the constitution of a Reassurance Company, which would encourage insurance companies to the covering of natural risks. The second part of the project was dedicated to the analysis of risk data necessary for the building of a quantitative basis for the study, which could evaluate the sustainability of natural risks by the insurance system, and, consequently, the convenience of such a policy for subscribers. Concerning this, the results of the analysis conducted with ANIA demonstrate a real possibility to have a sustainable product at a regional scale.

Key terms: Northern Sicily continental margin; Geohazard; Morphobathymetry; Submarine landslides; Volcanic activity

Slope instability and erosion, mass transport, volcanic and tectonic activity, fast sediment accumulation, fluid escaping are the main processes responsible for the geohazard in marine environment. A major knowledge about the geological setting of the offshore areas and related processes can be crucial to assess and manage the potential geological risks.

High resolution morphobathymetric surveys, yielded in the frame of the MaGIC project (Marine Geohazards along the Italian Coasts), integrated with previously acquired data, single-channel seismic reflection profiles, backscatter data (sss) and sediments sampling, allow to define the geomorphological, stratigraphic and structural features in the offshore sector located in the north-western Sicilian continental margin and in the Ustica area (Southern Tyrrhenian).

The main goals are: 1) to identify and map the main morphological-structural lineaments of the study area; 2) to correlate the main structural lineaments on- and offshore; 3) to highlight the instability phenomena of the continental slope, being the area seismically active; 4) to draw up risk maps and to individuate the main dangerous sites. Along the continental shelf to slope system we recognized erosional and depositional features, structural elements at regional and local scale, submerged volcanic edifices, structures related to fluid escape as mud volcanoes and pockmarks.

On the basis of the mapping of morphostructural elements, and their integration with seismic data and sampling, we identified the most likely elements of geological hazard. In detail we individuated: 1) in the Gulf of Palermo, canyons making the continental slope very rough, also due to the occurrence of widespread mass wasting; 2) between the Gulf of Castellammare and the offshore of the Palermo Mountains, channels and erosional furrows, slumpings, turbiditic fans, landslides, pockmarks and tectonic lineaments; 3) in the offshore of Ustica island, volcanic structures, some of which aligned parallel to tectonic lineaments as Arso fault.

The quantitative, GIS analysis allowed a better assessment of the real geohazard. Further investigation on the geological processes, ages of paroxysmal phenomena (eruption, landslides and earthquakes) are necessary to define the most appropriate monitoring strategies in order to assess possible risks for the coastal area and its infrastructures.

Presenter e-mail: laura.turconi@irpi.cnr.it

Key terms: geo-hydrological hazard; historical data; civil protection; chronological map events; Piedmont Region

The study here proposed is based on the historic analysis of landslide, flood and debris flow events which in the past have brought damages and deaths in the Piedmont. We may postulate that everywhere a debris flow or a streamflood process has occurred earlier, it will do the same in the future, possibly with enhanced or catastrophic effects if in the meanwhile buildings or infrastructures have been settled in vicinity; in that case a careful research not only into the present-day conditions of the concerned catchment(s) but also throughout the historic sequence of the events, should be a priority. Here we deal with a method of search based on multi-temporal aerial and terrestrial photographs, historic maps, archival and bibliographic documents. The bulk of the data refers to descriptions and chronicles of torrential flood events since 16th Century and especially concerning the last two centuries. Selected events have been investigated depending on the effects witnessed in the territory. A purposely-made database has been drafted through software ArcGIS® 9.1 (ESRI) at 1:10.000 scale. Selected informations have been ranged according key words in order to make easier to acquire the objects, even through direct access according to the Regional Alert Zones. Information is also available concerning the total number of known events for all torrents in the whole period taken into account (until 2006). Time-series analysis organized in 3 frequency classes allowed to select the streams which came into extreme flood in the last 30, 50 and 70 years. In the Piedmont 1050 flood-prone watercourses have been detected, 80% of which (i.e. 852) have been correctly mapped. Historical data on natural hazards have allowed for the first time in Italy to group different chronological and spatial units in the ambit of several valley systems, of the effects and damages over the territory. Such distribution is moulded through some 3000 case/events recorded over a time span of 400 years. In particular, it is since now possible to evidence, qualitatively, the different combinations or groupings of small basins distributed over the alpine area as a function of different meteo-hydrological events which originated torrential flood phenomena. Depending of the different liability to occur, processes and effects induced by extreme events in a given catchment or locality are thus enhanced, considering that they have occurred according a sum or combination of a set of concurrent physical preparatory causes, much differentiated not only according to the different geological, geographical, morphological and climatic sectors of territory but also according to the geologic-dynamic history. Based on the data base realized it is possible to broadly re-arrange different alert steps in case of incoming, possibly critical meteorological conditions. Results provided by the research above illustrated are to be regarded as a basis for a set of rules issued from Regione Piemonte, in accordance with a National statement (DPCM 27/02/2004): the Ordinance 25/06/2008 No. 14-9023 has established the institution of the so-called 'hydraulic and hydro-geological presidia of civil protection'. They are defined according to technical considerations and classified in three levels. Prevention and operational interventions throughout the whole areas are so ensured, especially concerning: possibly in conflict with flood dynamics; monitoring for avoiding possibly arising hazard; hydraulic survey; logistical supporting; spreading out civil protection actions according to communal plans. Several Bodies and Institutions, as well volunteers by hundreds are involved in operations virtually provided by hydraulic presidia. The presidia are activated by the Provinces in cases when the Functional Regional Center has issued the meteorological alert bulletin, instituted by Resolution 30/07/2007 No. 46-6578; exceptionally, the activation may start on request by Communes, Region and Prefectures

MOIST AIR AND SPELEOGENESIS: THE SUBTERRANEAN CLOUDS

BADINO Giovanni¹

1 - Dip. Fisica Generale Uni-TO, Associazione La Venta

Presenter e-mail: badino@to.infn.it

Key terms: cave atmosphere; condensation in caves; caves energy balance

Many different micrometeorological processes are able to create vapor supersaturation in the cave atmospheres: ascending air parcels, pressure drop behind bottlenecks, mixing of saturated air parcels at different temperatures, water flow fragmentation and Raoult's processes.

The high purity of caves air tends to delay condensation, which is concentrated where airflows are in close contact to the cave walls. It can be shown that the rate of aggressive water condensation on the walls is usually comparable to the external rain deposition, sometimes locally much greater, and then can play a leading role in speleogenesis.

MICROCLIMATE AND MICROMETEOROLOGY OF MT KRONIO CAVE SYSTEM (SICILY): PRELIMINARY RESULTS

BADINO Giovanni¹

1 - Dip. Fisica Generale Uni-TO, Associazione La Venta, Progetto Kronio

Presenter e-mail: badino@to.infn.it

Key terms: air circulation underground; cave atmosphere; Stufe di San Calogero

Mt Kronio is a limestone massif fronting the sea near Sciacca, in the eastern part of Sicily. It is well known and has been cited since classical antiquity due to the presence, at the summit (370 m asl), of many cave entrances (Stufe di San Calogero and 30 other caves) with strong, exiting hot airflow (37°C, RH=100%), which were used for calidaria since the Greek times. In the past centuries, these caves were explored several times, but the hot atmosphere and a shaft allowed very limited visits. We will present a general overview of first microclimatic results obtained in the context of the research project "Progetto Kronio" (CGEB-La Venta). The mountain is crossed by very intense airflows, in part entering in the lowest part (Cucchiara cave) but the first studies with sonic anemometers in coincidence have shown a strong gap between the known entering and exiting airflows.

External and internal thermal and airflow mapping, are showing a complex heat flow structure inside Mt. Kronio. The Cucchiara caves shows an extremely strong thermal air sedimentation, with temperature gradients up to 6.5 °C/m and permanent mixing clouds at the separation layer between different air fluxes.

THE EFFECTS OF GLACIER DYNAMIC ON THE EVOLUTION OF ENGLACIAL CAVES: THE CASE OF GLACIAR PERITO MORENO - SOUTHERN PATAGONIA, ARGENTINA

MECCHIA Marco¹, PICCINI Leonardo²

1 - La Venta Esplorazioni Geografiche

2 - Earth Science Department - Firenze

Presenter e-mail: leonardo.piccini@unifi.it

Key terms: englacial drainage; cryokarst; glacier caves; Perito Moreno

In the last decades the glaciers of Southern Patagonian Andes have experienced a very fast and intensive retreat, due to the current strong ablation considered as an effect of the "global warming". The Perito Moreno Glacier is an exception of this "rule". In fact, the most famous characteristic of this glacier is the cyclical advancement of the front which can reach the rocky spur of the Peninsula Magellanes, closing the water passage between the two braces of Lake Argentino. This obstruction causes the lake's level in the branch above it to rise up to 25 meters. With the increased water pressure, infiltrations through the ice fissures also increase, opening a tunnel through the glacial mass, with the consequent collapse of the ice bridge and the return to the lake's equilibrium level. The causes of this peculiar behavior are not completely clear.

Actually, the Perito Moreno hosts several pseudo karst forms due to surface and internal melting and we suspect that this phenomena could have a role in the internal dynamics of the glacier. In its current state, the glacier has three areas having morphological and hydrological conditions suitable for the formation of glacier caves. All three contain well developed superficial drainage networks which feed bedièrre up to over a kilometer long. The ablation area, which is of direct interest in the search for glacial cavities, is a tongue 15 km long and on average 4 km wide.

A comparison of the distribution and morphology of glacier swallow-holes in 1995 and 2010 year,s indicates a fragmentation of the epiglacial drainage probably due to the upstream widening of the distension zone and to the gravitational collapse of the ablation area.

10.1474/Epitome.04.0209.Geoitalia2011

COMPARISON OF SOME KARST SYSTEMS BY TRACER TESTS

BANZATO Cinzia¹, FIORUCCI Adriano¹, MARCHIONATTI Federico¹, VIGNA Bartolomeo¹

1 - Dipartimento di Ingegneria del Territorio, dell'Ambiente e delle Geotecnologie, Politecnico di Torino

Presenter e-mail: adriano.fiorucci@polito.it

Key terms: karst; tracer tests; aquifer

The study of karst systems often requires a multidisciplinary approach

that incorporates different scientific disciplines, including hydrogeology, especially through some of its applications. Among the different hydrogeological applications, those that provide very interesting results are the monitoring of spring water, geochemistry of water and artificial tracer test.

The tracer test, in addition to investigate the borders of a hydrogeological karst system, can provide very useful information about the behavior of the aquifer. In particular, tracer test, can monitor with high detail the arrival of the dye to the source by using automatic data loggers. Through the breakthrough curve and its interpretation (shape of the curve, time of first arrival and peak, maximum concentration) it's possible to identify different types of aquifer (dominant drain network, interconnected drains and dispersive circulation systems). The relationship between the rate of first arrival time and peak time (maximum concentration of dye), provides a coefficient (RVH), which characterizes very well the different karst systems.

This paper compares the results of artificial tracer test performed in several karst systems located in Piedmont (Borello, Vene-Fuse, Bossea), Tuscany (Corchia) and Sardinia (Su Gologone). These karst systems are characterized by different hydrogeological networks. Systems Corchia Borello and Vene-Fuse seem to be set in highly developed karst networks with the presence of large collectors able to drain very quickly the water flow. Systems Su Gologone and Bossea have sections with a significant development in the saturated area with wide and deep siphons. Another test is performed in a portion of the unsaturated zone Bossea system, where the flow is mostly set in the fractured network in the rock.

The results of these tracer test show tracer breakthrough curves very different for the distinct systems examined. The values obtained from the ratio RVH, seem to identify very well the different types of system investigated, too. Tests performed in the same aquifer, but in different hydrodynamic conditions, show breakthrough quite different

THE CONTRIBUTION OF SPELEOLOGY TO THE SCIENTIFIC RESEARCH IN GROTTA GIGANTE (CLASSICAL KARST)

GRILLO Barbara¹, CUCCHI Franco², GUIDI Pino², VISINTIN Luca³, ZINI Luca¹

1 - Dipartimento di Geoscienze - Università di Trieste
2 - Commissione Grotte "E. Boegan" S.A.G. Trieste

Presenter e-mail: grillo.barbara@gmail.com

Key terms: Classical Karst; Grotta Gigante; speleology; diver; hydrogeology

The Grotta Gigante is one of the most interesting and important tourist cave in Italy, open to the public since 1908. It is located in the Classical Karst and it was discovered in 1840 by Antonio Federico Lindner, a mining engineer who in the early XIX century became involved in the research of the underground course of the river Timavo. The cave consists of a large room 165 meters long, 65 meters wide and 107 meters high with a total volume of over 300000 cubic meters. These dimensions have led the cave to gain a place in the 1995 Guinness Book of World Records as the largest tourist cave in the world. The morphology, the central location within the Classical Karst and the possibility to access it with ease, have encouraged, over the years, the use of the cavities as a scientific laboratory and a point of reference in Earth Science studies. Today the cave hosts two horizontal geodetic pendulums, two clinometers, an I.N.O.G.S. seismology station, some stations that measure the intensity of karst leaching and dissolution through TMEM, some continuous sensors for Radon.

Recent explorations have discovered a series of wells which allow the cave to reach an altitude of 18 meters above sea level, for a total depth of 252 meters. Thanks to the efforts of the CGEB - S.A.G. Trieste cavers during several years of excavation, a new frontier of study has opened for Grotta Gigante and all the Classic Karst. The new bottom consists of a wide well intercepting a tunnel (still under excavation) near the base level, along which there are visible signs of rising groundwater. In order to quantify these hydrological signals, at the end of December 2009 the Department of Geosciences of the University of Trieste has installed a Diver - CTD for the continuous measuring of the water level, conductivity and temperature. The records include nine months of data sampling registered every thirty minutes. On two times, the level has shown an increase of more than 30 meters, confirming the hydraulic connection with the Timavo system. This new station complements the extensive karst groundwater monitoring network managed by the Department and it will permit to implement the knowledge of the hydrodynamic Classical Karst.

10.1474/Epitome.04.0211.Geoitalia2011

HYPOGENIC CAVES IN ITALY: GEOLOGY AND SPELEOGENESIS

MENICHETTI Marco¹

1 - Università di Urbino - Dipartimento di Scienze della Terra, della Vita e dell'Ambiente

Presenter e-mail: marco.menichetti@uniurb.it

Key terms: hypogenic cave; karst; speleogenesis; CO₂

The speleogenesis of carbonate karst system is commonly related to the seepage of the aggressive meteoric water rich of soil derived CO₂. This epigenic process propagates downward from the surface to depth through the drainage network.

Through more than one century of speleological research in Italy, many limestone caves have been explored and mapped. These caves are characterized by a variety of patterns and morphology sizes including three-dimensional maze systems and deep shafts, with both endogenic CO₂ vents and active sulfuric streams. An integrate approach take in account geological, hydrological and geochemical settings in these underground karst systems, permitted to recognize a new important speleogenetic process related to the hypogenic origin. The main cave-forming processes are related to deep-seated hydrogeological recharge where limestone corrosion is driven by endogenic agents with an upward flow. The whole Italian peninsula is rich in volcanic, crustal and mantle-derived CO₂ and H₂S emissions and all the end-members of these karst processes can be found, from solution caves to carbonate travertine deposits. The main hypogenic cave-forming processes are related to the H₂S oxidation to sulfuric acid, by oxygen-rich groundwaters as well as in the atmosphere. Both phreatic and vadose corrosion reactions involve chemotrophic microbial activity, with sulfur-redox bacterial communities that generate sulfuric acid as metabolic product. The bedrock corrosion produce sulfate ions in the phreatic zone and gypsum replacement in the

limestone walls of the vadose sectors of the caves. The caves are characterized by both fossil and active passages in which water rich in H₂S as well as endogenic CO₂ plays a determinant role in speleogenesis. The cave morphologies suggest that the oxidation zone of H₂S is not restricted to the shallow groundwater levels but can be extended to deeper sections of the aquifer to which input of fresh water via a complex regional hydrogeological circuit could occur.

Although sulfuric acid-related speleogenesis typically produces gypsum deposits, in caves where the karstification processes are driven by subterranean CO₂ sources, voids and speleothems are the only final products.

The hypogenic cave are known in different parts of the world, from Central Asia to North and South America, and especially the underground fossil systems in the Guadalupe Mountains in New Mexico and Texas. In Italy, hypogenic caves are distribute along the whole peninsula with a concentration for largest and both fossils and active systems in the Tuscany, Umbria, Marche and Latium regions. These consist of few tens of kilometers of solution passages with galleries and shafts, which are characterized by large rooms, cupola and blind pits, anastomotic passages, bubble trails roof pendants, knife edges, and phreatic passages. In many cases, the caves are developed at several levels related to the evolution of an external hydrographic networks. The smaller karst systems have a ramiform pattern of several large rooms with wide ceilings that end abruptly in narrow passages or fissures. Phreatic passages, often anastomotic, are also spread over large parts of the cave, where they constitute some network zones. Active smaller karst systems are known in Southern Italy related to the geothermal anomaly associated with CO₂ and H₂S degassing in Apulia, Campania and Sicily.

Even though the general speleogenetic reactions are known, the precise geological, hydrogeological and geochemical conditions of their occurrence need to be documented, in particular the role of gases (H₂S, CO₂) and their association with other mineral species. Hydrogeology and, especially, hydrochemistry are key in understanding the space/time evolution of the hypogenetic karst systems.

Presenter e-mail: sbiolchi@units.it

Key terms: coastal caves; coastal geomorphology; Istria; Gulf of Trieste

Istrian coast is almost completely carved on limestones, on which many coastal and submerged caves have been surveyed. These caves are well known by divers and fishermen, but no systematic studies have been carried out. Their present position with respect to the sea level suggests the joint contribution of different factors, both marine and subaerial, in the morphological evolution of the studied caves. In particular, we carried out a systematic underwater explorations of 5 coastal caves, along the shoreline of the Gulf of Trieste and Istria. The detailed surveying allowed to identify and evaluate the relationships between subaerial and seawater processes related to their widening and to produce a matrix embodying the genetic factors.

The studied caves are located at Duino, Rovinj, Stoja, Premantura and Brsec. They develop at the sea level and are partly emerged and partly submerged. Moreover, their entrance is always at present sea level. The surveyed caves are not much extended (max 20 m in length) and they are small in size.

The geological surveying of coastal caves in the Gulf of Trieste and in Istria suggested that they are developed mainly following faults, fractures and joints. The bottom of the all caves are covered by rounded cobbles and blocks, mainly in the inner sectors, due to the wave abrasion effects. Even if abrasion interests mainly very exposed coasts while in very sheltered coasts, as the northern Adriatic sea, limestone coastal morphologies are mainly due to bioweathering (De Waele & Furlani, 2010), the pressure effects of entering waves can easily produce abrasion forms. Even the walls that are in contact with these blocks are very smoothed. Potholes, up to 1 meter in size, can be found, sometimes filled by sediments. Even very smoothed rocks can outcrop at the bottom, usually where the bottom of the cave is sloping. Different kinds of speleothemes have been observed in the emerged position, while the submerged part is completely abraded by waves. No tidal notch occur, but sometimes wide submerged abrasion notches have been found. At Premantura this notch is very deep and wide, probably because of the exposition of the coast.

Considering the size of the caves, the results of sea level change studies concerning the tectonic subsidence of the area (Antonoli et al., 2007; Faivre et al., 2011; Furlani et al., 2011), their genesis probably started in a subaerial position, as suggested by the occurrence of speleothemes and scallops. Seawater effects, such as bioweathering, solution and abrasion affected mainly their recent morphological development, when sea level reached the present-day position.

LONG-TERM EROSION RATE MEASUREMENTS IN CUEVA DEL AGUA GYPSUM CAVE (SORBAS, SE SPAIN)

CALAFORRA José Maria¹; SANNA Laura¹; DE WAELE Jo²; FORTI Paolo²

1 - Water Resources and Environmental Geology Research Group, University of Almería, Spain

Key terms: Micro-Erosion Meter (MEM); gypsum karst; condensation-corrosion; Cueva del Agua (Almería, Sorbas); Spain

The present work deals with the results of long-term micro-erosion measurements in gypsum caves of Sorbas (Almería, SE Spain). It focuses on the Cueva del Agua, a cave with 34 upper entrances developed in gypsum rocks of Messinian age. The 12 km square-large karst massif of Sorbas is characterized by the almost complete lack of surface waters during most of the year and by an important well developed underground and active drainage network. Cueva del Agua is characterised by several small shafts that allow access to a 8.9 km-long series of sub-horizontal passages excavated along fractures, some of them developing vadose canyons. The micro-erosion meter stations are located at different positions and environmental situations along the main passage of the cave. Measurements have been carried out up to four times over a period of 18 years. The observations allow to collect important information on the recharge of the karst aquifer not only by rain water infiltration, but at the present climate conditions also by water condensation of air flow.

GYPSUM KARST SYSTEMS OF SOUTHERN-CENTRAL SICILY (SOUTHERN ITALY) AS POWERFUL MARKERS IN GEOMORPHOLOGICAL STUDIES

DI MAGGIO Cipriano¹, MADONIA Giuliana¹, VATTANO Marco¹

1 - Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo

Presenter e-mail: vattano@unipa.it

Key terms: Gypsum karst system; geomorphological evolution; erosion base level; Sicily

The importance of the gypsum karst systems in the geomorphological studies has long been recognized by many scholars. Gypsum karst systems are generally characterized by: a) few and large drainage tubes with narrow secondary tributaries; b) main passages accommodated to the highest discharge; c) different storeys of sub-horizontal galleries connected by deep shafts, developed generally in adjustment to the contemporary geomorphological setting; d) impossibility of developing conduits under the water table; e) rapid adjustment to the karst base level fluctuations.

The aim of this paper is to show the results of geomorphological studies carried out in several evaporite karst areas of southern-central Sicily, on the basis of the relationships between surface landforms and forms of underground gypsum karst systems.

The study areas are characterized by surface landforms due to downcutting processes, e.g. fluvio-karst canyons and V-shaped valleys, and to "planation" processes, such as karst planation surfaces, erosion glacia on soft rocks and marine terrace surfaces, developed downward in an arranged succession between 600 m a.s.l. and the actual sea level. Landforms produced by selective erosion and deep-seated gravitational slope deformation phenomena, connected to increased relief energy, have been also surveyed.

The gypsum karst systems consist generally of different storeys of sub-horizontal passages, connected by vertical shafts, and several narrow tributaries frequently filled by alluvial sediments.

The surface "planation" landforms and the underground sub-horizontal galleries have been correlated with stillstand phases of erosion base level, whereas the surfaces forms due to downcutting processes and the underground shafts have been associated with lowering phases of erosion base level.

Dataset analysis and comparison between surface and hypogean karst landforms allowed both to recognize a sequence of events, linked to stillstand or following lowering phases of the regional erosion base level, and to establish a temporal order of events responsible of the geomorphological evolution of these areas of Sicily.

Presenter e-mail: gueguen@imaa.cnr.it

Key terms: Morphostructural analysis; Karst; Alburni Mountains; southern Italy

The Alburni Mountains, in the area of the Cilento and Vallo di Diano National Park, represent the most important karstic area of southern Italy with around 500 registered caves and some important touristic sites (Castelcivita and Grotta dell'Angelo caves). The carbonate massif has been the goal of many speleological exploration campaigns since the early '70s. However, its geological and hydrogeological setting, and the karstic evolution, are still poorly known.

Aim of this work is to investigate the relationships between geological structures and cave development using a new geomorphological approach based on cumulative curves of geological and geomorphological data.

The Alburni Mts are mainly built of Mesozoic-to-Cenozoic carbonate rocks of the Alburni-Cervati Units belonging to the Campania-Lucania carbonate platform. They represent a huge 1500 m thick, southward dipping, monoclinical structure, which is locally overlain by Tertiary flysch units trapped in half-graben basins. The massif is limited to the NW by an important normal fault zone, whereas towards the NE it is limited by a complex fault system linking the Alburni Mts to the Monti della Maddalena structure across the Auletta basin and the Vallo di Diano valley.

The entire massif is structured by NW-SE trending transtensional fault systems delimiting the half graben basins, and offset by NE-SW trending faults.

In this paper, we have considered three sets of caves belonging to the different structural sectors identified in the Alburni massif:

1- caves located at the NE boundary;

2- caves located at the central portion of the massif;

3- caves located at the NW boundary.

A geological survey has been conducted within and outside of the caves to collect structural data. A morphological study has been performed on the horizontal maps of the caves in order to identify the main directions of cave development.

The first result of this work is that cumulative curves have shown to be a powerful analysis tool for comparing different types of data. The study has also confirmed the existence of different families of caves in the massif according to their location. Finally, the development of the caves is not only controlled by the main direction of structures at the map scale but also by local structures that in some cases play a major role.

CAVES STUDIES IMPORTANCE IN THE UNDERGROUND INFRASTRUCTURES DESIGN

VISINTIN Luca¹, CUCCHI Franco¹, ZINI Luca¹, GRILLO Barbara¹

1 - DIPARTIMENTO DI GEOSCIENZE-UNIVERSITA' DI TRIESTE

Presenter e-mail: lucavisintin@alice.it

Key terms: UNDERGROUND INFRASTRUCTURES; CLASSICAL KARST; STATISTICAL ANALYSIS; KARST; GEOMORPHOLOGY

The caves are the most characteristic landforms of karst rock masses. While the superficial forms often reveal the presence of a network of drainage well developed in depth, on the other hand, the correct location of the voids is extremely important in particular during the design of underground infrastructures. It follows that each new exploration of the underground environments contributes both to the statistical analysis of the karstification of the rock masses in a large scale and to a detailed hypogean feature analysis; it permits, with the interpretation of the recognized forms, to reconstruct and to assume the distribution of karst in the whole rock volume.

The Trieste Classical Karst claims a century-old tradition of caving that led to the discovery of nearly 3000 cavities; these explorations contribute substantially to the definition of karst criticalities in the land-use planning and in the infrastructures design. The analysis of the underground features distribution, their morphology and their genesis, together with a detailed study of the karst surface, allow the creation of thematic maps that represent the true strengths during the dialogue between karstologists and planners or local governments.

Recently, the Classical Karst has been interested by the design of an important high-speed/high capacity railway artery which will link the Western Europe trades and the Eastern Europe ones; the difficulties in the design and in the construction of this infrastructure in an heavily karstified area have already emerged during the feasibility studies. In particular, preferring to advance with underground construction techniques, the statistical studies on the distribution of the cavities in the rock volume has been the determining factor in the most suitable paths choosing; that has been both in an engineering point of view and in a perspective of their impact on groundwater resources and on the overall hypogean environment.

SCIENTIFIC RESEARCH IN SOUTH CHINA KARST OF THE CIVIC MUSEUM OF NATURAL HISTORY OF VERONA (ITALY)

ZORZIN Roberto¹, KANGNING Xiong², LATELLA Leonardo¹

1 - Museo Civico di Storia Naturale di Verona, Italy. Commissione Speleologica Veronese

2 - School of Geography and Biology Science, Guizhou Normal University of Guiyang, China

Presenter e-mail: roberto.zorzin@comune.verona.it

Key terms: scientific research; speleological explorations; South China

The results of 13 scientific expeditions organized since 1992 by Civic Museum of Natural History of Verona (Italy) to southern China are described and discussed. One-hundred-twenty-five caves were explored, for a total of more than 60 km in length. All the expeditions were multidisciplinary: they involved Italian speleologists, geologists, biologists, geographers, archaeologists and medical doctors. As a consequence, the results were very interesting and detailed, but the organizers had to face relevant difficulties related to the logistics and coordination of the activities. In fact, even if the research were conducted mostly in caves, the exploration of the surrounding areas took place as well, including study of water quality of superficial water bodies, of soil fauna, geological referencing, Radon measurements, and studies on human geography, water use and land management.

Regarding the more technical-speleological aspect, the large size of the most of the caves allowed for shortened investigation times by easing the exploration, combined with quite high air and water temperatures, allowed the researchers to remain for longer periods in the caves. As a consequence, in several cases, it was possible to collect replicate samples. A total of about 80 Italian (70 speleologists) and 200 Chinese researchers participated to the 13 expeditions. In particular, the 2000, 2001, and 2003 expeditions in Guizhou (Qianxi County - Honglin area) have been relevant for the amount of people and for the consequent amount of collected data.

The karstic area of Honglin has all the features for a turistic evaluation. Nevertheless, it should be noted that the karstic environments in the surroundings of Honglin are characterised by a fragile equilibrium. In fact, the elevated permeability of the rock substrate, the presence of water courses linked in diverse ways with the karstic basins and vice versa, imprint on the territory a remarkable vulnerability, especially in the case of an eventual rapid "turistic development" of the settlement center of Honglin without the realisation of the principal infrastructures needed for a correct management of the territory (adequate sewage system, correct disposal of swine effluent, improvement of the large refuse dump present in one of the caves, etc.). The caves in southern China could be considered a real resource.

From the biospeleological point of view, the Verona Museum research in China caves led to a record in the field of more than 200 taxa. Some of them have not yet been identified at the species level, some were already studied, and some are still in study.

Based on present knowledge, the area of China with the highest number of troglitic species is Guizhou Province. Several biological and paleogeographical factors analysed allow to hypothesize that Guizhou caves acted as refugial during the plio-pleistocene climatic events. The

alternation of numerous warm and cold periods allowed the colonization of the same caves, on different occasions, by species which are now taxonomically very close, but with a different degree of adaptation to life in caves. This hypothesis is supported also by paleogeographical and paleoclimatic studies which show the alternation of cold and warm periods in all China by the means of paleopollen, sedimentary series and fossil fauna distribution.

The elaboration of the data collected, together with the charts produced during the research, provide a useful tool for the protection and evaluation of the hypogean environments and the surface and subterranean water resources and also allow a more correct management of the environmental resources and local economy to be planned. These are, in fact, the basic principles of the concept of "sustainable development".

2 - Garyounis University, Benghazi, Libya

Presenter e-mail: info@cirrs-ragusa.org

Key terms: Libya; Cyrenaica; Karst; Speleology

A campaign of investigations has started in 2007 aiming at studying the karst morphologies of the Jabal Al Akhdar (Green Mountains). Such a campaign is within a research agreement stipulated between the Earth Sciences Department of Garyounis University of Benghazi, Libya and the Hyblean Speleo-hydrogeological Research Centre of Ragusa, Italy. Among the objectives of the project there are: that more general concerning the formulation of a speleogenetic model consistent with the geodynamic evolution and climate changes taken place in the tethyan-mediterranean region from the end of the Cretaceous; those with application fall-outs into the local socioeconomic framework addressing the finding out and protection of new water resources, the mapping of man altered areas, potentially at risk of instability and / or sinking because of the presence of karst voids, and the turistic use of caves with a particular aesthetic interest.

Al Jabal Al Akhdar belt is located in the northeastern part of Libya and it consists of a prominent promontory on the southern edge of the Mediterranean coast. It is 350 km long and 100 km wide. Tectonically, this belt is an inverted basin and has been affected by the Tethyan tectonic activities since its opening during the Jurassic. Lithologic outcrops of Al Jabal Al Akhdar belt involve limited exposures of upper-Cretaceous carbonates that constitute E-W to ENE-WSW structural inliers emerged within extensive exposures of Eocene, Oligocene and, sometimes, Miocene limestones.

The campaign of geospeleological investigations carried out in the 2007, 2008 and 2009 years has concerned the karst area of the coastal belt of Benghazi, Sousa and the plateau of El Marj, Al Bayda and Derna. The study of a series of large collapse dolines, connected with the network of conduits draining the ground water along the coast, was started in the area of Benghazi. Still in the same area, the Lethe karst system with a large underground lake, which was the subject of a tourist fruition during the Italian colonial period, is of particular interest, even historic. In the coastal area of Sousa a significant karst outcrop, surveyed and documented, is the Brag Notta system constituted by a collapse doline and a large neighbouring doline-lake connected hydrologically by a recent tectonic structure draining the brackish ground water now towards the sea now towards the hinterland, depending on the tidal excursions. In the raised areas of El Beida and El Marj plateau it is possible to observe some big dolines and dip shafts, inserted in the context of a typical cockpit relief, while in the plateau of Derna the exploration of a complex labyrinthine cave has allowed also the discovery of paleontological and archaeological finds. Speleological explorations and geological investigations of the above mentioned karst areas are still being carried out.

Key terms: Penultimate glacial; Last interglacial; Central Italy; Speleothems; Tana che Urla

Relatively few data are available for Central Italy concerning the climate condition during the Penultimate glacial phase (corresponding to marine isotope stage 6, MIS 6) and the transition to the last interglacial (e.g. Follieri et al., 1989; Bard et al., 2002; Drysdale et al., 2009). The Tana che Urla cave is a small cave located at 620 m asl in the inner side of the Apuan Alps (not far from Corchia cave), which preserves an interesting record of this period. Discontinuously monitored since the 2006, several flowstones of the main gallery were drilled in the 2009. In particular, two cores and one stalagmite, chronologically constrained by U/Th dating, have preserved two phases with 18O-depleted calcite at ca170-175 and 150 kyr (that is, during MIS6) interpreted as wetter periods. These two wetter period are in reasonable chronological agreement with similar data coming from the Argentario cave (southern Tuscany, Bard et al., 2002) and Soreq Cave (Israel, Bar-Matthew et al., 2000) records, supporting the notion that wet conditions were present all over the Mediterranean basin. In particular the older period substantially correspond to the phase of deposition of the cold sapropel S6 in eastern Mediterranean sea (Ayalon et al. 2002). Unlike Corchia, which shows a substantial difference between the isotopic records of oxygen and carbon (Drysdale et al., 2009), the transition to the Last Interglacial at Tana che Urla is marked by a substantial decrease of both oxygen and carbon isotopes records. This

difference could be interpreted as a different response to soil development at climatic forcing above the two caves, located at different altitude and with very different conditions of water infiltration and circulation.

INVESTIGATION ON THE ISOTOPIC COMPOSITION OF NITROGEN SOURCES IN THE HYGROPETRIC CAVE HABITAT OF THE GROTTA DELLA FOOS (NORTHERN ITALY): IMPLICATIONS ON THE ORIGIN OF THE NEGATIVE NITROGEN ISOTOPE COMPOSITION OF *CANSILIELLA SERVADII*

BRILLI Mauro¹, ENGEL Annette Summers², PAMIO Alberto³, PAOLETTI Maurizio Guido³, SQUARTINI Andrea⁴

Key terms: Nitrogen isotopes; *Cansiliella servadeii*; Hygropetric habitat; Moonmilk

The hygropetric habitat is one of the least studied habitats; it is found where a thin layer of water almost permanently covers a rock surface. In caves, the hygropetric habitat is fairly common. As cave hygropetric habitats provide special conditions for sustaining life, they require special adaptations. Living forms that have adapted to live in such habitats sometimes display unusual modifications: *Cansiliella servadeii* is a specialized troglitic beetle that lives in this habitat at a depth of about 450 m below the surface in the Grotta della Foos (northeastern Italy); this beetle's mouth apparatus has adapted in a peculiar way so as to allow semiaquatic feeding behavior. This species is essentially found browsing for food on calcite moonmilk, which is a thin deposit of calcite crystals, bacteria and water.

The beetle's mouth is not the only peculiarity of the *Cansiliella*. Nitrogen isotope analyses performed on the whole body, the gut and the exoskeleton of *Cansiliella* to examine the foodweb structure in the Grotta della Foos revealed surprising negative results, ranging between -2.5 and -7.8‰ with respect to atmospheric N. It is widely recognized that animals take on the isotopic composition of the food they eat with a small isotopic enrichment. Laboratory and field studies demonstrate increases in δ15N (about 2 to 3 ‰) between consumers and their diet. The troglitic and troglitic generally rely on food derived from non-living organic matter of surface origin transported to the hypogean environment in percolating waters. Nevertheless, the N isotope composition of the OM extracted from some samples of soil collected above the Grotta della Foos, is generally close to that of the atmospheric N.

The organic and inorganic sources of N were isotopically investigated by collecting different types of samples from the hygropetric habitat of the *Cansiliella* to trace the origin of the abnormally negative isotopic composition we detected. The organic N was extracted from the moonmilk that contains, besides calcite crystals, non-living OM and its microbial colonization; it presents an average isotopic composition of +2‰ (vs. AIR), which is even more positive than that of the surface OM. The inorganic N is instead dissolved in the dripwaters and sheetflow on the moist cave-wall surfaces. The most abundant N species in solution is nitrate, whose concentration ranges between 3.0 and 4.5 mg/l; less abundant is the ammonium, whose concentrations are as low as 0.2 - 0.3 mg/l. Nitrate, analyzed for N isotope composition, ranged on average between -10.9 and -5.0‰ (vs. AIR), which was more negative than the beetle. Oxygen isotopes of the nitrates ranged between +7.9 and +9.8 ‰ (vs. SMOW), thereby indicating that the nitrate originates at least partly from the oxidation of ammonium dissolved in meteoric waters. In the area of Grotta della Foos nitrates in meteoric precipitation displayed a similar N isotopic composition but an O isotope composition of +40‰, thereby showing that ammonium makes a marked contribution to the nitrate pool. Isotopes evidently rule out the possibility that OM in the moonmilk is an exclusive source of food for *Cansiliella*. The isotope analysis of the gut (-5‰) of *Cansiliella* also rules out the possibility that the negative isotope composition was due to the chitinous exoskeleton, which has in some insects proved to be strongly depleted in 15N (from -6 to -9‰) if compared with their diet. If we consider that inorganic N in the forms of nitrate and ammonium is much more abundant in this hypogean habitat than organic N, and that the isotopic composition of nitrate is the only value that is more negative than that of *Cansiliella*, the hypothesis that *Cansiliella* may use it as a food source, through microbial uptake, is conceivable. In nutrient-poor habitats, such as that found in the hygropetric cave, this alternative feeding mode may be a particular advantage.

Key terms: Mt. Canin; karst hydrogeology; isotopic analysis; cave diving

Recent results obtained from underwater cave explorations of Fontanon di Goriuda karst spring, have inspired new geochemical investigations. These study attempt to improve the hydrogeological knowledge and the groundwater paths considerations. The Canin massif contributes waters to three river basins (Tagliamento, isonzo-Soca, Slizza), and divide Adriatic Sea basin from the Black Sea basin. It is located at the border between Slovenia and Italy which follows the east-west top ridge. The massif is basically formed by Upper Triassic series of Norian dolomite ("Dolomia Principale") at the bottom and several hundred metres of Dachstein Limestone. It is bordered by the Moznica and Koritnica valleys in the northeast and east and by the Soca Valley in the south. On the west it is bordered by the Uccia Valley, the Idria fault zone, and the valley of the Resia River that flows into the Tagliamento River. The Raccolana and Rio del Lago valleys that form the northern boundary of the Canin massif run along the Raccolana fault zone. The geological structure causes springs to occur on its flanks, mainly in the Bovec Basin (Bocic, Boka, Sušec-Mala Boka, Zvika, Vodica, Glijun, Kladenki, Srnica) to the south and Moznica, Goriuda to the north.

In 1999 (Casagrande, Cucchi, Manca 1999) was carried out a monitoring campaign of karst springs in whole Canin massif. The aim of the experiment was monitoring in detail the behaviour of the springs during a strong rainy event. Were considered the following parameters: the discharge, the physical and chemical characteristic and the $\delta^{18}O$ and δD ratio. The springs were: Fontanone M. Sart (Resia), Fontanon di Goriuda, Sella Nevea and Rio del Lago springs, Boka, Glijun and Zvicar. Simultaneously were analyzed the precipitation collected from pluviometers installed in Val Resia (400m a.s.l.), Rifugio Gilberti (1850 a.s.l.) Val Raccolana-Fontanon di Goriuda (750m a.s.l.). Thanks to this first approach, together with other data from tracing tests, it was possible to classify Fontanon di Goriuda as a conduit dominated spring conditioned by rapid flow through larger channels in the system. The Karst springs collect water from different levels and have differing discharge regimes, a multi-level aquifer has developed along the main fissured zones. In 2009, 2010 and 2011, cave divers have sampled the waters of the three siphons inside the cave at different water depth and in different months as also the percolation along the main gallery after the siphons. These waters were analyzed for $\delta^{18}O$ and δD isotope determination. The $\delta^{18}O$ and δD ratio of the stream at the entrance, of the three siphons at the surface and a 6m deep so as the percolation, are depleted with the seasonal precipitation of the area. Instead the water of the II siphon at about 14m deep shows the absolute values of the isotopic data more negative than expected. This could indicate the presence of water infiltrated at highest elevation. This result is in accordance also with the isotope values and with the conductivity variation found at the Sella Nevea spring (Casagrande, Cucchi, Manca 1999). This important results open a new research in the karst spring of Fontanon di Goriuda. The future should be the automatically measuring device recording the water level, temperature and its conductivity.

Key terms: Speleogenic cave speleogenesis; cave minerals; U/Th dating; sulphur isotopes; geomorphic landscape evolution

The Montecchio cave (254 T/GR, close to Saturnia, Grosseto province) opens at 320 m asl, in a small outcrop of Calcare Massiccio, close to the Albegna river. Although known for a long time, there are no speleogenetic studies on this very special cave.

This cave, having over 1700 m of passage, is characterised by the presence of the thermal aquifer at a depth of 100 m below the entrance. The water temperature at this depth exceeds 30°C and the water has high sulphate content. The cave can thus be considered an active hypogenic system.

The cave hosts large gypsum deposits, starting 40 m below the entrance. This gypsum derives from the reaction between sulphuric acid and the carbonate host rock. This process, that occurs in the vadose (oxygen rich) environment, has created a set of typical morphologies such as replacement pockets and bubble trails.

The lower part of the cave hosts calcite cave raft deposits over 1 m thick, evidence of standing, probably thermal, water pools in strongly evaporative areas related to strong air currents. Eleven samples of weathering products have been sampled and analysed at the X-ray diffractometer and investigated using SEM/EDAX. The products of acid weathering are strictly related to the speleogenesis of the cave, having formed by the interaction between the host rock and the sulphuric vapors rising from the thermal aquifer, like those derived from calcite (gypsum) and from clays (alunite, jarosite and caolinite). Sulphur stable isotopes in three gypsum samples have given values ranging between -24.2‰ and -28.3‰, very similar to those obtained from other sulphuric acid caves such as Cueva de Villa Luz (Mexico), Lechuguilla (New Mexico, USA) and Frasassi (Italy).

The speleogenesis and minerogenesis of this cave is surely related to a lowering thermal water level where these processes are occurring at or near the water table, and are likely related to the river incision. Actually, the valley floor of the nearby Albegna river, that flows at a distance of some hundred meters from the cave entrance, is very close to the present level of the thermal water table in the cave. The low nitrate contents and the high temperature of the thermal cave water seems to

exclude a direct recharge from the river to the cave. U/Th dating of gypsum and calcite cave rafts and, possibly, 40Ar/39Ar dating of alunite will hopefully allow us to reconstruct the various phases of cave formation, and make contribution to the reconstruction of the river incision history as well.

In karst environments, quarrying is definitely among the human actions causing the worst impacts to the natural setting. Surface and underground quarries may intercept natural caves, and destroy them by producing direct impacts on the caves, or causing severe damage to the karst ecosystem, locally resulting in endangering very rare species. Reaching a balance between the need to carry out quarrying activity and the safeguard of karst environments is not an easy task. Legislation is often absent, or, when present, it remains actually only on paper, whilst the real enforcement of codes and rules is rarely pursued. In this paper, we present a case in which the Apulia regional legislation about underground protection has been effectively applied.

In the Minervino Murge area (Apulia, Southern Italy), a large quarry has been exploited for years leading to severe damage to the karst heritage, including total or partial destruction of caves, until quarrying operations were stopped in 2005 due to an inquiry and a protection procedure. This allowed to explore and survey the numerous karst processes present in the quarry. By chance the large size of the main caves avoided their complete destruction. On the other hand, the quarrying activities also brought to surface many new information on the geological and karst history of the region. Thanks to the protection procedure, it has been thus possible to fully document the high karst values of the studied area, which presents at least six caves of great interest for reconstructing the karst history of this sector of Apulia.

In this work, we describe both the surveyed caves and other karstic phenomenon, with particular regard to the geological setting of the area (local stratigraphy, main structural elements, etc.) and to the morphology and hypogean morphology of surveyed caves. Considerations about speleogenesis are also presented, within the context of a larger sector of Murge, which includes some of the most famous caves in the region (Grave di Faraualla, Grave di Masseria Preveticelli, Grave del Cavone and Grave Grande Campanelli).

Key terms: Karst; Tectonic; Speleogenesis

Spluga della Preta is one of the first caves in Italy to be well studied and described from a geological and morphological point of view. Eighty years after its first exploration a large amount of lithological and structural data were collected in the whole cave complex and detailed surface geological surveys were carried out. The step-like shape of the cave was initially considered as a consequence of the entrenchment of the nearby Adige River. In this work the lithological control of the horizontal passages is demonstrated, considering only the deepest passages to be paleo-phreatic. The main tectonic structures control the oldest and inactive parts of the cave, developed most in low-cohesive fault breccias, while the active streams are now deepened along secondary joints. The morphological analysis allows to infer a hypothesis on the speleogenetic evolution of the cave and on its relationship with an upper suspended aquifer hosted in the cretaceous Maiolica Formation.

Key terms: Speleogenesis; Transgressive contact; Erosion; Karst evolution; Mineralogy

Several important cave systems in Central East Sardinia develop, at least partially, along the contact between the granite or phyllite basement rocks and the covering fractured Middle Jurassic sediments. The latter are composed of layers of clays, marls, conglomerates and sands of variable thickness (generally some metres) followed by sandy dolostones, becoming increasingly carbonatic moving upwards in the sequence. These karst systems are fed by allogenic streams with flow rates ranging from a couple to some thousand of L s⁻¹. Parts of these vadose passages are sometimes developed in the insoluble basement rocks for some metres. In

the summer of 2010 cavers of the Centro Speleologico Cagliaritano have discovered a new cave, Gutturù 'e Murgulavò (Baunei), that hosts some passages entirely excavated in granitic rocks.

The typical morphology of all these caves is characterised by very large and rather low chambers, which floor is masked by important underground deposits. Locally the Palaeozoic bedrock is exposed along the underground streams.

Speleogenesis of these cave systems is very much relied upon weathering of the basement rocks and their successive erosion by flood waters, rather than on dissolution of the carbonate rocks. Mineralogical analyses of the weathering products at the contact between Palaeozoic rocks and Mesozoic sediments have revealed the presence of montmorillonite, kaolinite, chlorite and illite, typical weathering products of granitic rocks. Dissolution, however, plays an important role in the first stages of speleogenesis, dissolving the carbonate cement in the basal sandy dolostone beds, thus leaving loose sands that can readily be eroded by running waters. Once a critical dimension in void is reached, cave formation occurs very rapidly, leading to huge chambers in some thousands of years.

Key terms: hydromorphology; fluvial processes; morphological changes; hydrological alterations

The aim of this presentation is to provide a general overview of a relatively new discipline, hydromorphology, starting from its definition and briefly discussing its applications to river management.

The term "hydromorphology" was introduced by the Water Framework Directive 2000/60/EC (WFD), and includes the consideration of: (a) the extent of modification to the flow regime; (b) the extent to which water flow, sediment transport and the migration of biota are impacted by artificial barriers; (c) the extent to which the morphology of the river channel has been modified, including constraints to the free movement of a river across its floodplain. Following its introduction, many definitions of hydromorphology have been proposed, some of them emphasising physical habitats and related ecological aspects, and some focusing more on the hydrological and geomorphological aspects. However, according to a majority of authors, hydromorphology can be defined as the discipline that, by integrating hydrology and fluvial geomorphology, aims to study fluvial form and processes, their interactions with human impact, and the consequent implications on ecological processes.

Hydromorphology typically includes the following aspects: (a) river morphological changes and hydrological alterations; (b) interactions with ecological processes; (c) applications to river management and restoration.

In the past, and still nowadays, physical habitat assessment or river habitat survey have often been used as synonymous of hydromorphology. River habitat survey consists of a census and representation of the physical habitats existing in a given river reach and related to the morphological channel features. However, we argue that this is a very simplistic and 'form-based' approach, and alone is inadequate for a diagnosis and comprehension of hydrological and morphological problems. More than a representation of physical habitats, a more sound and comprehensive 'process-based' approach is needed to understand any physical alterations. This approach is also needed for an analysis of the influences and impacts when designing restoration actions, as required by the WFD.

ASSESSING HYDROLOGICAL AND THERMAL ALTERATIONS AT MULTIPLE TEMPORAL SCALES: ADIGE AND NOCE RIVER, ITALY

SIVIGLIA Annunziato¹, ZOLEZZI Guido¹

- 1 - University of Trento

Presenter e-mail: nunzio.siviglia@ing.unitn.it

Key terms: hydrological alterations; thermal alteration; water frame directive; hydromorphology

Under the Water Framework Directive (WFD), member states of the European Union should aim to achieve a "Good Status", comprising Good Chemical Status and Good Ecological Status, in all bodies of surface water and groundwater, and to prevent deterioration in the status of those water bodies. It is now broadly recognized that the hydro-morphological pressure is one of the most relevant cause limiting the achievement of the targets imposed by the WFD.

In this context, the hydroelectric production play a fundamental role because of the alterations of the natural flow and the thermal regime which are imposed at different time scales.

In the present study we analyze hydrological and thermal alterations induced by hydropower plants on both the Adige and Noce River (Trentino region, northeastern Italy).

We analyze an 83 years (1923-2006) streamflow data set collected daily on the Adige River and a 1 year (2007) streamflow and temperature data set collected every 30 minutes on the Noce River. We make use of the well-established range of variability approach (RVA) and wavelet

transform (WT) to identify the most relevant scales of variability and to detect their alteration independently.

Use of the range of variability approach and the wavelet transform analysis allows a better separation between natural and human-induced effects at ecologically relevant scales of variability, thereby identifying changes and trends due to hydropower management.

From the analysis of the Adige River set of data we observe that starting from the 1960s, after the construction of the reservoirs currently in operation, a progressive flattening of the hydrograph, which attenuated the amplitude of seasonal variations.

This negative tendency worsened in the last few years, possibly as an effect of the reduction in winter snowfall. Wavelet analysis shows that hydroelectric production caused the high-frequency components of the signal to increase in amplitude and number, with fairly regular weekly and daily oscillations and sharp transitions. The whole spectrum of low flows is significantly altered.

Analysis of thermal alterations induced by dam operations (hydropeaking) in the Noce River

is performed by applying the Wavelet Transform Analysis which allows to separately investigate the thermal regime alterations at sub-daily, daily and weekly scales. The outcomes of our study confirms that the strongest variability is detected

at the smaller scales, with a strong increase in temperature variability at sub-daily scales. Finally we show that at a seasonal scale, clear alteration can be detected and quantified.

Presenter e-mail: vittoriascorpio@yahoo.it

Key terms: Biferno river; GIS analysis; Recent channel adjustments; land cover changes; climatic and anthropologic factors

The Biferno river with its length of ca. 90 km and a catchment area of ca. 1300 km² represents the major water course in Molise region (southern Italy) flowing into the Adriatic Sea.

This river has suffered in recent times major channel adjustments including pattern changes, channel and floodplain narrowing and channel lowering, which are thought to be largely induced by human interventions on the catchment and on the river system.

The main purpose of our study is to reconstruct in detail the recent morphological evolution of the Biferno river, and to gain data on the effects on the riparian vegetation and on the possible role played by the Ponteliscione dam which is located ca. 28 km from the river mouth and captures the water supply of ca. 70% of the catchment from the mid-70's. Channel adjustments have been investigated for the time-window 1869-2007 by a multi-temporal analysis performed in ArcGIS using the historical I.G.M. topographic map of 1869 and the large scale topographic map (CTR) edited by Molise region in 1992, medium-scale orthophotographs of 2007 and medium-scale aerial photographs dating to 1954 and 1977, respectively. The investigated valley floor system was subdivided in two sectors which are separated by the Ponteliscione dam. The sector located upstream the dam, very narrow with a current average width of ca. 200 m, has a longitudinal average gradient of 4 degrees. The confining, low to moderate steep valley slopes are deeply affected by mass movements and erosion due to running water which frequently interact with the fluvial dynamics. The valley floor sector located downstream the dam is much more larger (on average 1250 m) and has an average longitudinal gradient of 1 degree.

With the exception of the ca. 10 km long reach preceding the river mouth, showing a meandering pattern which has only slightly evolved in the considered time-window, the Biferno river has registered important pattern changes in both sectors from braided in 1954, to transitional in the late 70's and to sinuous in 1992.

Simultaneously, a progressive narrowing of the channel-floodplain system occurred, less intense in the upstream sector than in the downstream sector. In particular, it could be observed that channel narrowing reached 75% and 85%, while the adjacent floodplain areas even increased about 50% and remained approximately constant, respectively. Channel narrowing and pattern changes were accompanied by intense to very intense channel incision which affected the entire valley bottom system and led to the formation of three orders of terraces (T3-T5) that characterize, together with the first and second-order terraces of pre-1869 age, the current valley floor morphology.

Valley floor terracing occurred simultaneously upstream and downstream the Ponteliscione dam, with terraces T3, T4 and T5 that formed during periods 1869-1954, 1954-1977 and 1977-1992, respectively.

While the terraces T3-T4 can be explained taking into account the climatic amelioration that followed the Little Ice Age and the human interventions on the catchment and on the river system occurred in the first part of the 20th century, the T5 is clearly related to the presence of the dam. The dam in fact has introduced an important modification in the local base level of erosion for the upstream sector, as highlighted by the overall increase of the floodplain areas, while the related alteration of original flow and related sediment regimes provoked the formation of the T5 terrace within the downstream sector.

The observed channel adjustments had major effects on land use and especially on the evolution of the riparian vegetation. In fact, channel adjustments were accompanied by a strong expansion of agricultural areas and broad-leaved forest at the expense of the natural riparian vegetation (especially shrub and/or herbaceous vegetation). The most substantial part of these land cover changes had already occurred in 1977.

MONITORING THE RIVER'S EVOLUTION THROUGH

MULTI-TEMPORAL LIDAR ANALYSIS: AN INTRODUCTION TO THE "ACTIVITY INDEX"GIORDAN Daniele¹, ALLASIA Paolo¹, BALDO Marco¹, LOLLINO Giorgio¹
1 - CNR IRPI

Presenter e-mail: daniele.giordan@irpi.cnr.it

Key terms: Morphological river evolution; LIDAR; activity index

The analysis of the recent evolution of rivers implies the use of monitoring techniques that allow accurate evaluations of the volumetric changes occurred. In this context, the comparison of multi-temporal digital terrain models (DTM) represents an effective solution. Indeed, this monitoring technique may allow for quantitative evaluations of the change occurred over large areas with accuracies hardly achievable with other methods. However, the use of such as monitoring techniques requires the definition of algorithms and procedures for a correct interpretation of the results. In this work, we propose a new method to interpret the recent evolution of river beds by considering multi-temporal DTMs generated via airborne LiDAR surveys. The methodology herein presented provides accurate information that evidenced both the occurred volumetric change and the morphological variations of the riverbed. Moreover, we also defined a new quantitative parameter to better interpret our results: the "activity index". The latter is defined as the ratio between areas where important volumetric variations occurred and the total area of the river bankfull. We present several case-studies where our procedure has been successfully applied and the activity index was very helpful in evidencing the predisposition to changes of the river paths. In particular, the methodology has been applied to the Orco River as well as along reaches of the Secchia and the Taro Rivers to test the activity index efficiency on different morphological contexts. Finally, we present the last part of the research project that is related to the comparative analysis between the activity index and the standard discharge evaluations to detect a possible analytical relationship between these two parameters.

STOCHASTIC ANALYSIS OF THE WIDTH OF A MOBILE BED ALLUVIAL RIVERBARBERO Giuseppe¹, PELLEGRINI Luisa²1 - DIPARTIMENTO BEST - POLITECNICO DI MILANO
2 - DIPARTIMENTO DI SCIENZE DELLE TERRA E DELL'AMBIENTE - UNIVERSITA' DI PAVIA

Presenter e-mail: sgpp@iol.it

Key terms: alluvial river width; mobile bed; stochastic process; markov chain; Apennine Po river tributaries

In this paper, the maximum width of a mobile bed alluvial river is represented as a continuous stochastic process. The process is assumed spatially homogeneous and the time is considered a discrete parameter. The considered models are, in principle, non-stationary; however they are referable to an AR(1)-process (autoregressive process of order 1). To define the models the coefficient of variation, the first order autocorrelation coefficient and the skewness must be assigned. The continuous stochastic process is transformed into a Markov chain, in order to estimate the not overcome probability of an assigned of the maximum river width.

The analysis has been applied to the plain reach of three Apennine Po river tributaries: the Scrivia river (Piedmont region) between Cassano Spinola and Castelnuovo Scrivia, the Trebbia river (Emilia-Romagna region), between Mirafiori weir and TO-PC railroad bridge, and the Nure river (Emilia-Romagna region), from Ponte dell'Olio to PC-BO railroad bridge. The width and vertical channel changes of these rivers have been studied and pointed out in several previous works developed within the PRIN project (2005 and 2007) and related to the geomorphological evolution. In particular, the narrowing and widening have been calculated through measure of cross-section of the bankfull, 25m spaced, on aerial images and historical maps, that was scanned and georeferenced. The database of the widths include 15 years for Scrivia River, 12 years for Trebbia and 10 years for Nure, since the end of the 19th century to the 2010.

This paper resumes and processes the results of these analysis to determine the statistical parameter of the considered models.

FLUVIAL PROCESSES AND RIPARIAN VEGETATION IN DISTURBED RIVERSMAO Luca¹

1 - Free University of Bozen-Bolzano

Presenter e-mail: luca.mao@unibz.it

Key terms: Riparian vegetation; Gravel-bed rivers; Human impacts

Riparian vegetation plays a crucial role in determining the morphodynamics and the ecological values of river systems. The significant impact of vegetation growing on bars, islands and floodplains on channel morphology has been increasingly verified in the field, numerically as well as experimentally, demonstrating the remarkable influence of riparian vegetation in stabilizing banks, increasing mean channel depths and significantly reducing the number of channels per river cross section (the braiding index). The geomorphic effect of living plants continues even after their erosion from the banks and transportation within the fluvial network. In fact, dead or living pieces of large wood can exert a tremendous influence on river erosion and sedimentation processes, channel morphology, channel hydraulics, as well as ecological diversity.

The pattern of riparian vegetation in gravel bed rivers depends on the climate, hydrological regime, and the morphological settings of the river. Also, the marked spatial variability of density, height, species diversity, age, and rates of growth reflects the very complex nature of bed colonization, the strong influence of sequences and magnitude of floods, and the feedbacks between morphology, vegetation and hydraulics. Furthermore, a wide array of human impacts acting at either the basin or river network scales can influence substantially the morphodynamics and thus the characteristics, types and distribution of vegetation within the river corridor. A better understanding of how vegetation reacts to natural and anthropogenic impacts is needed in order to increase our ability to predict the response of river systems to flood events, and to assess the human impacts on river dynamics due to different management strategies

of riparian vegetation and river restoration schemes. Moreover, the need for such improved understanding is also enhanced by a requirement to better predict river system and ecological habitat response to environmental change, notably climate and land use alterations. The aim of the contribution is to illustrate the importance of riparian vegetation in determining fluvial shape and processes, and habitat ecology. A special emphasis will be given to describe the vegetation types, structures and distribution patterns in Italian gravel-bed rivers suffering from various degrees of human pressure and disturbances. The case of the Piave river, which suffered intense and multiple human impacts especially due to dam building and in-channel gravel mining, is taken as a reference for discussing the relationship between the vegetation structure and the morphological characteristics in an impacted river. The Piave river shows a complex pattern of vegetation distribution along the cross-sections, with no clear relationship between the elevation and the "maturity" of plant communities as a result of a recent tendency of active channel widening after a long period of channel narrowing. Parallel to the substantial active channel narrowing and incision occurred during most of the twentieth century, the proportion of the fluvial corridor covered by vegetation at the channel margins has experienced a significant increase. These extensive mature riparian areas within the fluvial corridor have beneficial effects on the overall ecological potential of the area, and are in fact sometimes protected. However, these forested areas lie on former active channel portion of the river corridor and their protection could hamper efforts directed at promoting river restoration through channel expansion and aggradation. Furthermore, these areas could represent significant sources of drift wood if eroded and transported downstream during high-magnitude events.

THE DENDROGEOMORPHOLOGICAL APPROACH TO INVESTIGATION THE RECENT CHANNEL ADJUSTMENT: THE CASE STUDY OF THE TREBBIA RIVER (EMILIA ROMAGNA, ITALY)BOLLATI Irene Maria¹, PELLEGRINI Luisa², PELFINI Manuela¹, DUCI Gabriele², BAZZI Alessandra¹

1 - Università degli Studi di Milano

2 - Università degli Studi di Pavia

Presenter e-mail: irene.bollati@unimi.it

Key terms: Dendrochronology; Fluvial dynamics; Minimum age

The reach of the Trebbia river in the plain shows mobile alluvial channels with braided, wandering and meandering patterns. Evident channel changes have affected this river and recent studies have pointed out the processes of both narrowing, during the twentieth century, and widening, since 2000. In such an active environment, where the modifications can occur in a few years or, sometimes, during severe flood events, it is very interesting to locate and to date, if possible, the stable surfaces.

The proposal approach has the main aim of integrating the evaluation of river-bed erosion and/or deposition, deduced from geomorphological studies, geomorphic indices and their cartography and topography restitution, with the dating of geomorphological surface through dendrochronology.

The selected area for dendrogeomorphological sampling was chosen through aerial photo analysis of the landform modifications of the Trebbia river over time, in order to trace the dynamics of the river influence on the stabilization of bars and alluvial plains. The 93 sampled trees of "Populus nigra" L., whose ring boundaries have been in some cases difficult to locate in the phase of laboratory analysis, were collected from nine sampling clusters in which the changes had been evident between the beginning and the end of the 1980s. These more stable portion of the riverside should be populated by trees whose rings record covers almost the entire time interval. In order to date the geomorphological surface the "ecesi" (time taken by trees to successfully germinate on a bare surface) was considered and, as indicated in the literature, "Populus nigra" L. takes a little time to start settlement on fluvial bars and alluvial plains. In addition, the microscopic analysis of abrupt growth changes in annual tree rings can again provide interesting information to be crossed with the cartographic data.

The geomorphological investigation and the aerial photos analysis through GIS procedure made possible to place the period of maximum narrowing between 1980 and 1990 and the minimum bankfull width in 1990. Starting from 1996 the bankfull began a new phase of widening. The minimum age of vegetation investigated on fluvial bars and islands allows us to limit the interval of minimum bankfull width, indicating that probably it had already been reached in 1985-87 when the areas, that had been part of the active bankfull in 1980, were colonized by vegetation. Here, aerial photo interpretation and tree rings analysis allow better time location of the recent river-bed modification. Once the temporal resolution and the error of dating of the dendrogeomorphology tool have been tested in an area with a good deal of geomorphological data available (aerial photos, topographic maps, etc.), dendrogeomorphology can be used to refine geomorphology investigations and to integrate lacking data in those areas not well provided with other typologies of data.

3 - King's College London

Presenter e-mail: walter.bertoldi@ing.unitn.it

Key terms: braided rivers; riparian vegetation; river bed morphology; LIDAR data

The increased availability and accuracy of remotely sensed data open new possibilities to investigate the relationship between fluvial geomorphology and vegetation development. This paper combines archived remotely sensed data (airborne LiDAR and digital colour air photographs) with non-synchronous ground observations to quantify the impact of colonization of exposed river sediments by riparian trees on channel form. The study site is a 21 km reach of the braided, gravel-bed Tagliamento River, Italy, which is characterized by a wide range of vegetation conditions. Therefore, we have been able to explore the ways in which riparian tree growth moderates the morphological structure of braided river reaches under circumstances where other influential factors such as

peak discharges, slope and grain size remain approximately constant. LiDAR data are analyzed to extract a 2 m resolution DEM and determine riparian vegetation extent, height and structure within the active corridor. Aerial photographs are used to map the topography of the submerged parts of the corridor. These data are divided into 1 km length sub-reaches, which possess strong contrasts in vegetation height and extent. Joint analysis of vegetation and morphological properties of these sub-reaches reveals significant associations between vegetation properties and reach morphology. We analysed the bed elevation frequency distribution, showing that heavily vegetated areas are associated with the appearance of secondary peaks describing island formation. The analysis demonstrated that sub-reaches with an extensive, relatively mature cover of vegetation in the form of patches of varying size up to islands several hundred meters long, exhibit a different morphology from sub-reaches with limited vegetation cover. The skewness and kurtosis of the elevation frequency distribution within each of the sub-reaches are both significantly correlated with vegetation extent, height, median elevation and growth rate, indicating a clear topographic signature of vegetation development along this braided river that reflects sediment accumulation within and around the vegetated patches.

Key terms: riparian vegetation; fluvial landform; morphological evolution; channel adjustment; human impact

Several studies have recently focused on the relationship between riparian vegetation and fluvial geomorphology. Anyway few studies have analyzed in detail the relations and feedbacks between channel adjustments and vegetation dynamic in heavily incised alluvial rivers.

This study analyzes: i) the relationship between fluvial landforms and characteristic plant species; ii) the species composition and distribution as indicator of the active channel evolution, iii) the role of the human impacts on the structure and composition of the vegetation in fluvial ecosystems. The study combines the analysis of the morphological changes (aerial photos analysis, longitudinal profiles and field observations) and a detailed phytosociology analysis of the existing vegetation ("Braun-Blanquet" method, 1965).

The study area includes 38 km of the Panaro River (MO), characterized by high incision and general river degradation. The riparian vegetation is at most natural or sub-natural.

Results show clearly relationship between fluvial landforms and types of vegetation, even if we recorded significant deviations from the typical correlation pattern existing between morphology and vegetation. The types of human alterations, their intensity and influence on the relationship between vegetation and fluvial landforms are also discussed. The aim of this study is to provide a useful model to support the understanding of human-modified fluvial systems and to provide tools for environmental and territorial management, for the objectives of the WFD (2000/60/EC).

Key terms: Indice di Qualità Morfologica; dragonflies; hydromorphology; ecological indicators; Alps

The study aims to assess the morphological and ecological conditions of some Italian alpine alluvial rivers, using specific indexes, and to analyze the relationships between these two components of the fluvial environment. Another topic of the research is to test Odonata as ecological indicators over a set of reaches with different channel morphologies (from braided to single-thread) and different human impacts.

The study cases are 7 alpine alluvial rivers, 4 coming from the central-western Alps and 3 from the eastern portion of the Alps. Three reaches will be studied for each river and they'll be located in different physiographic context: one reach in the alpine-prealpine region, and the other two in the High and Low alluvial Plain. The chosen reach should be representative of the whole segment (defined by the intersection of the borders of the physiographic units with the river itself), in terms of morphological and ecological characteristics, human impacts and expected quality.

The recently developed IQM (Indice di Qualità Morfologica - Morphological Quality Index) will be used to evaluate the morphological conditions of the study reaches. The index, which is obtained through remote sensing analysis and field-collected data, is composed by 28 indicators divided in 3 categories: 1) functionality of geomorphological processes; 2) presence of artificial elements; 3) recent channel changes. IQM allows an assessment of the fluvial reach in a five-tiered classification scheme, as required by EU Water Framework Directive (WFD).

Dragonflies (Odonata) will be used as ecological indicators to evaluate the ecological integrity of river-floodplain ecosystems in the study reaches. Previous works have shown that dragonflies are good indicators of ecological quality of land-water ecotones, habitat heterogeneity and hydrological dynamics of water bodies. Dragonflies should allow a more global ecological assessment of the fluvial reach, respect to what is possible with other categories of bioindicators that are generally strictly aquatic organisms (diatoms, aquatic macrophytes, benthic macroinvertebrates and fishes). Within each study reach 4 sites will be selected for dragonflies surveys, that are based on adult observations,

larvae and exuviae sampling. Every site will be visited four times a year, to determine the autochthonous dragonfly community. The sites should be representative of the diversity of habitat that are present in the reach, following, if possible, an ideal transect from the main channel to secondary channels or non-flowing channels, up to isolated ponds - backwaters located in islands or in the floodplain. Dragonflies community data will be used to calculate OHI (Odonate Habitat Index), after having checked the possibility to import this Austrian index in the Italian context, or to develop a new index, based on the theoretical basis of the OHI. In any case, also the ecological index will follow a five-tiered classification scheme, to be easily compared with IQM and the other indexes based on bioindicators used in Italian rivers.

First preliminary results of the research are presented and discussed, analyzing the relationships between the response of the two indexes to common impacts and pressures that are present in the study reaches.

EVALUATION OF RIVER HYDROLOGICAL REGIME ALTERATION BY MEANS OF A SYNTHETIC INDICATOR: IARI

BRACA Giovanni¹, BUSSETTINI Martina¹, LASTORIA Barbara¹

1 - ISPRA - Italian National Institute for Environmental Protection and Research

Presenter e-mail: giovanni.braca@isprambiente.it

Key terms: hydromorphology; hydrological alterations; fluvial processes; hydrology

The hydrological regime of a natural watercourse represents a set of intrinsic characteristics of river flows, in terms of timing, magnitude and frequency..

It is generally admitted that flow regime, together with river morphology, is the main driving element shaping the structure and functionality of river ecosystems.

European Commission Water Framework Directive 2000/60/CE requests evaluation of the hydrological regime alteration in order to assess the high ecological status..

Many procedures, more or less complex, have been developed in Europe and USA to take into account the hydrological regime alteration rate with particular attention to the change due to anthropogenic actions.

In order to implement Water Framework Directive, within the scope of its mission, the Italian Institute for Environmental Protection and Research (ISPRA) has developed a procedure for assessing the river hydrological regime alteration by means of a synthetic indicator named IARI (acronym of Indice di Alterazione del Regime Idrologico).

The definition of this indicator follows the IHA (Indicators of Hydrologic Alteration) procedure implemented by The Nature Conservancy.

The IARI procedure takes into account the availability (usually low) of recent and past hydrological and flow data and recent climate conditions by means the SPI index.

In this paper an illustration of the whole procedure is given and tests on different hydrological regimes are presented.

THE STUDY OF RIVERS GEOMORPHOLOGY IN THE MANAGEMENT OF SEDIMENTS THROUGH THE APPLICATION OF GEOMORPHOLOGICAL QUALITY INDEX. PIEDMONT CASE HISTORY.

SILVESTRO Chiara¹, GAIDO Giorgio¹, SENESI Massimiliano¹, ZERBATO Marina¹

1 - regione piemonte - Direzione Opere pubbliche, difesa del suolo, economia montana e foreste

Presenter e-mail: chiara.silvestro@regione.piemonte.it

Key terms: sediments; directive; geomorphology

In Italy the mining of sediments from river bed is a major business, so some years ago the River Po Authority issued a specific Directive about. The aim of the document is to identify homogeneous methods and procedures to be applied in the river Po basin to manage sediment mining. In the directive, actions on river sediments have to be defined after researches on significant river stretches are done. The scope is to define the river's dynamic equilibrium through the study of three important characteristics: hydraulic, geomorphology and ecology. A multi discipline approach that involves different professional figures.

In 2009, as specified in the Directive, the Region Piedmont began working on the definition of an intervention program for the mining of the sediments in some of the Cuneo province most important rivers: Varaita, Maira, Stura di Demonte and Tanaro (in this case the Asti province territory was also involved). The research also studied the geomorphology of those rivers in details.

As the Po Authority suggested, the Region Piedmont has analyzed geomorphologic aspects through the application of the quality geomorphologic evaluation method, that ISPRA proposes to apply at the Water Framework Directive (2006/60/CE).

The method applied to sediments managements is useful as it also looks into not strictly geomorphologic aspects but still closely related to them. For example it analyses matters as riparian vegetation or hydraulic aspects promoting the integration between different topics: one of the Directive scope.

Applying the ISPRA method on several rivers is also interesting since allows comparisons between the results. For example, it is possible to analyze the same issues at the same scale on different water bodies, or at different scales (river basin, stretch) on the same river; to make hypothesis on the connections between morphological development and natural or human actions;...

In our experience it is not so important the value of the index IQM that the method suggests, but the possibility that the method offers to study several topics, thus make a connection among many aspects and comparing the results.

Sometimes we found difficulties using the ISPRA method to collect informations and elaborate data. Very often we haven't informations on digital support but also we have to go on site to be sure of your data lots of time. The time you need is quite a lot and the hazard is to have a work where the personal interpretation play an important rule.

The application of the method to evaluate the IQM index permitted to describe the actual rivers evolution, their actual situation of equilibrium or of disequilibrium, (as we experimented for Varaita, Stura di Demonte, Tanaro and Maira) and it's a good help to reach one of the aim of the directive.

Our experience says that the IQM evaluation could be a reference method also in different fields, not strictly related to WFD.

Key terms: Fluvial Dynamics; Water Framework Directive; Morphologic Quality Index; GRASS GIS

Recently, ISPRA (Advanced Institute for Environmental Protection and Research, Italy), has acknowledged the indications of the Water Framework Directive 2000/60/CE, and has developed a methodology to survey the hydro-morphologic characters, finalized to the calculation of an index (MQI, Morphologic Quality Index) that can represent the "state of morphologic quality" of the streams, in natural and/or anthropic environment (Rinaldi et alii, 2011).

The method consists of a first phase of subdivision in homogeneous reaches, carried out by means of analysis of aerial images and bibliographical informations, for which the GIS software represents a fundamental tool. The subdivision, in fact, is carried out by determining some morphologic parameters (among these: area of water-drainage, slope, confinement of the stream, sinuosity, tendency to braiding and/or to anastomosing, riverbed width, extension and types of sedimentary bodies etc) that can be calculated by means of simple but frequent measures.

These operations are rather expensive in terms of time and, therefore, they can be favorably automated by GIS.

The note describes 4 codes for the automated calculation of the main parameters, written in python and implemented within GRASS GIS. These need, in input, some morphologic elements in vector format: boundaries of the alluvial plain, of active riverbed and of channel, valley and riverbed axis, banks, bars, islands.

The codes are: Profilo.py, to extract longitudinal profile from a high resolution DTM; Confinamento.py to calculate the Confinement Degree and Index; Sinuosità.py to calculate the Sinuosity Index; Alveo.py to calculate the total width, the real width, Braiding Index, Anastomosing Index.

The method has been experimentally applied to some reaches of Umbrian streams (central Italy), under different morphologic conditions and human impact. The preliminary results are here reported.

COUPLING NUMERICAL AND CONCEPTUAL MODELS TO ASSESS MORPHOLOGICAL EVOLUTIONARY TRAJECTORIES OF RIVER CHANNELS

ZILIANI Luca¹, SURIAN Nicola¹

1 - Università di Padova

Presenter e-mail: luca.ziliani@unipd.it

Key terms: evolutionary trajectories; numerical modeling; conceptual model; Tagliamento

Most Italian rivers have undergone notable alterations of their morphological characteristics over the last decades. Such alterations have effects on their ecological condition and it is therefore needed to identify management strategies that can improve morphological condition of rivers. Critical issue for management is assessment of potentials and limits for such morphological improvement, that is definition of possible evolutionary trajectories of river channels in the near future. The aim of this work is to address this issue in the Tagliamento River, a large gravel-bed river in north-eastern Italy, combining conceptual and numerical models. The conceptual model derives from reconstruction of past and present evolutionary trajectories of alluvial rivers in Italy and, more specifically, of gravel-bed rivers in north-eastern Italy. Numerical modeling was carried out using CAESAR, a reduced complexity model which allows application to long reaches over long time scales (i.e. several decades). Future evolution of river channels is assessed according to scenarios that take into different management strategies (specifically concerning sediment management) and changes in hydrological regime. The application was carried out in a 33 km reach characterized by a braided morphology. This reach underwent remarkable narrowing and some incision in the past while, more recently, a moderate recovering (i.e. widening and sedimentation) is taking place. Numerical simulations were carried out to explore channel evolution over the next 80 years. A What-if scenarios strategy was adopted. These scenarios take into account effects of different management strategies which may act both at reach and basin scales. For instance, it was assessed channel response to increase or decrease of bank protections. Besides management, the influence of flood magnitude and frequency on channel evolution was addressed. Results from this application suggest that an integrated modeling approach (conceptual and numerical) may increase our ability to predict future evolutionary trajectories of river channels. Overall there is good agreement between results from the two models. On the other hand the cellular model allows a better appreciation of processes that are simplified or neglected within the conceptual model. For instance numerical simulations show that input of coarse material from lateral erosion, rather than input from upstream, is a driving factors of channel evolution over examined timescales (i.e. tens of years).

4 - Istituto Superiore per la Protezione e la Ricerca Ambientale (ISPRA), Roma

Presenter e-mail: mrinaldi@dicea.unifi.it

Key terms: hydromorphology; channel dynamics hazard; stream morphological quality; IDRAIM

The EC Water Framework Directive 2000/60/CE requires hydromorphology to be considered as a component of stream quality conditions and the implementation of restoration actions, whereas the EC Flood Directive involves the identification of measures to mitigate floods and related hazards. To achieve the objectives of both directives (river ecological quality and public safety, respectively), there is an increasing need for approaches and methods based on geomorphological processes responsible for river dynamics and related hazards.

In Italy, as in many other European countries, hydromorphological degradation is a major cause of alteration in rivers and, on the other hand, hazards related to fluvial dynamics, each year, determine considerable damages and casualties. Consequently, the Italian National Institute for Environmental Protection and Research (ISPRA) has recently promoted a research program with the objective of developing a comprehensive methodological framework to support the management of river processes, integrating ecological quality and safety objectives according to the two directives 2000/60/EC and 2007/60/EC, respectively. The methodological framework (IDRAIM: system for stream hydromorphological assessment, analysis, and monitoring) stems from existing experiences of geomorphological approaches developed in other countries (e.g. the River Styles Framework), but it accounts for the specific Italian context in terms of channel adjustments and human impact, and also includes the fluvial dynamics hazard component. The general structure includes the following four stages: (1) the general basin setting and its segmentation; (2) the present morphological conditions and past evolution; an assessment of morphological conditions is performed, with particular emphasis on sediment dynamics at the catchment scale, trajectories of channel changes, and implications for fluvial hazards; (3) future geomorphic trends; predictions of likely future channel adjustments and their implications on river morphology and hazard conditions are considered; (4) integrated management: the final step involving the integration of the two objectives, i.e. the improvement of river morphological quality and the mitigation of hazards related to fluvial dynamics.

MODELLING RIVER EVOLUTION: A COMPARISON BETWEEN REAL AND SIMULATED CELLULAR AUTOMATA DATA ON PELLICE RIVER (NORTH WESTERN ITALY)

AUDISIO Chiara¹, PASCULLI Antonio¹

1 - University "G. D'Annunzio" - Chieti and Pescara (Italy)

Presenter e-mail: chiaraudisio@gmail.com

Key terms: river geomorphology; cellular automata model; CAESAR; Pellice River; North western Italy

The past two decades have seen significant improvements of the studies about the rivers morphology, in particular regarding analysis of the processes governing the fluvial evolution resulting from the erosion and transport of the sediments. Important results have been achieved thanks also to the evolution of both instrumental and computational tools. In the first case the new technologies have allowed a more detailed representation of the territory (DTM obtained by LIDAR survey) while in the second case the computational speed of the recent platforms, besides the developing of more advanced mathematical modelling and numerical algorithms, suggest a promising research line in order to simulate or, at least, to estimate the rivers evolution in a more and more suitable and realistic way. In order to model the rivers evolution, essentially two main approaches have been adopted in the literature: CFD and cellular automaton. Within the CFD framework, based on "First Principle Approach", Navier Stokes equations are solved by different numerical techniques: FEM (Finite Element Method), FVM (Finite Volume Method), FDM (Finite Difference Method). The Cellular Automata Model is suitable for analyzing the evolution of landscapes using a grid of interacting cells. Each cell is connected to the small volume around selected points belonging to the system. Then the evolution of a selected phenomenon is studied through the evolution of the "state" related to the mechanical, morphological and so on characteristic of each cell, through their mutual interaction. The interactions among cells (automata) are ruled by simplified versions of the related governing laws of physics. In particular, in within the fluvial geomorphology framework, Cellular Automata physics is based on a simplified or "relaxed" version of the complex flow equations employed in CFD models.

Consequently, it might be interesting to explore how the simplification of the physics adopted by Cellular Automata may affect the adequacy of its numerical response in comparison with experimental data. For this reason, the main target of this paper is to explore the feasibility and suitability of the Cellular Automata technique to simulate, for instance, the evolution of a North Western Italy river (Pellice River), comparing numerical results to experimental measures. Thus, an available Cellular Automata research code (CAESAR) has been selected. CAESAR, Cellular Automaton Evolutionary Slope and River model, is an open source cellular model which can be run in two modes: a "catchment" mode with no external influxes other than rainfall; and a "reach" mode with one or more points through which sediment and water enter to the system. The CAESAR model employs a scanning algorithm that "pushes" water across a grid to the cells in front, along four directions.

The model has been applied to Pellice River, an alpine tributary of Po River in North - Western Italy. It drains 906 km² and its channel is about 53 km long. In the selected reach, 2 km long, the channel is incised in cobble-gravel deposits and shows a single-channel thread. In the past the river channel showed almost everywhere a multi-thread pattern, somewhere braided.

The starting data for the model are a digital terrain model (DTM) obtained by a LiDAR survey dated back on February 2007, water discharge and depth data derived by a hydrometric gauge (ARPA Piemonte), the Corine Land Cover is used for vegetation and some granulometric investigations was made in the selected reach.

Different simulations, covering the period 2007-2010, have been carried out and discussed. In particular, the numerical results have been compared with some GPS cross-sections, related to October 2010. Some important results have been obtained by the comparison: the adopted modelling approach seems to be adequate regarding the depositional processes, even if some problems are still unsolved with the lateral

erosion.

2 - University of Rennes 2, COSTEL CNRS-UMR 6554 LETG

Presenter e-mail: bellettib@gmail.com

Key terms: braided rivers; river landscape; morphological evolution; aerial photographs; regional pattern

Despite their strong disappearance during the last centuries, several braided reaches remain in French Alpine rivers.

This study is focused on 53 braided reaches in the Rhone basin representing 139 km of the 650 km remaining braided cumulated length. We made a diachronic comparative analysis of the evolution of the river landscape between 1950 and 2000, using aerial photographs from the French National Geographic Institute (IGN).

The objective of this study is to support the understanding of the functioning of braided rivers in terms of dynamic and evolution at the regional scale and in relation to recent human pressure. The morphological evolution of the river planform has been put in relationship with the sedimentary evolution during the last century and with the flood history.

The results show a general narrowing of the active channels due to vegetation encroachment and island development. Some reaches, mainly situated in the Durance basin, show a different behavior. A multi-temporal analysis on a subset of 12 reaches has also been made, with the aim to characterize the river morphology evolution in relation to the biggest floods.

This study enables the identification, amongst braided rivers of the Rhone basin, of the most dynamic braided rivers versus those which are in equilibrium or those which are changing their fluvial pattern. We also proposed and discussed a regional typology.

The evolution of these river systems is studied to define actions of conservation and restoration and to achieve the objectives of the WFD.

COARSE SEDIMENT DYNAMICS IN FIELD INSTRUMENTED STREAMS

MARAGA Franca¹; ARATTANO Massimo¹; PELLISSERO Chiara¹

1 - Cnr-IRPI, Unità di Torino

Presenter e-mail: franca.maraga@irpi.cnr.it

Key terms: research instrumented basin; channel bed changes; sediment transport; alpine environment; Italy

Monitoring experiences of sediment dynamics are presented that regard two small mountain research basins, well equipped to sediment transport measurements of bed load and debris flow in Alpine regions (Italy). Field measurements are tested to investigate the coarse sediment transfer in gravel bed reaches at the outlet of the basins. The small basin Valle della Gallina (1 km² in area; basin outlet elevation 300 m a.s.l.) is selected to represent bed load processes in the region of north western Alps, as a tributary of the upper plain of Po river system (Lozzolo, Vercelli, Piemonte Region), and it is under observation since 1982. The small basin Rio Moscardo (4.1 km² in area; basin outlet elevation 890 m a.s.l.) is selected to represent debris flow processes in the region of eastern Alps as a tributary of the upper valley of the Tagliamento river system (Paluzza, Udine, Friuli Venezia Giulia Region), and it is under observation from 1985 to 2005.

The aim of the experimental small basins is a long term monitoring of the hydro-sedimentary response to explore and compare the changes of coarse sediment transport and channel bottom in changing environment. The experimental basins are promoted and managed by Cnr, Institute for the Geo-hydrological protection (IRPI), branch of Turin.

Bed load experiences (since 1982) - the Valle della Gallina research basin represents a pre-Alpine landscape bordering the Po river plain with a continental-Mediterranean climate. The main stream is equipped with one in-channel natural debris pool regularized into the bottom bedrock, in order to measure the delivered volumes (from 0 m³/year (1985 and 2008) to 73 m³/year (2002)). Average sediment yield from the basin is 32 m³ (1982-2009), grain size distribution ranges from 0.06 to 258 mm.

Furthermore, an instrumented reach is equipped 120 m long upstream the debris pool (slope 1%) in order to measure sediment transfer distances by autochthon pebble tracers. Measurements show an exponential dependence of displacements on the peak flows. The travelled distances show dependence on the pool and riffle sequences as well as on protruding boulders or bedrock, while trapped volumes reveal a dependency on the sediment feeding in the stream.

Seismometers record water and simultaneous sediment transport pointing up the pulse dynamics in sediment transfer.

The total bed load is measured, including the largest sandy fractions moving as bed load. The sediment suspension processes proved to be irrelevant in comparison with the sediment delivering volumes. An explanation for the sediment decrease below the mean after 2000 could be found in the spreading of the coppice vegetation cover up to the head slopes.

Debris flow experience (1985-2005) - Investigation about the coarse sediment evolution also address the issue of the transport produced by debris flows and in 1985 a debris flow prone basin was instrumented (Rio Moscardo) for the purpose.

Researches mainly regarded the monitoring of flow height through ultrasonic sensors, of the vibration induced in the ground through geophones, of surface velocity through fixed videocameras and of the rainfalls through rain gauges.

Measurements of front velocity and peak discharges was also possible and an estimation of transported volumes was performed for the recorded events. These volumes, estimated during a period of almost 20 years, ranged between few hundreds and 60 thousands cubic meters.

A decrease in number of debris flow occurrence was also observed during the years. At the beginning of the monitoring activities a mean of 2/3 events per year was observed, while at the end of the observation period the debris flows reduced to less than one per year.

This decrease was only partially explained by some systematic works that took place at the beginning of the current century.

CHANNEL MODIFICATION OF THE FOGLIA RIVER DURING THE LAST 200 YEARS

DE BERARDINIS Antonello¹; NESCI Olivia²; SCIBERRAS Caroline²; TEODORI Sauro²

1 - State Archives of Pesaro

2 - Department of Earth, Life and Environmental Sciences, University of Urbino "Carlo Bo", Urbino, PU, Italy

Presenter e-mail: olivia.nesci@uniurb.it

Key terms: Fluvial Terraces; Channel adjustments; Historical cartography; Foglia river; Marche region

In the Foglia River basin, as in all the rivers of the Marche region, four orders of polygenic terraces dating back to the Middle/Upper Pleistocene are recognizable. The largest terraced plain, attributable to the last Pleniglacial period (20,000 years ago), is bevelled with minor terraces, probably relating to climatic events occurring in the Holocene.

Unfortunately, these terraces have not been accurately dated. Through a geomorphological analysis, however, at least two levels of terraces may be recognized, the lowest of which is easily distinguishable from confined paleomeanders indicating a high sinuosity channel. The study of differently dated aerial photos together with field surveys reveals significant changes in the lateral and vertical river dynamics over the last 60 years. In particular, we note that these variations are more pronounced in certain sectors of the valley where we recognized a general downcutting trend of the riverbed and a vertical incision. However, a comparison clearly shows a stronger variability in the channels of the middle section of the valley with maximum reduction peaks of over 300 m with riverbed values generally between 50 and 200 m (Tiberi et al. 2009). The presence of detailed historical cartography made available by the State Archive (Gregorian Register, 1835) allows to evaluate the channel evolution over the past 200 year and its latero/vertical modifications. This analysis constitutes a new source of data to verify the persistence of continuous changes along the entire longitudinal section. The Gregorian Register cartography, contained in a GIS format, when compared with the more recent channel changes, will allow to better illustrate the evolutionary trends improving the understanding of the causes of channel adjustments. TIBERI V., DI AGOSTINO V., TROIANI F., NESCI O. & SAVELLI D. (2009) - Bedrock channel reaches morphology: examples from the Northern Marche Region (Italy). GRA vol. 11, EGU2009-A-3432.

HISTORICAL ANALYSIS AS A TOOL TO IDENTIFY PLANIMETRICAL AND ALTIMETRICAL VARIATIONS IN A RIVER CHANNEL: THE CASE OF THE PO RIVER AT CASALE MONFERRATO (NORTHWESTERN ITALY)

TURITTO Ornella¹; MAGNARINI Giulia¹

1 - Cnr-IRPI Torino

Presenter e-mail: ornella.turitto@irpi.cnr.it

Key terms: river morphology; channel adjustments; human impact; Po River; Northwestern Italy

Information gleaned from historical maps, published or unpublished documents, and hydrometrical data can provide a valuable support in the analysis of morphological variations in river channels.

This case study describes a 15-km reach of the Po River upstream and downstream from the Casale Monferrato bridge (drainage basin area, 13.940 km²) where a hydrometrical gauging station was installed in 1882. Comparison of historical and recent maps showed a marked reduction (up to 80%) in the total channel width (wet channels with islands and bars) over the last 200 years. The channel width decreased progressively from 1-2 km (early 19th century), to 300-700 m (early 20th century) to 200-500 m (early 21st century). This has been accompanied by morphological changes in the channel pattern from a multi-thread to a single, sinuous channel with small sporadic bars and a gradual disappearance of the islands as they merged with the surrounding floodplain.

From a review of Ministry of Public Works technical reports and plans, we identified the channel regulation works constructed over the past two centuries and the effects they have had on channel dimension and pattern:

- ° since 1808 all peripheral ramifications of the river have been artificially closed off;
- ° in 1840 the old boat bridge at Casale Monferrato was replaced by a new bridge;
- ° over the course of the 19th century continuous embankments where filled in on the left and right sides of the river to control flooding;
- ° mainly after the 1940s bank protections to prevent bank erosion where placed at each fluvial bend or at the embankment foot.

These changes have also resulted in severe channel incision, as inferred from a progressive decrease in the minimal annual water level recorded at the Casale Monferrato gauging station. A clear incision started in 1915 reaching -3.70 m in 1968 (-1 m in 1915; -2 m in 1942; and -3 m in 1955). Between 1950 and 1980, the incision process was additionally exacerbated by excessively deep and widespread gravel and sand mining. Encroachment into the river corridor by agriculture and urban use has opened new areas for development, but also triggered severe and recurrent failures at the bridge, bank protections and embankments.

QUALITY ASSESSMENT OF PHOTOGRAMMETRICALLY-DERIVED DTM IN THE EVALUATION OF RIVER CHANNELS ADJUSTMENT

ZIZIOLI Davide¹; DUCI Gabriele¹; PELLEGRINI Luisa¹; ZUCCA Francesco¹

1 - Dipartimento di Scienze della Terra e dell'Ambiente - Università di Pavia

Presenter e-mail: davide.zizioli@dst.unipv.it

Key terms: PHOTOGRAMMETRY; DTM; CHANNEL CHANGES; TREBBIA RIVER; SCRIVIA RIVER

Developing accurate Digital Terrain Models (DTM) has always been a goal of researchers interested in quantifying land surface topography and processes. In fluvial geomorphology they are a very useful stuff to quantify river morphological changes both width and vertical, comparing multi-temporal and heterogeneous surveys. Prior to the introduction of LIDAR, traditional methods such as photogrammetry and field surveys were conducted to produce DTMs. While these methods can generate DTMs with acceptable levels of accuracy for certain applications, both methods are time and labour intensive. Furthermore, in the presence of steep slopes or high biomass, traditional DTM generation methods are difficult to implement, often leading to reduced levels of accuracy. Researches has demonstrated that LIDAR DTM generation is more efficient and accurate as compared to traditional methods. However the LIDAR datasets are available only since a few years and they are very expensive, while the aerial photographs of the Italian territory are numerous, cheapest, easily affordable and, often, if carried out at low altitude, have a fine ground resolution thus offering the opportunity to do a photo-interpretation finalized to identify objects and vegetated patches. On the other hand, due to the presence of a single return, is more difficult to filter photogrammetrically-derived points clouds to eliminate artefacts in elevation due to the top of the canopy correlation.

This study investigate the accuracy of three methodologies to create a digital terrain model from raw photogrammetrically-derived points clouds in braided bed river. The first one classify ground versus non-ground points using a supervised classification based on NDVI (Normalized Difference Vegetation Index). The second and third are known morphological algorithm frequently used to filter LIDAR dataset relative to forested environments. They are the "MCC, Multiscale Curvature Classification" (Evans and Hudak 2007) from Moscow Forestry Sciences Laboratory and the "BCAL LIDAR Tools" an open-source tools developed by Boise Center Aerospace Laboratory. All methods were tested along stretches of Trebbia (PC) and Scrivia (AL) rivers using aerial images of the years 1980, 2006, 2010 and collecting ground control points using RTK GPS. The accuracy tests were carried out using a raw dataset of GPS points and topographic sections surveyed in 2009 - 2010. Preliminary results show that digital terrain models obtained by filtering the points clouds using morphological filters have greater accuracy with less artefacts, especially along vegetated river banks. The average obtained accuracy, corresponding to about 20 cm, fall in the standards of this photogrammetrically derived DTM. This level of uncertainty is low enough to allow a quantitative comparison of the difference in surface elevations from digital elevation models (DTMs) derived from repeat topographic surveys; however must be taken into account when processing DoD (DEM of Differences) for example using GCD algorithm that provides a suite of tools for quantifying those uncertainties independently in each DEM and propagating them through to the DEM of difference.

OBSERVING AND MODELING WOOD TRANSPORT IN BRAIDED RIVERS

BERTOLDI Walter¹, WELBER Matilde², GURNELL Angela³
 1 - University of Trento + Queen Mary, University of London
 2 - University of Trento
 3 - Queen Mary, University of London

Presenter e-mail: walter.bertoldi@ing.unitn.it

Key terms: Wood transport; Braided rivers; Flume modeling; Tagliamento River

Drift wood is a relevant component of river corridors, strongly affecting fluvial morphology and ecology. Over the last three decades, research has highlighted strong links between driftwood dynamics and river morphology at multiple spatial scales, but few studies have addressed this topic in a braided river context. Little is known about wood recruitment, transport and deposition processes in spatially complex, constantly evolving multi-thread systems. We analyzed coupled examples of riparian trees recruitment from eroded banks and wood deposition on immediately downstream bars combining remotely sensed data and field measurements.

The research has been conducted on the Tagliamento River (Italy) a highly dynamic gravel-bed braided river, with large established islands. A pre-flood LiDAR survey provided information on the vegetation extension and density. Two automatic, fixed digital cameras made possible the monitoring of during-flood process of erosion and deposition of the riparian trees with a high temporal accuracy. We surveyed the position, diameter and length of the deposited trees with the aim to: i) quantify the proportion of trees deposited on the first available bar; ii) explore the relationships between log dimensions, number of trees in each cluster and position on the bar; and iii) assess the temporal dynamics and relate the deposition rate with the hydrological and morphological pattern.

The analysis showed that a large proportion of trees is deposited on the first downstream bar, ranging from 15 to 50% as a function of the flood stage and the position inside the network. The highly variable morphology of braided rivers and the strong variability of the channels width as a function of the water stage causes the distribution of the trees on a wide area, with generally small clusters (on average 2 - 3 logs).

The process of wood transport was reproduced on a large flume model (3x25 m, at the Hydraulic Laboratory, University of Trento). The braided morphology was developed freely with constant water and sediment input and wooden dowels of various sizes were used as surrogate logs.

Preliminary results show that the physical model is able to reproduce the characteristic wood dispersal phenomena observed in real-scale streams. The bar-scale morphological structure appears as a major driver of driftwood dispersal, governing transport distance and deposition pattern, with dowel size playing a secondary role on wood mobility.

"SALINE AND ALENTO RIVERS" - A SITE OF NATIONAL INTEREST RESULTS OBTAINED FROM THE PROCESSING OF THE DATA DURING THE CHARACTERIZATION PHASE AN APPROACH TO THE STUDY OF FLUVIAL SEDIMENTS

LUCHETTI Lucina¹, PERACCHIA Francesca¹, MARCELLI Tiziano¹
 1 - ARTA Abruzzo, Distretto Provinciale di Chieti

Presenter e-mail: l.luchetti@artaabruzzo.it

Key terms: Site of National Interest; fluvial sediments; contaminated sites; chemical and ecotoxicological analysis

The present study reports the very first results of the chemical and ecotoxicological analysis of the final stretch of the Alento river (CH) (about 8,000 metres) involved in the S.I.N. Project "Saline and Alento rivers (Abruzzo).

Aim of the study was to both determine the non-site specific screening levels in common with the CSC for soils and subsoils (D.lgs. 152/06) and the definition of the basic values of contaminants in the water streams' sediments in compliance to the criteria contained in the "A proposal of evaluation system on the qualitative state of the fluvial sediments in the Site of National Interest for the Saline and Alento rivers" drawn up by APAT (April 2007-2009).

The qualitative state of the sediments has been evaluated in those riverbed tracts subjected to a potential contamination through an integrated approach which, starting from the acquisition and evaluation of the historical data, takes into consideration both the chemical components (by definition the chemical levels of reference, CLR) and those ecotoxicological ones.

The characterization survey has been carried out by collecting riverbed sediment samples at 16 different spots (plus an extra natural basic sample), by performing acute toxicity tests on interstitial water obtained by centrifugation of the sediment using as target organism *Vibrio fischeri*, a gram negative bioluminescent bacteria. Furthermore, the research of both inorganic and organic contaminants, paying a special attention to: dibenzo(a,h)anthracene, lead, benzene, selenium, DDE and PCB in the sediment, as sampled.

Toxicological analyses of interstitial water obtained from sediments, point out in the vast majority of them, different levels of biostimulation or hormesis. Just in one sample, inhibition of bacteria luminescence of 52.5% has been observed. This sample can be considered toxic according to the suggestion contained in APAT guide lines (Proposal of technical guide of analysis methods for soil and contaminated sites by using biological and ecotoxicological indicators. RTI CTN_TES 1/2004).

The chemical analyses data show a critical state in a greater number of samples for the following parameters: dibenzo(a,h)anthracene, lead, benzene, selenium, DDE and PCB.

We can assume that the discrepancy between toxicological and chemical results could be related to a different polluting bioavailability between the interstitial water and the sediment as sampled.

4 - Istituto Superiore per la Protezione e la Ricerca Ambientale (ISPRA), Roma

Presenter e-mail: mrinaldi@dicea.unifi.it

Key terms: Morphological Quality Index; IQM; Water Framework Directive; morphological assessment

The stream Morphological Quality Index (IQM) is the procedure for the assessment of river morphological quality which has been formally approved as the standard hydromorphological method to comply with WFD requirements in Italy.

The methodological approach is based on an integration of: (1) field surveys and interpretations; (2) remote sensing and GIS analyses. The evaluation of present morphological conditions is carried out by using a series of forms allowing a guided analysis of the following aspects: (a) longitudinal and lateral continuity; (b) channel pattern; (c) cross-sectional configuration; (d) bed structure and substrate; and (e) vegetation in the riparian corridor. The analysis is carried out with reference to the previous five aspects considering three components: (1) geomorphic functionality; (2) artificiality; (3) channel changes. A scoring system is used to obtain a Morphological Alteration Index (IAM) and a Morphological Quality Index (IQM), thus allowing the classification of the morphological conditions of a stream.

A first data set of applications mainly carried out by the developers of the method is presented in this paper. The data set includes about 100 river reaches, mainly located in Central and Northern Italy. These reaches are sufficiently representative of different morphological conditions (confined, semi-unconfined, meandering, braided, etc.) and of various situations of artificiality (ranging from relatively natural to highly artificial streams).

The overall analysis of this initial data set permits the acquisition of some general information on the morphological status of Italian rivers for the different morphological types. Potentialities of more detailed information that can be obtained through use of the index are also shown. Some study cases are used to investigate downstream changes and causes of morphological quality.

Presenter e-mail: santo@unina.it

Key terms: Karst; Collapse sinkhole; Geostructural analysis; Southern Apennines

Recent studies about sinkholes on the carbonatic massif of the Central-Southern Apennines have highlighted a strong correlation among

their formation, recent tectonics, presence of mineral springs and hyperkarst processes. Sinkholes are recognized just in areas where the previously mentioned parameters coexist.

In this paper we aim to deepen the relations occurring between geo-structural context and sinkhole at different scale of investigation. At large scale we have tried to understand which is the regional and geodynamic context in which the sinkholes are developed. We observed that most of the sinkholes are located along large cataclastic areas related to the activity of regional Plio-Quaternary faults bordering both the peri-Tyrrhenian graben (Latina and Caserta mounts) and some inner areas of the chain (Aterno valley, areas around Telesse, Solopaca, Contursi villages). Such faults follow an apenninic trend along the Tyrrhenian coast, while they follow in some cases an anti-apenninic trend in the inner areas of the chain. Rarely, the regional faults follow a W-E trend, such as in the case of Contursi.

Thanks to a detailed survey it has been possible to recognize that the grade of fracturing of the rocks inside every single sinkhole is always pretty high, and we have observed that in most of the cases the RMR Beniauskis values characterize rocks of low to very low quality. The work has allowed to observe that sinkholes are developed in areas characterized by regional cataclastic belt. Their perimeter may be important because these areas may be considered susceptible to other collapses and because of the seismic macro- and micro-zonation studies addressed to site amplification. Another important aspect of these studies is related to the paleoseismicity because it is well known that the sinkholes may be a geomorphic evidence of strong earthquakes. Finally, also in the urban planning and in the engineering planning of large works and infrastructures we should consider the presence of large cataclastic belt and high concentration of sinkholes.

Key terms: Gypsum karst; suffosion sinkholes; risk mitigation; permeability; grouting

Punta delle Pietre Nere, NW of the Gargano promontory and Lesina lagoon, is considered a particularly interesting geological site, being the only formation of magma rocks on the entire Adriatic coast (the name actually translates as "black rocks"). About 60 million years ago these rocks came to the surface together with a gypsum dome of a diameter of about 1 km. These rocks, normally buried under a layer of several meters of continental and marine sands, emerged in 1930 with the building of a channel which connected the lagoon with the sea, with the mouth right at the head.

Since 1970 the area has been characterized by an intense building program, with the development of a tourist settlement. Since 1990, sinkhole phenomena have been noted on the sides of the canal; their marks on the surface evolve in clusters along well defined directions, ending close to the new building area. Further studies have clarified the context and the causes of this instability phenomenon. It can be associated with the structure of the evaporitic rocks, a widespread presence of discontinuity and voids for violent tectonic shifts and the superimposition of a paleocarsism at different depths, corresponding to the different levels of the sea standing, the reactivation of karst phenomena and of suffosion processes triggered by the movement of groundwater, following the presence of the new channel. More specifically, the groundwater regime is strictly connected to the complex sea-channel-lagoon system, defined by an inland flow towards the channel modulated by the tide with a variable width depending on factors such as the distance from the oscillating border.

The channel has thus determined a new hydraulic regime condition at the core of the area of maximum emersion of gypsum mass, with the complication that such a condition does not correspond to a static level but, according to what was previously stated, to an oscillating level with complex sinusoidal function, to which a variable field of temperature, electrical conductance and flow corresponds. The latter also seems to be able to invert in specific conditions the direction near the channel. Appropriate action in mitigating sinkhole risks in the area must first address the restoration of the hydro-geological regime to its previous state before the digging of the channel.

This, however, cannot be achieved with the simple elimination of the channel, as 80 years of the new hydro-geological regime have seriously modified the permeability and the storage qualities of the evaporitic mass bedrock.

Therefore the contrast of the new karst evolution and of the suffosion phenomena have been taken into account in modifying the permeability and the storage capacity on the left side of the canal with the systematic filling-in of underground voids. As a result, a barrier has been established with a reduced permeability towards the channel.

Along the border of the area affected by sinkholes, close to the built-up zone, the voids have been filled through small diameter drillings to a depth of 28 m and with an average spacing of 6 m. Subsequently, the filling phase of the voids and of the underground hollows was carried out by grouting in two phases with rising pressure of specific mixtures. The filling phase was completed by grouting in a further series of borings arranged in staggered rows with respect to those of the first group.

The effects of the action carried out on the rocks, initially evaluated by numerical models, have been verified through specific surveys in two significant areas; they have highlighted different hydraulic behavior in the aquifer and a notable reduction in underground voids, with a general decrease in gypsum mass permeability.

Presenter e-mail: ebianchi@ir-plc.com

Key terms: Sinkhole; Po Plain; GPS; PSInSAR; Geomorphological

In Italy, natural sinkhole phenomena which are not connected to any type of karst processes are relatively frequent. In the plains of Veneto and Emilia-Romagna, for example, several small sub-circular lakes are described since a long time, whose formation is thought to have been caused by evorsion (erosional processes related to vertical turbulence) and/or piping in alluvial sediments.

This paper deals with particular phenomena and related landforms, recently studied in the Po Plain, clustering in some areas in the provinces of Modena and Bologna. These processes have periodically produced shallow sinks, up to 2 m wide and deep, that disrupted agricultural works and exposed farm operators and equipment to hazard, requiring costly remedial measures. In some cases, the land productivity itself was impaired. On the basis of literature information, as well as available geological, geomorphologic and geotechnical data, the possible triggering factors and the evolution of these phenomena are described.

An inventory carried out some years ago shows that these phenomena tend to develop in different geological settings, from the apex of the alluvial fans down to the lower alluvial plain (i.e., from 64 to 6 m a.s.l.), generally within relatively short distances from streams and artificial channels, independently of the deep geological setting. In most cases, the affected soils have silty-sandy textures, related to alluvial ridges. The latter are composed by sandy channel fills, bounded by levees of mixed sand and silt, which pass outwards to finer silts and clays of interchannel zones. In fact, as sediments accrete, distributary streams shift laterally, forming new channels. Old channels are then gradually buried under interchannel silts and clays. As a result, the silty-clay body of the alluvial plain is laced with intersecting strings of loose sands surrounded by less permeable sediments. These sand strings, recharged by streams and channels, may behave as artesian aquifers at their distal ends.

On the basis of a large number of Cone Penetration Tests (CPTs), some of the affected areas have been characterized with reference to lithology, stratigraphy and relevant geotechnical parameters. The results of the investigations show that under an overconsolidated cohesive unit, with sufficient clay fraction to form and retain shrinkage cracks in the so-called active zone, at a depth in the order of 6 meters, a sandy unit can be typically found, that has shown to be susceptible of liquefaction as a consequence of natural or artificial causes (seismic shaking, water table sudden drawdown, heavy vehicles transit etc.). The liquefaction and subsequent packing of loose sediments leads to the development of proto-chambers, that become sinkholes when their roofs collapse. No particular relations have been observed between gas flux from the soil and sinkhole development.

In the proposed conceptual model, triggering and evolution of these phenomena depend therefore on the grain size of the near-surface sediments, and on specific hydraulic conditions related to the distal sectors of alluvial ridges in a recent alluvial plain.

To test this model, data collection on boundary conditions and a number of further field experiments is ongoing. In particular, the research is focused on two main issues:

- ° the analysis of surface displacements in key areas at a local and regional scale, in terms of horizontal (geodynamic) and vertical displacements (natural and/or artificial subsidence) and their relationships with the development of sinkholes. This will be performed through the exploitation of dedicated PSInSAR multitemporal data and the deployment of a new continuous GPS monitoring network;
- ° geological and geotechnical characterization of soils, in terms of liquefaction susceptibility. This will be accomplished by a number of continuous boreholes, trenches and CPT tests for building cross sections and 3D models of areas prone to sinkhole development.

THE UNIFIED REGIONAL CATALOG OF LATIUM SINKHOLES AND RISK AREAS

MELONI Fabio¹, NISIO Stefania², LIPERI Lorenzo², TONELLI Valter¹, ZIZZARI Pietro¹

1 - REGIONE LAZIO - AREA DIFESA DEL SUOLO

2 - ISPRA - SERVIZIO GEOLOGIA APPLICATA ED IDROGEOLOGIA

Presenter e-mail: fmeloni@regione.lazio.it

Key terms: SINKHOLES; LATIUM REGION; CATALOG; RISK AREAS; RULES

Lazio is a land particularly affected by catastrophic collapses. It shows some areas where the sinkholes appear to be sporadic and, on the contrary, other areas that are particularly affected by sinkholes (St. Victorinus and the Pontine Plain).

The event can cause considerable damage when it occurs in a urban areas or in areas with infrastructural networks. In Lazio, the last event of considerable size occurred in 2003, near the town of Marcellina in agricultural area, without causing damage to nearby infrastructure (high-voltage electricity grid and pipeline).

For years, the Lazio Region conducted studies on Sinkholes in order to define and govern the risk areas. The first example of rules in Latium region were those imposed for St. Victorinus plain (RI) and for a small land in the Pontine Plain (Lt). It was subsequently produced the first catalog and the first regional regulation to determine the studies that they have to conduct in risk areas when propose it for the edification (2002). Then it was followed by a new study for a better identification and classification of risk areas (2009, in progress). This studies involved the use of cartographic sources, historical documentation, as well as field trips, and allowed to reach a significant increase in the number of sinkholes.

In order to obtain a more complete mapping of the phenomenon both as number of events either as completeness of the information we made the unification of the catalog of Latium Region and the National ISPRA catalog. In particular ISPRA, which is forefront in the study of the phenomenon, has carried out a consistent catalog for Latium region, based on detailed studies, on historical sources and on old maps.

The effort has been to eliminate some sinkhole duplication and to equip them with more historical information in order to characterize the moment of genesis, or at least a range of time as close as possible to the date of the event (eg with historical evidence of the presence of the sinkhole to a given time or with more maps in a range of time). As well, to characterize the geological and hydrogeological environment, the water type, the surrounding vegetation and degree of urbanization. Correlations were also performed with the tectonic and structural trends.

The ultimate goal is now to understand the sinkhole genesis and frequency of occurrence in each area and to establish a rule for the use of

all these areas, based on the risk level.

2 - Ellegi srl

Presenter e-mail: vbuchig@tin.it

Key terms: Sinkhole; Monitoring; Survey; GBInSAR; Ground Based SAR

In October 1995 a sinkhole of about 35 meters of diameter took place in the urban area of Camaiole municipality and caused the sinking of a 3 floors house and seriously damaged 5 buildings, later demolished. This phenomenon that would have had catastrophic effect on human lives led the Municipality and the Local Authorities to seriously assessing the problem and searching for the best methodology to be used in sinkhole prevention and analysis.

Since then, a series of multidisciplinary studies have been carried out in different phases, allowing the collection of a huge and comprehensive quantity of geological, stratigraphic, hydrogeological, geophysical and geochemical database. Furthermore, the displacements' time series of a few control points spread on the territory have been collected.

After this first series of surveys the water pumping activity running in wells located at about 900m far from the sinkhole area has been discarded as a main triggering factor in case of normal pumping rates, while it is not completely excludable during the summer periods when the average pumping rates can be up to 360 l/sec with peaks of 500 l/sec.

These surveys led to the identification of Camaiole sinkhole triggering factors in the weakness of the carbonatic substrate (affected by paleo-carsism), in the location of the collapsed area that lies inside a tectonically active region having a relevant seismic event registered close to the sinkhole location only 8 days before its collapse, and the presence of big structural lineations intersecting in the sinkhole neighborhoods. A second series of surveys were extended to the whole territory of the Camaiole municipality by means of geophysical prospections (micro-gravimetric, geoelectric and seismic surveys) and geochemical inspections (endogen gas analysis), allowing the elaboration of maps displaying abnormal gravimetric and endogen gas values, as well as the geoelectric tomographical profiles.

A side result of the wide and intensive studies performed on this phenomenon is the detection of other areas affected by the same problems inside the urbanized district.

The integrated analysis of the structural, geognostical, seismic, electrochemical and gravimetric data collected since 1995 shows the presence in the whole area of several clues linked to anomalies at different depths.

The knowledge acquired was recently used to design and to implement an integrated monitoring system including: a) a seismic monitoring network, constantly acquiring data from three different sensors located in strategic points of the Camaiole municipality; b) a periodic monitoring of the water table of the aquifer through water-level tapes or transducers; and c) the implementation of a monitoring system using two different technologies to draw the superficial displacements field of the inspected area and allowing a fully automatic and continuous detection of the premonitory signs ("precursors") of an impending disaster or of those events that are particularly interesting to be analyzed. The technologies involved are GPS and Ground Based SAR interferometry (GBInSAR) measurements, in addition to the seismic control of the underground.

The main component of the monitoring network is the GBInSAR LISALab system implemented by Ellegi srl that constantly updates the values of the multi-temporal displacements field measured in the Camaiole municipality.

The main target of the monitoring network is setting up an effective monitoring methodology to prevent the hazards potentially impending over the urban area of Camaiole.

The Authors would like to present the different survey methodologies implemented in the specific case of the Camaiole sinkhole and the related results that have been used in the design and in the implementation of the monitoring system, as well as the results of the analyses performed over more than 3 years of uninterrupted measurements.

THE STUDY CASE OF BEVAGNA SINKHOLES (PERUGIA DISTRICT)

ALBANESI Matelda¹, NISIO Stefania², PICUTI Maria Romana³, SCARPIGNATO Marisa³

1 - collaboratrice Soprintendenza per i Beni archeologici dell'Umbria, Perugia
2 - SPRA-Dipartimento Difesa del Suolo-Servizio Geologico d'Italia, Roma
3 - Soprintendenza per i Beni archeologici dell'Umbria, Perugia

Presenter e-mail: mariaromanpicuti@alice.it

Key terms: Bevagna (Perugia District); alluvial plain, springs; SINKHOLES; sacred complex; II sec. B.C. - IV sec. A.D.

Bevagna area (Perugia district) is located at the cross of some rivers: Topino, Timia, Teverone, Clitunno in an alluvial plain rich of numerous springs. Other little lakes and springs (now filled) are represented in ancient maps.

One little sub-circular lake, Aiso lake is located near Bevagna town (ancient town of Mevania); it shows 25 m of diameter and 13 m of depth; at the bottom are presents some springs. Some geochemical analysis are conducted.

It was originated probably in historical age (pre-roman age); some legends refer the origin (perhaps from the 1300) with a quick catastrophic collapse. The water of the Aiso lake runs in an other sub-circular pond (Aisillo Mattoli lake), also originated with a catastrophic subsidence. The analysis of all Bevagna territory have been showed other small lakes and dry cavities (es. Madonna delle Rose cavity, some Aisilli little lakes). These morphologies could be due to deep piping sinkhole phenomena. This hypothesis is supported by geological, hydro-geological and structural setting of the Bevagna plain area. The Bevagna plain area is characterized by alluvial sediments (clay and silt with more than one hundred of meters) at the top of a main syncline, with N-S trend. Some fault systems cross the Topino alluvial plain: the cavities are locates with NS trend. In the Bevagna plain area are present aquifers related to deep hydro-geological circuits (confined aquifers).

In the Aisillo Fanelli area, four campaigns of archaeological excavation (in the 2004, 2005, 2009 2010), are brought to individuate a part of a sacred complex. The sacred complex was frequented between the beginning of the II sec. B.C. and the beginning of the IV sec. A.D., but its sacred title, at the moment, unknown.

The peculiarity of this sacred site is the presence of a spring with a great circular structure in the centre of the monument. The architectonic type send back presumably to a cult of the sanatio. Some analogies of geographic and topographical type indicate a similitude with the temple dedicated to the God Clitumnus, famous from the epistle of Plinio the Young (VIII, 8). The sacred site confirmed, in republican age, the role of Mevania town like a religious center of the Umbrian people and it suggests the sacred role represents by the Aisillo spring

Key terms: anthropogenic sinkhole; cavity; urban areas

Anthropogenic and natural cavities represent a serious hazard for the built-up environment in many Italian towns and cities. They could propagate upward in urban surface producing the formation of sinkholes. In the last years the number of the sinkholes in urban areas is increasing, due to urban expansion, particularly in the large cities as Rome, Naples and Cagliari.

Underground quarrying was developed in the past in some Italian towns, due to presence in the subsoil of soft rocks (especially volcanic or limestone rocks) suitable to be used for building purposes.

The soft rocks were therefore quarried underground producing an extensive network of galleries.

The underground galleries and caves have been progressively abandoned; somewhere they were used in other ways and finally they were filled or obliterated by urban infrastructures.

Some Italian towns, like Rome, Naples and Cagliari, are nowadays located just above network of cavities and the people loss the memory of the presence of the underground galleries; actually, with the exception of Naples, not exists a detailed cartography of the cavities and their exact localization.

The lost knowledge of the network of cavities produces a potential risk for the human structures and activities with a increment of anthropogenic sinkholes.

In Italy is not present yet a catalog or adjoined database of the sinkholes occurred in urban center provoked by anthropogenic activities.

This paper presents the results of the researches conducted by ISPRA "Sinkholes in urban centres Project". The aims of the study are to census sinkholes in urban centres, to census and map the net of underground cavities, to realize an anthropogenic sinkholes database and to compare sinkhole susceptibility in the three cities above mentioned.

HISTORY OF SINKHOLE EVENTS IN APULIA, ITALY, WITH PARTICULAR REGARD TO THE INTERACTIONS WITH THE ANTHROPOGENIC ENVIRONMENT

FIORE Antonio¹, PARISE Mario²

1 - Basin Authority of Apulia
2 - Institute of Research for Hydrogeological Protection, National Research Council, Bari

Presenter e-mail: antonello.fiore@adb.puglia.it

Key terms: sinkholes; hazard; artificial cavities; collapse; damage

In karst territories, sinkholes represent the most peculiar typology of hazards, being related to the presence of underground voids. These latter may be of natural origin, due to the solutional processes which affect soluble rocks, or caused by man's activities, through excavation of anthropogenic cavities underground. Whether the origin, presence of voids may result in sinkhole formation, causing heavy economic losses, if not casualties to the human society.

In the last years, a worrying increase of sinkhole events, related to both natural and anthropogenic cavities, has been registered in Apulia, southern Italy. Apulia region is actually well known since a long time for the occurrence of such events, as experienced for instance during the crisis that hit the towns of Canosa di Puglia and Andria; therefore, the possibility of occurrence of sinkholes is not unexpected for the area.

However, starting since the first years of the present century, the frequency of events have had a definite increase, which reached a peak during 2009 and 2010. It has to be noted that, in any case, the documented events represent only a small part of what is actually occurring, since many others (likely, the majority) are not registered due to lack of information, or to rapid infilling of sinkholes by the land owners. Our analysis started from historical researches, consisting of the scrutiny of many different sources, including but not limited to scientific publications, newspapers, chronicles, technical reports, and interviews with professionals. Critical analysis of such amount of data resulted in the creation of a database about sinkhole events in Apulia, that was further integrated by direct surveys from the authors in the last years. Overall, the database consists so far in several tens of cases of sinkholes for which a chronological reference (a date, even though generic) was found.

Information on timing of occurrence was considered of great importance in our research. In the analysis of sinkholes, as of any other natural or anthropogenic danger, knowledge of the temporal occurrence of the events is crucial to properly define the hazard. Lack of data about the timing of the events determines the impossibility to actually evaluate the hazard, which forces the analysis to be limited to the susceptibility assessment.

As already experienced in previous researches about other types of

natural hazards (mass movements, floods) in Italy, reliability of the temporal information can be highly variable, depending upon the type of source and the degree and amount of available information. Nevertheless, the sinkhole database we produced represents a valid starting point for examining in greater detail the temporal occurrence of phenomena in Apulia, with particular reference to their relation with different types of triggering factors.

A PRELIMINARY SINKHOLE SUCEPTIBILITY MAP OF THE LATIUM REGION

TEOLI Pamela¹, LA VIGNA Francesco¹, MAZZA Roberto¹, CAPELLI Giuseppe¹
1 - Università degli Studi Roma TRE

Presenter e-mail: lavigna@uniroma3.it

Key terms: sinkhole hazard evaluation; hydrogeology; probabilistic approach

Several and frequent studies were internationally presented about landslide susceptibility, meanwhile in literature is missing a broad diffusion of studies regarding sinkhole susceptibility. That's why sinkhole recurrence depends on several geological conditions related to specific geological and hydrogeological context (sinkhole prone area) that vary case by case. Notwithstanding this regionalization problem of sinkhole recurrence, in the central Apennine sedimentary basins (Italy) a certain number of geological, geomorphologic and hydrogeological conditions (sinkhole predisposing issues) can be considered in common between the surveyed sinkholes. Eventually this could be compared with similar geological conditions and sinkhole occurrence in the rest of Italy or in other countries.

In this case study is presented a probabilistic approach regarding the Latium Region deriving from the comparison between the regional sinkhole inventory realized during a precedent project and the dataset of the new Hydrogeological Map of Latium Region (scale 1:100,000). Indexed elements, chosen because associated to the majority of sinkhole phenomena, are: outcropping lithologies, slope value, foothills distance of carbonate ridges (in a plain), main faults (even if buried), gas sources, hydrothermal springs, piezometric gradient and land use. These indexed elements were weighted and combined in a matrix which preliminary result is the sinkhole susceptibility map of Latium Region. When definitively validated, this approach could be suitable for local authorities to planning more targeted studies in major hazard areas.

Presenter e-mail: stefano.margiotta@unisalento.it

Key terms: SINKHOLES; MORPHOLOGY; STRATIGRAPHY; GEOPHYSICS; SALENTO

In the Apulia region, the low-lying coasts of the Salento peninsula are significantly affected by land subsidence and sinkhole phenomena on both the Adriatic and Ionian coastal territories. Sinkholes are observed at different evolutionary stages, from those occurring at present to other relict features creating peculiar coastal morphologies. The study of sinkholes, specifically addressed to the understanding of their mechanism of formation, is of great importance for the safety of coastal settlements. Long stretches of the Salento coastline were affected by urban expansion in the last decades with residents strongly increasing during the summer season. The construction of new houses, pipelines and roads in areas subjected to subsidence and/or sinkhole phenomena results in great economic losses.

Casalabate, in the province of Lecce, is a small town located along the Adriatic coast that suffered a sequence of eight sinkhole events in the last 20 years. The local stratigraphy is well documented by many borehole data and the area is particularly suited to the investigation of the sinkhole hazard.

The critical analysis of core data integrated by detailed field mapping allowed the recognition of the local bedrock represented by the Pleistocene Gravina calcarenites overlain by Holocene organic-rich marsh deposits and sandy beach and coastal dune deposits. Due to their critical geotechnical properties, the occurrence of organic-rich marsh deposits is of particular importance in the overall stratigraphy. The sites affected by sinkholes in the past 15-20 years were subjected to specific geophysical surveys, consisting of combined georadar (GPR) and electrical resistivity tomographies (ERT). These surveys highlighted the effectiveness of GPR in identifying active sinkholes and lithologic changes and of ERT as an optimal descriptor of the geometry of sinkholes, thus indicating their evolution.

The integration of the geophysical, stratigraphical and morphological studies indicate that the main mechanisms of sinkhole formation are the cover collapse and the cover suffusion, and allowed a preliminary zonation of the sinkhole hazard.

Presenter e-mail: mike.difilippo@mcclink.it

Key terms: sinkholes; gravity survey; risk

In Italy, natural sinkhole phenomena which are not connected to karst

processes are relatively frequent. In the southern plain of Latium (Pontina area) for example, several small subcircular lakes are described, whose formation is thought to have been caused by erosional processes related to vertical turbulence and/or piping in alluvial sediments. At the present it is impossible to think about an estimation attempt for the hazard/risk due to the complete lack of adequate information about the whole plain.

A gravity survey carried out some years ago in whole plain shows several negative gravity anomalies. Later, in the last decade, some negative gravity areas were also studied by microgravity surveys.

Microgravity results show that these phenomena could tend to develop in different geological settings, from the apex of the alluvial fans down to the lower alluvial plain, generally within relatively short distances from streams and artificial channels.

Gravity information set can allow us to select a peculiar areas to be submitted to further intensive monitoring and surveys such as:

- 1) microgravity surveys to detect negative gravity anomalies;
- 2) high-resolution geophysical surveys;
- 3) continuous areal leveling to detect the (negative and positive) vertical motion;
- 4) gas seepage monitoring;
- 5) water seepage monitoring.

In terms of hazards, at the present, it should at least ask whether the sinkholes on the inner side of embankment body could also evolve towards underseepage phenomena, where negative gravity anomalies was detected.

SINKHOLES IN GESSOSO SOLFIFERA FORMATION (CENTRAL SICILY): HISTORICAL RESEARCH

LIGUORI Vincenzo¹, MANNO Giorgio¹, SAIA Salvatore²

1 - Dip. di Ingegneria Civile Ambientale e Aerospaziale, Facoltà di Ingegneria, Viale delle Scienze, Ed.8, I-90128 Palermo Italy

2 - Dip. Protezione Civile Provincia di Caltanissetta

Presenter e-mail: vincenzo.liguori@unipa.it

Key terms: sinkholes; mines; Gessoso Solfifera Formation; evaporite dissolution

The Sicilian sinkhole areas, are diffused on central zone of the island.

Indeed in these areas the sinkholes have a higher probability of occurrence and a greater genetic diversity, because there are the evaporite rocks. This is because evaporites have a higher solubility and, commonly, a lower mechanical strength. The evaporite environment is very sensitive to changes in the local hydrology and hydrogeology, so that human factors such as groundwater extraction, drainage, and irrigation can act as triggering factors to collapse events. The presence of mining-related cavities (workings, shafts and tunnels) or karstic (solution cavities and sinkholes in evaporitic rocks) within the top 100 m in the rock mass restricts land utilisation, and their migration to the surface may damage property or services or cause loss of life.

The Sicilian sinkholes develop in chalks and the salts. In the central-southern Sicily there is a thick formation of evaporitic rocks, deposited during the salinity crisis, happened in the Mediterranean sea in upper Miocene.

The salt in these layers is white coloured and normally has an average grade in NaCl superior to 98%, which is comparable to the best of such layers in the whole world. In some mines KCl salts are extracted. Given the remarkable mining importance of the products of the Gessoso-Solfifera Formation, since the antiquity, different mining centers for the extraction of potassic salts and/or of rock salt have been developed and the greatest of them falls into the provinces of Enna and Caltanissetta. Among the many existing mines in the Sicilian territory at the moment, only two are active. All the others are disused and abandoned, sometimes without any control. These mines, built on more levels than one, had the typical structure of a gallery; chambers and pillars. The infiltration of waters in the subsoil has produced salts dissolution. This process has created a weakening of the hollow vaults of the mining tunnels producing, in extreme cases, sudden and local collapses. This contribution presents examples of sinkhole induced by human activities that cause fresh water to flow through salt formations. The Racalmuto mining basin, classified as one of the greatest in Sicily, is a concrete example of the geomorphologic modifications of the territory linked with the presence of the mines that are now abandoned. The sinkholes, occurring in these areas, are numerous and often situated in correspondence with the meeting points of the mining galleries. They have almost always sub-circular shapes and diameters varying in depth. The dimensions of the greatest sinkhole are approximately of 100 m in width and of 200 m in depth. The sinkholes currently individualized can be found in anthropic areas with road infrastructures and residences, and in sites used by man for cultivation and/or pasture. In many cases they are reasons for damages to houses and the activities that develop in the near areas. Anyway the key measures to prevent sinkholes in mining areas are to control the amount of mine drainage and if present reduce water level fluctuation.

As discussed above the need an accurate evaluation of the risk caused by this phenomenon, and a correct management programme of the territory are born. Before risk assessments for sinkhole damage and indemnification are developed, a data base must be created to predict the occurrence and distribution of sinkholes. Historical data are necessary to develop and calibrate risk-assessment models, and ancient sinks provide an important means of establishing confidence and continuity in the models. With high-quality data, local risk maps and estimates of sinkhole probability can be developed.

THE VALLECORSIA SINKHOLES (FR, LATIUM) BETWEEN HISTORY AND CURRENT EVENTS

MELONI Fabio¹, CATALANO Giacomo¹, LIPERI Lorenzo¹, NOTARMUZI Carmela¹, SERICOLA Adelaide¹, ZIZZARI Pietro¹

1 - Regione Lazio - Area Difesa del Suolo

Presenter e-mail: fmeloni@regione.lazio.it

Key terms: SINKHOLES; CARSISSMO; VALLECORSIA; MONTI AUSONI; LAZIO

Lazio is a land particularly affected by catastrophic collapses. It shows some areas where the sinkholes appear to be sporadic and, on the

contrary, other areas that are particularly affected by sinkholes (St. Victorinus and the Pontine Plain). There are different geological contexts: areas of open plain (Pontine Plain, Acque Albule Basin, Fosso di San Martino Area, etc.) and areas enclosed within mountain reliefs (St Victorinus, Arcinazzo Plateaus, etc.). In some cases the context is of endoreic karst valleys or valleys closed by a very narrow threshold that makes difficult the water runoff. Often these areas are historically occupied by large lakes, then drained by water drainage and reclamation. In a similar context is the Vallecorsa valley (Fr), a very narrow valley into the Ausoni Mountains, in southern Lazio. The valley follows the tectonic lineaments and shows a shape at "Y" upside-down, in agreement with apenninic, anti-apenninic and meridian tectonic trends. The calcareous bedrock is buried under an alluvial and colluvial coverage, about a ten meter thick. In this valley you have two different types of sinkholes: a tract, at the intersection of the three fault systems, where the valley is quite wide, with high frequency of occurrence and small sinkhole shapes (2-3 m large and 3-4 m depth); an other sector, that stretches through the distal end of the valley with a N-S narrow shape, where you experience the most striking sinkhole phenomena (20-50 m large and 6-10 m depth). While the little sinkholes are quickly buried by human activity and have little days of life, the large sinkholes are persistent for several centuries and intersect with the history of the country of Vallecorsa and with the life of its inhabitants. In fact, the large sinkholes were utilized for many years for daily activity of inhabitants and use and protection of them was regulated by severe rules since 14th century. The different sinkhole shapes are probably correlated with the calcareous bedrock and in particular with the mechanism of capture and of removal of floods through the karst caves and tunnels.

Presenter e-mail: stefania.nisio@isprambiente.it

Key terms: Sinkhole; Umbria; Perugia; Lago di Casigliano; Lago di Sugano

Many sub-circular ponds, lakes and dry cavities in Umbrian territory, originated in historical age, should be due to piping sinkhole phenomena. This hypothesis is supported by the geological, morphological and hydro-geological setting of the area interested by the sinkholes. The small lakes have diameters from few to hundreds of meters and depth up to fifteen meters. The names are of dialectical origin and usually they indicate a kind of sinking (es. abyss). Some legends refer the origin of the lakes to a quick catastrophic collapse. Usually these depression are originated by karst erosion (collapsed dolines). Sometimes the genetic process should be related to the presence of artesian, mineralized waters and gas emissions (mainly CO₂ and H₂S) that contribute to the formation of the sinkholes through a mechanical upward erosion (deep piping process; NISIO, 2003).

These cavities are water filled (drown sinkholes) and are located on thin grained impermeable or semi-permeable sediments (silty clay, silt) more than 100 m thick.

The correlation between collapses and piping sinkholes is confirmed by the "drowning" of the cavity soon after the formations creating a ponds or a sub-circular lake, sometimes with underwater springs that feed the small lake.

In some cases are recognized many informations about the date and the modalities of the cave genesis (Aiso lake, Alto lake, Sugano lake etc.). The sinkhole ponds (more than 50 phenomena) are concentrated in Umbrian alluvial plains (Tiber, Topino, Tinia river plains).

In this work are considered some sinkhole prone areas of Perugia and Terni districts.

SINKHOLES IN THE FROSINONE REGION: FONTANA LIRI AS CASE STUDY

NISIO Stefania¹, CARAMANNA Giorgio², SCAPOLA Fabiana³

1 - ISPRA - Dipartimento Difesa del Suolo - Servizio Geologico D'Italia

2 - CICCIS-NCCCS, The University of Nottingham, Nottingham, UK

3 - Libero Professionista

Presenter e-mail: stefania.nisio@isprambiente.it

Key terms: Sinkhole; Fontana Liri; Frosinone; Solfatara; Bucone

The area surrounding the village of Fontana Liri (Frosinone) is characterized by a large flow of mineralised groundwater as evidenced by the presence of several sulphurous and gas-enriched springs. The quaternary, alluvial, lacustrine and slope deposits are affected by a fault system with NW-SE, NS and NE-SW trend. The carbonatic bedrock is overlaid by the sedimentary cover which is 100 metres thick.

In the beginning of the twentieth century, a group of springs named "Le Caldane" was characterized by high temperatures. These springs were initially exploited by a thermal bath that was successively closed due to the temporal instability of the geothermal emissions.

A small lake, "La Solfatara" has a sub-circular shape, and is fed by submerged springs with the presence of gas emissions. Nearby this lake there is another pond smaller in size named "Bucone" that is fed by mineralised spring-waters without the presence of gas. It has a cylindrical shape with very steep shores and lies in the slope deposits.

The chemical-physical characteristics of the lakes suggest its deep origin with a flow through the terrigenous cover. "La Solfatara" shows strong fluctuations in the water level; for some periods, it remains completely dry. However, the numerous other springs in the area are always active. These spring-lakes, as described by Plinius the Elder and known as such since Roman times, have shown chemical and thermal changes throughout the different periods.

We noted a close correlation between the behaviour of the spring-lakes, specially "La Solfatara", and the seismic activity in the area. From 2005 till December 2008 the "La Solfatara" was practically dry. Matching this datum with the local seismic activity, we observed that 2005 was a year without relevant seismic events and with very low local background seismicity. A stronger micro seismicity started in 2006 in the Cassino area (less than 30 kilometres from the lake) with an increasing number of events in 2007. In 2008 seismicity affected mostly the Sora area (less

than 15 kilometres from the lake). By late 2008/early 2009, "La Solfatara" was back in the old location, with an increased flow of the submerged springs and remarkable emissions of gas. On the occurrence of the 6 August 2009 seismic event (MI 3.9), localized few kilometres east of Fontana Liri, the gas emissions inside the lake increased. The surrounding area was also affected by a widespread degassing. Moreover, warm (20-21°) air fluxes were recognized across the travertine banks along the Liri river. In this study we present the first stratigraphic, historical, geological and hydrogeological data that support the theory that the spring-lakes were created by sinking phenomena.

Presenter e-mail: ascorda@arpa.sardegna.it

Key terms: SINKHOLES; SARDINIA; MINES; SULCIS IGLESIENTE; CAGLIARI

The opening of sinkholes in urban and industrial areas of Sardinia, in relatively recent times, triggered by the presence in the subsol of empty mines and karst cavities, pose serious threats to the protection and safety of the territory, especially in urban centres.

For decades we have witnessed, both in the areas of Sulcis-Iglesiente and in the city of Cagliari, the sudden opening of large sinkholes following the collapse of underground natural and anthropogenic cavities, with major repercussions and reverberations on the surface, in particular when located at a few tens of meters depth from buildings, roads and rail infrastructures, and from industrial areas. We should mention the large soil collapses, attributable to anthropogenic, sinkholes in the city of Cagliari, in the mining town of Carbonia, the villages of Bacu Abis and Cortoghiana, as well as in the metalliferous mining areas of Iglesias-Iglesiente (Acquasera, Nebida, Monteponi, Montevecchio). Over the past 20 years the deterioration of the stability of the mining voids, facilitated mainly by the closure of mines, has resulted in an exponential increase of mining collapses and related surface disturbances. have been recorded, so far, 60 sinkholes distributed in as many sinkhole risk areas, for a total extension of over 10 sq km. In these areas, to testify the past mining activities on the island and the impending risks, it is still present in the subsol a dense network of superimposed tunnels which developed in a straight line of several tens of thousands of km, partly buried by groundwater, including spacious mining rooms not always stabilized by mines fills.

In the same areas, but triggered by other factors, other 50 sinkholes were detected, associated with natural karst phenomena. They are distributed in the inland and coastal flood plains of Sulcis-Iglesiente and are often located in geological settings characterized by prevailing quaternary alluvial deposits with underlying Cambrian karst calcareous rocks. These include the sinkholes opened in the alluvial plain of the rio Cixerri (for a total of 26), along the rail track at km 33+330 of the Villamassargia-Iglesias line, at about 30 meters from the center line of the track (they were already known in the years '50), in the locality of Caput Acquis and in the narrow limestone valley of rio Corongiu, between the town of Iglesias and Villamassargia. Other sinkholes are located in the town of Carbonia (locality of Cannas n.3 and Serbariu n.2), in the plain of Narcao and in the locality of Acquacadda" in the vicinity of Nuxis (n.14), in the narrow limestone valley of Guttururu Saidu (n.5), at the administrative boundary between the village of S. Anna Arresi and Teulada.

This paper presents the results of the research into the sinkholes in the Sardinia Region, which was started in 2010 by the Regional Geological Service of Arpa Sardegna-Regional Geology Department in collaboration with the Province of Carbonia-Iglesias, the Municipality of Iglesias, the Mining Service of the Sardinia Region, and the Italian State Railways (Rete Ferroviaria Italiana S.p.A.).

An initial census of the active disruptions has been drawn up, including in depth bibliographic and historical mining studies, integrated, in their turn, with inspections and detailed geological surveys. At this stage the activities carried out have allowed to reach a preliminary region profile, which outlines the areas of the region at increased sinkholes risk, useful as a method of spatial planning and for safety interventions, monitoring and control of the environment as well as for the inclusion of these areas among those under P.A.I. regulation (Hydrological plan).

LAKE VADIMONE IN THE MIDDLE VALLEY OF TIBER: A POSSIBLE SINKHOLE.

PIRRO Mario¹, PAGLIUCA Nicola Mauro¹

1 - INGV

Presenter e-mail: mario.pirro@ingv.it

Key terms: Sinkhole; Cimino Volcano; middle valley of Tevere

In proximity of the right bank of the middle valley of Tiber (Lazio) in the Orte area, it is located a pool, with a circular shape locally known as Lake Vadimone. This small lake is famous in the history because the legend tells that near its sides, in the period around the 7th-6th c. BC, was fought a bloody battle between Romans and Etruscans, following which the latter definitively were defeated.

The floodplain where is homonymous pool is also known with the toponym of Lucignano area which is characterized by a thin travertine deposits (Upper Pleist.-Holocene). Further in Lake Vadimone there is a peculiar mineral spring whose water flows into the Tiber through a canal with a NW-SE direction. The plain of Lucignano is also characterized in the inner and southern sector by other springs with sulphurous nature linked to the quiescent phase of the near Cimino Volcano.

The geological characteristics of the terrains and the quaternary tectonics of the studied area have probably favorite the formation of Lake Vadimone as sinkhole.

The aim of our study is to investigate whether the processes related to the origin of Vadimone Lake are similar to those that generated other sinkholes found in the central Italy e.g., Lake San Giovanni which is located in the Acque Albule Basin (Lazio). In addition, we are interested to investigate the impact of the local seismicity and of the strong

earthquakes occurred in the central Appennine and in the near Tuscia area.

2 - IRPI-CNR, Via Amendola 122-I, 70126 Bari (Italy)

Presenter e-mail: asuncion@unizar.es

Key terms: Sinkholes; Evaporites; Carbonates; Human influence; Hazard

Sinkholes of different types and mechanisms occur worldwide in soluble rocks (mainly carbonates and evaporites), and represent one of the most typical features of karst settings. Their analysis may start from several standpoints, depending on age of the sinkhole, involved rocks, hydrogeology, relation with underground caves, connection with voids of anthropogenic origin, and so on. Whether the approach, study of sinkholes has necessarily to begin with a detailed research about the geological setting, in order to identify the most likely conditions leading to sinkhole occurrence.

Comparison of different study areas, therefore, may be extremely useful for a definition of the main factors acting in both the predisposition of terrains to sinkholes, and their trigger as well; such data will be useful for any further work addressed to definition of the sinkhole susceptibility and hazard. With this aim, two areas have been here considered: the Quaternary deposits of the Ebro River in northeastern Spain, and the Salento peninsula of Apulia, in southern Italy. The two areas are characterized by frequent occurrence of sinkholes, of natural and anthropogenic origin, and are being studied since a long time. Involved rock masses are different, being Miocene evaporites in Spain, and Pliocene-Pleistocene calcarenites in Italy.

In particular, the Spanish test site is located in the central Ebro Basin where Quaternary coarse detrital deposits (mainly fluvial in origin) overlie Miocene evaporites (gypsum and more soluble salts). The dissolution of Tertiary beds has caused the generation of cover collapse and suffusion sinkholes being, at present, a very active phenomenon. Since 1970, wide karst areas were urbanized and important damages, with the subsequent economic losses, have been constant in this region. A striking feature in the area is the existence of palaeosinkholes generated during the Pleistocene time indicating that karstification developed by environmental conditions without human influence.

Salento is the terminal portion of Apulia, the heel of the Italian boot, and is an entirely karst land. Recent calcarenites, overlying the local bedrock represented by Cretaceous limestones and Miocene marly carbonates, are affected by a number of sinkhole phenomena, mainly covering the typology of collapse, cover collapse and suffusion sinkholes. In addition, several cases have been recorded in the last years as related to underground quarries, with heavy consequences in terms of economic losses for the society.

Starting from a deep knowledge acquired in the last decades about the geological and morphological setting of the two study areas, we present in this work a first comparison of the sinkhole occurrence, with particular regard to frequency and distribution of sinkholes, morphometric features (size, depth), and relation with the anthropogenic environment. The latter topic is of particular importance, as a matter of fact, being strictly linked to definition of the total risk related to sinkholes. Old and recent sinkholes are analyzed and compared, in order to define likely changes in size of the observed phenomena, possibly linked to climatic changes and/or human interferences.

Presenter e-mail: vattano@unipa.it

Key terms: anthropogenic sinkhole; underground quarry; Sicily

The territory of Marsala, in western Sicily (southern Italy), is characterized by numerous quarries for extraction of calcarenite rocks to be used as building material. Many of these are underground quarries which were realized at depth ranging from a few meters to about 25 m, on a single or two levels, following the excavation technique of galleries and pillars. With time, the underground quarries have been progressively abandoned because of several reasons, including the decay in the physical and mechanical properties of the calcarenite rock mass, the interaction with the groundwater, the high costs of extraction, the dangers and difficulties encountered in working underground.

Since the 1960's the quarries have been subject to instability processes, through collapse and deformation of vaults and pillars. These phenomena are often propagated upward until the topographic surface with the formation of sinkholes which affected also the built-up area causing extensive damages.

The aim of this paper is to provide a description of the most significant events, in the attempt to understand the factors responsible of the instability processes and the genetic mechanism of anthropogenic sinkholes by means of numerical codes and field surveys, as already performed in other areas of Italy.

THE ENVIRONMENTAL EVOLUTION OF THE HISTORIC CENTRE OF VELLETRI (RM): THE PROBLEM OF THE ANTHROPOGENIC SINKHOLES

D'ANIELLO Valentino¹, AVERSA Mario²

1 - AGI

2 - ISPRA

Presenter e-mail: valendan@tin.it

Key terms: VELLETRI; SINKHOLES; GIS; HISTORIC CENTRE

Velletri, a small town of Latium, is populated from thousand years, especially for its location, its fertile soil and a mild climate. In the proximity of Rome, of the current pontina valley and of the southern Latium, Velletri has always been crossroads of peoples, armies and, often, it has been theatre of very harsh conflicts which caused a partial destruction of the city.

Built in the shelter of the Vulcano Laziale, it has been constantly scourged by earthquakes, registered in a particularly high number, which have caused damages to structures in particular, but which rarely brought about casualties.

Then, the history of Velletri is characterized with cyclicity by constructions, destructions and reconstructions, which changed the aspect of the city centre up to 22nd January 1944, when a devastating air raid almost laid waste the town; a new reconstruction, maybe was more devastating than the destruction, overlapped upon its rubble.

Furthermore, Velletri's historic centre suffered, in the last sixty years, a widespread depopulation. From the second half of the last century, while the whole number of the dwellers has went on growing, it has been registered a gradual abandonment of the habitation located in the most ancient part of the city, with the subsequent displacement of dwellers in its more external areas. This had a significant influence upon the loss of the utilization of caves, underground passages and galleries, used in the past both for preserving wine and as an underground system of communication, today almost unknown to people.

In this scenario takes part the analysis made during this work, led up to keep one's mind on a phenomenon that, in the last years, affects Velletri time and time again and, specially, its ancient part; it is built upon a close network of caves by now well-nigh totally forgotten and in which the services as sewers and water system are some centuries-old; it is often affected by episodes of anthropic sinkhole, which, unfortunately, in some cases caused dead persons and injured.

The first stage of this study is based on the use of multifarious sources of information, among the others historical records, newspaper libraries, ancient texts and modern images surveyed by environmental satellites.

In the second stage of the study we proceeded to the creation of a Geographic Information System (GIS), to insert and handle all the recorded data. It has been created a rich database of sinkholes occurred in the district of Velletri from 1967 to nowadays. All the events that have been identified have been georeferenced, can be distinguished the zones of the built-up area most affected by the phenomenon. Afterwards, we proceeded to the subdivision by typology of the sinkholes events.

Furthermore, has been highlighted a mutual relationship between the formation of unexpected swallow-holes and striking showers. A further stage if the study has been the location of the city zones that, in conformity with the recorded data, in theory are exposed to the higher risk of subsidence.

The developed analysis and the creation of the Geographic Information System tend to be the starting point of a program of territorial management for the local government of Velletri and, in particular, of its historic centre, with the purpose to clamp down the phenomenon of sinkholes.

Key terms: sinkholes; interferometry; remote sensing; monitoring; hazard

Sinkholes represent the main hazards in karst areas, characterizing such territories because of the presence of natural and anthropogenic caves.

Dissolution in soluble rocks (carbonates, evaporites), and later evolution of karst caves due to breakdown processes are at the origin of sinkhole events related to underground voids of natural origin. In many regions of Italy, the presence of anthropogenic cavities, excavated underground for different reasons and in different epochs, and generally located at low depth from the ground surface, creates a further hazard, which becomes extremely dangerous in built-up areas. Loss of memory of these underground cavities results, as a matter of fact, in building above voids, which extension and stability conditions are not known. As a consequence, the upward evolution of instabilities phenomena occurring underground may reach the ground surface, thus creating sinkhole events.

In order to mitigate the risk related to such phenomena, the identification of likely premonitory signs preceding the catastrophic phase of collapse may be extremely important. Both remote sensing and surface monitoring can be used at this aim: multi-pass space-borne Differential Synthetic Aperture Radar Interferometry (DInSAR) techniques, for instance, provide a valid support to remotely investigate the sinkhole susceptibility at the regional scale. Especially when integrated by classical topographic surveys at the surface, and by monitoring campaigns underground, significant data can be collected.

In this work, the advanced DInSAR approach referred to as Small Baseline Subset (SBAS) is used and compared to surface data for investigating sinkhole deformation in southern Apulia, with particular reference to some recent events related to underground quarries. Both descending and ascending ENVISAT images spanning the 2003-2010 period have been analysed, allowing to map active areas of surface deformations, and to compare such areas with the real occurrence of sinkholes. Eventually, some considerations about the potentialities of the interferometric approach in the analyses of sinkhole phenomena and in the assessment of the related hazard and risk are presented.

USING GIS TECHNIQUES TO ASSESS THE SINKHOLE SUSCEPTIBILITY

PEPE Pietro¹, GARZIANO Giuditta¹, PARISE Mario²

1 - Apogeo, Altamura

2 - CNR-IRPI, Bari

Presenter e-mail: apogeo.altamura@libero.it

Key terms: sinkholes; susceptibility; GIS

The town of Altamura, in the Murge plateau of inland Apulia (Bari province) has been affected since 2006 by a number of sinkholes related to the presence of underground quarries of calcarenite, the local rock mostly used for building purposes. Being the calcarenite generally located below a cover of a few to 15 meters of clays, quarries developed underground, and are at present at the origin of several instability problems in the area. This is due to abandonment of the quarries, and progressive weathering of the rock mass, which brought to development of failures from both the walls and vaults of the underground quarries. Eventually, such instabilities may propagate upward until reaching the surface, thus creating sinkholes. Since sinkholes developed within the urban area of Altamura, and/or in areas interested by recent or future constructions, the local Authority established in 2008 a code according to which all the buildings located in territories considered at risk had to perform geological studies aimed at verifying, and eventually removing, the hazardous situations. These studies brought in the last years to collect a wide amount of data from different sources, and of different typologies, which management had necessarily to be performed in a GIS environment.

With this goal, a project has been started by Apogeo and CNR-IRPI, taking advantage of a grant by Apulia Region ("Back to future" call by Apulia Region, POR Puglia F.S.E. 2007/2013, Official Bulletin of Apulia Region, no. 203, 17/12/2009) to implement the structure of a dedicated geo-database to collect, analyze, represent and use all the available information. The database was created by subdividing the information into seven groups (feature datasets), which, in turn, were divided into layers dealing with a peculiar feature of the database: cartography, land use, geomorphology, hydrology, direct and indirect surveys, caving explorations, existing codes. All these data have been collected and analyzed for that portion of the Altamura municipality which is considered to be at risk from a hydro-geological standpoint. Analysis of the available data, including the time and site of occurrence of sinkholes in the last decades, allowed to develop models to produce a sinkhole susceptibility map. Such a map represents a first result deriving from the high level of acquired knowledge on the geological features of the territory, and is, at the same time, a useful tool for mitigating the risk related to anthropogenic sinkholes.

SESSIONE C5

Effetti delle variazioni climatiche oloceniche sui processi di erosione/sedimentazione

C5-1 Key Lecture Giraudi, Carlo

10.1474/Epitome.04.0272.Geoitalia2011

THE HOLOCENE CLIMATE OF PENINSULAR ITALY AND ALONG A N-S TRANSECT BETWEEN LATITUDES 45° AND 16° N.

GIRAUDI Carlo¹
1 - ENEA

Presenter e-mail: carlo.giraudi@enea.it

Key terms: Holocene climate; environmental variations; Italy; Mediterranean basin; Sahara desert

Examination of a series of proxy data relating to continental deposits in peninsular Italy has indicated that many environmental variations produced by climatic changes took place in the Holocene. The studied environments (periglacial and glacial high mountain zones, caves, lakes of various origin and size) were influenced in a different manner by these variations. Even though it appears evident that the response to these climatic changes is strongly conditioned by local factors, a basic coherence emerges between the data examined and a number of apparent contradictions may be explained within the context of the overall interpretation of the proxy data taken into consideration.

Apart from the climatic evolution of peninsular Italy, the results will be presented of the studies of the Holocene evolution of sites located along a N-S transect including the island of Lampedusa (35°N, 12°E), the Jebel Gharbi zone in Libya (30-32°N, 10-14°E), the Gobero area, and the Teneré Desert in Niger (16°N, 9-10°E) studied in the course of investigations conducted in the last ten years. In particular the correlations, or the lack of correlations, will be evidenced between humid and arid periods in the southern Sahara affected by the expansion of monsoon rains in the course of part of the Holocene, in the northern Sahara and in the southern and northern Mediterranean area. Particular attention will be paid also to aeolian activity in the desert areas and to the Holocene aeolian deposits present on Lampedusa and in peninsular Italy.

The dating of the environmental variations in the various zones has made it possible to verify that there can be chronological correlations between phases of climate change in the Mediterranean and Saharan area and Ice Rrafted Debris Events in the North Atlantic, mainly during the second half of the Holocene. The variations in air circulation linked to processes that occur at high latitudes in the northern hemisphere could therefore be one of the causes of the climatic variations. However, correlation with events in the North Atlantic appears far less reliable during the early Holocene when insolation, linked with the astronomic position of the Earth, was greater.

10.1474/Epitome.04.0273.Geoitalia2011

HOLOCENE SLOPE EROSION IN THE NORTHERN APENNINES AS REVEALED BY LANDSLIDE EVENTS

CHELLI Alessandro¹, TELLINI Claudio¹

1 - Dipartimento di Scienze della Terra-Università degli Studi di Parma
Presenter e-mail: alessandro.chelli@unipr.it

Key terms: landslide; reactivation; climate variation; Holocene

In the last few decades, globally distributed proxy data demonstrated that Holocene has been characterized by climate variations at different time (from centuries to millennial) scales. Even if the debate on the true significance and pattern of these variations is still open, shifts in temperature and hydrological condition have been frequent in the last 10,000 years.

Around the Mediterranean basin, the occurrence of wet periods is reflected

by data on palaeofloods, erosion processes and slope wasting. Nevertheless, landslides are strictly connected with morphological, geological and hydrological condition of the slopes and, probably, periods of one or more years with long-lasting and/or intense rainfalls episodes determine, even though during relative dry time intervals, the occurrence of debris, earth and mud flows.

In the Northern Apennines, about sixty radiocarbon datings of late Quaternary landslide events, most of them from landslides in the territory between the Secchia and the Taro rivers, have been collected in different datasets. Most of the dated landslide events are reactivations of large earth flows or complex (rotational and/or translational slide-earth flow) landslides. In fact, reactivations of large complex landslides are sensitive to the variation of pore water pressure inside the landslide bodies. Tree remains (roots, pieces of trunks or branches) and organic bulk samples, found inside the landslide bodies, were some of the materials collected and the datings through radiometric and AMS techniques have been performed. Many events are referred to the same landslide body and the stratigraphic setting of the landslide reactivations has been accounted for. During the Holocene, the landslide events cluster round different time periods. In fact, a part from some scattered datings in the late Pleistocene, landslide events are in the time intervals 9,500-8,500 cal yr BP, 6,300-1,800 cal yr BP and 1,000 cal yr BP to present.

The clusters of landslide events found for the western Emilian Apennines are in concordance with landslide datings found in the Alps and in the western and central Europe highlighting phases of enhanced erosion controlled by the hydrologic condition of the slopes in turn due to wet climate periods or to episodes of prolonged and/or intense rainfalls.

10.1474/Epitome.04.0274.Geoitalia2011

HOLOCENE ALLUVIAL EROSION/DEPOSITION RELATED TO CLIMATIC CHANGE IN BASILICATA, SOUTHERN ITALY

BOENZI Federico¹, CALDARA Massimo¹, CAPOLONGO Domenico¹, PICCARRETA Marco¹

1 - DIPARTIMENTO DI GEOLOGIA E GEOFISICA, UNIVERSITA' DEGLI STUDI DI BARI

Presenter e-mail: marcopiccarreta@geo.uniba.it

Key terms: Paleofloods; Gullies; Climatic change; Holocene; Basilicata

Paleofloods and their related geomorphological effects are the result of climate variability and specific environmental conditions and changes in the past. Reconstructing the past hydrological events is one of the main aims of the more recent research in Geomorphology. The natural records of these processes, including fluvial terraces, floodplains, colluvial, paludal and slope deposits and paleosols, can be assessed through geomorphological, sedimentological, pedological and chronostratigraphical methods. Many results on Holocene landscape evolution are available from case studies of river catchments, with data for sediment transport and deposition extracted from colluvial deposits, lake sediments and floodplain sediments. Critical studies about Italian ancient paleofloods both on national and on regional scale are scarce. For the Basilicata region, southern Italy, several studies of both the deposits filling the incisions and those forming the Upper Holocene terraces in the Bradano, Basento and Cavone river basin, dated with radiocarbon techniques, have been conducted in the last three decades (Neboit, 1977; Brückner, 1983; Abbott and Valastro, 1995; Small et al., 1998; Boenzi et al., 2008). All these data can be used to analyze the Holocene paleoflood frequency in Basilicata. The high number of dated samples compared to the extension of the study area allows a very reliable reconstruction. In the last decade, different researchers (Macklin and Lewin, 2003; Gregory et al., 2006; Thorndycraft and Benito, 2006a, 2006b; Zielhofer and Faust, 2008; Hoffmann et al., 2008, 2010) have used the cumulative probability density functions (CPDFs) of 14C-ages obtained on alluvial deposits to reconstruct Holocene phases of increased geomorphic activity in Europe and Northern Africa river basin. The authors focused their attention especially on 'change dates', indicating 14C-ages which coincided with an abrupt modification in alluvial sedimentation structure or rate. The 14C-ages are classified to represent activity, stability and transitional phases based on the depositional environment of the dated sample. The method consists in a probability plot, summed for all the analysed dates, where the y-axis is probability per year and the x-axis is the calibrated radiocarbon age. The plot provides a best estimate for the temporal distribution if the dates entered into the calculation, enabling comparison between the chronologies of the different data set analysed. The same approach has been applied to the Basilicata 14C-database of fluvial 14C-ages. The data recovered from this study have been integrated with those from literature (Neboit, 1977; Brückner, 1983; Abbott and Valastro, 1995; Small et al., 1998; Boenzi et al., 2008). A reliable chronological dataset of 34 radiocarbon dates has been created, which allowed a better reconstruction of the events that occurred in Basilicata during the Holocene. Radiocarbon ages of the Basilicata dataset were calibrated using CALIB 6.0.1 14C age calibration program (Stuiver and Reimer, 1993; Reimer et al., 2004) and plotted as CPDFs. The critical analysis of the 34 radiocarbon dates has identified eight periods of increased fluvial activity in this area, namely: 7200-6800; 4800-4550; 4300-4100; 3400-3100; 2350-1850; 1700-1320; 1050-800 and 300-120 cal years BP. Many of these phases coincide with the main flooding events recorded elsewhere in the Mediterranean. The record is discussed in relation to high-resolution central-southern Italy pollen and lake level records and Alps and Apennine (central Italy) glacier variations to identify relationships between geomorphic activity and Holocene environmental change. The data comparison suggests that aggradational and incisional episodes were primarily climatically driven, whereas flooding coincided with colder and moister phases, while incision (i.e. gully formation) occurred during dry-warm periods due to high magnitude, low frequency alluvial events.

GLOBAL CHANGE, MARINE ACIDIFICATION, AND THE ALGAL CARBONATES

BASSO Daniela¹

1 - Univ. Milano-Bicocca, Dip.to di Scienze Geologiche e Geotecnologie
Presenter e-mail: daniela.basso@unimib.it

Key terms: calcareous algae; carbonate production; high-Mg calcite; marine acidification

The global change is producing global warming and ocean acidification. The commonest red calcareous algae on the world's modern shelves are

the Mg-calcite Corallinales and Sporolithales and the aragonitic Peyssonneliales and Nemaliales. They are vulnerable to a lowering pH, because of the mineralogy of their thallus. Among them, coralline algae are ecosystem engineers and major carbonate sediment producers in temperate and cold seas. They are negatively affected by marine acidification and rising temperature, showing decreased net calcification, decreased growth and reproduction, reduced abundance and diversity leading to death and ecological shift to dominant non-calcifying algae. Despite their key ecological and sedimentological role, and because of their vulnerability to marine warming and acidification, we need to improve our knowledge of the distribution of coralline-dominated habitats and the quantification of their carbonate production, in order to allow proper environmental management and confident modelling of global carbon budget.

4 - School of Architecture and Design "Eduardo Vittoria" - University of Camerino (Italy)

Presenter e-mail: marco.materazzi@unicam.it

Key terms: *Fluvial and coastal morphodynamics; Holocene; Central Italy*

The present work shows the results of many researches carried out from some tenth of years on the fluvial-coastal system of the central Adriatic Italy. The physical landscape, from west to east, is characterized by three territorial units: i) the central Apennine Chain, constituted by calcareous and marly calcareous rocks (late Trias-Oligocene) deformed and cut by folds, thrusts and faults; ii) the wide pedemountain belt, slightly sinclinal, modeled on the Messinian marly-arenaceous turbidites; iii) the monoclinical hilly landscape, verging towards the east and ending on the Adriatic coast, modeled on a Pliocene-Pleistocene sedimentary succession made by though pelitic units with interbedded sandy-conglomeratic levels at different heights. Continental deposits of different genesis and thickness (middle Pleistocene - Holocene), cover the bedrock on wide sectors.

The topographic surface is extremely articulated, because systematically dissected by hydrographic basins, roughly W-E oriented, with outlet along the Adriatic coast. The fluvial axes and the correspondent mouths and beaches show a complex evolution occurred through at times conflicting processes.

The period comprised between the early Holocene and the beginning of the XXth century is characterized, as like as in other areas of the Mediterranean, by an intense phase of deposition both along the river valleys and on the mouths, with consequent strong advance of the shoreline. This evolution is generally congruent with that observed by many authors and concerning the effects on the fluvial dynamics produced by the numerous "cold" and rainy phases of the early Holocene, of the early Middle Age and, mostly, of the Little Ice Age. During this last phase a very important role is played also by the "anthropic resistancy" conditions: the human transformations on the slopes, in fact, favored erosion and transportation processes from the slopes to the hydrographic network.

In the first half of the last century, after a former phase characterized by fluvial erosion and shoreline retreat, the environmental setting is considered almost stable. On the other hand in the second half, said erosive processes (sometimes alternated by depositional ones) occurred with particular strength; about their activation and evolutionary control, the anthropic role (huge quarrying, narrowing of the natural fluvial cross-section etc..) is considered almost exclusive.

2 - Dipartimento di Geoscienze, Università degli Studi di Trieste

3 - INGEODAV, Universidad de Buenos Aires

Presenter e-mail: elodolo@ogs.trieste.it

Key terms: *Eastern Lago Fagnano; Holocene sediments; Proxies for environmental studies*

Lago Fagnano is located in a tectonic depression developed along the Magallanes-Fagnano transform fault, a major segment of the South America-Scotia plate boundary. It is 110 km long and its width varies from 2.8 to 9.7 km, and has a maximum water depth of 206 m. The tectonic structure of the Lago Fagnano formed presumably during the Paleogene, and its morphological setting was subsequently modified by glacial erosion, especially during the Late Quaternary.

During a joint Italian-Argentinean acquisition campaign (March 2010) funded by the Italian Ministry of Foreign Affairs, a total of 30 sediment samples were taken from three piston cores collected on the bottom of the easternmost part of Lago Fagnano, in the vicinity of the Rio Turbio inlet. Piston cores CF-1B, CF-3A and CF-F were retrieved at water depths of 20.4 m, 19.8 m and 36 m, respectively, and recovered 80 cm, 92 cm and 90 cm of lacustrine deposits. These sediments have been investigated for their mineralogy (X-ray powder diffraction) and geochemistry (rare earth elements, along with major redox-sensitive elements), with the aim of evaluating the suitability of these proxies for environmental studies. Sedimentological and mineralogical analyses showed that these samples are characterized by a silty-clayey fraction that is mainly constituted by quartz, feldspar and clay minerals. Chondrite-normalised rare-earth elements patterns are similar to those of the lighter upper continental crust, with some depletion of heavy rare earth elements. The analytical results lead to the conclusion that mineralogy and geochemistry provide key clues to the understanding of this depositional environment.

GIS MODELLING OF THE GELASIAN FARFA RIVER CATCHMENT (CENTRAL ITALY)

FUBELLI Giandomenico¹, AMATO Gabriele¹

1 - Università Roma Tre - Dipartimento di Scienze Geologiche

Presenter e-mail: fubelli@uniroma3.it

Key terms: *Paleoshoreline; Paleosurface; Uplift*

Air-photo interpretation and GIS analysis can be a valuable key to reconstruct past landscapes and landscape-forming processes, where the investigated area is too wide to be studied with conventional methods. In this perspective we applied a simple GIS based method to model the Farfa River paleo drainage basin.

The present Farfa River, a left tributary of the Tiber River, has a 132 km² wide drainage basin. It flows from the Sabini Mts. (Central Apennine) crossing the "Transitional Sabina Sequence" (Lias to Miocene in age) made of limestone, marls, calcarenites and flysch deposits.

In the upper basin sector the river cuts fluvial conglomerate and sands Gelasian in age. Downstream, on the left side of the Tiber Valley, the facies of the incised sediments shows deltaic to frankly marine characters, that indicate the presence of the Gelasian paleo shoreline. This is also testified by the finding of lithodomus holes in the calcareous bedrock at an elevation of 260-290 m a.s.l. The shape of the Gelasian alluvial plain and delta has been outlined and redrawn by means of GIS techniques. Starting from this, we reconstructed the ancient Farfa River drainage basin whose surface area, more than 1000 km², was much wider than the present one. The reconstruction of the top surface of the old alluvial plain allows to recognize the occurrence of Quaternary faults in the study area. Finally, from the shoreline elevation, an uplift rate of 0.12/0.14 mm/yr has been calculated.

10.1474/Epitome.04.0279.Geoitalia2011

THE SEDIMENTARY BEDFORMS IN THE CHANNELS OF LA MADDALENA ARCHIPELAGO (NW SARDINIA, ITALY): A PRODUCT OF THE HOLOCENE SEA LEVEL RISING.

BARTOLE Roberto¹, DE MURO Sandro²

1 - Dipartimento di Geoscienze, Università degli Studi di Trieste

2 - Dipartimento di Scienze della Terra, Università degli studi di Cagliari

Presenter e-mail: bartoler@units.it

Key terms: *La Maddalena Archipelago; upper continental shelf; acoustic facies; bedforms; last eustatic cycle*

The use of a Chirp high-resolution acoustic source made it possible the differentiation of acoustic facies in the recentmost sediments of the channels of the La Maddalena Archipelago and the recognition of large scale bedforms linked to the last eustatic cycle.

The acoustic facies, distinguished on the basis of their reflectivity characters, show a substantial coherence with the distribution of the sedimentary facies described by previous Authors. In the channels of the archipelago flat bottom sediments with medium to poor reflectivity correspond to sands, gravels and muds mainly of bioclastic composition deriving from the high CaCO₃ productivity of the Posidonia Oceanica seagrass that populates the flanks of the channels down to about - 40 m. On the contrary sediments on the flanks, which are mostly non-reflective, are mainly represented by silico-clastic sands resulting from the degradation of the granitic structural highs. Sediments of the most proximal and protected bays are characterized by higher reflectivity and correspond to finer deposits such as silts and sandy silts.

The Chirp survey highlighted the occurrence of large scale, low-H/L-ratio bedforms not evidenced on SSS survey because of their too low relief. In the channels roughly oriented W-E sedimentary bodies up to 3 km long and some meter thick occur in axial position. Two larger and thicker transversal bodies are present in two N-S trending channels, where they act as bathymetric thresholds between the adjacent islands. All these acoustically opaque bedforms, classified as sand ridges or sand banks are younger than the underlying sediments. They are mainly composed of bioclastic sands and gravels and represent the product of the present hydrodynamic regime.

Seafloor undulations of sand wave type occur in the main channel along the Gallura coast down-flow to the headlands with respect to the dominant, eastward directed current. Symmetric forms may be attributed to stormy wave motion, while the asymmetric ones to the seabed current. Sand ridges and sand waves are significant sedimentary bodies in the archipelago depositional system as they witness the importance of the currents in the hydrodynamic regime. These features are overprinted by smaller sedimentary features such as comet marks, small scale sand waves, sand ribbons and ripple mark fields, which indicate the axes and directions of the sedimentary transport.

The large-scale sedimentary bedforms of the channels of La Maddalena archipelago are the result of the hydrodynamic regime set up after the slackening of the sea-level rise, mainly between 6 - 5 ky B.P. This event brought to the stabilization of the sea level and the formation and maintenance of the bedforms.

GEOMORPHOLOGY OF THE COASTAL LANDSCAPE OF TARANTO (ITALY)

MASTRONUZZI Giuseppe¹

1 - Dipartimento di Scienze della terra e geo-ambientali, Università "Aldo Moro", Bari, Italy

Presenter e-mail: g.mastrozz@geo.uniba.it

Key terms: *coastal morphology; suffosion; sapping; Taranto; Italy*

Taranto is located between the Apulian foreland and the Bradanic foredeep on the lowest marine terraces, part of a staircase of flat sub-horizontal surfaces generated during the Middle - Upper Pleistocene. Along the coast,

raised marine bioclastic sandstones overlap in transgression the sandy-clay of the Argille subappennine formation, Plio-Pleistocene in age. Numerous absolute age determination (U/Th) and racemisation analysis performed on the senegalensis faunal assemblage characterising the sediments suggest their correlation to the MIS 5. Although MIS 5.1 has been identified due to the extensive presence of the *Strombus bubonius* specimen, the detection of the MIS 5. 3 and 5.5 sediments is still matter of debate.

In the span of time characterised by the deep glacial regression that culminated about 20 ka in the LGM the entire coastal areas was deeply cut by the water flows nourished by the water deriving from the karstic springs extensively present. During the Olocene transgression, river valleys were filled by the sea generating deep inlets like that who attribute to Taranto the appellation "two seas city". All the coast south of the Ionian city is marked by smaller inlet. Always shaped in the clay/sandstone sequence, they derive by suffusion and sapping processes generated by the fresh water flux at the top of the Argille subappennine formation.

10.1474/Epitome.04.0281.Geoitalia2011

ROCKY LANDFORMS AS INDICATORS OF HIGH SEA LEVEL STAND ALONG THE NORTH-WEST COAST OF EGYPT

AMR Saleem¹

1 - Ain Shams University, Egypt

Presenter e-mail: amr_saleem@art.asu.edu.eg

Key terms: Mediterranean Coast of Egypt; Sea level changes; Rocky Coasts; Marine boulders; Elevated platforms

Many evidences reveal that sea level is changing over geological time scale. The rocky coasts are suitable preservation environment of sea level imprints since late Quaternary. Using interdisciplinary approaches and sophisticated laboratory analyses leads to significant improvements of sea level studies all over the world.

On a regional scale there is huge work concerning sea level changes along the Mediterranean Coasts. In spite of this, few studies on the old shorelines and their relation to sea level changes during Quaternary at the Mediterranean coast of Egypt have been made. Previous works in Egypt are concentrated in a limited area surrounding Alexandria region. The present study highlights such issues over the widespread coastal plain westward Alexandria up to the Libyan borders.

The North-West Mediterranean Coast of Egypt is split into three main sectors; the eastern, the central and the western. The eastern and western sectors are characterized by wide plains with a retreating escarpment; the dominant view is an alternation of oolitic Limestone ridges and depressions. In contrast, the central sector is the zone of rocky headlands and coastal ridges which represent ideal sites for sea level changes indicators.

Three exploring field studies have been carried out by 2010 toward the central sector; their findings are the core of the present investigation. The main feedbacks of the field work are:

- I. Studying the coastal ridges (first order ridge) in details
 - II. Positioning the elevated wave cut platforms and parallel marine notches
 - III. Identifying the elevated marine boulders accumulations in 15 sites
- The origin and ages of such relict landforms are highly debatable. Employment of dating techniques such as C14 are critically needed to present strong evidence of higher sea level stand in a finite period.

Presenter e-mail: bini@dst.unipi.it

Key terms: Sea level markers; Patagonia; Holocene

The Atlantic Patagonia coast preserves unique archives of late Quaternary relative sea level changes useful for testing geophysically based models for an area affected by significant glacioeustatic adjustment (Milne et al., 2005). However, relative sea level reconstructions so far proposed (notably the recent review for the Holocene of Schellmann and Radtke, 2010) are poorly accurate due to the stormy conditions and macrotidal regime characterising this area; many sea level markers employed are rather indicators of surf/storm activity than of mean sea level. Detailed fieldwork on selected sectors of the Atlantic Patagonian coast between ca 44° and 47° S have allowed to identify different typologies of sea level markers so far ignored as research target for the Patagonian area. In particular, we illustrate for the first time how abrasive notches and barnacle levels can be confidently used to reconstruct relative past sea levels. For instance, at Puerto Deseado village (lat 47°45'S, long 65°52'W) detailed description of currently forming abrasive notches allowed to understand that they mark the high tide level, and that this information can be applied for the relict raised counterpart landforms there recognised at different elevations. At Bahía Camarones instead (lat 44°48', long 65°44'), in situ barnacles (*Austromegabalanus psittacus*) levels allow a confident estimation of the Holocene high stand for the area, showing how previous estimation was substantially incorrect, even if a direct dating of these levels is still in progress. The use of accurate sea level markers, providing reliable estimates of age and elevation of former sea levels, is going to enable to propose, in the near future, an update of sea level curves for the area, to be compared and contrasted with geophysical model estimations.

STEPPED POST-LGM SEA-LEVEL RISE: EVIDENCE FROM THE NORTHERN ADRIATIC SEA

GORDINI Emiliano¹, ZECCHIN Massimo¹, RAMELLA Riccardo¹

1 - Istituto Nazionale di Oceanografia e di Geofisica Sperimentale - OGS

Presenter e-mail: mzecchin@ogs.trieste.it

Key terms: Northern Adriatic Sea; Post-LGM sea-level rise; Melt-water pulse; Paleoshoreline

The northern Adriatic is an epicontinental sea, up to 20 m deep, developed after the inundation of a Late Pleistocene lowland triggered by the post last glacial maximum (LGM) glacio-eustatic rise. On the basis of oceanic evidence, some authors highlighted that the post-LGM phase was punctuated by faster episodes of sea-level rise called melt-water pulses (MWP), characterized by peaks that reached 60 mm/yr. Evidence of MWPs was recently recognized also along the Ionian margin of Calabria and in the Adriatic Sea, south of the Po delta.

New seismic and core data from the northern Adriatic Sea, off the Tagliamento river delta, allowed the recognition of a partially eroded sand ridge at 12 m water depth, which has been interpreted as a submerged wave-influenced delta, having associated coastal spits. The delta shows local channel fill features, interpreted as the result of the migration of distributary channels and/or inlets connecting the open sea with ancient bays placed adjacent to the delta. The present interpretation resembles the present day setting of the Tagliamento delta.

Taking into account the considerations of previous studies on drowned barrier islands south of the Po delta, it is inferred that the recognized delta developed during a phase of slower glacio-eustatic rise, allowing the rate of sediment supply to outpace the rate of relative sea-level rise and promoting the progradation of a deltaic system and associated shoreline. As the depth of the delta ranges between 18 and 12 m, its development might be linked to a phase of slow glacio-eustatic rise occurred between MWP 1C and MWP 1D, when sea level rose from about 15 to 10 m below present day sea level, between 9 and 8 kyr B.P. New studies are therefore needed to recognize submerged deltas and barrier islands, which may allow the reconstruction of the post-LGM sea-level rise in the Mediterranean and of the position of ancient paleoshorelines.

THE SVALBARD INTEGRATED ARCTIC EARTH OBSERVING SYSTEM (SIOS) ESFRI INITIATIVE

VITALE Vito¹

1 - ISAC-CNR, Via Gobetti 101, 40129 Bologna, Italy

Presenter e-mail: v.vitale@isac.cnr.it

Key terms: ESFRI infrastructure; Svalbard; multidisciplinary observing network; climate change; Earth System Models (ESM)

Environmental and climate changes are currently observed at a global scale and in particular in the Arctic. In order to give better estimates of the future changes, the Arctic has to be monitored and analysed by a multi-disciplinary observation system which is suited to validate and gradually improve Earth System Models. The best chance to achieve significant results within a relatively short time frame is found in regions with a large natural climate gradient, and where processes sensitive to the expected changes are particularly important.

Svalbard and the surrounding ocean areas fulfil above criteria: Svalbard is located in a region with a very large climate gradient, being alternately influenced by cold central Arctic or mild marine climate conditions at time scales of weeks to years. It is also located in the region with the strongest inflow and outflow processes between the Arctic and lower-latitude oceans. In addition, Svalbard is the only region in the world (and has the facilities) where one can study and quantify one of the remaining unknowns in the climate puzzle: the extraterrestrial and especially solar influence on climate. Svalbard is located under the Earth magnetic field's cusp region, an area which is directly exposed to the solar wind, and where one can expect these influences to be most pronounced.

On the base of the above remarks, a proposal to establish an (Arctic) multi-disciplinary Earth System Observing Facility on and around Svalbard were submitted by Norway to the European Strategy Forum on Research Infrastructures (ESFRI), and included at the end of 2008 in the roadmap of this Consortium (including at the end of 2010 44 proposals). The main aim of SIOS is to have an optimised observational infrastructure which can match advanced Earth System models with observational evidence and provide near-real-time information on Arctic change to relevant stakeholders. This will include existing, upgraded and new infrastructure constituting a comprehensive Earth System research infrastructure, organised into a limited number of observation platforms, e.g., space, atmosphere, ocean, land, ice. As the major innovative element, SIOS will have a Knowledge Centre (KC) which will be the "melting pot" where interaction between observation, modelling and process research takes place. SIOS aims to be a pilot study for and future component of the envisaged SAON network as well as the mechanism to develop an internationally coordinated Arctic research hub.

At the moment, preparatory Phase of the Project (PP) is in progress, to establish the formal framework needed to operate a geographically distributed and thematically structured multi-national research infrastructure across Svalbard.

Key elements of SIOS and PP will be presented, together with information on the state of the PP work. Particular attention will be devoted to topics SIOS will intend to address when on place, and opportunities SIOS will offer to the Italian scientific community, taking into account that a fundamental element of SIOS will be to provide access to the Earth System Science research facilities in Svalbard to scientists from all over Europe and beyond. A similar access has been provided, under the coordination of NPI, by the multi-national facilities in Ny-Ålesund since 1996, but SIOS will enlarge the opportunities for such access considerably, since it comprises many more sites and platforms, both ashore and offshore.

GPS NETWORK FOR IONOSPHERIC PERTURBATION DETECTION OVER ARCTIC

ROMANO Vincenzo¹, ALFONSI Lucilla¹, DE FRANCESCHI Giorgiana¹, SPOGLI Luca¹

¹ - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: vincenzo.romano@ingv.it

Key terms: Positioning; GNSS; Ionosphere; Polar network

A specially modified GPS receiver for Ionospheric Scintillation and TEC Monitoring (GISTM) was deployed in September 2003 by Istituto Nazionale di Geofisica e Vulcanologia (INGV) at the Italian Arctic station "Dirigibile Italia" in Ny Alesund (79.9° N, 11.9° E, Svalbard, Norway), in the frame of the ISACCO (Ionospheric Scintillations Arctic Campaign Coordinated Observation) project. The receiver computes and records GPS scintillation indices and Total Electron Content (TEC). Phase and amplitude data, either in raw form or detrended (to remove systematic variations), can also be logged at 50-Hz. Nowadays ISACCO counts on three GISTM receivers at Svalbard (Norway), and three in Antarctica. Post processed and raw data are available in near real-time at INGV site: www.eswua.ingv.it. Visiting this web site is possible to access the INGV database, realized to organize and manage the large amount of information acquired by the INGV instruments measuring the ionospheric plasma parameters.

The importance and the amount of the data collected by INGV has encouraged original investigations on the formation of the ionospheric irregularities causing scintillations and on the dynamics of the high latitude plasma under disturbed conditions. The upcoming solar maximum, which is expected to reach its peak around May 2013, occurs at a time when our reliance on high-precision GNSS (such as GPS, GLONASS and the forthcoming GALILEO) has reached unprecedented proportions. Knowledge and monitoring of scintillations are essential, so that warnings and forecast information can be made available to GNSS end users, global system and local augmentation network administrators in order to guarantee the necessary levels of accuracy, integrity and availability of high precision and/or safety-of-life applications. Especially when faced with severe geospatial perturbations, mitigation tools to minimize destructive effects on satellite signals tracking (loss of lock, degradation of accuracy resulting in poorer satellite availability) are also needed.

This paper gives a general overview on the scintillations and TEC Arctic observatories, on the organization of the data collected, on the international collaborations and projects in which INGV is currently involved and on the scientific investigations aimed to GNSS and Space weather applications.

BIO-OPTICAL CHARACTERIZATION OF THE ARCTIC OCEAN BY LASER-INDUCED FLUORESCENCE AND SATELLITE RADIOMETRY

FIORANI Luca¹, COLAO Francesco¹, MARULLO Salvatore¹, PALUCCI Antonio

¹ - ENEA, UTAPRAD-DIM

Presenter e-mail: luca.fiorani@enea.it

Key terms: laser-induced fluorescence; spectrofluorometer; lidar fluorosensor; ocean color; phytoplankton

Global warming is particularly evident in the Arctic Ocean. Ice extent in September decreased from 8 million square kilometers at the end of the sixties to 5 million square kilometers today. If scientific research wants to support sustainable development in the Arctic Region, the biogeochemical cycles taking place in the surrounding ocean has to be clearly understood. This paper report on a research carried out by the Diagnostics and Metrology Laboratory (UTAPRAD-DIM) of the Italian National Agency for New Technologies, Energy and Sustainable Economic Development (ENEA) in the framework of a collaboration with the Institute of Oceanology of the Polish Academy of Sciences. UTAPRAD-DIM deployed its laser-induced fluorescence sensors CASPER, ELF and POLI on-board the research vessel Oceania during three oceanographic campaigns off the Svalbard Islands in 2006, 2007 and 2008.

CASPER is a laser spectrofluorometer based on double filtration and double excitation and has been applied to detect both dissolved and particulate components of natural waters coming from aquifers, rivers, lakes and seas. It has been patented and has been awarded the "Research and Innovation Prize 2005" by Business Innovation Center Latium.

ELF is a lidar fluorosensor: the main parts of the system are a frequency tripled Nd:YAG and a telescope detecting Raman scattering by water and laser-induced fluorescence by chromophoric dissolved organic matter (CDOM) and algal pigments (chlorophyll-a, phycoerythrin and phycocyanin).

POLI (patented) is the natural evolution of ELF. All the subsystems, i.e. laser source, collecting telescope, detection optics and acquisition electronics (patented) are completely new and allowed the miniaturization of the apparatus now contained in a fly case of 0.7×0.7×0.8 m³.

While CASPER analyzed water samples collected at different depths, ELF and POLI sounded remotely the water surface operating H24. As a result, spectrofluorometer and lidar provided a spatio-temporal picture of CDOM and algal pigments in a wide oceanic region. That information has been used for cal/val of ocean color satellite radiometers in the sea region off the Svalbard Islands.

D1-5 Orale Pisano, Eva

10.1474/Epitome.04.0287.Geoitalia2011

ARCTIC FISH: SNAPSHOTS ON RESEARCH IN A CHANGING ENVIRONMENT

, PISANO Eva¹, GHIGLIOTTI Laura¹, VACCHI Marino²

¹ - University of Genova, Italy

² - ISPRA, Rome, Italy

Presenter e-mail: pisano@unige.it

Key terms: Arctic fish; biology; ecology; biodiversity; marine ice

The unique biological and ecological features, and the evolutionary history of the polar fishes, related to adaptation to an extreme habitat, have been attracting the interest of the scientific community for many years. Nowadays, the attention devoted to this fauna is even higher, being the fish living in polar regions regarded as "sentinels" for climate changes.

Fishes play a key role in the marine food web, acting as predators and/or consumers at the lowest trophic levels, and as preys of the large vertebrates (marine mammals and birds) at the top of the food chain; as such, any effect of the climate change on fish will have implications on the entire marine ecosystem.

At present, the information on the Arctic ichthyofauna is scanty if compared to the large amount of data available on the Antarctic fish fauna counterpart. Such an imbalance is mainly due to different financial and logistic efforts, that, in the last 20 years, favoured researches in Antarctica as opposed to the Arctic. This is paradoxical in the light of the easy accessibility of European countries to Arctic areas. Nevertheless, some Italian teams are participating in Arctic research, mainly in collaboration with Norwegian groups, and relying on various local infrastructures for the field activity. For instance, our group, at the University of Genova, based on experience and technical expertise acquired during similar studies in Antarctica, is contributing, since 2001, to projects dealing with fish biodiversity in Arctic. These studies are included in the TUNU MAFIG (Marine Fishes of North East Greenland - diversity and adaptation) Programme, organized and managed by the University of Tromsø (Norway); despite the lack of specific funding we participated in all the five expeditions on board of RV Jan-Mayen (pre-TUNU and TUNU cruises), also contributing to the IPY international activities. The amount of data collected between Svalbard and Greenland during the TUNU cruises are of huge value as baseline to monitor the biodiversity in a rapidly changing environment. Another Italian group lead by ISPRA (Institute for Environmental Protection and Research, in collaboration with the University of Genova and the University of Tromsø, has recently started a project addressing the relationships between polar fish and marine ice, including a comparison between Arctic and Antarctic species. These issues require urgent attention due to the discovery that the key fish species of the coastal Antarctic ecosystem, the Antarctic silverfish (*Pleuragramma antarcticum*), uses the seasonal pack ice as spawning ground. This recent finding stresses the need to investigate the type and degree of the relationship between the life cycle of polar fish and the ice, in order to assess their vulnerability to the ongoing changes in sea ice dynamics.

With present contribution we intend to provide some snapshots on our ongoing research on Arctic fish, with focus on biodiversity, and vulnerability to climate change. Some major challenges in biological and ecological Arctic research will be also discussed. Effective future research on Arctic fish should be comprehensive and interdisciplinary, integrating biology, ecology, oceanography and glaciology, and will require adequate infrastructures for sampling and operating all year round.

Key terms: Barents Sea; Glacimarine Trough Mouth Fan; Glacigenic debris flow deposits; Submarine Landslides; Seismic reflection profiles

The north-western margin of the Barents Sea has been investigated by two companion research cruises carried out within the International Polar Year (IPY). The Spanish SVAIS cruise (BIO Hespérides, summer 2007) and the Italian EGLACOM cruise (R/V OGS-Explora, summer 2008), both contributed to IPY Activity 367 NICE-STREAMS (Neogene ice streams and sedimentary processes on high-latitude continental margins), aiming at understanding erosion and depositional systems associated with ice streams. Data acquisition focused on the Storfjorden and Kveithola Trough Mouth Fans (TMFs) and included collection of multi- and single-channel seismic profiles, swath bathymetry, sub-bottom profiler data and sediment cores.

Sedimentation on the Storfjorden and Kveithola TMFs and on the other northern TMFs surveyed within our data (Kongsfjorden, Isfjorden, Bellsund) has been influenced by the presence of ice during the late Cenozoic and reflects past ice sheet expansions and recessions. Beside the common sedimentary processes operating at low latitudes (as transport and deposition by contour currents, turbidity currents and mass-wasting), these systems are affected by glacial processes, which characterizes the nature and rates of all sedimentary processes. Major periods of margin progradation are associated with relatively short time intervals of ice terminating at the shelf break during glacial maxima. Fleets of icebergs and associated Ice Rafted Debris (IRD), cascades of meltwater and large quantities of suspended sediments (plumes), and unsorted debris, concentrate at the mouths of fast-flowing ice streams occupying cross-shelf troughs. These sediments are efficiently reworked and delivered into the basins by Glacigenic Debris Flows (GDFs) that form the building blocks of the large polar TMFs.

Contrary to low-latitude fans that are fed by rivers through a channel levee complex, glacier-fed TMFs, receive their main sedimentary input from a glacier margin at the shelf break. As a result, high-latitude depocenters are mostly elongated across the upper slope, whereas low-latitude deep-sea fans lie on the middle slope. In contrary, in shallow-bank areas between ice streams, where slower ice reached the shelf break and TMF are not present, the continental slope is characterized by large-scale sediment landslides and canyon systems. Giant paleo-landslide deposits, detected by MCS profiles, are characterized by chaotic acoustic units up to about 250 m thick on the lower continental slope. The thickest, oldest landslide, dated between 1 and 0.8 Ma, took place just after the large-scale intensification of glaciation in the Barents Sea. The apparent spatial coincidence of landslides and channels with the boundary between the two ice-stream generated TMF systems suggests a common controlling climatic process for their development. Most probably the landslides are related to the abundance of basal meltwater beneath the ice sheet, which in addition to determining ice stream motion and

lubrication also influences the behavior of mass wasting processes.

Presenter e-mail: lpetronio@ogs.trieste.it

Key terms: Seismic oceanography; Barents sea; reflection; thermohaline structures; ocean circulation

In the frame of the EGLACOM (Evolution of a Glacial Arctic Continental Margin) project a combined offshore reflection seismic and oceanographic cruise was carried out along the north-western Barents Sea continental margin. This cruise was funded by the Italian Istituto Nazionale di Oceanografia e Geofisica Sperimentale (OGS) in the framework of the International Polar Year (IPY). Simultaneous seismic and oceanographic data acquisition were performed to study the thermohaline structures, the ocean current circulation and to evaluate the feasibility of the seismic oceanography approach.

The studied area has a high relevance from the climatic and oceanographic point of view due to the presence of the Arctic front which separates waters of Arctic origin from the warmer and saltier Atlantic Water (AW) flowing northwards, along the western Svalbard margin. Along the Arctic front important heat fluxes take place, which deeply influence the regional climate as well as the overall circulation. Detailed characteristics of the front are still not very well resolved and a combined approach based on high resolution seismic profiles along the water column and conventional oceanographic methods may provide useful information on the vertical distribution of the different masses.

Over 1000 km of multichannel seismic reflection lines were acquired simultaneously with several types of oceanographic data. Seismic data interpretation is supported by 60 XBT (Expendable Bathy-Thermograph) profiles obtained concurrently during the seismic acquisition, 6 additional CTD (Conductivity-Temperature-Depth) casts carried out within 10 days from the XBT launches and by sea-surface temperature and salinity measurements acquired continuously by a thermosalinograph installed on the vessel prow. In addition, Vessel-Mounted Acoustic Doppler Current Profiler (VM-ADCP) data were acquired during navigation to continuously monitor the current velocity distribution in the upper water column (about 400-500 m). The velocity field, together with remote sensing images of the sea-surface temperature acquired from the NOAA-18 satellite were used to depict the dynamic oceanographic background of the area. The results obtained display a strong correlation between seismic reflectors and discontinuities in vertical temperature and salinity gradients and allow to recognise the spatial extension of the water masses of Atlantic and Arctic origin present in the area.

Until now strong efforts have been devoted to define a viable seismic data processing strategy to enhance the imaging of the water column reflections. Future activity will be focusing on the interpretation of the seismic images on the basis of available oceanographic data.

Key terms: Storfjorden TMF; sedimentary processes; climatic changes; plumites; last glacial maximum

The continental margin of the Southern Storfjorden trough-mouth fan was investigated within two coordinated Spanish-Italian projects: the SVAIS (BIO Hespérides cruise, August 2007) and EGLACOM (R/V Explora, July-August 2008) projects contributing to IPY Activity N. 367 NICE STREAMS (Neogene ice streams and sedimentary processes on high latitude continental margins). The objectives were to investigate the glacially-dominated late-Neogene-Quaternary sedimentary architecture of the NW Barents Sea continental margin to reconstruct the response to natural climate changes of this sedimentary system. Palaeo-ice streams in Storfjorden had a relatively small catchment area draining ice from southern Spitsbergen and Bear Island. The short distance from the ice source to the calving front produced a short residence time of ice, and therefore a rapid response to climatic changes.

Piston cores recovered the last few thousands years sedimentary sequence representing the Last Glacial Maximum (LGM) and the following deglaciation phase. Inter-core correlation and stratigraphic constraints were based on detailed palaeostratigraphic investigations, down-core logs of magnetic susceptibility, palaeomagnetism, and sedimentary lithofacies with absolute age control from the 26 AMS14C dating. Most cores display at the base Mass Transport Deposits (MTDs), including slumps/debris flows and over-consolidated glacialic diamictites. The latter were deposited during the last glacial stage when the ice sheet was grounded at the shelf edge. MTDs are overlain by an oxidized interval resulting from the massive release and sinking of fresh, cold and oxygenated melt-waters at the inception of the deglaciation phase.

On the upper slope the oxidized interval is overlain by several meters of interlaminated sediments composed of sandy-silt layers cyclically recurring

within finer-grained laminated mud. Textural and compositional analyses suggest preferential deposition by settling from meltwater sediment-laden plumes (plumites) during deglaciation. The laminated sequence is topped by a glaci-marine diamicton consisting of massive or layered IRD-rich sediments which compositional characteristics indicate a renewed strength of the warm North Atlantic Current (NAC). On the mid slope the plumites are only a few cm-thick and are topped by crudely laminated, diatom-bearing sediments overlaid by intensively bioturbated, bioclast-rich silty-clays representing the most recent interglacial sedimentation. The composition of these lithofacies indicates that the NAC progressively had a stronger influence on sedimentation and a fundamental impact on timing of glacial retreat after LGM.

Key terms: Arctic; ecostratigraphy; paleoceanography; late Quaternary

The Storfjorden sedimentary system (north western Barents Sea continental margin) was investigated during the EGLACOM cruise (R/V OGS-Explora, summer 2008).

EGLACOM (Evolution of a Glacial Arctic Continental Margin: the southern Svalbard ice stream-dominated sedimentary system) project is the Italian contribution to the IPY Activity n°367 - NICE STREAMS in combination with the IPY-Spanish SVAIS project. One objective of this project was the study of the late Quaternary paleoclimatic and paleoceanographic evolution of these glacially-dominated areas.

Four EGLACOM sediment cores were collected from the slope and shelf areas and scanned for radiographs and multi-sensor core logger for physical properties. Samples were collected every 10 cm, and analyzed for textural and compositional characteristics including the biogenic components. Paleomagnetic and rock-magnetic investigations were carried out at high-resolution along the cores length. The studied data sets contributed to develop an high-resolution age model by combining biostratigraphy (using foraminifera, diatoms, nannoplankton and ostracods), AMS 14C dating and paleomagnetic records.

On the upper slope, coarser-grained sediments containing abundant pebbles (IRD-rich facies), overlain a sequence of laminated mud, late Quaternary in age, which is interbedded with silt layers (laminated facies), having scarce, badly preserved and often reworked biogenic fraction. On the middle slope, the uppermost sequence is formed by fine-grained bioturbated sediments with IRD and abundant planktonic and benthic foraminifera reflecting open-ocean conditions similar to present days. The dominance of the benthic foraminifer *Stainforthia wellerstorfi* indicates well oxygenated bottom waters at the base of Holocene, as recorded by the calcareous nannofossil assemblage belonging to *Emiliania huxleyi* Acme Zone. Here, the planktonic foraminifers are mainly represented by *Neoglobobulimina pachyderma* (s) and *Turborotalita quinqueloba*. The bioturbated facies overlay an interval of late Quaternary crudely laminated mud interbedded with silt layers. This laminated facies generally has a scarce, badly preserved and often reworked biogenic fraction including Quaternary, Paleogene and Cretaceous species. It contains a peak of diatoms and sponge spicules corresponding to an increase in planktonic foraminifers content, mainly represented by *T. quinqueloba*. At the base of this siliceous-biogenic interval the pteropod *Limacina helicina* is very common, its presence is probably due to a deepening of the ACD (aragonite compensation level) and/or a rapid burial of the aragonite trests.

The sedimentary sequence recovered from the shelf of the Kveithola trough contains mainly Holocene IRD-rich sediment topped by 10 cm of massive sands including large clasts. The biogenic fraction contains well preserved foraminifers, mollusks, ostracods and sponge spicules. Both Arctic and Arctic-Boreal benthic foraminifers are present with *Cassidulina teretis* and *C. reniforme* (Arctic species) as dominant species, followed by *Melonis barleeanum* and *Islandiella* spp. At the core bottom, the common *C. teretis* indicates the influence of the cold and salty Atlantic Intermediate Water. The uppermost sediments record a climate improvement, for the presence of the boreal, *C. laevigata* and *T. angulosa*, among the foraminifers and the termophylic *Muellerina abyssicola* among the ostracods.

The clay mineral assemblages includes illite, chlorite, kaolinite, and smectite. and they reflect the sediment provenance. Gneisses and amphibolites in southern Spitsbergen can represent the source rocks for illite and chlorite. Smectite derives from alteration of volcanic rocks and can be transported and deposited along the margin by the North Atlantic Current.

Presenter e-mail: leonardo.sagnotti@ingv.it

Key terms: paleomagnetism; paleosecular variation; Holocene; Svalbard; geomagnetism

A high-resolution paleomagnetic and rock magnetic study has been carried out on 8 cores sampled in the hemipelagic fine-grained (silty-clays) sediments from the continental shelf and slope of the Southern Storfjorden trough-mouth fan, on the north-western Barents Sea. The Storfjorden sedimentary system was investigated during the SVAIS and EGLACOM cruises, when 10 gravity cores, with a variable length from 1.03 m to 6.41 m, have been retrieved. Accelerator mass spectrometry (AMS) 14C analyses on 26 samples (mainly foraminifera, and a few mollusc shells) demonstrate that the cores span a time interval that includes the Holocene, the deglaciation and in some cases the Last Glacial Maximum (LGM). Rock magnetic and paleomagnetic measurements were collected at 1-cm spacing on u-channel samples. The data indicate that the sediments carry a well-defined characteristic remanent magnetization (ChRM) and have a valuable potential to reconstruct the paleosecular variation (PSV) of the geomagnetic field, including changes in ChRM inclination and declination as well as in relative paleointensity (RPI). The paleomagnetic data obtained from the SVAIS and EGLACOM cores allow us to reconstruct dynamics and amplitude of the geomagnetic field variations at high northern latitudes (75°-76° N). These data are important for testing models on the geomagnetic dynamo and the outer core dynamics, since they bring direct experimental constraints on the geomagnetic secular variation within the inner core tangent cylinder, an imaginary cylinder parallel to the Earth's spin axis that circumscribes the equator of the inner core and intersects the surface of the Earth in the polar regions in both hemispheres at a latitude of 69.6°. The Holocene PSV and RPI records appear particularly sound, since they are consistent between cores and they can be correlated to the available regional stacking curves (UK PSV, FENNOSTACK and FENNORPIS) and global geomagnetic models for the last 7 ka (CALS7k.2), matching the obtained 14C dates. We therefore propose a Holocene PSV and RPI stack for the Storfjorden area. Furthermore, the rock magnetic and paleomagnetic data allow a high-resolution correlation of the sampled sedimentary sequences and the development of a refined age model for the cores. These data provide a firm temporal framework for the reconstructed post-LGM sedimentary processes and evolution.

Presenter e-mail: paolo.favali@ingv.it

Key terms: ESFRI Infrastructure; Permanent European underwater network; Multidisciplinarity

EMSO, an ESFRI large-scale Research Infrastructure (European Strategy Forum on Research Infrastructures Roadmap, <http://cordis.europa.eu/esfri/roadmap.htm>), is the European-scale network of multidisciplinary seafloor and water column observatories from the Arctic to the Black Sea with the scientific objective of long-term real-time monitoring of processes related to geosphere/biosphere/hydrosphere interactions. EMSO will enhance our understanding of processes through long time series appropriate to the scale of the phenomena, constituting the new frontier of studying Earth interior, deep-sea biology and chemistry and ocean processes. EMSO will reply also to the need expressed in the frame of GMES (Global Monitoring for Environment and Security) to develop a marine segment integrated in the in situ and satellite global monitoring system.

EMSO is presently at the stage of Preparatory Phase, funded in the EC FP7. The EMSO status, the perspectives and relations with other existing or incoming sensor networks and data infrastructures are outlined. Also the synergies with other ESFRI projects like SIOS are also discussed.

BSR VERSUS CLIMATE CHANGE: EXAMPLE OF PERI-ANTARCTIC REGIONS

TINIVELLA Umberta¹, GIUSTINIANI Michela¹, ACCETTELLA Daniela¹
1 - OGS

Presenter e-mail: utinivella@ogs.trieste.it

Key terms: BSR; gas hydrate; climate change; slope stability

Submarine slides are global phenomena occurring on slopes that may be considerably less inclined than their terrestrial equivalents due to the presence of excess water; they can displace huge amounts of material over great distances. During the last decades, a debate has been started regarding the relationship among gas hydrate, climate change and slope stability. In fact, gas hydrates represent a significant geo-hazard that is of immediate importance to near and offshore developments. Human activities and installations in regions of gas-hydrate occurrence must take into account the presence of gas hydrate and deal with the consequences of its presence. The hydrate stability zone in marine environments is a function of the water depth, the seafloor temperature and the geothermal gradient. Any temperature and/or pressure changes, both at the surface and in the area adjacent to the hydrate, affect the thickness of the stability zone. Although temperature and pressure are the main controls in the formation of gas hydrates and the thickness of the hydrate stability zone, other factors, such as gas chemistry and gas availability, alter the thickness and location of the hydrate stability zone. Dissociation of

hydrate may trigger the sudden release of large amounts of methane through the ocean into the atmosphere, leading to accelerated climate warming. Hydrate dissociation and gas release in the atmosphere have been proposed as a significant mechanism to explain the rapid and significant climate change during the Paleocene-Eocene Thermal Maximum. This hypothesis has been challenged by different studies, which suggest that methane from dissociating hydrate may never have reached the atmosphere. Alternatively it has been proposed that methane release may follow, rather than lead, climate change. In the last years, several authors have investigated the relationship between the gas hydrate dissociation and the increase of pore fluid pressure below the bottom simulating reflector, which is the seismic indication of the base of the gas hydrate stability zone. In fact, dissociation of gas hydrates at the BSR, in response to a change in the physical environment (i.e., temperature and/or pressure regime), can liberate excess gas and elevate the local pore fluid pressure in the sediment. The increase in pore fluid pressure has the effect of decreasing the effective normal stress on any assumed failure surface, so that less shear stress is required to initiate failure. Whether free gas liberation by gas hydrate dissociation can singularly cause a slide, rather than just being a contributing load or the final trigger, is dependent on various factors. These include rate of dissociation, sediment permeability, depth below sea level, and depth below the seafloor. In this work, we investigate the relationship between climate change and hydrate stability in two peri-antarctic areas: Antarctic Peninsula and South Chile. We consider these areas because the polar and sub-polar areas are the most sensitive about global change. The zone, where the methane can be easily released by hydrate melting, is the shallow water, i.e. in proximity of the intersection between the BSR and the sea bottom. In order to simulate the effect of climate change on hydrate stability, we consider the following seven scenarios for both areas: present environmental condition; sea bottom temperature increase/decrease of 1 °C; water depth increase/decrease of 100 m; sea bottom temperature and water depth increase/decrease of 1 °C and 100 m respectively. On the basis of our result, we can draw the conclusion that the modeling is a useful tool to understand the effect of the climate change on hydrate stability. Moreover, in these areas where the sea bottom temperature is influenced by temperature increase, such as Arctic and Antarctica, slides could be easily triggered by hydrate dissociation.

PRELIMINARY RESULTS FROM OCEANOGRAPHIC, BATHYMETRIC AND SEISMO-STRATIGRAPHIC INVESTIGATIONS IN THE KONGSFJORDEN, SVALBARD ISLANDS

GIGLIO Federico¹, LANGONE Leonardo¹, DEL BIANCO Fabrizio¹, MISEROCCHI Stefano¹, ALIANI Stefano³, GASPERINI Luca¹

2 - ISMAR - CNR Marine Sciences Institute in La Spezia

Presenter e-mail: federico.giglio@ismar.cnr.it

Key terms: climate change; seismic features; Kongsfjorden; Mooring Site

The Kongsfjorden is a narrow fjord of the Svalbard archipelago. It is 20 km long and 4-10 km wide, elongated in SE-NW direction and the exchanges with the Arctic Ocean occur at the northwestern mouth, along the western coast of the Spitsbergen island.

During September 2010, an instrumented oceanographic array was deployed by CNR-ISMAR in the Kongsfjorden with the purpose to monitor the possible impact of the climate change on the interplay between the Atlantic water influx (the northern branch of Gulf stream and the Arctic-type coastal water) and the melting of tidal glaciers (Kongsvegen, Kronebreen, Blomstrandbreen), both being linked to global climate variability.

In order to choose the best site to locate the moored instrumentations, a seismic survey was performed in the inner part of the fjord, which is recently become accessible by the rapid glacier retreating. Over 130 miles of Chirp sub-bottom profiles (4kW Benthos DSP-662 Chirp III with 4 towed transducers) were acquired, with the purpose to describe the morpho-bathymetric features and surficial seismo-stratigraphy. The bottom of the fjord is dominated by a widespread outcrop of bedrock. Several structures were detected, mainly related to relict sub-glacial and ice-scoured topography produced during the glacial re-advances of the Weichselian (20 ky BP) and again during the last major Holocene re-advance of the Little Ice Age. These features are several tens meter high above the sea bottom level, and in the southeastern part emerges as small islands separating the inner fjord into two parts.

The area located at the inner part of the fjord, close to the calving line, is characterized by higher sediment accumulation rates, and a thin (<10m) layer of coarse-grained sediment thickness can be observed, probably due to the interaction of the 3 proximal ice-tongues. The high-resolution seismic data set allowed us to select the optimal site for the mooring deployment. During early September 2011, the mooring will be serviced and short sediment cores will be collected to investigate and discriminate the late Quaternary climatic events recorded in the sedimentary sequence.

INTERACTION OF SEAWATER AND GLACIER TONGUES INTO INNER KONGSFJORDEN, SVALBARD ISLANDS

ALIANI Stefano¹, BERGAMASCO Andrea¹, CARNIEL Sandro¹, DEL BIANCO Fabrizio¹, GASPERINI Luca¹, GIGLIO Federico¹, LANGONE Leonardo¹, MISEROCCHI Stefano¹

1 - CNR-ISMAR UOSS Bologna and La Spezia

Presenter e-mail: federico.giglio@ismar.cnr.it

Key terms: Kongsfjord; seawater-glacier interaction; glacier melting; sea-ice melting

The Arctic glaciers release every year millions of m3 of fresh water from the iced reservoirs to the ocean and the total amount will probably increase in next years following the global warming. The knowledge of the dynamics involved in the Arctic melting zone needs improvements from the physical oceanography point of view in order to better understand the effects produced by ice melting on the hydrological features of the sea and on the transport pathways from the glacier to the open sea by currents. In the inner part of Kongsfjord (Svalbard Islands) close to Ny Alesund Base large ice tongues (from Blomstrandbreen, Kongsbreen, Kronebreen and Kongsvegen glaciers) reaches the sea. Large research vessels study the outer part of the fjord, from the open sea until the moraine, glaciologists study ice tongues until its border but the inner part of the

fjord between the moraine and the marine border of the glaciers has been poorly known. This inner part is very interesting because is the major source of freshwater inputs in the fjord and important chemical-physical and biological processes (i.e. flocculation, algal blooms...) occur in this critical area. Salt water from the fjord enters the basin inside the moraine along the complete water column in the southern passage. It gets colder and fresher mixing with the ice melting water and outflow the basin running toward West through the northern passages. It mainly runs across the passage between Blomstrand Island and Blomstrandbreen glacier that used to be covered by ice in the past but is free from ice now. Sea level records indicate a seiche that is present in the outer part but poorly visible in the inner basin.

The presentation aims to describe some aspects of the physical oceanography of the interface area where glaciers get in touch with the sea in the inner part of Kongsfjord. In particular a description of temperature and salinity and currents of the inner Kongsfjord close to glaciers will be done.

SEISMIC IMAGING OF THE POLAR OCEANS: A NEW CONTRIBUTION TO OCEANOGRAPHY?

PETRONIO Lorenzo¹, CARNIEL Sandro², LIPIZER Marina¹, BERGAMASCO Andrea², DE SANTIS Laura¹, REBESCO Michele¹

1 - OGS Trieste
2 - CNR-ISMAR Venezia

Presenter e-mail: lpetronio@ogs.trieste.it

Key terms: Seismic oceanography; polar oceans; offshore reflection seismic; Arctic; Antarctic

The existing conveyor belt circulation triggers the global climate, controlling heat and water fluxes with the oceans and the atmosphere from tropical to polar regions, and vice versa. Within this large scale and relatively stable circulation, characterized by having a time scale in the order of thousands years, a key-role is played by the Arctic, as well as Antarctic, regions. However, despite this well-recognized importance in the climate system regulation, data collected in these areas are still rare and sparse.

Moreover, in the last decades there have been rising evidences of deep changes in the Arctic climate, both via direct and remote-sensed observations as well, that appears to be changing faster than many other regions. This is particularly true with respect to the sea ice formation rate and size.

The relatively high contrasts existing between water masses in the polar oceans makes them an ideal target for seismic oceanography (SO), a novel technique to detect boundaries in the water column. SO was primarily designed to image sub-seafloor geologic structures, and recently was shown to be capable of providing clear pictures of water mass interfaces in the ocean, when used in conjunction with classical oceanographic measurements.

Since polar oceans represent a key study area for the global circulation and, ultimately, for the earth climate, we started to reprocess offshore seismic data collected for geological targets focusing on the water column in order to evaluate the capability of SO to support physical oceanography studies.

We present two examples of seismic oceanographic data acquired in Polar Regions.

In the first case we show a reprocessing of seismic data acquired off Wilkes Land (East Antarctica) in the framework of the WEGA project. In this area the deep water formation process is responsible for triggering the Global Thermohaline Circulation. Along the continental slope, a complex reflection pattern in the seawater column was detected. As no contemporary in situ hydrographic data were carried out during the seismic survey, we used CTD data acquired in the same area, but in a different period, to validate the common-mid-point (CDP) stacked section. The synthetic seismic traces were computed starting from velocity and density, derived by means of empirical formula from CTD data. The comparison between real and synthetic data shows a qualitatively good agreement.

The second example derives from the data collected in the frame of the EGLACOM project, a multidisciplinary combined offshore reflection seismic and oceanographic cruise carried out along the southern Svalbard continental margin. First results display a strong correlation between seismic reflectors and discontinuities in vertical temperature and salinity gradients. XBT sections and CTD profiles allow to recognise the spatial extension of the water masses of Atlantic and Arctic origin present in the area, and show the progressive cooling and shallowing of the warm and salty Atlantic Water proceeding northwards.

ENVIRONMENTAL-GEOLOGIC PROBLEMS RELATIVE TO SOME LANDFILLS LOCATED IN THE PIEMONTE HIGH TERRACES (NORTH-WESTERN ITALY)

BAIMA Lucia¹, BOVE Annalisa², COGGIOLA Fabio², DESTEFANIS Enrico¹, MASCIOCCO Luciano¹

1 - UNIVERSITA' DEGLI STUDI DI TORINO
2 - AMA - Azienda Monregalese Ambiente SpA

Presenter e-mail: lucia.baima@libero.it

Key terms: LANDFILLS; HIGH TERRACES; MONITORING WELLS; PROBLEMS

Some environmental geologic problems at two landfills for municipal solid waste are exposed in the present work. The landfills are situated in Piedmont high terraces zone, one in the municipality of Magliano Alpi in the Cuneo district, the other in the municipality of Grosso Canavese in the Turin district.

The plant of Magliano Alpi is located on a high terrace emerging from the eastern part of Cuneo plain the plain of Cuneo, the terrace has formed

consequently to the Pleistocene capture of Tanaro River and the successive remounting erosion of the whole river network. The sedimentary sequence observed from the surface downward shows a Holocene complex around ten meters thick, a low permeable Villafranchian Complex (Plio-Pleistocene) and a marine Pliocene Complex constituted by an alternative permeable sands and unproductive clays.

The landfill of Grosso Canavese is located on the high terrace that remains as a relic of the ancient alluvial fan of the Stura di Lanzo River around 30 km north-west of Turin. It is realized in the Mindel glaciofluvial deposits (Pleistocene), more than 40 meters thick.

For both the sites, a hydrogeological study has been carried out, especially referred to the monitoring wells, in order to characterize the groundwater from both the quantitative and qualitative. Piezometric maps have been realized for visualizing the general direction of the groundwater flow and water samples have been analyzed at the monitoring sessions in order to control the water quality.

During these activities, problems relative to a correct sampling from the monitoring wells have been almost always encountered, as well as inconsistencies in the interpolation of water levels. Sometimes the wells were dry, while, in many cases, the regular purging of the wells before the sampling has caused a too slow recovery of the water level.

The hydrogeologic study has revealed that in both sites the monitoring wells don't tap an aquifer, but a saturated but generally low permeable soil. A local permeability may be related to the presence of lenses of permeable soil (sand, silty sand) in a less permeable matrix, and the different modalities of charging and emptying of these lenses could explain in that way the different levels in the monitoring wells.

In both experiences, the data recorded by the monitoring wells are probably affected by uncertainties attributable to the well monitoring efficacy. Given their importance for proper hydrological and environmental data acquisition, a correct design as well as a special care in all phases of their realization are fundamental for the monitoring wells.

Proposals have been provided for identifying the depth of the underground aquifer below the landfills and properly design the monitoring wells, in order to take samples of water at different depths.

OCCURRENCE AND MANAGEMENT OF WATER RESOURCES IN THE HILLY TERRITORIES OF CENTRAL PIEMONTE (NORTH-WESTERN ITALY)

CAVIGLIA Caterina¹, DE LUCA Domenico Antonio¹, DESTEFANIS Enrico¹, FORNO M. Gabriella¹, LASAGNA Manuela¹, MASCIOCCO Luciano¹

1 - Dipartimento di Scienze della Terra - Università di Torino

Presenter e-mail: caterina.caviglia@unito.it

Key terms: Water resources; Hilly territories; Central Piedmont; Aquifer; Water management

About 30% of the Piedmont region (North-Western Italy) is represented by hilly territories.

In the Central Piedmont, the Torino Hill, Langhe and Monferrato constitute the most representative Piedmont hilly territories for both extension and inhabitants. This region is geologically made up by the deposits of Tertiary Piedmont Basin, a marine Oligo-Miocene sequence, structurally separated in five different sedimentary basins, also depending on the geological pertinence of the substrate: Torino hill, Langhe, and Alto Monferrato lie on an Alpine substrate, while Monferrato, and Lemme-Staffora sector appear to be of Apennine pertinence. The Tertiary Piedmont Basin is mainly consisting of conglomeratic, sandy, marly-silty and evaporitic formations, characterized by very low permeability from the hydrogeologic point of view. Above the sedimentary sequence of the Tertiary Piedmont Basin, a covering of marine Pliocene and transitional Plio-Pleistocene sediments complete the lithologic set of the study area.

In the paper, a hydrologic balance of the examined region finalised to the assessment of the water resources has been carried out. Starting from meteorological data of Central Piedmont weather stations, the mean annual isohyetal map has been drawn in order to evaluate the average rainfall in the area. Evapotranspiration has been calculate using different empirical methods, and, by difference, the water resources have been estimated. From the water balance, the examined territories result not too rich in water resources. The subdivision between superficial and underground water resources has finally realized by means of runoff coefficients depending upon the land use, soil type and slope of the watershed.

In the second part of the work, an overview on the water supply of the hills municipalities has been provided. Referring to the local institutions for water management (ATO - Ambiti Territoriali Ottimali n. 3, 4, 5 and 6), the different kinds of water catchments and their peculiar features: wells and springs for groundwater, and aqueduct taps for surface water. Cause of the poorness of the hilly water resources, almost all the water supply comes from sources external to the examined area.

For instance, the Torino Hill, falling in the territory of ATO 3, is supplied by Turin aqueduct (30% from the Po River, 70% from wells tapping the plain aquifers). Similar states have been verified for the hilly territories of Cuneo district (ATO 4) and Alessandria district (ATO 6).

The territory corresponding to ATO 5, entirely included in the hilly studied area and quite superimposable to the territory of Asti district, is partly supplied from a well field located in the Po Plain near the confluence of Dora Baltea River in the Po River (Cascina Giarra - Acquedotto del Monferrato) and, for the remainder, from a well field situated in the Valle Maggiore (Asti district). In this case, the well field is located within the studied area, and the wells tap the Pliocene aquifer occurring in the Sabbie di Asti Formation, but the groundwater recharge come from the western sector of the Piedmont where the Po River enter the Cuneo plain.

Presenter e-mail: marco.chini@ingv.it

Key terms: extractive area; remote sensing; automatic detection

A multidisciplinary study, based mainly on interpretation and analysis of remote sensing collected data, has allowed to define status and evolution of the marble quarry area of Coreno Ausonio (Southern Latium, Central Italy). The examined area is part of the Eastern Aurunci mountain chain. The Aurunci range is constituted of massive, mainly Mesozoic carbonate sequences. The lithotype subject to extraction is a sedimentary rock known as "Calcare a Briozoi e Lithothamni", registered under the trade mark Perlatto Royal Coreno © 2004. More specifically, the Calcare a Briozoi e Lithothamni belong to the sedimentary series of the Latium and Abruzzo regions and they constitute the last occurrence of carbonatic deposition before the onset of terrigenous sedimentation. The study has been conducted through multiscale and multitemporal interpretation of the orthophotos taken in 1996, 2000, 2005, 2009. In particular the bidimensional photointerpretation, concerning extractive activities, was calibrated using stereoscopic photographic coverage by the Volo Italia 1988-89 and by the Volo TerraItalia Regione Lazio 2000. All data were implemented on a GIS platform. In addition to the areal estimate of the entire field, as well as of each quarry, at the time of the orthophotographic coverage used, the researchers proceeded with a volumetric estimate obtained through the difference in digital models (TIN- Triangulated Irregular Network) properly gained via the digitalization of contour lines and elevation marking points surveyed in 1954, 1990, 2009. An automatic procedure for the identification of the marble quarry area has been implemented as well, through an unsupervised classification with a multiscale approach. The automatic procedure has been obtained in two steps. First, by means of morphological filters with different window sizes, a morphological profile has been created based on the original multispectral image, accounting for the geometric characteristics of objects. Second, the morphological profile previously extracted, plus the multispectral image, were the input to an unsupervised K-means clustering algorithm. It is worth noticing that the peculiar signature of some objects is not of spectral type but can be associated to specific shapes and size. For this reason, the mathematical morphology is a powerful tool to overcome this kind of problems of classification, i.e. different classes with similar value of radiance, such as building roofs or roads, could have similar radiance value with respect to the quarry class. The automatic approach has been validated by comparison of the obtained map with the one from visual inspection with an overall accuracy of 97%.

SOIL LOSS AND LANDSLIDE SUSCEPTIBILITY EVALUATIONS AT THE HILLS OF FREISA VINEYARDS (CENTRAL PIEDMONT, NORTHWESTERN ITALY)

AJASSA Roberto¹, CAVIGLIA Caterina¹, DESTEFANIS Enrico¹, MANDRONE Giuseppe¹, MASCIOTTO Luciano¹

1 - Dipartimento di Scienze della Terra - Università degli Studi di Torino
Presenter e-mail: enrico.destefanis@unito.it

Key terms: Soil loss; Landslide susceptibility; Piedmont; Hill territories; Terroir of Freisa

In the paper, the potential soil loss and the landslides susceptibility have been evaluated means of empirical models at one of the hilly sites candidate as "Typical Piedmont Vineyard Landscapes: Langhe, Monferrato, Roero" to the World Heritage List of UNESCO. The study area is defined as "Core 1 - Freisa" and its territory is included within the municipalities of Albugnano, Castelnuovo Don Bosco, Moncucco Torinese and Pino d'Asti all in the Asti district.

It is located along the north-western boundary of the Piedmont central hill system, outlined by a wide ridge crown converging towards the Chieri Plain, near the administrative border of the Turin district. The territory possess a historical viticulture tradition, characterized by the culture of the autochthon vines of Freisa and Malvasia. The viticulture is diffused on the sunny slopes, with high quality production and increasing extension; an intricate shrub and wood vegetation grows on the steeper slopes and the lateral watershed. The rich culture mosaic presents parcels of small size also with seminatative cultures, separated by tree fruit rows. The historical settlements are located on the height sites (characteristic is the Albugnano borough), while the rural settlements occurs in isolated or aggregated buildings, disposed on the better exposed slopes. Among the significant historical sites, excels the Vezzolano Abbey, low medieval complex of regional relevance.

The USLE method has been applied in the study for evaluating sheet water erosion. For that scope, the main factors causing erosive processes have been computed from experimental or literature data: rainfall erosivity, soil erodibility, topography of the slopes (length and slope), cropping factor, conservation practice factor. In particular the difference of potential erosion at the vineyard slopes has been evidenced in presence or not of a grass cover among the vine rows.

A simplified method for the assessment of the shallow landslide susceptibility has been applied in the study area. The model takes in account both the rainfall infiltration in the soil and her influence on the slope stability. For the infiltration analysis the model uses the Green-Ampt method that considers the downwards advancement of a saturation front from the ground surface in consequence of a project rainfall. The thickness value of saturated soil is used as input information for the stability analysis according to the infinite slope method. The utilization of the Safety Factor equation permits to relate the project rainfall with the landslides trigger, through the h value, assuming very low values for cohesion and friction angle.

At last, the slope exposure and the layer arrangements (dip direction, dip angle) are elaborated in a simplify model for the evaluation of the susceptibility of the examined territory to the translational landslides.

10.1474/Epitome.04.0302.Geoitalia2011

THE ROLE OF SATURATION OF SOILS IN RELATION TO THE TRIGGERING OF LANDSLIDES IN THE ASTI PROVINCE IN THE EVENTS OF DECEMBER 2008, APRIL 2009 AND MARCH 2011.

DI MARTINO Luca¹, RICCA Giuseppe¹, TOJA Maurizio¹
1 - Regione Piemonte

Presenter e-mail: luca.dimartino@regione.piemonte.it

Key terms: saturation of soils; landslide; flood

From the geological point of view, the Asti Province is part of that domain paleogeographic, usually reported in the literature as the Tertiary Piemonte Basin (TPB). The southern sector is characterized by the presence of a thick marly succession - sandstone (turbidite deposits oligo

- Miocene), while the central-northern area is characterized by a monotonous succession, mainly Pliocene in age, of silty - sandy (sands of Asti) and marly - clay (Argille Azzurre). The northern border of the province is characterized by predominantly siliciclastic lithotypes referable to the Monferrato-Torino Hill domains.

In the geological context outlined, the Province of Asti was characterized in the last four years (November 2008 - March 2011) by three natural disasters that have affected the secondary drainage network of both hills and valley areas.

In particular, each event was marked by hundreds of landslides that have affected both main and secondary roads and also residential areas.

With this memory we will analyze the triggering of landslides in relation to the degree of saturation of the soil and the intensity of rainfall, as each of the three events considered presented mode of initiation, type and extent of the phenomena significantly different.

We will provide a detailed series of rainfall, on a number of reference stations, previous and concomitant to each event. The analysis of the series in relation to effects on the land will lead to some reflections about the factors predisposing the onset of the different types of landslides in the hilly province of Asti.

A first analysis has revealed as the event of November-December 2008 has been greatly influenced by heavy snowfall that led to the saturation of the soil, leading to the development of gravitational movements due to landslides and liquefaction for saturation coverage of the surface layer, without the involvement of the substrate, characterized by rapid linkage.

The event in April 2009 was instead characterized by significant rainfall intensity and duration, that have acted on already heavily saturated soils under conditions of imminent collapse, that in some cases was already occurred.

In a scenario of generalized crisis, widespread landslides and deep involvement with local substrata, even on weak gradients slopes took place.

In March 2011, the Province of Asti was marked by a meteoric event with rainfall of about 100 mm in 24 hours. Despite the modest rain height numerous landslides deep rotational, translational and complex involving large areas and some towns took place.

ENVIRONMENTAL GEOLOGY AND KARSTIC LANDFORM: SOME EXAMPLE IN THE FINALESE AREA (LIGURIAN ALPS, NW ITALY)

BENEDETTINI Andrea¹, BRANDOLINI Pierluigi², FACCINI Francesco², FIRPO Marco², MAIFREDI Alessandro¹, PERASSO Luigi¹

1 - geology and speleology consultant

2 - University of Genoa, Dip. Te. Ris.

Presenter e-mail: faccini@unige.it

Key terms: karstic environment; geomorphic hazard; water resource; Finalese; Ligurian Alps

In the framework of the 39 karstic areas spread over all ligurian region the attention has been focused on Finalese area in the Province of Savona, within the catchment of the Sciusa Stream and in particular in the Ponci Valley (about 6 km²), that represents its northeast sector.

The purpose of this study is the environmental-geological description of the karst area so as to identify the main geomorphological hazards and risk scenarios.

Karstic rock masses develop in the San Pietro dei Monti Dolomites, in the Finale Ligure Limestone ("Pietra di Finale") and in the Val Tanarello Limestones. Geomorphological features are associated with the presence of a karstic plateau, divided in some further elements.

Among the surface landforms the sinkholes of Pian della Noce and Pian della Brera, the swallow-holes, the limestone tower of the Rocca del Corno, the canyon of the Sciusa Stream can be observed. In particular the Ponci Valley represents the relic of a palaeovalley that was more extensive than the current surface: it was spread to North past the San Giacomo saddle and was later occupied by the Sciusa and Corealto Streams.

As for beneath landforms, over forty caves have been listed in the Speleological Inventory with a total length of over 2.3 km. The most extensive hydrogeological complex is the Grotta superiore sorgente Priamara (Upper Cave Priamara spring) (almost 1.7 km long), the deepest known is the Grotta Mala (more than 65 m deep).

The hydrogeological features involve a meteoric water absorption either scattered or concentrated: among major aquifers mention can be made of the Pian della Noce-Priamara complex (dolines, swallow-holes, caves and springs) and the Mala-Andrassa-Acquaviva complex (swallow-holes, sub-riverbed cave, springs).

The lithological features, geomorphological evolution and morpho-structural relationships between the outcropping rock masses (biocalcirudites, dolomitic limestones) cause a great infiltration of rainfall and an underground water flow towards the adjacent Sciusa Valley, that is rich in karst springs: the Acquaviva spring supplies the Noli waterworks. Among the geomorphological hazards that can cause risks mention must be made of sinking ground owing to the vaults collapse of caves, ground subsidences as a consequence of deposits settlement after hollows filling, rocks collapse from the scarps due to karstic landforms, floods partly associated with either the obstruction of the swallow holes or heavy rainfall.

Among the assets at risk on this area, in addition to the anthropogenic element that visits the territory partly for tourism purposes, in Ponci Valley there are five bridges of the Roman age - three of them still well-preserved - embankment protection works and some remains of the road "Via Iulia Augusta", a peculiar example of the ancient communication routes of western Liguria. Moreover remnants of an ancient underground mine of bioclastic limestones are left.

In conclusion this is one of the major karstic areas of the Liguria region for the number of peculiarities: it is a prominent archaeological site that, together with its geomorphological and hydrogeological configuration, represents a cultural and landscape asset of great interest for which protection and enhancement measures must be undertaken so as to preserve it.

Presenter e-mail: faccini@unige.it

Key terms: geohazard; landslide monitoring; deep seated gravitational slope deformation; ophiolites; Ligurian Apennine

This work is a scientific contribution aiming at identifying the Deep Seated Gravitational Slope Deformations, which have been accurately investigated only over the last couple of decades, and to manage them according to their geomorphological hazard.

Camegli hamlet, located in the Ligurian Apennine a few miles from Riviera di Levante, was built over large landslides as well as the majority of settlements in Liguria; these mass movements were probably triggered during lastly Pleistocene following climate changes which fuelled conditions of geomorphological instability.

The area features, as well as covers related to mass movements, serpentinites, basalt and gabbros outcrops belonging to the Bracco-Val Graveglia Unit. The tectonic profile shows a series of faults lineaments, which can be ascribed to the main direction N-S along which the hydrographical network settled and also ascribed to the second direction NO-SE where the valley established.

The work was first carried out through references research regarding both scientific papers and studies related to land planning, secondly through an accurate field survey, supported by photo interpretation analysis of the built-up areas and of a relevant neighbourhood of the landslide bodies, including secondary watershed ridges. Available cartographies of different times, since the end of the XVIII century to date, were compared.

In the area geognostical surveys, by means of piezometers and inclinometers, geophysical prospecting, laboratory tests of the soil and geotechnical tests in situ such as SPT were carried out.

Geotechnical and hydrological monitoring data, based on instruments reading over twenty years, were compared with available targets detected by radar interferometry. The last method aspect involves the inventory of the damaged artefacts of the built-up areas with the purpose of identifying possible correlations between current kinematic mechanisms and implications on buildings.

The settlements of Camegli were built over some landslides which can be ascribed to a deep seated gravitational movement. Going from the ridge toward the valley, various slope failures are observed: they show clear reverse slopes representing the top sector of a series of rock blocks, which locally developed into more recent landslides. Larger trenches were filled up by lacustrine deposits, as indicated by the toponyms Camegli and Case Il Lago. With reference to the landslides classifications this phenomenon appears to be similar to the rock flow type.

Data obtained by inclinometer cases show a good matching with the targets detected on the earth surface carried out by satellites and with the situation derived from the detailed survey of all damage involving man-made structures: relevant deformations are observed in the Case Il Lago slope sector, whereas the deforming sectors do not show important ongoing movements.

The measured total displacements - which are included in a typical kinematic mechanism that can be ascribed to extremely slow movements - goes from a few mm/y to 30 mm/y.

The whole monitored slope features a water table varies 2 to 10 m from ground level: year variations are even lower than 1 m consequently deep source mechanisms can be suggested without a clear correlation with rainfall.

Key terms: QUARRIES; GIS; APULIA

In the Apulia region (S Italy) there are 440 authorized quarries, 68% of which are in activity. The extractive industries make an important contribution to economic development in Apulia. This region has been interested for many centuries in quarrying activities, principally related to limestone, calcarenite and clayey materials. These activities have strongly contributed, with regard to extraction of the main carbonate rocks that were used as ornamental and building stones, to creation of Apulian architectural styles. The uses of clayey materials are various, from that artistic to that in which the clay is used for its impermeable properties, for example in discharge areas. The exploitation of weak rocks, such as calcarenites and second category ones, generally takes place in open quarries. However, underground extraction is not uncommon especially in cases where the calcarenite does not crop out and the removal of surface terrain would be expensive either because of its depth or in order to avoid the resulting loss of the terrain for agricultural production.

Many of the quarries operating today have a history of operation from before the introduction of the Local Government (Planning and Development) Act, 1985, whether permanently or on a seasonal or occasional basis. Quarries which never received planning permission or which received permission many years ago may be operating to older standards of environmental control than modern quarries, other than through voluntary compliance with the industry's codes of practice. However, given their authorised status, it has been difficult to require such quarries to seek consent for any expansion in their activities. Apart from the negative effects directly derived from quarrying, other effects have to be addressed after extraction, when the sites are abandoned without any reclamation work provided, often becoming illegal landfills. Here, we present the results of two projects between "Regione Puglia, Settore Attività Estrattiva" and University of Salento and ARPA Puglia for the study of guidelines to better administrate quarries both in activities (University of Salento) and abandoned (ARPA Puglia). A standard method to geologically map the quarries is proposed. In this project, geographic

information systems (GIS) and relational database technology have been utilized to adapt that reference into a system where spatially arranged collection site features are related to geological data through a series of common fields among tables in a geodatabase. Besides, a methodology to safely quarry related to the destination use has been developed. ARPA Puglia, in the study for the recovery of degraded landscapes from abandoned mining on the region, identifies the variables for the characterization of these landscapes through an analysis of specific indicators. It also defines the criteria for intervention priorities and methods of environmental restoration and landscape, offering private-management models and regulatory instruments applicable to its recovery.

These Guidelines seek to identify those issues and to suggest best practice in dealing with them. However, the operation of quarries can give rise to land use and environmental issues which require to be mitigated and controlled through the planning system.

1 - Comunità Collinare Alto Astigiano
2 - Dipartimento di Scienze della Terra, Università degli Studi di Torino
3 - Regione Piemonte Settore OO.PP. e Difesa Assetto Idrogeologico di Asti

Presenter e-mail: silvia.pastormerlo@yahoo.it

Key terms: slope stability; landslides; Piemonte; Alto Astigiano; hill roads

After the severe rainstorms of December 2008 and April 2009, the situation of slope instability along the hill roads in the territory of the Alto Astigiano Hills Community has become more and more worse. The Italian Government has recognised the natural calamity of national interest for the two events. For such landslide susceptibility, a constant monitoring activity in the Alto Astigiano territory (13 communities of the central Piedmont hills) had to be carried out by the public administration. A research finalized to the production of a guide to the correct land use has been realized with the cooperation of Alto Astigiano Hills Community, Regione Piemonte and Turin University (Dipartimento di Scienze della Terra).

From a geologic point of view, the studied area is located in the Tertiary Piedmont Basin, composed of Upper Eocene to Messinian sediments. In the northern part, the tertiary series forms anticlines more or less accentuated, repeating in a sub parallel way (directed NW-SE). The Eocene and Oligocene terrains result raised in large extent, in some cases sub vertical or strongly troubled. Southward, starting from the Miocene terrains, the slope decreases quite regularly from 40° to around 20°-10°, until, from the Upper Miocene, it reduces to 8°-5° up to vanishing in the Pliocene Deposits. Litologically, the oldest and more resistant terrains, situated in the northern sector, are represented by carbonate sequences of Cretaceous-Eocene and by sandstones formations of Oligocene. Miocene is characterized by alternative marls and sandstones (with lenses of anhydrite and gypsum in the marl formation of Upper Pliocene). In the central and southern part of the study area outcrop the Pliocene terrains, constituted by fine sediments at first (blue clays or Argille di Lugagnano Auct.) and the sands of Sabbie di Asti formation, representing the more widespread lithology outcropping on the territory of the Alto Astigiano Hills Community.

The research activity has been articulated in the following steps:
° enumeration of more than 50 cases of instability reported in the last years by the communities and homogeneously distributed on the territory;
° investigation (technical-geological surveys, measurements, photos, etc.) on every site and finding of data relative to the individuated instability (eventual technical reports, photos just after the occurrence, testimonials, ...);

° drafting of a technical schedule for every case of individuated instability with the identification of the natural, anthropogenic, predisposing, and determining causes of the instability;
° classification of the examined cases in typologies of recurring instabilities for the studied territory;
° for every class of instability typology, individuation of preventive measures and intervention (right land use) for the attenuation of the geomorphologic risk;
° indications for sector laws;
° editing of the guide to the correct land use

The examined cases of instability generally cover landslides both upward and downward the roadways but also flooding of the roads; instabilities occurred almost always because of the faulty drainage of the runoff. Some suggestion for the regular maintenance of the road sides and for the repair of the road bed and surface have been provided in the guide, as well as the temporary and definitive engineering interventions after a road break. But the principal efforts have focused on the importance of an effective runoff disposal for a correct management of the hill territory.

ENVIRONMENTAL GEOLOGY AND SLOPE STABILITY IN REZZOAGLIO VALLEY (AVETO REGIONAL PARK, LIGURIA)

ROCCATI Anna¹, FACCINI Francesco¹, PICCAZZO Mauro¹, POGGI Flavio²

1 - Università di Genova
2 - Regione Liguria

Presenter e-mail: anna.roccati@unige.it

Key terms: Environmental geology; Permanent Scatterers technique; Deep-seated gravitational slope deformation; Applied geomorphological map; External Ligurides

The work presents the case-study of a large slope instability along the left orographic side of the Gramizza Stream (Upper Aveto Valley). This area represents the best-known and typical part of the Aveto Natural Park for its valuable geodiversity that features it (Mt. Penna and Mt. Aiona area). The interest in this slope is determined both by its geological features - for its lithological and tectonical setting and geomorphological peculiarities - and because of engineering geology aspects, owing to the extensive presence of instability phenomena. These movements frequently involve man-made structures, as shown by the number of damages that can be observed on the buildings in the villages of Magnasco and Cerisola.

The geomorphological interpretation of these areas is not easy and univocal, as shown by the number of detected landforms and processes. Such a complex situation often led to discordant interpretations given by various Authors who studied this area in the past (i.e. the large covers featuring the entire slope that have alternatively been interpreted as either glacial deposits, landforms related to a periglacial environment or gravity-induced deposits). Similarly, the scarps that can be observed on the northern slope of the Mt. Aiona are still commonly interpreted as cirques, despite the scarce scientific evidences supporting the hypothesis of a glacial landform.

This complexity mainly depends on the peculiar geological and tectonic-structural setting: in this sector, indeed, flysch deposits, ophiolitic and ultramafic masses, associated with heterogeneous breccias and olistolithes, detached from their original site (Ottone Tectonic Unit - External Ligurides), crop out.

The field survey shows that the entire sector features landforms, processes and deposits due to gravity, running waters, structural elements and periglacial processes. These originated large-scale landslide, favoured by geomorphological features of the rock masses, highly fractured and jointed, due to the heterogeneous nature and structural characteristics of the External Ligurides geological formations. It is hypothesised that the entire system ridge-slope-valley is characterized by a deep-seated gravitational slope deformation; several geomorphological evidences have been detected (double ridges, counterslopes, trenches, closed depressions, etc.) involving extensive ridge portions, remobilizing and revising deposits of various origin. Some landform might be related to periglacial processes (wetlands, endoreic depressions, block stream, etc.) points out the typical periglacial morphogenesis characterizing this area.

The investigation procedure followed for this study starts from a preliminary bibliographic and maps research, including both engineering geomorphological scientific notes and land-planning tools; bibliographical data have been integrated by an accurate geological and geomorphological field survey. The photo-interpretation of aerial photographs and the development of digital stereoscopic models preceded the survey.

Geophysical surveys have been carried out to evaluate the thickness of the large landslide and to obtain a preliminary engineering geological model. Further indications for the interpretation of the kinematic mechanism and state of activity of the detected gravitative phenomena have been obtained from the analysis of the satellite-monitoring data PSInSAR™ (Permanent Scatterers), radar interferometric technique.

The obtained results have been included in the applied geomorphological map of the slope bounded by the mounts Penna, Aiona, degli Abeti and the Gramizza stream. This geoenvironmental map, of recognized scientific value, currently represents a useful tool for correct land planning and management, and for risk mitigation purposes.

Presenter e-mail: asacchini@unige.it

Key terms: Ligurian Alps; Karst aquifer; Intrinsic vulnerability; SINTACS method; Bric Tampa

Karst aquifers are an important and strategic water resource. UNESCO data show that in 1975 about 30% of drinking water available on world scale came from carbonatic massif and that in 2005 this value was about 80%.

Water in karst areas is a fundamental resource for the supplying of many Italian town like Trieste, Roma and L'Aquila. In Ligurian area ground water tables contained in alluvial plain, are over-exploited, so the interest in karst springs, many of them are already utilized from local aqueduct, is increasing.

As is known, karst aquifers are vulnerable to possible sources of pollution. The analysis of problems related to karst areas has been poorly developed because of the complexity that this hydrogeological system presents.

Only in recent years, the attention on karst hydrogeological complex has been growing, for the need to develop researches on new water resources and for the simultaneous need to preserve these delicate ecosystems.

The aim of this research is to assess the intrinsic vulnerability of karst aquifer in Bric Tampa (Ligurian Alps), by applying the SINTACS method, proposed in different studies on the vulnerability of the aquifers.

The SINTACS method utilizes the following seven parameters: depth to ground water, effective infiltration, unsaturated zone attenuation capacity, soil attenuation capacity, hydrogeologic aquifer characteristics, hydraulic conductivity range and hydrological role of the topographic surface.

The application of the SINTACS methodology in a Ligurian environment allows comparison with other national case studies, especially performed in karst massifs of the Ligurian Alps and Triestine Carso; in this way it's possible to obtain both the right calibration of the model and the experimental proposal of modifications and integrations, considering the geological and geomorphological Ligurian peculiarity.

Bric Tampa is one of the 39 karst areas in Liguria and covers an area of approximately 3 km and 6 km of underground development detected. Bric Tampa, belonging to M. Carmo Unit, consists of the Dolomie San Pietro dei Monti and Quarziti di Ponte di Nava Formation.

Structural complex is a anticline recumbent fold, overturned toward N, in it turn warped by a series of transverse folds; as a whole it can be described as a complex antiform dome.

The hydrogeological system consists of a complex underground aquifer karst in dolomitic rock masses and of some karst springs tied with effective infiltration, contributing to the formation of congruent groundwater resources.

The hydrodynamics of the system is characterized by a movement in large ducts: the general system is powered by the secondary infiltration, meaningful and focused in the outcrop areal of dolomitic storage. The latter, based both on several geomorphological indications and on geological structure, is also affected by Quaternary tectonic-gravitational phenomena.

To assess quantitatively the hydrogeological characters of the aquifer, hydraulic conductivity and the type of karst network, a multi-parameter probe for continuous monitoring of the Cave Garbo de Cunche has been installed. This cave spring supplies the municipal aqueduct of Giustenice. The results of flow, conductivity and temperature monitoring, in relation with external rainfall, have allowed the definition of the type of

underground drainage network, that is a dominant drainage type. Research has finally allowed the reconstruction of the catchment area, highlighting the contributions of outside water, including the hidden precipitation that are particularly significant in the Ligurian area.

10.1474/Epitome.04.0309.Geoitalia2011

ENVIRONMENTAL IMPACT OF MASS WASTINGS PROCESSES IN LIGURIAN SCRIVIA VALLEY (NORTHERN APENNINE, ITALY)

SACCHINI Alessandro¹, FACCINI Francesco¹, PICCAZZO Mauro¹

1 - Università di Genova, Dip.Te.Ris.

Presenter e-mail: asacchini@unige.it

Key terms: Ligurian Apennine; Scrivia Valley; Mass wastings; DSGSDs; Environmental Impact

Environmental and applied geomorphological surveys are getting more and more important especially in land planning and risk assessment. The Upper Scrivia valley lies in the Ligurian Apennine, along the Alps-Apennine junction, characterized by a significant geological and geomorphological complexity associated with its evolution and various processes (gravity, running waters, structural elements and periglacial processes) that have - nowadays and in the past - originated its landforms. Cretaceous shales and marly limestone flyschs outcrop in the valley, characterized by both Alpine and Apenninic deformations. Oligocene conglomerates of the BTP (Tertiary Piedmont Basin) outcrops above these Formations linking Alpine and Apenninic Units. These geological and geomorphological characteristics cause susceptibility to mass movements along the slopes, together with a high annual (till over 2000 mm) and daily rainfall (over 700 mm) amounts measured in some Scrivia valley weather stations. The Scrivia Valley is located on the Apenninic slopes of the Po valley only a few kilometers away from the Ligurian Sea and the regional capital and it is characterized by a general moderate steepness near the watershed. These particular conditions has led to its historic vocation of main liaison between the Po plain and Genoa harbour. In the valley there are also important naturalistic areas, biotopes, SIC (Sites of Community Interest) and geosites in the Regional Natural Park of Mt Antola. A significant presence of large landslides, more than national and regional average, has been mapped. In addition many deep-seated gravitational slope deformations (DSGSDs) are located along the slopes. They are mapped with geomorphological forms like scarps, counterscarps, double ridges, trenches, crestal troughs, closed depression, valley bulging, pseudo or para-karst forms. The DSGSDs distribution is particularly related to the geomorphological conditions of geological contacts between the hard rock Oligocene conglomerates and the Cretaceous flyschs, with prevalent weak behaviour. The distribution of these mass movements is also associated with lithological differences in the Cretaceous flysch and local tectonic and neo-tectonic conditions, above all linked to pliocenic and pleistocenec uplift. The mapped landslides are often distributed along DSGSDs which have an extension higher of more than one order of magnitude. In addition data from drillings and monitoring have allowed to analyse some case studies among large landslides surveyed in the valley. Large landslides and DSGSDs have an important impact on land planning and infrastructures but also directly on the population, as people have always settled there owing to favourable conditions of steepness and agriculture.

FLOOD 15-16 MARCH 2011 - MAJOR LANDSLIDES THAT HAVE AFFECTED COUNTRIES IN PROVINCE OF ASTI

TOJA Maurizio¹, DI MARTINO Luca¹, RICCA Giuseppe¹

1 - Regione Piemonte

Presenter e-mail: maurizio.toja@regione.piemonte.it

Key terms: saturation of soils; landslide; flood

This paper aims to be a deepening of our previous memory "The role of saturation of soils in relation to the mode of initiation of landslides in the Province of Asti in the events of December 2008, April 2009 and March 2011" and focuses on the effects on the ground in consequence of the event of 15-16 March 2011.

This event, in the opinion of the authors, presents some peculiarities that lead to distinguish it from recent events registered in December 2008 and April 2009.

The amount of rainfall during the event was of modest importance (about 100 mm in 24 h) and not to justify the initiation of landslide hazards; moreover, in the previous months, no significant rainfall responsible for prior charge of saturation of the soil were registered.

Nevertheless in the event of March 2011 extensive and deep landslides of rotational, translational and complex dynamic took place, involving some settlements dislocated in the whole Asti Province.

Were analyzed five case histories of landslide that affected the municipalities of concentric Aramengo, Casorzo, Mombaruzzo, Montegrosso d'Asti San Marzano Oliveto.

A detailed study of most representative cases is in progress, this study will be focused on triggering and predisposing causes of the phenomena. In particular the following aspects will be analyze:

- Previous rainfall series;
- Previous temperature excursions;
- Saturation index measured in each site;
- Any anthropogenic interference in steady-related discharges water;
- Local factors.

The analysis of all these aspects will contribute to gaining the necessary elements for a better understanding of the event and of its effects on the territory, also in order to make appropriate interventions for both prediction and prevention of landslides.

10.1474/Epitome.04.0311.Geoitalia2011

SUSTAINABILITY OF WASTE MANAGEMENT IN HILLY LANDSCAPE OF THE EASTERN IRPINIA (CAMPANIA)

VALENTE Alessio¹, RUSSO Filippo¹, SISTO Michele¹

1 - Università degli Studi del Sannio, Benevento

Presenter e-mail: valente@unisannio.it

Key terms: ENVIRONMENTAL GEOLOGY; WASTE MANAGEMENT; CAMPANIA

Irpinia is a historical region situated in Campania and coincides largely

with the present province of Avellino. Within this region, the eastern sector is characterized mainly by a hilly landscape that stretches for about 1476 sq. km. Insist on it 40 small towns of the 119 total in the province of Avellino, only five of these exceed 5000 inhabitants. Most of these villages spread between 500 and 700 m above sea level.

The geological connotation of the Eastern Irpinia is the presence of an extensive and articulated plateau incised by an immature hydrographic network, which flows into the Ufita River to the north and in the Ofanto River to the south. This plateau is mainly composed of clay and sandy lithologies, attributable to several terrigenous units variously classified in literature as pre- and post-orogenic as well as to a regressive cycle deposited in an epicontinental sea in the Pliocene. On top of these sediments are the degradation products of Quaternary.

The plateau, located between the outermost thrusts of the Apenninic chain, is the result of Plio-Pleistocene tectonic even if paroxysmal seismic events still alive in the memory of places and peoples, like the earthquake of 23 November 1980. In addition, the modeling by means of rain and washout is the direct cause of extensive erosion which affects the slopes of the hills. No less important is the flooding caused by the local rivers, which are mostly characterized by torrential runoff. Obviously these hazards make precarious settlements and human activities in the area.

The Eastern Irpinia has a distinctive rural identity, although the progressive abandonment of the countryside and the depopulation of the settlements are affecting further development. In the landscape other detractors are the widespread areas of extraction, in some cases with a very strong visual impact. In this context, biodiversity and historical-architectural structures must be protected.

However, these aspects, rather than being a barrier to development, can be seen as an opportunity to protect and enhance the landscape in order to define opportunities for development. Such opportunities arise from the potential in the area that, properly planned with a view to a good policy to mitigate risk and danger, making them less vulnerable to anthropogenic and environmental conditions favoring a proper local land-use in compliance with the obligations Act for areas subject to protection in various ways.

In dealing with the Strategic Environmental Assessment of Waste Management Plan of the Province of Avellino has shown that there are potential problems of the actions of the Plan against the geological environment and landscape, especially of Eastern Irpinia. This despite the fact that these actions indicate both a reduction in the use of the storage of waste, which directly affect the geological environment, is a balanced budget plan is proportional to the production of type and amount of waste per inhabitant, which generally results in localized environmental effects and indirect.

Therefore, these problems result in part from the location of treatment plants in areas or placed next to them (for example, from river areas, geological constraints, vulnerabilities inherent hydrological, ecological corridors, etc.) and partly by the intrinsic fragility of the geological territory that changes in appearance due to the fast erosion particularly effective. The latter aspect determines effects not only at the plant, but also on work of man (roads, infrastructures, etc.) necessary for the management of waste. Finally, in this area some specific geomorphological conditions can lead to severe penalties in case of earthquakes.

THE FLOOD EVENT OF OCTOBER 4, 2010 IN GENOA - SESTRI PONENTE (LIGURIA, ITALY)

BOZZANO Silvio¹, BRANDOLINI Pierluigi², FRANCIOLI Gloriana¹, ROBBIANO Alessandro¹, VINCENZI Enrico¹

1 - Settore Protezione Civile, Comune di Genova

2 - Dipartimento per lo studio del Territorio e delle sue Risorse, Università degli Studi di Genova

Presenter e-mail: brando@unige.it

Key terms: rainfall; flood; landslide; environmental risk; Genova, Liguria

The paper describes and analyzes the rainfall event that occurred in the west-central portion of the Ligurian coastal zone on October 4, 2010, with particular regard to the district of Sestri Ponente, in the Municipality of Genoa.

Specifically, attention is focused on the basin of the Chiaravagna stream, which was affected by flooding in its final stretch, and on the basin of the Molinassi stream affected, besides its flooding, by a large number of shallow landslides, debris flows, gully erosions, especially in the upper part of the basin.

Meteorological causes that led to exceptional rainfall intensity and subsequent ground effects have been analyzed and described.

In the Genoa - Sestri Ponente area (where the maximum rainfall intensity occurred) the total cumulated precipitation recorded approximately 400mm in six hours, with peaks of over 120mm/h and 18mm/5min.

These rates are similar to those recorded during previous flood events that have repeatedly affected the central area of Liguria, typically occurring in the transition period between late summer and autumn, such as in October 1970, September 1992 and September 1993.

In response to these heavy precipitations, all rivers in the area of Sestri Ponente flooded, in particular along their final stretches, which are heavily constrained because of intense urbanization over the last half century.

The part of the urban area located in the fluvial-coastal plain has been almost completely affected by flooding, for a total surface of 0.7km², with an average water table height of 0.5 m.

A number of erosional and gravitational processes have mobilized a large amount of detrital material along the drainage network, in particular in the upper part of the Molinassi valley, heavily increasing the solid transport and therefore reducing the stream flow capacity and increasing the effects of floodings.

As a consequence of this rainfall event severe damages have occurred both in the urban area located on the level ground affected by flooding and in the slopes rising just above the built up area, where landslides caused widespread disruption of hill roads and evacuations of houses for reasons of public safety.

AQUIFER VULNERABILITY ASSESSMENT THROUGH RISK ANALYSIS LABORATION. A CASE STUDY IN THE PESCARA RIVER VALLEY (ABRUZZO-ITALY)

DILIGENTI Antonio¹, LUCHETTI Lucina¹

1 - ARTA Abruzzo - Distretto Provinciale di Chieti

Presenter e-mail: a.diligenti@artaabruzzo.it

Key terms: risk analysis; vulnerability; aquifer; contaminated sites; waste sites

We consider the Chieti Scalo industrial compound and farmland area, that is located in the right hand side of the medium-lower portion of the Pescara river valley. The topography characterizing this sector consists of hills and top surface that reach altitudes of 15-250 meters a.s.l.. The observed stratigraphy, consisting essentially of alluvial deposits, reflects the typical succession of the fluvial environment. In particular this succession, starts from below with lower Pleistocene marine silty clays (Mutignano Fm) followed by upper Pleistocene terraced alluvial deposits and holocene conglomerates containing silty and clayey beds and lenses. These deposits have been recently referred to the *Sintema di Valle Majelama* (Late Pleistocene p.p) which is subdivided in the *Chieti Scalo* and *Vallemare Subsintema*.

Considering the large site dimension, over 100 drilling points are utilized to assess the geological and hydrogeological characteristics in addition to the source of chemical contamination, with the aim to obtain a solid conceptual model necessary to evaluate the possible mechanism of groundwater and human risk exposure.

Regarding the hydrogeological features, two main aquifers have been surveyed, which are separated by an aquiclude level with thickness ranging from 0 to 7 meters that is located at depth of 8-10 m. Therefore, two groundwater systems are identified within the aforementioned aquifers, which are called, in the following, *superficial* and *deep*, respectively. In several zones the aquifers are connected, due to stratigraphic (the aquiclude level shows pinch-out closures) and anthropic activities reasons. Anthropic activities have profoundly reworked the deposits so locally the original stratigraphy can not be recognized at all. In fact, the intense extraction which activities essentially concentrated along the holocene alluvial plain and mainly related to the iron-steel and tannery industry on the fluvial terraces, determined zones with elevated critical environments.

The alluvial deposits was removed to a depth reaching in some cases 10 m., causing the replacement in the terraces, containing the *superficial* aquifer, with mixed heterogeneous material and urban-special waste often dip in the groundwater. Taking into account the distinctive impact regarding the groundwater, as demonstrated by contamination (heavy metals, metalloids and chlorinate solvents), we consider the aquifer intrinsic vulnerability valuation through usual weights and points methods not appropriate. For this reason we approached the hydrogeologic-hydrodynamic conditions and the contamination of the groundwater, through the deterministic and probabilistic methods of the Risk assessment. As the valuation of the intrinsic vulnerability, the Risk analysis elaboration, combining several geometric properties of the site with others parameters, such as contamination levels and final receptors.

Since the intense human activities radically changed the original site-specific conditions valuation of vulnerability can be assessed directly through the Risk analysis procedure. The collected site-specific data and the results of the risk analysis are processed in a GIS environment geodatabase through geostatistic and deterministic applications, such as kriging and linear triangulation respectively, realizing maps of groundwater direction, contamination plume extension and map of Risk.

In conclusion, the risk assessment of aquifer contaminated sites is the main tool for defining both the site cleanup goal and the response of aquifer to anthropic pressure supporting environmental decisions.

THE FLOOD RISKS ON THE KARSTIC MURGE HILLS (CENTRAL APULIA, SOUTHERN ITALY)

PENNETTA Luigi¹, MARSICO Antonella¹

1 - dipartimento di Scienze della Terra e geo-ambientali Università degli Studi "Aldo Moro", Bari

Presenter e-mail: a.marsico@geo.uniba.it

Key terms: Murge hills; huge rainfall; land use; flood damages

The Murge plateau is the hilly central part of the thick carbonate Mesozoic sequence of the Apulia platform. Cretaceous carbonate platform deposits are known as "Calcarei delle Murge" Group. The carbonate rocks are overlaid by thin transgressive calcareous and marly-calcareous deposits of Tertiary and Lower Pleistocene known as the "Calcareni di Gravina" Formation. The whole area is characterised by developed karst landforms. The "Murge" karstic area exhibits a well developed drainage-network, formed by a dense dendritic pattern in the headwater zone ("Murge Alte") which evolves into regularly spaced, incised valleys moving towards the coastal area ("Murge Basse"). These channels are locally named "lame", and show subvertical rocky flanks and a flat bottom. The drainage channel system develops mainly along N and NE directions.

In the whole area the agriculture is developed and the growing is mainly cultivated where the soil is thick, such as the bottom of both dolines and drainage channels. Moreover, the socio-economic development of the last 60 years caused the enlargement of towns and of industrial districts with no respect for the environment and hydrogeological features. So, houses, commercial and industrial buildings, roads, railroads and service infrastructures as well as vineyards and cultivated fields are located next or in the "lame".

The occurrence of calamitous meteoric events is unusual in the Murge area since the dry climate: the value of the annual mean rainfall is about 600 mm and events of large intensity occur mainly in autumn season. Usually rainwater rapidly infiltrates, feeding a wide, deep karst aquifer. However very intense rainfalls occur causing emergency states and flood damages, involving people as well as socio-economic property because the use of high flood risk areas.

Historical records report that floods occurred in the city of Bari every 10-20 years until 1926 while recent severe floods took place the night between the 22nd and 23rd of October 2005. Other flooding events happened on the south-western Murge side the 8th September 2003 and in the south-eastern part on 29th September 2003, 21st October 2005 and 20th May 2010.

During each of these events, the great amount of rain fallen in few hours caused a huge water flow that carried away soil, growing, road embankments, bridges, walls and other infrastructures, flooding into private houses and industrial buildings. These events also caused the loss of some human lives swept way by water while travelling on roads.

The occurrence of damages clearly shows either that the flood areas were underestimated and, in general, that a bad territory management has been carried out without taking into account the sustainable development. Several studies were carried out in the last years in order to map flood risk areas to define special planning restrictions and providing

contributions to a better management of the area.

GEOLOGICAL PROCESSES AND THEIR RELATION WITH HUMAN ACTIVITIES, EXEMPLIFIED IN A HILLY VINEYARD AREA OF CENTRAL PIEMONTE (PROGEOPIEMONTE PROJECT - GEOTHEMATIC AREA 4)

AJASSA Roberto¹, BONETTO Sabrina¹, CAVAGNA Simona¹, CIGOLINI Corrado¹, CLARI Pierangelo¹, COMINA Cesare¹, DELA PIERRE Francesco¹, DESTEFANIS Enrico¹, FORNO M. Gabriella¹, FRATIANNI Simona¹, GATTIGLIO Marco¹, LOZAR Francesca¹, MANDRONE Giuseppe¹, MARTIRE Luca¹, MASCIOTTO Luciano¹, PIANA Francesco², et al.

2 - CNR - Istituto di Geoscienze e Georisorse - Torino

Presenter e-mail: luciano.masciocco@unito.it

Key terms: Geological heritage; Piemonte; Vineyard; Geosite; Hills territory

The multidisciplinary research project "PROGEOPIEMONTE" aims to achieve a new conceptual and operational discipline in the management of the geological heritage of the Piemonte Region by means of the development of techniques for recognizing and managing its rich geodiversity at the local and regional scale. After a systematic review of inventoried geosites, 9 strategic geothematic areas will be investigated to represent the geodiversity of Piemonte, each characterized by high potential for scientific studies, enhancement of public understanding of science, recreation activities and for economic support to local communities. Geological history, climate and environmental changes, natural hazards, soil processes and georesources will be popularized not only with geosites but also with museum collections, evidences of mining activity and quarrying, science exhibits and nature trails. The recognition of the economic value of geodiversity will lead to the production of regional guidelines for Geoconservation integrated quality management system, suitable for tourism and sustainable development strategies. An international advisory board will evaluate yearly project advancements, proposed strategies and products.

The fourth geothematic area of PROGEOPIEMONTE PROJECT is represented by a hilly vineyard area of central Piedmont.

Starting from their evolution in the last period of the geologic history, the hilly territories of Central Piedmont (according to many Authors, the structural limit between the Alpine and Apennine chains) will be analyzed with regards to their geo-resources (soil and climate for vineyards, mineral water springs and mines) and geo-hazards (erosion, shallow and deep landslides).

Five research activities have been developed in the study hilly area.

° In the Torrente Traversola Deformation Zone, the origin and evolution of deformation zone in the western area of the Asti Reliefs have been studied leading to geological mapping and reconstruction of the structural evolution.

° The complex Geosite of Passerano Marmorito, a tectonic cross road in Monferrato recording past methane-rich fluid emissions, has been defined investigating the origin and the reciprocal genetic relationships of different methane-derived rocks such as fossil-rich Lucina limestones, and fossil-free cemented clastic sediments documenting seeping at the sea floor and in the subsurface respectively.

° A cultural and geological heritage of the Monferrato hills like the gypsum quarries and the Upper Pleistocene fossil deposits has been investigated in Moncucco, Castelnuovo Don Bosco and Murisengo sites improving the geological knowledge of the gypsum ore bodies and the valorization of the local traditional activity of the gypsum exploitation.

° The Bardella mineral spring of Castelnuovo Don Bosco has been characterized from both hydrogeological and hydrogeochemical point of view.

° At last, climatic and pedologic analyses, as well as the assessment of geomorphological hazard linked to accelerated erosion and landslides have been realized in the Freisa d'Asti terroir, comprising the territories of Castelnuovo Don Bosco, Pino d'Asti, Moncucco and Albugnano, and representing one of the nine areas proposed for inscription in the list of UNESCO world heritage sites.

Geodiffusion actions contemplate geological routes in the hilly area to show key outcrops equipped with illustrative panels. More detailed information could be available in the tourist centers of the principal villages.

The field itineraries should be of interest not only for a large public interested in improving the geological knowledge but also for specialists wishing to visit key outcrops with comparison purposes.

ZINC BIOMINERALIZATION PROCESSES AT INGURTOSU MINE (SW SARDINIA)

DE GIUDICI Giovanni¹

1 - Università di Cagliari

Presenter e-mail: gbgiudic@unica.it

Key terms: heavy metal; biomineralization; environmnet; mine; tailings

The Ingurtosu Pb-Zn mine (S-W Sardinia) was exploited for about a century until 1968. Huge amounts of tailings were abandoned, resulting in long-term heavy metal dispersion processes in both stream sediments and waters. Zn and Pb concentration in tailings and stream sediments attains values up to thousands of mg per kilogram. The maximum Zn concentration in water attains several hundreds of mg per liter, whereas Cd and Pb concentrations are in the order of thousands of µg per liter. Heavy metal concentration in waters of Rio Naracauli, the main stream of the area, is abated by seasonal biomineralization processes. Precipitation of hydrozincite [Zn₅(CO₃)₂(OH)₆] and of a Zn-rich amorphous phase results in a decrease of Zn concentration down to a few mg per liter. Other metals such as Pb, Cd, Cu, and Ni are coprecipitated with the Zn

phases. TEM analysis of hydrozincite has shown that nanocrystals that are approximately 3 nm long aggregate by an imperfectly oriented aggregation mechanism (De Giudici et al. 2009). This results in the formation of mesocrystals. These are hydrozincite platelets flattened onto the (100) crystal face that were observed by SEM. Hydrozincite globules are made by a further aggregation of these micrometric platelets. SEM images of hydrozincite show that both shape and size of globules are apparently influenced by environmental conditions (namely sunlight, rainfall, runoff, stationary hydraulic conditions; Medas et al. 2011). The cell parameters of Naracauli hydrozincite are all similar, and slightly different with respect to the published structures, possibly suggesting a different stacking order along *ao*.

The nature of binding of Cd and Pb to hydrozincite was investigated by X-ray absorption spectroscopy (XAS). For Cd, the results of extended X-ray absorption fine structure (EXAFS) analysis, backed by anomalous X-ray diffraction, suggest a disordered mode of occurrence, presumably as an amorphous surface precipitate (Lattanzi et al. 2010b), while for Pb a more complex model is suggested (Lattanzi et al. 2010a): this metal is supposed to occur partly as an amorphous surface carbonate, partly either as a substituting ion in the tetrahedral Zn site of the hydrozincite structure, or as an inner-sphere surface complex. Microscopic and spectroscopic investigation on the Naracauli zinc silicate are undergoing. Acknowledgements. This paper was funded by EU grant 226870 UMBRELLA (coordinator Erika Kothe, University of Jena).

SEASONAL VARIABILITY OF HARMFUL COMPONENTS IN DIFFERENT AQUEOUS FRACTIONS IN NATURAL WATERS

CIDU Rosa¹, BIDDALU Riccardo¹, DA PELO Stefania¹

1 - Università di Cagliari

Presenter e-mail: cidur@unica.it

Key terms: HYDROGEOCHEMISTRY; FILTRATION; NITRATE; SEASONAL VARIABILITY; HARMFUL ELEMENTS

The distribution of aqueous components, including toxic and harmful elements, in different aqueous fractions can be investigated via their determination in non filtered and filtered water samples. Concentrations determined in non filtered samples can be roughly regarded as total amounts. Filtration through 0.45 µm pore-size filters is conventionally used to remove the matter in suspension, thus concentrations determined in the water fraction <0.45 µm might be regarded as 'dissolved amounts'. However, in this fraction the aqueous components may occur either as 'truly dissolved' species or hosted in fine particles of <0.45 µm size, such as clay and colloidal materials.

Results of hydrogeochemical surveys carried out in Sardinia (Italy) showed significant differences in concentrations of specific components when water was sampled under different seasonal conditions, and analyses were carried out in different aqueous fractions (non filtered samples, aliquots filtered through 0.45 µm and 0.15 µm pore-size filters).

Concentrations of nitrate in surface water and groundwater did not significantly change when determined in different aqueous fractions (unfiltered and filtered aliquots), indicating that nitrate occurs as truly dissolved species. However, nitrate concentration in river and stream waters sampled under high flow condition was higher than that in water collected under low flow condition.

Variations in the dissolved amount of trace elements appeared to depend on the composition of rocks drained, and the occurrence of mineral deposits. Concentrations in river and stream waters were also dependent on hydrological conditions, such as runoff, flow and turbulence. Specific trace elements showed distinguished trends.

The elements B, Li, Rb, Sr, Ba, As, Sb, Mo, and U in the studied waters showed small differences in concentrations determined either in non filtered or filtered water samples. Their concentrations were often positively correlated with total dissolved solids (TDS) and/or major ions. Dissolved concentrations in surface waters were higher in summer, when the contribution of rainwater to the rivers was minimum. These elements occurred as truly dissolved species (either as free ions or aqueous complexes), which concentrations appeared related to the intensity of water-rock interaction processes.

The elements Al, Fe, Pb, Zn, Cd, Co, Ni, Cs, Y, REE and Th were not related to TDS and/or major ions; they showed higher concentrations under high flow conditions; marked differences occurred between total and dissolved amounts; concentrations in the water filtered through 0.015

µm were much lower than in the water filtered through 0.4 µm, especially when sampling was carried out after storm events that enhanced the load of solid matter in the water. These observations indicate an aqueous transport of these elements mainly via sorption processes on very fine particles.

Considering that seasonal variability in concentrations of harmful components may affect the water quality, results from this study can be useful to understand the human health and aquatic life risk exposure to potential contaminants.

DIEL CYCLES OF DISSOLVED ZINC AND ARSENIC IN THE BACCU LOCCI STREAM (SARDINIA, ITALY) AFFECTED BY PAST MINING

FRAU Franco¹, CIDU Rosa¹, ARDAU Carla¹

1 - University of Cagliari

Presenter e-mail: frauf@unica.it

Key terms: Diel cycle; Trace elements; Sorption; Baccu Locci mine; Sardinia

Short-term changes in water chemistry, and especially in dissolved trace element concentrations, associated with diel cycles during base-flow conditions at a specific sampling station in the Bacchu Locci stream draining the homonymous old mine area in Sardinia (Italy) were investigated. Diel fluctuations in pH and alkalinity were correlated with the temperature-dependent CO_2 solubility and the biological-induced CO_2 production, both of which were higher during the night. Adsorption/desorption to/from streambed material, in particular ferrihydrite, is believed to be the main in-stream mechanism causing the observed diel variations in dissolved concentrations of As and Zn. Arsenic was mainly affected by the dual action of temperature and competing carbonate ions, whereas pH seemed less important. Temperature acted in accordance with the exothermic feature of anion sorption onto hydrous metal oxide surfaces; aqueous carbonate species exerted their competitive effect in relation to alkalinity variation. Zinc was primarily affected by temperature, in accordance with the endothermic feature of metal cation sorption onto hydrous metal oxide surfaces, and secondly by pH. Co-precipitation of As and Zn with calcite is another possible mechanism that, to be better investigated, would require a further finalized examination of inorganic and biological materials coating the streambed. All these processes potentially controlling the diel cycles of trace elements should be carefully considered to assess the effectiveness of remediation actions currently in progress at Bacchu Locci.

GENERATION OF ACID MINE DRAINAGE FROM DISSOLUTION OF SECONDARY METAL SULFATES: THE CASE OF MELANTERITE

FRAU Franco¹, CIDU Rosa¹, DADEA Claudia¹

1 - University of Cagliari

Presenter e-mail: frau@unica.it

Key terms: Melanterite; Dissolution; Acidity; Modeling

Oxidation of metal sulfides, in particular pyrite, by oxygen or Fe(III) is considered the main process generating AMD (Acid Mine Drainage). However, secondary minerals from sulfide oxidation can significantly contribute to AMD generation. Secondary metal sulfates are common phases in sulfide ore mines and their formation-dissolution cycle is often influenced by climatic conditions. Melanterite, the heptahydrated ferrous sulfate, is one of the most diffuse oxidation products of pyrite. Moreover, its presence has been recently hypothesized in the evaporites on the surface of Mars. Field observations in mine sites show that melanterite is associated with acidic waters and laboratory experiments confirm this finding. However, simple dissolution of melanterite, without oxidation of Fe(II) to Fe(III), cannot generate AMD because the hydrolysis of Fe(II) is not able to significantly lower the water pH. Both commercial and natural melanterites always contain small amounts of Fe(III), probably as a ferric sulfate of some sort. Modeling of laboratory batch experiments with PHREEQC has shown that Fe(III) concentrations in melanterite in the range of 0.16-0.20 wt. % are sufficient to significantly lower the pH of very dilute interacting waters as a consequence of Fe(III) hydrolysis. Since melanterite is very soluble, its rapid acid-generating dissolution can occur without invoking oxidation of Fe(II) to Fe(III) that is slow under acidic conditions, as well as without involving the acidity-generating precipitation of a Fe(III) phase. In the field, the rapid dissolution of Fe(III)-bearing melanterite by rain water may thus generate AMD and also provide a supply of Fe(III) for subsequent sulfide oxidation. These results should be taken into account when evaluating the origin of AMD in mine sites in order to prevent its impact on the environment and plan its treatment.

ENVIRONMENTAL GEOCHEMISTRY OF AN ACTIVE MINING AREA: THE HUANUNI BASIN (BOLIVIA)

DINELLI Enrico¹, KRALI Martina¹, MARCHESI Massimo², SOLER Albert², LAFUENTE S³, CORONADO Felipe³, ZANNONI Denis¹

1 - CIRSA, University of Bologna, 48123 Ravenna, Italy

2 - MAIMA, Universitat de Barcelona, Barcelona, 080028, Spain

3 - PQII, Universidad Tecnica de Oruro

Presenter e-mail: enrico.dinelli@unibo.it

Key terms: acid mine drainage; sequential extraction; bolivia; water; sediment

Mining activities, concentrated on cassiterite exploitation, developed in the Huanuni basin are operating without any responsibility for the environment and the population living in the catchment. The area, with a population over 50,000 inhabitants approx. is located in the Oruro department, Bolivia. Active mining operations discharge liquid and solid wastes without any treatment directly into various rivers. A detailed study on the geochemistry of water, bedload sediment and suspended material has been carried out in the area to evaluate the degree of pollution in the area, better constrained by the application of a sequential extraction analysis on selected bedload and suspended sediments. Samples were collected around three active mines in the Huanuni basin following the occurrence of Acid Mine Drainage in the area. Electrical Conductivity, temperature, pH, were measured directly in the field, filtered and acidified and unacidified water samples were collected for the analysis of major and trace elements and the anionic composition. The fraction < 63µm of the bedload sediment, directly sieved in the field, and in selected sites the suspended sediment were collected and analysed for total metal content by XRF. Their bulk mineralogical composition has been determined by XRD. To selected samples, a 3-step plus aqua regia sequential extraction procedure has been applied in order to constrain metal distribution within the sediment.

Surface water show strong acidic conditions (pH 2.9-4.5) in several sites, with high SO_4^{2-} concentrations (up to 2400 mg/L), and high metal contents (580 mg/L Fe, 141 mg/L Zn 82 mg/L Al, 6000 µg/L Cd, 5650 µg/L Cu, 2600 µg/L Pb, 1440 µg/L Co, 540 µg/L U, 24 µg/L Ti), generally decreasing downstream from the active mine areas. Their distribution is however different between the mines impacting the catchment and can be used as traces of the source area.

The bedload sediment chemical composition is characterized by high concentrations of Cu, Zn, Pb, but also Sn, As reach high values. Concentrations of Cd, Co, Cu, Cr and Zn are higher in suspended sediments. In general a decrease in sediment concentrations is observed downstream from the active mines, and also for bedload sediments differences can be outlined among the different mines. The results of the

sequential extraction point out differences in metal distribution: in the most polluted sites Cd, Co, Cu and Zn are associated preferentially to an oxidizable fraction and it is important to note that in the suspended sediments the proportion associated to the exchangeable fraction is higher. A completely different distribution is displayed for example by Arsenic or Pb, which are almost completely associated to the residual fraction.

The study shows the hazard of the suspended sediment release in the river system and the possibility to reduce the contamination removing the disposal of the liquid waste. Sequential extraction data suggest that care must be taken for the different geochemical behaviour of critical elements.

MERCURY DISTRIBUTION AND TRANSPORT IN THE ECOSYSTEM OF PAGLIA RIVER (MONTE AMIATA, ITALY)

RIMONDI Valentina¹, COSTAGLIOLA Pirlorio¹, GRAY John E.², LATTANZI Pierfranco³, VASELLI Orlando¹, BENVENUTI Marco¹

1 - Dipartimento Scienze della Terra - Università di Firenze

2 - U.S. Geological Survey, Denver

3 - Dipartimento Scienze della Terra - Università di Cagliari

Presenter e-mail: valentina.rimondi@unifi.it

Key terms: Environmental pollution; Mercury; Methyl-mercury; Monte Amiata; Stream sediment

Mercury (Hg) is a heavy metal of environmental concern as it is highly toxic to living organisms. The most toxic Hg compound is methyl-mercury (MeHg), which is a neurotoxin that biomagnifies in the food chain. Of particular concern around Hg mines is the conversion of inorganic Hg (e.g., cinnabar and elemental Hg) to MeHg, which is primarily by the action of bacteria in the sediment column. Fish accumulate MeHg, thus, representing the dominant pathway of Hg to humans who consume fish. As a result of historical exploitation of Hg deposits worldwide, downstream ecosystems are potentially contaminated by Hg and MeHg, both in abiotic and in biotic compartments. The Monte Amiata Hg district, located in Southern Tuscany, represents one of the world's largest Hg deposits. About 102,000 t of Hg were produced between 1850s-1980s, ranking it as the 4th largest Hg district worldwide. Mine waste calcine deposits, resulting from Hg ore roasting to extract Hg, are located proximal to the abandoned Hg mines, thus, representing the dominant source of Hg to the surrounding environment in this area. The Paglia River drains the east side of Monte Amiata, which hosts the largest Hg mine of the Tuscan district, the Abbadia San Salvatore mine (ASSM). Detailed studies of Hg transport in the Paglia River ecosystem and of Hg speciation are lacking. Therefore, the main objectives of this study are to evaluate: 1) the transport and distribution of Hg in the Paglia River ecosystem, 2) the formation of MeHg in the downstream environment, and 3) Hg concentrations in local freshwater fish.

Samples of stream sediment and water were collected from the Paglia River both upstream and downstream the Hg mines. In addition, calcine samples were collected from mine wastes located in and around ASSM. Regional baseline concentrations of Hg were established by stream sediment and water samples collected distal from the ASSM. Concentrations of Hg in stream sediment samples range from 0.10 to

14 µg/g, whereas Hg in water ranges from 3.2 to 1360 ng/l. Elevated Hg concentrations in stream sediment are found downstream from the ASSM

at a distance of 5 and 20 km (14 and 10 µg/g, respectively). Significantly

lower Hg concentrations (0.35-0.79 µg/g) were found in stream sediment collected 7.5-12 km from the ASSM. A similar trend is shown in stream water, with the highest Hg concentration (1,350 ng/l) found at a distance of 5 km from the ASSM. Mine waste calcine samples contain elevated

concentrations of Hg (up to 1,500 µg/g).

Concentrations of MeHg range from 0.04 to 6.4 ng/g in stream sediment and from 0.10 to 3.0 ng/l in water samples. Concentrations of MeHg as high as 22 ng/g were found in calcine samples. The ratio of MeHg/Hg is higher in stream sediment (0.01-0.44%) as compared to that in calcine (0.00-0.02%), but was found to be highest in stream water (up to 9.1%). Historical mining of the ASSM has affected the surrounding Paglia River ecosystem, where concentrations of Hg and MeHg are elevated above baselines both in stream sediment and stream water. More than 40% of

the stream sediment samples exceed the 1.06 µg/g Probable Effect Concentration (PEC) for Hg, the concentration above which harmful effects are likely in sediment-dwelling organisms. However, only one stream water sample contained a Hg concentration exceeding the 770 ng/l limit established by the USEPA to protect against chronic effects to aquatic wildlife. The presence of significant concentrations of MeHg in sediment and water of the Paglia River ecosystem suggests methylation of Hg in the sediment column, which is then transferred to water and eventually to biota, such as fish. Most important are Hg concentrations in fish muscle as generally greater than 90% of Hg in fish is MeHg. Studies of Hg in fish are in progress to evaluate any adverse effects of Hg to fish as a result of Hg runoff from the ASSM.

LOCAL TECTONIC CONTROL ON HYDROLOGICAL PATTERNS: A KEY TO UNDERSTAND THE AS-SB CONTAMINATION IN THE ABANDONED TAFONE MINE AREA

LUCCI Federico¹, PETRINI Elisa¹, ARMIENTO Giovanna², NARDI Elisa², PACIFICCO Renata², MOTTANA Annibale¹

1 - Università degli Studi Roma TRE

2 - ENEA - Roma

Presenter e-mail: flucci@uniroma3.it

Key terms: As-Sb contamination; Tafone mine; Quaternary Tectonic; Hydrography; Environment

Southern Tuscany "Colline Metallifere" are one of the principal epithermal district of Italy: carbonate rocks hosting mineralizations occur at the edges of major epithermal fields as Larderello, Mt. Amiata and Latera district. Mineralizations are typically localized at the contact between carbonate rocks (mainly "Calcare Cavernoso" Fm.) and the overlying flyschoids units ("Ligurides and Sub-Ligurides" AUCT.) or "Macigno" sandstones. Stibnite (Sb carrier) and pyrite (As carrier) are the most common sulfide epithermal minerals: here mining activity is historically

dated back at least to Etruscan times [1]. The "Colline Metallifere" epithermal district is co-genetic to Neogene magmatism (Tuscan and Roman provinces) emplaced during the last phase (late Miocene till now) of the Apennine extensional regime: genesis of NW-SE trending grabens filled by late Miocene-Pliocene sediments lastly faulted by Plio-Pleistocene NW-SE direct and NE-SW strike-slip systems [2]. Tafone mine represents an important area (a NW-SE graben less than 7 km length and up to 2 km large) to evaluate the impact of As and Sb contaminations. The stibnite and pyrite mine is located on the southwestern flank (Monte Maggiore) of the Tafone Graben (TG), near the "Fosso del Tafone" (FdT). The mineralization system outcrops at the intersection of the southern NW-SE extensional system of TG, with one NE-SW trending strike-slip segment. Mineralizations are hosted in Triassic dolostone and in Calcare Cavernoso Fm. overlying the paleozoic metamorphic phyllades and partially overthrust by dark shales and calcarenites (Ligurian units). FdT flows, from NW to SE, on the southwestern flank of the TG along the extensional lineament. Tributaries are, instead, distributed perpendicularly to the FdT, and evolved over NE-SW strike-slip minor tectonic discontinuities. Our focus is the presentation of a comprehensive dataset of As-Sb contaminations in the area along FdT, and their spatial correlation with local tectonic settings i.e. tributaries distribution. It has been observed a strong variability of As-Sb contents in waters (As: 1-20 microgrammi/L; Sb: 0.9-119 microgrammi/L), in stream sediments (As: 23-3060 mg/kg; Sb: 16-1360 mg/kg) and in soils (As: 61-1360 mg/kg; Sb: 23-5140 mg/kg) with maximum concentration of As in stream sediments and Sb in soils [3]. The peculiarity of the study area is represented by a discontinuous distribution of As-Sb along FdT: for example in the mining zone (i.e. the expected most contaminated area), it is possible to observe an anomalous strong downfall of the As-Sb contamination due to the confluence with northern side tributary "Fosso del Molinaccio". We focus on dilution, by a local tectonic controlled hydrographic pattern, of the As-Sb concentrations along the FdT. Accumulation of toxic elements as As and Sb represents a serious hazard for both environment and human health. Considering the wide extension of Tuscan epithermal district and the large population living in the area, the understanding of the geological factors controlling the spreading of toxic elements in the environmental system is highly relevant.

ANTIMONY CONTAMINATION FROM MINING AND METALLURGICAL WASTE DEPOSITS IN THE VILLASALTO OLD MINE AREA (SE SARDINIA, ITALY).

NAITZA Stefano¹, BUOSI Mauro², CONTINI Enrico², PERETTI Roberto³, TOCCO Sandro¹, ZUCCA Antonio³
 1 - DIGITA - Università di Cagliari
 2 - IGEA S.p.A. - Iglesias
 3 - IGAG - CNR - Sezione di Cagliari

Presenter e-mail: snaitza@unica.it

Key terms: Old mine; Waste deposits; Antimony contamination

The historical mine and smelter of Villasalto-Su Suergiu (SE Sardinia) operated from 1882 to 1981, being the largest industrial complex in Italy for antimony ore extraction and metallurgy. The site is characterized by the presence of several mining and metallurgical waste deposits. Environmental surveys and studies performed from 2006 by IGEA S.p.A and DIGITA evidenced, over an area >6km² downstream of the old mine, that soils, stream sediments and waters are affected by serious Sb and As contamination and by the presence of high levels of toxic metals (Zn, Pb, Cu, W). Sb contamination, in particular, attains several orders of magnitude beyond the limits of Italian and EU regulations. The Su Suergiu mine exploited quartz-calcite-sulfide-scheelite veins and lenses, hosted by cataclastic Silurian-Devonian carbonaceous black shales and limestones. The ore included stibnite (main economic mineral), scheelite, arsenopyrite and Zn-Pb-Cu sulfides. The smelter produced metallic Sb and various Sb oxides and sulfides. Mining and metallurgical waste dumps are the most relevant centers of pollution in the area. Three kinds of wastes have been identified: a) mining wastes - 13 heaps of waste rocks (about 130.000 m³ in total); b) metallurgical wastes - 1 large heap of various pyrometallurgical residues (about 50.000 m³); c) mixed wastes - 2 heaps of mixed mining and metallurgical residues (about 70.000 m³). The solid transport downstream has been considerable over the years; about 20000 m³ of waste residuals have been assessed along two watercourses that cross the area. In Su Suergiu area, seepage waters show Sb and As contents up to 32 mg/l and 3,8 mg/l respectively; mine drainage waters show up to 2,6 mg/l Sb and 0,1 mg/l As. The influence of Su Suergiu polluting centers extends well away from the mine; up to 8,8 mg/l Sb have been determined in stream waters at the confluence with the Flumendosa river, 4,5 km far from Su Suergiu. The metallurgical residues show the most relevant contaminating potential. They include 7 different types of slags, casting residuals, metallurgical dusts that have been characterized by ICP-OES, ICP-MS, AAS, XRPD, SEM-EDS; contamination potential has been determined by leaching tests (DLgs 152/06). Vacuolar coarse-grained slags are the most abundant metallurgical residues. They are constituted of gangue and ore minerals remnants in a glassy matrix rich in Ca-Al-silicates, with Fe (Zn, Cu) sulfides and oxides, metallic Sb, Sb oxides. Sb contents are up to 2,7 wt%. Eluates from standard leaching tests evidenced up to 107 mg/l Sb. Metallurgical dusts are prevailing fine-grained materials consisting of quartz, Na-Al hydrated silicates, Na-Sb hydroxides (mopungite, NaSb(OH)₆), Sb oxides (sernamontite, cervantite), Fe hydroxides. XRPD analyses evidenced the presence of amorphous matter. Although not abundant (<10000 m³), dusts have high metalloids and toxic metals contents (6-8 wt% Sb; 0,8-1,3 wt% Zn), associated to soluble Sb phases, like mopungite. Eluates from dust leaching tests show very high Sb contents (120 -150 mg/l Sb), and are distinctly alkaline (pH 10,4 - 10,8). The contaminating potential of metallurgical wastes is therefore related to high Sb availability and is controlled by an alkaline environment that enhance Sb mobility. A new research program on these issues, funded by Sardinia Regional Administration (L.R. 7/07), is currently under way, carried on by a DIGITA and IGAG-CNR work group with the collaboration of IGEA S.p.A. The program includes a further sampling of waste deposits, particle size analyses in order to define the distribution of the contaminants in the different size classes, leaching tests, studies on Sb speciation. Moreover a laboratory investigation will be carried out on mining and metallurgical residues, and on mine and seepage waters, aimed at eliminating or

stabilizing the toxic elements in order to reduce their migration to the surrounding areas, applying different techniques.

ARSENIC CONTAMINATION IN "CERRO TUZGLE ACTIVE VOLCANIC FIELD" (NORTHERN ANDES, JUJUY PROVINCE, ARGENTINA)

PETRINI Elisa¹, LUCCI Federico¹, ANGELONE Massimo², DE CATERINI Giovanni¹, MENIS Marco¹
 1 - University of RomaTre, Dept. Earth Sciences, L.go S.Leonardo Murialdo 1, 00146 Roma, Italy
 2 - ENEA-UTPRÀ, Via Anguillarese 301, 00123 Roma, Italy

Presenter e-mail: epetrini@uniroma3.it

Key terms: arsenic; cerro Tuzgle volcano; NW Argentina; contamination; environment

Arsenic, a toxic element with metalloidal properties, is almost often present in environmental samples, especially in volcanic area. Its accumulation in environment has been found to be hazardous to both the ecosystem and human health.

Unfortunately arsenic is extremely common in numerous areas from NW Argentina and in particular in volcanic areas of Puna (Jujuy Province). Concha et al. (2006) pointed to the As content in Puna waters ranging

from 140 to 220 µg/L. In particular, in shallow and drinking waters the As concentration ranges from 40-10100 and 10-790 µg/L, respectively,

reaching values up to 12800 µg/L at thermal springs. Clearly this represents a serious hazard for the population, demonstrated by numerous signs of poisoning as: dermal lesions, peripheral vascular disorder and other internal injuries, that could lead to premature death. The focus of this study is to highlight, in a natural laboratory such as an active volcanic field, the links between As contamination and the geological setting.

Cerro Tuzgle (5486 m.a.s.l.) represents an HK-calcalkaline stratovolcano surrounded by small shoshonitic centers, dated back to late Miocene to present as confirmed by numerous active thermal springs. These eruptives are distributed along the eastern edge of Puna Plateau, following a N-S trend similar to regional thrusts [2]. The Tuzgle volcano and minor centres emplaced at intersection of N-S elements with left-lateral segments of transpressive "El Toro" system, thus remarking that volcanism derived from magma uprising, facilitated by the brittle failure of the Puna back-arc crust [2]. N-S distribution of basement superunits (Ordovician sediments and Faja Eruptiva; Tertiary-Quaternary clastics and evaporites) outlines the importance of inherited tectonic lineaments in the area. Tuzgle volcanic field produced an alternation of effusive flows (andesitic and shoshonitic, to dacitic-rhyodacitic) and explosive pyroclastites (rhyolites), as recognized by field and fabric analyses [2]. Hot hydrothermal springs and fumaroles are distributed along local tectonic discontinuities; furthermore also hydrographic pattern seems to be strongly related to the local faults distribution: the two major N-S rivers are Rio de Agua Castilla and Rio de Agua Caliente and along them are settled the three major villages of the area: Puesto Sey, Pastos Chicos and Huanacar. In order to map arsenic concentration and understand its relationship with geological framework, different kinds of samples were collected: rocks, soils, stream sediments and waters. Thin sections and XRD analyses indicate that all samples are mainly constituted by the same mineral assemblage: quartz, micas (Bt+Ms), feldspars (Sa+Pl) and accessories (Di-Aug+Kat-Hbl±Fo±Sp) pointing to genetic link between recent volcanics and soil-sediment system. Thermal analyses show presence of organic matter in lasts. Contamination has been finally measured on volcanic rock, soil, stream sediment and water samples evidencing a very high concentrations of As, in the ranges

2-4150, 28-890, 11-625 mg/kg and 11-12880 µg/L, respectively pointing to maximum values reached in rocks (source?) and water (carrier?). Informations on potential As mobility, have been obtained applying standard sequential extraction BCR procedure on soil and sediment samples. Results demonstrate that As is weakly bounded to matrix host and can easily mobilized becoming environmental-bioavailable. Mineralogical analyses highlight the common origin of sediments and soils from the recent volcanics, and point to water as main carrier of As. If the volcanic system could represent the As-reservoir, the tectonic of the area seem to be the controlling factor on As distribution, since thermal springs and rivers follow the brittle failure pattern of the area.

NEW METHODOLOGIES FOR THE DEFINITION OF SOME HEAVY METALS ORIGIN IN SEDIMENTS: A CASE HISTORY COMING FROM AN APPLICATION IN PONTINA PLAIN

BARBIERI Maurizio¹, SAPPA Giuseppe², VITALE Stefania²
 1 - Dipartimento di Scienze della Terra - Sapienza Università di Roma
 2 - Dipartimento di Ingegneria Civile, Edile ed Ambientale - Sapienza Università di Roma

Presenter e-mail: giuseppe.sappa@uniroma1.it

Key terms: Background; geochemical; sediments; As; metals

Metal elements like Cr, V, Pb, Ti, U, As are often present with high concentration in soils and one of the most frequent problem coming out in environmental applied geology is to set up if this concentration is referred to the background of the soils, or it is due to anthropogenic activity, as in many cases it is requested to dig and move the soil in the aim of build a new work. In this framework a correct geochemical characterization of soil outcropping in the work area, is needed to better understand the actual nature of this elements concentration. The natural chemical composition of soils depends on the mineralogical structure of rocks they come from and on the weathering processes these rocks have been subjected in the geological time.

As a matter of fact to establish the real health state of a soil and its potential contamination state it's very important to set up the background values of some heavy metal elements present in it. These background values can be reached by different methodologies, most of them are based on statistical elaboration of data referred to chemical composition of the soil under study. In the last years it has been outlined, on the other hand, the importance of the application of geochemical parameters to

understand the actual origin of these elements in the soils. In the case history under study, referred to a site placed in Pontina Plain, in the South Latium Region, where sedimentary deposit coming from the weathering of volcanic rocks, it has been set up the geological and hydrogeological framework of the area, in the aim of investigating the origin of the natural presence of some elements. Then, it has been made the granulometric analysis to set up their geometric distribution and separate the fraction minor than 2 mm, which has been used in the chemical analysis as it is asked by the Italian law. Chemical analyses have been carried on for the determination of the concentration of Cr, V, Pb, Ti, U, As and the other major elements which are the most important constituents of sediments, outcropping in this area. Geochemical analyses results have been, then, elaborated by statistical methods following the Italian guidelines, released by ISPRA, referring to the definition of groundwater and soil background values definition. The background values output by the statistical elaboration, have been compared by the results come out by the application of geochemical methods for the definition of the health state of the soil. These methods employ two different parameters the Igeo, (Müller, 1979; Förstner & Müller, 1981) which an accumulation index of metals in the soil and the EF, Enrichment Factor (Muller, 1969; Forstner e Muller, 1973). These two parameters, to be calculated, need the values metal concentration of in samples coming from the top-soil (20-30 cm under the topographic level) and from the sub-soil (at least 90-100 cm under the topographic level). The two different depth of sampling the soil are needed in the aim of analyzing also soils which are certainly not affected by anthropogenic activity. The comparison of results, reached by different methods to set up the background values of some metals in the soil, is discussed in this paper, to highlight as the application of geochemical methods can give more effective indications on the actual health state of the soil, and on the possible anthropogenic impact, as they can better represent the real history of the sediments, and the geological, geochemical and pedological processes involved in their composition.

THE GEOGENIC NATURE OF SOME HARMFUL ELEMENT ANOMALIES IN THE CENTRAL SECTOR OF THE PELORITANI MOUNTAINS (SICILY, ITALY)

COSENZA Antonio¹, ALBANESE Stefano², AYUSO Robert³, DE VIVO Benedetto¹, LIMA Annamaria², MACAIONE Elisa¹, MESSINA Antonia¹

Presenter e-mail: cosenza.a@tiscali.it

Key terms: Southern Sector of the Calabria-Peloritani Arc; Peloritani Mountains; Topsoil samples; Geochemical maps; Ratios of lead isotopes

In the Southern Sector of the Calabria-Peloritani Arc, the Peloritani Mountains extend in the NE Sicily. They consist of a stack of nine continental crust tectonic units, involving Pan-African and Variscan crystalline basements, and remnants of Meso-Cenozoic sedimentary covers. Basements and covers are locally affected by an Alpine overprint. Geometrically to the bottom and geographically to the south, the Units are: Aspromonte, Mela, Piraino, Mandanici, Ali, Fondachelli, San Marco d'Alunzio, Longi-Taormina, Capo Sant'Andrea. The Pan-African basement (Aspromonte Unit) derives from a Proterozoic plutonic and metamorphic low crust, the Variscan basements (other units) from Paleozoic sedimentary-volcanic sequences.

Sulphide and sulphosal mineralizations are very widespread in the study area.

Topsoil samples (n=122) have been collected over an area of 300 sqkm in the Central Peloritani Mts., from the Ali to the Bafia Villages, and the concentrations of 53 elements, including potentially harmful metals, have been determined by means of ICP-MS after an aqua regia acidification. Concentration data have been georeferenced and geochemical maps have been produced by means of a GIS aided spatial interpolation process. In accordance with a regional study carried out by De Vivo et al. (1999), on 1198 stream sediments, collected across the Peloritani Mts. area, results obtained by the present study show that higher values of Pb, As, Zn, Cu and Sb are mostly concentrated in a spatially limited area between the Fiumedinisi and Ali Villages.

As a matter of the fact, Pb shows anomalous concentration values in correspondence with both C. Postlioni (Mandanici) (>1600 mg/kg) and Fiumara di Ali (>400 mg/kg). As presents values of concentrations higher than 700 mg/kg between Fiumedinisi area and Ali and Cd is 8 mg/kg in correspondence with the Fiumara di Fiumedinisi. Concentrations of Pb, As and Cd often exceed the trigger and action limits established by the Italian environmental law (D. Lgs. 152/06) for both a residential and an industrial/commercial land use.

To discriminate between an anthropic and a geological origin of harmful elements (mostly metals), in the soils of the central sector of Peloritani Mts. the ratios of ²⁰⁶Pb/²⁰⁷Pb versus ²⁰⁸Pb/²⁰⁷Pb isotopes both in local galena and soil samples have been determined. The isotopic ratios of Pb have been obtained at USGS (United States Geological Survey) in Reston (VA, USA) by means of mass spectrometry after a step-leaching procedure producing a leachate and a residue fraction of each soil sample. Results show that the leached fraction of soil samples with more 1600 mg/kg of Pb (C. Postlioni, Mandanici) has ratio ²⁰⁶Pb/²⁰⁷Pb=1.169539 and ²⁰⁸Pb/²⁰⁷Pb=2.460557 which indicates that contamination of soils collected in the area between the Mandanici area and Ali Village are geogenic and mostly related to the presence of sulphide and sulphosal minerals.

A factor score analysis was also ran on the dataset and results obtained show that the Ag, As, Sb, Pb, Cd, Zn, Hg, Ni can be associated in a unique factor since they clearly marks the areas where old mines were present: San Carlo, Vacco, Magliuso, inside the Fiumedinisi territory, and Tripi, inside the Ali territory.

BIOAVAILABILITY AT HEAVY METAL CONTAMINATED SITES: FROM CONCEPTUAL MODEL TO REMEDIATION

PETRUZZELLI Gianniantonio¹, PEDRON Francesca¹

1 - Istituto Studio Ecosistemi CNR Pisa

Presenter e-mail: petruzzelli@ise.cnr.it

Key terms: bioavailability; contaminated sites; conceptual model; remediation

Bioavailability concepts originates from the knowledge that adverse effects in exposed humans and ecological receptors are not caused by total concentration of chemical compounds released into the environment but only by a certain fraction that is biologically available.

From the toxicological point of view, the concept of bioavailability implies that the danger represented by a substance is explained simply in terms of the fraction that can interact with a specific biological site.

In the environmental studies the concept of bioavailability assumes very different meanings that range from the fraction of a substance available for absorption by a living organism, to the amount that can be released from the solid phase of an environmental matrix. Naturally the various aspects of bioavailability are interrelated and in order to understand the complexity of the issue as regards interactions between organism and environment, we tend to refer to processes of bioavailability. By this we mean a combination of reactions that identify not only the different aspects, but also the different temporal stages involving the processes that define bioavailability in a specific situation for a specific organism. Bioavailability is the key to understand the environmental behaviour of heavy metals, the hazards deriving from pollution and to define appropriate strategies of remediation.

Clean up procedures, at heavy metal contaminated sites, are often very laborious and expensive. For a better use of the limited resources available for remediation the use of knowledge of bioavailability processes can be of noteworthy utility. Bioavailability may be a key component of exposure evaluation which has significant implications for the preparation of the conceptual model and the technology selection.

Key terms: Zn-Al-sulphate LDHs; arsenate-sulphate exchange; mine water treatment

Layered double hydroxides (LDHs), a group of compounds with general formula $M^{2+}_xM^{3+}_y(OH)_{3x+2y}(An)_{z-n} \cdot yH_2O$, have a high anionic exchange capacity (AEC), which can widely vary as a function of their composition. The potential use of LDHs for As removal from contaminated mine water is based on the fact that the aqueous speciation of As under natural oxidizing conditions is dominated by oxyanions such as $H_2AsO_4^-$ and HSO_4^- . In this study we investigated the efficacy of natural and synthetic Zn-Al sulphate LDHs in removing As(V) from water solution in batch experiments. This choice ensued from field investigations, which pointed out the capacity of natural Zn-Al sulphate LDHs in attenuation of dissolved As content in NAMD (Net Alkaline Mine Drainage) of the old Bacca Locci mine (southeastern Sardinia, Italy).

Preliminary results showed that Zn-Al sulphate LDHs are effective removers of As(V) from water solutions through anionic exchange with sulphate in the interlayer, while minor amounts of As(V) are likely removed by surface adsorption. The efficiency of As(V) removal increases with Zn/Al ratios in LDH, because of the reduced ionic charge of the metal-hydroxide layers that facilitates the release of sulphate to solution and the entrance of arsenate in the interlayer.

In the laboratory experiments with synthetic LDHs, we used As concentrations of several orders of magnitude higher than found in the field at Bacca Locci. However, experiments with natural LDHs showed a similar capacity in removing As(V) from water solution, indicating that their potential exchange capacity is only partially exploited in the natural system.

The AEC shown by Zn-Al sulphate LDHs encourages further investigation of more complex aqueous systems and different inorganic pollutants.

IMMOBILIZATION OF HEAVY METALS IN WATER AND SOIL BY PHOSPHATE TREATMENT

MIGNARDI Silvano¹, CORAMI Alessia¹, FERRINI Vincenzo¹

1 - Sapienza Università di Roma

Presenter e-mail: silvano.mignardi@uniroma1.it

Key terms: Heavy metals; Immobilization; Phosphate treatment; Mine waste soils

Heavy metals such as Pb, Cd, Cu, Zn, Hg, Cr, and Ni are the main contaminants of surface water, groundwater, and soils. The heavy metals are of great concern because of their extreme toxicity even at low concentration and the tendency to accumulate in the food chain.

Conventional methods for heavy metal removal from water and soil include chemical precipitation, filtration, solvent extraction, electrochemical technique, ion exchange, and adsorption. In particular, chemical immobilization is one of the most used for reducing the bioavailability of heavy metals. The aim is to immobilize the ions trapping them in minerals with low solubility and stable in the environment in a wide range of conditions. Synthetic or natural apatite and phosphate rock have been proved to immobilize divalent heavy metal ions such as Pb, Zn, Cd, Cu, Co, Cr, Ni, and Sb in contaminated waters and soils. The mechanisms of metal removal include ion exchange, surface complexation and dissolution/precipitation.

In this study the removal of Cd, Pb, Zn, and Cu from aqueous solutions by both synthetic hydroxyapatite (HA) and natural phosphate rock (FAP) was investigated in batch conditions at $25 \pm 2^\circ C$. The metals were applied both as single- or multi-metal (Cd + Pb + Zn + Cu) systems with initial concentrations from 0 to 8 mmol L⁻¹. The removal capacity of phosphate amendments generally ranges between 50 and 99%. In the multi-metal systems competitive internal metal sorption reduced the removal capacity by 13-83% compared to the single-metal systems. The sorption of heavy metals by phosphate amendments follows the Langmuir model. Heavy metal immobilization occurs through a two-step mechanism: rapid surface complexation on the $\equiv POH$ sites followed by partial dissolution of phosphates and ion exchange with Ca resulting in the formation of heavy metal-containing phosphates.

The sorption of Cu on HA was further investigated by means of the results of a combined structural simulation and EXAFS analysis. The EXAFS results suggest that the heavy metal is present in the Cu²⁺ form. The structural experimental and theoretical analysis shows that Cu is bonded to about four O atoms at a distance of about 1.95 Å. In all the studied cases the immobilization site of Cu is the same. The fixation of Cu occurs in the surface sites of hydroxyapatite whereas the sorption in the Ca sites in the inner part of the structure is unlikely. The effectiveness of phosphate treatment for Cd, Pb, Zn, and Cu immobilization in mine waste soils from sulfide mine areas (tailing dumps, ore stocking areas, streams, etc.) in Tuscany and Sardinia (Italy) was examined in batch conditions. Application of HA and FAP effectively reduced the heavy metals water solubility generally by about 84 to 99%. Between the two amendments evaluated, HA was slightly more effective with respect to FAP in immobilizing heavy metals. Although the lower effectiveness of phosphate rock, its application to reduce metal solubility in contaminated soils may minimize soil acidification and potential risk of eutrophication associated with the application of highly soluble phosphate sources.

Key terms: natural waters; geochemical mapping; stream sediments; spatial analyses; Tuscany

A research agreement was approved in 2009 among the Tuscany Region, the Institute of Geosciences and Earth Resources of CNR based in Pisa and the Tuscan Universities of Florence, Pisa, and Siena, for the implementation of a research and innovation project in the field of environmental geochemistry, named "Geobasi Toscana". The aims of this two-year project are the determination of the natural geochemical baselines for several substances, some of which are potentially harmful, as well as the reorganization and elaboration of all available geochemical data for natural waters (including surface-, ground-, and transition-waters) and active stream sediments.

The "Geobasi Toscana" project continues along the path opened in 2004-2006 by the "Geobasi" project, which was funded by the ministry of the University and Scientific Research of Italy and involved several Italian universities to tackle the complex meaning of elemental compositions in different geo-environmental matrices by means of an integrated multidisciplinary approach. In turn, the roots of the "Geobasi" project are found in the guidelines outlined through a previous APAT-CNR research agreement, whose main outcome is the National Geochemical Archive of Italy (Otonello, 2008).

In this reference framework, it was possible to test innovative approaches in geochemical mapping during the development of the "Geobasi Toscana" project. These methods were then applied to study the behavior of Cd, Hg, Ni, Pb, As, and Cr in the active stream sediments of the Siena area as well as the distribution of other parameters, including U, Cl, SO₄, and Hardness in the fluvial waters of the whole region. Analytical data used to study stream sediments refer to 417 samples collected in the Siena province over a total surface area of 2000 km² approximately, with a density of 1 sample each 5 km². Analytical data of 949 fluvial water samples come from CNEN geochemical surveys carried out in the sixties. They were processed using both deterministic and geo-statistical approaches.

In particular, methods of spatial analysis developed for studying compositional data were applied. In this type of data (percentages, parts per million, molar fractions, etc.), each variable represents a given proportion of a total, which is fixed a priori. From the geometric point of view, compositional data does not occupy the real space, whose dimensions are equal to the number of variables, but are situated in a restricted space, known as simplex (Aitchison, 1986), which is part of the real space. This constrained, non-Euclidean geometry causes several problems if data analysis is approached using the methods of classic statistics. In this research works, new graphical and numerical methods were therefore proposed, respecting the geometric peculiarities of the sample space. Results were discussed in the light of the geochemical behavior of the considered elements and taking into account the geo-lithological characteristics of the investigated areas.

MINERALOGICAL AND GEOCHEMICAL CHARACTERIZATION OF OCHREOUS PRECIPITATES FROM THE ROSIA MONTANA GOLD MINE (ROMANIA)

LUCCHETTI Gabriella¹, AZZALI Eva¹, CARBONE Cristina¹, DINELLI Enrico², MARESCOTTI Pietro¹

- 1 - DIPTERIS, University of Genova, Italy
- 2 - Dip. Scienze della Terra, University of Bologna, Italy

Presenter e-mail: lucchett@dipteris.unige.it

Key terms: AMD; Rosia Montana; Schwertmannite; Jarosite

The Rosia Montana gold mine (Apuseni Mountains, Romania) is characterized by active and intense Acid Mine Drainage (AMD) processes that cause the widespread circulation of strongly Acid Sulphate Waters (ASW; pH ≤ 3) containing very high levels of ecotoxic elements deriving not only by the sulphide mineralizations but also from host-rock and gangue minerals (such as Cd, As, Cu, Pb, and Zn) [1; 2].

The Rosia Montana hydrothermal ore deposit is hosted in andesites and dacites of Neogene age piercing the prevolcanic sedimentary basement as breccia pipes [3]. The volcanic and subvolcanic rocks show pervasive adularia alteration with a phyllic overprint, as well as local silicification and argillic alteration. They host polymetallic sulphides and Au-Ag-Te mineralizations that are mainly present in epithermal veins, mineralized phreatomagmatic breccias, and stockworks [4]. The ore deposit was mined both in underground and in open pit for more than 2000 years. In the mining area, contaminated waters mainly flow in the watershed of the Rosia and Abrud Rivers, which are indirect tributaries of the Danube River. In order to monitor the mineralogical variations and to evaluate the toxic elements partitioning between contaminated waters and authigenic minerals, twelve samples of ochreous precipitates and the associated mine waters were sampled in July 2010.

The mineralogy of the precipitates was made by XRPD, whereas their bulk chemistry by ICP-MS. T, pH, Eh, and electrical conductivity (EC) were measured *in situ* with portable instruments. The chemical analyses on mine waters were made by ICP-MS, AAS, and chromatography. Two groups of waters were distinguished on the basis of pH, Eh, SO₄, EC, and dissolved metal contents. The first group corresponds to the ASW, characterized by the lowest pH (2.70-3.08) and the highest Eh (460-484 mV), SO₄ (688-4800 mg/kg), EC (1073-5780 μS/cm), and metal contents (Fe, Zn, Mn, and Co). The second group includes either unpolluted and mixed waters, characterized by a general reduction of metal load as well as by significant variations of pH (3.77-6.50), Eh (237-363 mV), SO₄ (326-436 mg/kg), and EC (249-619 μS/cm).

The XRPD analyses evidence that the precipitates are characterized by K-jarosite [K Fe³⁺(SO₄)₂(OH)] and schwertmannite [Fe₈O₈(OH)₂(SO₄)₂] in different proportions. As expected, after the mixing of the ASW with the Rosia and Abrud Rivers, the presence of minerals of detrital origin significantly increases.

The bulk chemistry of the precipitates evidenced significant enrichment in Fe (up to 41.27 wt%) and S (up to 5.01 wt%) and high concentrations of trace metals and As (up to 2930 ppm). Moreover, a positive correlation between Fe and S with As, V, and P have been observed, whereas most of the other elements shows the opposite trend (e.g. Al, Ti, Cu, and Ni). These data suggest a strong control of schwertmannite and jarosite on specific trace elements of environmental concern (particularly As).

Crystallochemical investigations by TEM and spectroscopic techniques will be performed to better understand the interactions of authigenic Fe-oxyhydroxysulphates with metals in the contaminated waters from the Rosia Montana Mine area.

COMBINATION OF LEACHING AND COLUMN TEST FOR THE ASSESSMENT OF AMD GENERATION FROM THE HOP WASTE-ROCK DUMP (ROSIA MONTANA, ROMANIA)

PORRO Silvia¹, DE CAPITANI Luisa¹

1 - Università degli studi di Milano

Presenter e-mail: silvia.porro@unimi.it

Key terms: AMD; kinetic test; heavy metals; arsenic

The production of Acid Mine Drainage (AMD), as a result of the oxidative dissolution of sulphides, and the release of hazardous elements in the environment are main pollution problems affecting natural watercourses in mining areas, with sulphide-rich residues. An important tool for geochemical assessment of abandoned mine areas are kinetic tests, as they provide an insight into the behaviour of the waste-rocks during the interaction with meteoric waters, giving also useful indications of metal mobility and chemical composition of the run-off waters.

In this study two different kinetic tests were applied to assess the generation of AMD from the run-off water of the Hop waste-rock dump, at the Rosia Montana ancient mining area (Apuseni Mountains, Romania). This hydrothermal ore deposit is hosted in andesites and dacites of Neogene age, piercing the prevolcanic sedimentary basement as breccia pipes [1]. They host polymetallic sulphides and Au-Ag-Te mineralizations and the ore deposit was mined both underground and in open pit for more than 2000 years. Intensive alteration due to AMD processes is testified by acid sulphate waters.

The eastern side of the Hop waste dump (2.5 ha area), where the waste has been piled up between 1998 and 2000 from Cetate open-pit, was subdivided in a 30x30 m grid to obtain a final collection of 27 samples. First, the Modified E.P.A. Method 1312 (SPLP) [2] was applied to 20 of them: the < 2 mm grain-size fraction of the solid material was shook for 18 hours in a rotary agitator, together with a slightly acidified de-ionized water, that simulated natural precipitation (water:solid ratio 20:1). The pH value, Electrical Conductivity, sulphate concentration and by ICP-AES total Cu, Zn and As content of the solutions were analyzed.

One sample was then chosen for further investigation: a modified column test [3] was applied to study the different behaviour of the grain-size fraction < 1, 1-2 and > 2 mm. A different weight of each fraction, representing an area of about 100 m², was separated and put in a PET column with 100 mL of tap water. Every week for one month an aliquot of the solution was taken for the same analyses performed with the previous method.

SPLP results showed that eco-toxic elements content in filtered solutions is generally low: Cu ranges from 0 to 98 ppb (mean 14), Zn ranges from 21 to 570 ppb (mean 155) and As ranges from 1 to 7 ppb (mean 2.5). These data are in agreement with the results of bulk waste-rock material chemical composition, whose metal concentrations are in the range of tens of ppm with the exception of As, that shows a content one order of magnitude higher [4]. The pH values vary greatly from 2.9 to 8.9, according to mineralogical and geochemical composition of the waste material. The sulphate content ranges from 13.5 to 475 ppm and exceeds the European limit for drinking waters (250 ppm, [5]) in 6 samples. A significant positive relationship between sulphate content and EC was found.

Modified column test results showed that geochemical features of the solutions tend to stabilize after 3 weeks: pH values grow from 2.5 to 2.7

(mean values) while EC values and sulphate concentration, though highly variables for the three different grain-size samples, clearly decrease. The fraction 2-4 mm is the more reactive one, with a final Cu content of 720 ppb, Zn 880 ppb and As 25 ppb.

The comparison between the two methods allowed to suggest that the first is more useful for materials with fine and homogeneous grain-size, as tailing samples. On the other hand, the column test can be successfully applied on waste rocks, made by heterogeneous grain-size materials.

ZINC ISOTOPIC FRACTIONATION DURING PRECIPITATION OF HYDROZINCITE, RIO NARACAULI, SARDINIA, ITALY

Key terms: ZINC ISOTOPES; HYDROZINCITE; SARDINIA

In southwestern Sardinia, Italy, the rio Naracauli drains an area of abandoned mines that produced zinc and other metals until 1968. The stream has near-neutral pH, Zn concentrations exceeding several 100's of mg/L, and seasonally high alkalinity (De Giudici et al., 2009). These conditions contribute to the biologically mediated precipitation of hydrozincite {Zn₅(CO₃)₂(OH)₆} (Podda et al., 2000). As the hydrozincite precipitates, the concentrations of Zn and co-precipitated metals (Pb, Cd, etc.) decrease dramatically in the stream water.

Streamwater samples were collected from rio Naracauli from October to December, 2009, using standard sampling methods. At the same time, samples were collected of the hydrozincite that was in contact with the stream water. We also collected several samples of sphalerite from mine dumps in the area to check the isotopic composition of the Zn source. Zinc was separated from all samples using the chromatographic separation methods of Borrok et al. (2007) and Pribil et al. (2010). Purity of separates was checked with conventional ICP-MS analysis, and Zn isotopes were measured on a Nu Instruments high-resolution MC-ICP-MS, using standard-sample bracketing to correct for instrument drift and mass bias. Multiple replicate separations and MC-ICP-MS analyses were used to check the quality of the results. Zinc isotope compositions of the samples are reported as ratios of either ⁶⁶Zn or ⁶⁸Zn relative to ⁶⁴Zn using the standard δ notation, against the isotopic standard JMC 3-0749-L. Precision of the measurements is generally better than $\pm 0.1\text{‰}$.

Values of $\delta^{66}\text{Zn}$ in all samples (solids and water) ranged from -6 to +0.3 ‰; $\delta^{68}\text{Zn}$ ranged from -1.00 to +0.8 ‰ relative to the JMC standard. A plot of $\delta^{66}\text{Zn}$ vs. $\delta^{68}\text{Zn}$ has a slope of 1.98 and $r^2 = 0.97$, indicating that all fractionation of Zn in this sample suite is mass dependent.

Sphalerite had $\delta^{66}\text{Zn}$ values near -0.1 ‰, with almost no variation between samples. In the highest headwater samples, dissolved $\delta^{66}\text{Zn}$ was around -0.2 to -0.3 ‰, with a trend towards slightly lighter values downstream. If sphalerite is the main source of Zn to the stream, then the dissolved $\delta^{66}\text{Zn}$ should be closer to the sphalerite (Fernandez and Borrok, 2009). The fact that dissolved Zn in rio Naracauli headwater samples is 0.1 to 0.2 ‰ lighter either suggests a different Zn source or some in-stream process that modifies the Zn isotope ratio.

The $\delta^{66}\text{Zn}$ values of hydrozincite samples were 0.25 to 0.3 ‰ heavier than the waters with which they were in contact, which would explain the lighter $\delta^{66}\text{Zn}$ values in water samples. Continued precipitation of

hydrozincite also would explain the progressive decrease in $\delta^{66}\text{Zn}$ values for downstream water samples. It is known that the formation of the hydrozincite is biologically driven (De Giudici et al., 2009), but the exact mechanism of Zn fractionation is as yet unknown.

Key terms: beryllium; baseline levels; site characterization; Roman Comagmatic Province; mobility

Beryllium is widely distributed in soils at low levels (crustal abundance 2-6 mg/kg), but it can also occur naturally in higher concentrations in a variety of materials exploited for many industrial applications. Unfortunately, beryllium is also one of the most toxic natural elements and is known to be a human carcinogen.

We report and analyze a diffuse, unusually high (up to 80 mg/kg, average approximately 18 mg/kg), natural occurrence of beryllium in pyroclastic layers related to the Pleistocene activity of the Vico volcano (northern Latium).

The naturally occurring beryllium content in most of the studied samples is extremely high and even greater than that found in sites contaminated by the accidental release of beryllium into the environment by industrial activities. Only 8 out of the 120 analyzed samples gave values below the Italian limit for potentially unacceptable risk for industrial soil-use (10 mg/kg); in no case values below the limit for residential soil-use (2 mg/kg) were observed.

Additionally, experiments to define Be leachability have been carried out for selected samples, providing evidence of significant mobility in contrast with data presented in the literature that indicate beryllium as an element with low mobility in oxidising surface environmental conditions. This is a crucial point to consider, because a relatively high mobility under certain pH and redox conditions involve a significant risk factor.

The geochemical behavior of the element explains the anomalous Be concentration values because its incompatibility in common rock-forming silicate minerals is concentrated via fractionation during magma crystallization. An additional contribution may be related to the volcanic late-stage fluids permeating through the emplaced rocks.

Combined mineralogical (optical microscopy, SEM-EDAX, EMPA and X-ray diffraction) and geochemical analyses suggests that the higher beryllium concentration in pyroclastics and associated soils are related to the presence of finely dispersed Be-containing minerals, such as gadolinite (Cámara et al., 2008), or hellandite-group minerals (Oberti et al., 2001). However, the possible presence of Be in volcanic glasses is also presently under investigation.

Finally the occurrence of such natural high background concentrations of potentially harmful elements, as it is the case for beryllium studied here, highlights the need for systematic geochemical studies and mapping to produce multi-purpose reference databases for risk assessment and land management.

Key terms: Arsenic; Southern Tuscany; Fluid Inclusion; Quaternary sediments; Hydrothermal systems

Recent studies showed that Quaternary deposits of Pecora Valley (southern Tuscany, Italy) display anomalous As concentrations (up to more than 1000 ppm) (Costagliola et al., 2010 and references therein). Based on these results, the origin of As can be imputed to the dismantling of sulfide mineralization hosted by the pelitic-arenaceous member of Palombini Shales, widely cropping out in the Mt. Arseni and Accesa Lake areas. The Bruna river catchment borders to S-SE the Pecora river catchment, through a watershed that divides them. The two areas, based on paleo-hydrographic reconstructions reported in literature, show a common paleo-hydrological history. This leads to the hypothesis that the As anomaly affecting the Pecora Valley (PV) can also influence the Bruna Valley (BV).

To highlight the geo-environmental evolution of this part of southern Tuscany, the mineralogical and geochemical characteristics of the BV sediments were determined and a study of fluid inclusions found in quartz hosted in BV and PV Quaternary sediments was carried out.

The study included: 1) sampling of sediments, quartz veins and crystals, both in PV and BV Quaternary deposits; 2) study of the mineralogical features of the sediments; 3) determination of the As content of the sediments; 4) microthermometry of fluid inclusions.

The BV Quaternary deposits show mineralogical features and concentrations of As comparable to the Quaternary deposits of the PV, emphasizing the presence of a common source of the metalloid for both areas. They differ only for a different content in trace elements (Zn and Pb), stressing a higher affinity of the BV deposits to base metals mineralization.

Quartz from all the examined areas trapped two-phase (liquid + vapor) aqueous liquid-rich inclusions. Homogenization temperatures of these inclusions are mostly in the 200-275°C range, whereas the computed salinity values are from 0.1 to 13.8 wt% NaCl equiv.. In some cases, such inclusions coexist with vapor-rich inclusions, suggesting boiling processes.

The estimated minimum trapping depth for two-phase inclusions is between 200-600 m, under hydrostatic conditions. Such features indicate an epithermal style of fluid circulation, a quite common occurrence in southern Tuscany. In particular, microthermometric data of two-phase inclusions are similar to those of fluid inclusions hosted in minerals from some pyrite and/or base metals mineralization located close to the examined areas. In one sample (collected near the Accesa Lake)

three-phase fluid inclusions (liquid H₂O + liquid CO₂ + vapor CO₂) were also observed, in addition to two-phase inclusions. The computed salinity of three-phase inclusions is between 0.8 to 12.8 wt% NaCl equiv., and homogenization temperatures fall in the 265-275°C range. Such inclusions probably testify the production of CO₂-rich fluid from decarbonation processes during thermo-metamorphism related to the emplacement of Pliocene-Quaternary intrusions. The estimated trapping depth for such inclusions is at least at 1900 m depth under lithostatic pressure. These data suggest the presence of a complex hydrothermal system located at different depths, that could potentially mineralize several hundred meters of crust. The subsequent dismantling of the mineralized rocks would result in an As anomaly of regional importance, affecting most Quaternary deposits cropping out in southern Tuscany (PV, BV, probably Cornia Valley and the marine sediments off the coast of Piombino up to Elba Island). Thus, the data obtained in this work suggest that PV is only a portion of a larger area affected by As anomaly.

ANOMALOUS ARSENIC CONCENTRATIONS IN SOILS FROM THE VITERBO AREA

CIARDI Alessandro¹, BENVENUTI Marco¹, COSTAGLIOLA Pilario¹, LATTANZI Pierfranco², PAOLIERI Mario¹, RIMONDI Valentina¹

1 - Dipartimento Scienze della Terra - Università di Firenze

2 - Dipartimento Scienze della Terra - Università di Cagliari

Presenter e-mail: valentina.rimondi@unifi.it

Key terms: Arsenic; Sequential Extraction; Soil; Travertine; Viterbo

The presence of anomalous concentrations of As in the groundwater of the volcanic complex of Monti Cimini (Viterbo, Italy) has been documented in literature by a number of papers (Cremisini et al. 1979; Vivona et al. 2007; Angelone et al. 2009). Specifically, Angelone et al. (2009) ascribed the As enrichment of the aquifer to deep thermal waters belonging to the hydrothermal system active in this area.

Thermal waters in the Viterbo area are known to precipitate calcite, as a consequence of CO₂ degassing, when hydrothermal fluids emerge to the surface. The continuous precipitation of calcite led to the formation of a number of travertine plateaux having variable extensions: one of the largest is located a few kilometres westward of Viterbo, in the so called Bullicame area.

At Bullicame, travertine rocks crop out in close proximity to the present day thermal spring (the Bullicame spring), whereas in the remaining area of the plateau travertines are relatively scarce, and are strongly pedogenised.

Very little attention has been devoted up to now to the presence and availability of arsenic in soils and in the underlying travertines in the Bullicame plateau. The aim of this work is to give a first assessment of the environmental impact of arsenic in this area.

A relatively small area, with respect to the entire plateau, has been studied (approximately two hectares centered around the Bullicame main spring); four soil and ten travertine samples were collected.

For all samples, major and trace elements were determined by XRF, while As was determined by hydride generation flame atomic absorption spectrometry. Furthermore, all soil samples and four travertine samples underwent a sequential extraction procedure (SEP), modified after Wenzel et al. (2000) by introducing a carbonatic extraction step, in order to take into account the mineralogical nature of the Bullicame samples.

Almost all the samples showed As concentrations far above the maximum permissible limit set by Italian law (20 mg/kg for residential areas, and 50 mg/kg for commercial and industrial sites, as stated by D.Lgs. 152/2006), both in soils (As range 81 to 651 mg/kg, with a mean value of 347 mg/kg) and in travertines (from 39 to 279 mg/kg, mean value 136 mg/kg).

SEP results for calcites in travertine showed that arsenic is almost exclusively bound to carbonates (the acetic buffer extracts over 95% of total As) only when Fe concentration is very low (<<1%wt): when Fe exceeded 1wt%, arsenic yields from the acetic buffer step dropped down to 36% of the total. In soil samples As is instead primarily associated with the Fe(Al)-oxyhydroxide fraction (about 80% of the total).

Collected data suggest a widespread presence of As in both soils and travertines of the Bullicame area. Arsenic is mainly associated in the Fe(Al) fractions in soils whereas in the travertine calcite and Fe-oxyhydroxides may behave as traps for the metalloid.

Key terms: Arsenic; Heavy metals; Soil; Coastal plain

Southern Tuscany hosts a number of ore deposits which have been actively exploited since the Etruscan period until very recent time. Natural processes of rocks weathering led to the dispersion in the environment of toxic elements.

The Department of Earth Sciences of University of Florence has conducted over the past ten years, numerous studies about the distribution of arsenic and heavy metals in mineralized areas of Tuscany, particularly in the Pecora basin.

The Pecora river drainage-basin is located in the SW part of Colline Metallifere. The area hosts several polymetallic ore bodies and a pyrite ore deposit. The studies have identified several geochemical anomalies (As, Cu, Pb, Zn...) both in the areas which host the ore bodies and in the coastal plain (Scarlino Plain).

The studies suggest that in Scarlino Plain the primary geogenic geochemical anomalies have been overprinted by an anthropogenic input. To increase the knowledge concerning the distribution of As and heavy metals in other Tuscan coastal plains, research is under way in the alluvial plains of the Bruna, Cornia and Alma rivers.

The Bruna Valley is the catchment area adjacent to the Pecora Valley, bordered on the S-SE with the latter through a watershed that divides them. The two areas, based on paleo-reconstructions hydrographic studies, show a relatively recent common history.

The Cornia Valley is the catchment area bordered on the N-NO by the Pecora basin. This basin hosts several polymetallic ore bodies and high-enthalpy geothermal fields, located around the area of Sasso Pisano. Finally, the Alma basin is bordered on the north by the Pecora basin and on the south by the Bruna basin. This small size basin has lithologies common with neighboring basins, but not directly affected by mineralizations. The "Pian d'Alma" coastal plain may represent the geochemical baseline of the Southern Tuscany.

The preliminary analysis have focused on soils and stream sediments, to better understand the correlations between the downstream transport of rivers and the soils. The soil represents together with water (even from a legal point of view) the matrix of most interest to the risk of human exposure to contamination by heavy metals and toxic elements.

We have made physico-chemical analysis, particle size analysis, mineralogical analysis for X-ray powder diffraction, chemical analysis for

the determination of major element (X-ray Fluorescence) and for the

determination of 35 minor elements and traces (AAS and ICP).

The preliminary results show high concentrations of As (21 - 57 mg/kg) in the coastal plain of Piombino (Cornia basin). These values exceed the law limit of 20 mg/kg for Private and Public Land Use and several samples are also over the law limit of 50 mg/kg for Commercial and Industrial Land Use (D. Lgs. 152/06). The samples which present high concentration of As, also have contents in Co over the law limit of 20 mg/kg.

The values in soils sampled indicate that also in the coastal plain of Castiglione della Pescaia (Bruna basin), there are several samples which have concentrations of As (7 - 29 mg/kg), Zn (31 - 163 mg/kg) and of Co (8 - 36 mg/kg) that are over the law limits (20 mg/kg, 150 mg/kg and 20 mg/kg respectively - Private and Public Land Use). Instead, the soils sampled in Pian d'Alma present concentrations below the law limits, with the exception of a sample which shows an anomalous concentration of Pb (612 mg/kg), over the law limit (100 mg/kg - Private and Public Land Use, D.Lgs. 152/06).

Soils and stream sediments of the all three basins of interest are still under investigation.

HEAVY METALS IN CONTAMINATED SOIL: "PASSIVE APPROACH" AS A TOOL FOR REMEDIATION

PETRUZZELLI Giannantonio¹, PEDRON Francesca¹, ROSELLINI Irene¹

1 - Istituto Studio Ecosistemi CNR Pisa

Presenter e-mail: petruzzelli@ise.cnr.it

Key terms: contaminate sites; chemical test; biological test; remediation

Human and ecological risk assessment of metals in contaminated soil is a powerful mean to evaluate environmental quality objectives in the remediation of contaminated sites.

Risk based clean up procedures are carried out by a tiered methodology, which consider sources reactivity and mobility of metals in the soil environment. Among the exposure pathways which link the source of contamination to the potential receptor, the transfer of heavy metals from soil to plant, and by food chain to human beings is greatly influenced by the processes of bioavailability.

Bioavailability is the key to understand the environmental risk derived by metals, since adverse effects only occur when related to biologically available forms of these elements.

Extraction test generally used in soil chemistry were originally developed to predict metal deficiencies, and tend to be fairly aggressive to simulate plant behaviour. The action of plant in the rizosphere is not particularly aggressive, so "passive approach" have been developed. They include the collection and analysis of pore water with different means, (artificial roots, field lysimeter) or the use of passive extraction, water or neutral salts are generally used to mimic plant uptake of metals from soil which occur only via soil solution.

Coupling passive approach with bioassay in which plants growing in the contaminated soils, are used as an extractant, seems to provide a powerful tool to use in the risk assessment procedure. Moreover the results can be utilized to select the best remediation technologies for metal contaminated sites.

Presenter e-mail: epetrini@uniroma3.it

Key terms: cesium; arsenic; cation-exchange; environmental application

During a survey of the As environmental distribution in NW Argentina, we observed a Cs-rich arseniate phase. The mineral occurs in a rhyolitic rock, collected near one hydrothermal spring on the slope of Tuzgle volcano (Puna region, Jujuy Province), as a thin crusts consisting of very small

tetrahedral crystals (average < 2 μm), covering the walls of the rock cavities. Preliminary SEM/EDS and microdiffraction X-ray analysis in thin section, suggested the mineral to be very close to pharmacosiderite KFe₄(AsO₄)₃(OH)4·6-7H₂O, but with anomalously high Cs contents.

Complete WDS-EMP analyses gave a composition compatible with the formula (Cs_{0.47}K_{0.42})Σ0.89Fe_{4.25}(As_{0.96}P_{0.04}O₄)₃(OH)₄·6.43H₂O, thus confirming the similarity of the Cs-bearing phase with pharmacosiderite. The structure of pharmacosiderite [1] consists of FeO₆ octahedra and AsO₄ tetrahedra connected to each other to form a three-dimensional network of channels. The pore has 8-membered ring openings, with alternating arsenic tetrahedra and iron octahedra. Each channel, approximately 3.5 Å in diameter, is occupied by charge neutralizing K⁺ extra-framework cations and H₂O molecules [2]. All the structural sites can be occupied by many other elements: Al, Fe, Ge, Mo, Ti at the octahedral sites, and As, Ge, P, Si at the tetrahedral sites [3].

The extra-framework cations can be Ag, Ba, Cs, H, K, Li, Na, NH₄, Pb, Rb and Tl. This makes possible the existence of many microporous inorganic compounds, isostructural with pharmacosiderite and characterized by remarkable ion-exchange properties. Buerger et al. [1] investigated a synthetic Cs-pharmacosiderite obtained treating natural pharmacosiderite with an aqueous solution of CsOH at room temperature. However, until now the occurrence of a natural Cs-pharmacosiderite was not yet

observed. If confirmed, the observed Cs → K cationic exchange will imply the definition of a new mineral belonging to the pharmacosiderite group. Moreover, the occurrence of a new Cs-bearing natural phase would be relevant to the search for new materials that can be used as selective absorbers for the ¹³⁷Cs isotope from solutions of radioactive wastes and as containers for disposal of radioactive metals [4].

SOIL CONTAINING ASBESTOS: ANALYSIS AND PROBLEMSMARINI Paola¹, ZANETTI Giovanna¹

1 - DITAG - Politecnico di Torino

Presenter e-mail: paola.marini@polito.it

Key terms: ASBESTOS; ANALYSIS; threshold value; SOIL; PCOM

The goal of this work is to emphasize the various problems that exist concerning asbestos in nature and how these problems are often difficult to solve. An example of this concept is the analysis of contaminated soil, encountered during the excavation of the foundations of a building in the village of Sommarese, 3 km from Emarese (the Aosta Valley), a site of national interest because of the presence of asbestos.

The soil has been analysed by means of optical microscopy in phase contrast (PCOM), adopting a particular methodology with the aim of obtaining a direct weighing of the asbestos fibres: the sample was divided into granulometric classes, the granular fraction was separated in wet conditions, and the wood fraction, present in a high percentage, was partially or totally burnt in a muffle furnace.

The indirectly weighed asbestos was measured according to Italian regulation on the fibres, adopting SEM counting (Ministerial Decree 06/09/94); then the semi-quantitative grades were obtained taking into account the mineral volumic mass.

The results have shown the presence of asbestos in a quantity that almost reaches the threshold value dictated by Italian regulations concerning ground, (Legislative Decree 471 1999) that is, 1000mg/kg. The ground in the old village of Sommarese is therefore polluted naturally. Some questions therefore arise: should the ground be disposed of in an asbestos dump or it is better to leave it where it is, where all the unexcavated soil has the same level of contamination? And if so, what interventions should be made to make the site safe?

2 - AZIENDA USL PARMA

3 - AZIENDA USL FORLI

Presenter e-mail: osala@arpa.emr.it

Key terms: exposure to asbestos fibres; ophiolitic materials; Phase Contrast Microscopy; Scanning Electron Microscopy

The highest concentration of active green stone quarries of Emilia Romagna is located in the province of Parma. Between 2002 and 2004, a regional survey was carried out with the purpose of characterising the extracted materials and defining the exposure to asbestos fibres of workers employed in the mines. In 2009-2010 a further assessment was carried out in order to improve the survey.

The productive sector taken into consideration employs just a few tens of seasonal workers whose number is strongly affected by the market demand for ophiolitic materials. The ophiolitic materials coming from the Apennines are peculiar as the presence of both fibrous and not fibrous serpentine makes the comparison between different microscopic analytical methods interesting.

The 11 mining sites, managed by 8 different companies and employing 30 people as a whole, are homogeneous in terms of kind of activities carried out (with the exception of one quarry only where explosive charges are used): extraction, screening, grinding, loading and transport.

In 4 of these active sites, personal monitoring was carried out on the operators of the typical tasks carried out in the quarry - excavator driver, dumper driver, lorry driver, crusher operator. Despite the limited amount of samples, it is possible to make remarks on the characterisation of the tasks.

The sampling was carried out in accordance with the methodology provided by the UNI EN 589/97 standard. No.13 persona samples (Cp) were taken, corresponding to 7 exposures during a working shift. As specified by the WHO 1997 method, the following instruments were used:

- calibrated portable pumps (Q=2 l/min),
- conductive open face sampling heads with cylindrical extension,
- gridded membrane filters (mixed esters of cellulose).

The filters were analysed both in Phase Contrast Microscopy (PCM) and in Scanning Electron Microscopy (SEM), and compared with the Limit value (LV), concentration in ff/cc and/or ff/litre, in order to compare the two methods and to quantify the presence of asbestos fibres.

The data of the personal exposures have been statistically processed to check the enforceability of UNI EN 689/97 standard. Log-normal distribution, GSD and homogeneity of the group examined were determined and, as a consequence, the exceedance probability of the LV (% Pn) with its confidence interval was calculated using the application software ALTREX.

Regressions were performed so as to make a comparison between the analytical methods and to count the quantity of asbestos fibres and of fibres as a whole.

The results of the survey lead us to consider the extraction process of green stones a situation to be kept under control (ORANGE level as per Annex D of UNI EN 689/97). In particular it is deemed necessary to assess the way the mining activities are performed at the quarry and how the extracted materials are used (coarse pieces rather than powder).

QUALITATIVE AND QUANTITATIVE DETERMINATIONS OF CHRYSOTILE IN MASSIVE SERPENTINITES THROUGH THERMAL ANALYSIS METHODSVITI Cecilia¹, GIACOBBE Carlotta², GUALTIERI Alessandro²

1 - Dipartimento Scienze della Terra Università di Siena

2 - Dipartimento di Scienze della Terra Università di Modena e Reggio Emilia

Presenter e-mail: vitic@unisi.it

Key terms: serpentinite; chrysotile; lizardite; thermal analysis; asbestos

One of the main problem in the study of serpentinitic rocks is the accurate determination of serpentine mineralogy, because of the typical coexistence of different serpentine polymorphs in ultrafine, poorly crystalline assemblages, difficult to investigate by conventional methods, such as X-ray diffraction or microanalytical approaches.

In this study, we have collected thermogravimetry (TG), differential thermogravimetry (DTG) and differential thermal analysis (DTA) data for carefully checked serpentine samples, finding that lizardite (lz), antigorite (atg) and chrysotile (ct) have distinctive thermal behaviour, with main differences in the dehydroxylation range (500 - 800 °C). DTG and DTA peak temperatures progressively decrease from antigorite (720 and 715 °C, respectively) to lizardite (708 and 714 °C), polygonal serpentine (685 and 691 °C) and chrysotile (650 and 654 °C). Antigorite has a further diagnostic signal at ~ 740 - 760 °C, always absent in the other serpentinites.

TG, DTG and DTA data have been also collected for lz + ct and atg + ct mixtures, obtained by combining known amounts of the previously investigated reference samples. Deconvolution processing of DTA endothermic signals revealed good linear correlation between peak area ratios (for both ct/lz and ct/atg mixtures) and chrysotile content (with R2 of 0.99 and 0.96, respectively). The DTA correlation curves have been used to estimate the chrysotile content in two unknown samples (massive serpentinites with lz + ct pseudomorphic textures), revealing surprisingly high chrysotile content.

Based on the above results, we suggest that thermal analysis may represent a promising and straightforward method for qualitative and quantitative mineralogical determinations of bulk massive serpentinites, with important petrological and health-related implications.

Key terms: Chromium; Serpentinites; Serpentine soils; Weathering; Chromite

Serpentine outcrops, such as the altered ophiolites cropping out in the Tuscany (Western Italy), bear high level of Cr (and Ni) that can be released into ecosystems during weathering. Cr is predominantly contained in spinel-group minerals, such as chromite (Chr), that are highly resistant to weathering causing their accumulation within the soil. The role of chromite as source of Cr in the environmental processes is still under debate. Some authors argued that Cr-spinel is not a significant source of Cr in serpentinite soils, particularly compared to Cr-bearing silicates. Other authors demonstrated that Chr, which may undergo a chemical modification during weathering/pedogenesis, could represent a diffusive minor source of Cr due to its high concentration in soils and its slow weathering with time. Regardless of the composition of the hosting minerals, Cr is generally present in the not bioavailable trivalent state which may be oxidized to the highly toxic hexavalent form (Cr(VI)).

RESPIRA project, financed by EU and Regione Toscana, aims to study processes that promote the leaching of chromium from primary (peridotite) to secondary minerals until to the groundwater, following a multidisciplinary approach.

A serpentinite quarry in the coastal Tuscany was chosen due to the favorable rock exposure, the occurrence of well-developed soils at the top of the quarry, and spring waters at the bottom of the quarry.

XRF analyses of two soil profiles revealed a weak variation in Cr from values comparable with serpentinite bedrock (3100 ppm; deepest horizons) to depleted values into the uppermost horizons (2765 ppm). This variation reflects the mineralogical composition of the soils horizons: Cr-bearing phases occur preferentially in the deepest horizons.

Preliminary FEG-SEM and EMP results revealed that Cr is mainly hosted by spinel-group minerals, such as Mg-Chr. Cr2O3 content of Mg-Chr vary from ~ 23 to 43 wt. %, with the lowest and highest values relative to crystals from soil samples. Mg-Chr is generally replaced by Fe-Chr and magnetite towards the rims and/or near fractures. In several cases, the alteration products of the Mg-Chr may contain variable amounts of SiO2 (5-27 wt. %) inversely correlated with Cr2O3 contents (11-24 wt.%). The SiO2 values apparently give a measure of the extent of Mg-Chr alteration during serpentinization and suggest the presence of fine-grained silicate aggregates. Indeed, locally these alteration products show a microporosity. Appreciable Cr contents (0.5 wt. % < Cr2O3 < 1.5 wt.%) have been obtained from the rare relicts of the minerals of the peridotitic paragenesis (e.g. piroxenes). Generally, the Cr contents of serpentine group minerals is low (< 0.2 wt. %) with the exception of serpentine analysed from bastite pseudomorphic textures and late veins, where Cr2O3 may reach 1.70 wt. %. Garnet and chlorite are secondary phases containing less than 1.0 and 1.3 wt. % of Cr2O3, respectively.

Two springs emerging directly from serpentinites were sampled and preserved for Cr (VI) and Cr (III) analyses. These waters are Mg-bicarbonate and show alkaline pH values (8.1±0.1) as consequence of the interaction with ultramafic rocks. Spring waters collected from the surroundings, and circulating within ophiolites are Mg-bicarbonate with pH values around 7.5 and pCO2 from 3.8E-3 to 7.20E-3 atm. Groundwater circulating in carbonates and marls (sedimentary cover of ophiolites) are Ca-bicarbonate with slightly acid pH (6.8±0.2). Their pCO2 range from 2.3E-2 to 1.0E-1 atm. The total chromium content in groundwater and in the two springs from quarry is about 5 ppb and the prevailing form is Cr (III). They show an enrichment of Mg related to the degree of interaction with the rock.

These preliminary results reveal that integrating geochemistry and petrography should be successful to model the Cr mobility from natural outcrops and quarries. Further investigations will improve our results.

CHROMIUM (III) AND CHROMIUM (VI) IN SERPENTINITE-HOSTED SPRING WATERS FROM TUSCANY (ITALY)BANESCHI Ilaria¹, LANGONE Antonio¹, BOSCHI Chiara¹, AGOSTINI Samuele¹, DALL'AI Luigi¹, DINI Andrea¹, GUIDI Massimo¹, TONARINI Sonia¹ - IGG-CNR of Pisa

Presenter e-mail: i.baneschi@igg.cnr.it

Key terms: serpentinites; spring waters; Chromium

Serpentinites and serpentine soils in Tuscan area display high concentrations of Cr, dominantly in the form of Cr (III), as well as other potentially toxic elements including Ni. Geochemical interactions during serpentinite weathering and soil formation may provide oxidative pathways allowing the formation of Cr (VI). In fact, spring waters in serpentinites along coastal Tuscany may have high Cr (VI) contents, indicating a possible remobilization of Cr into groundwaters. Despite the availability of measurements from different systems (rock, soil and water) in Tuscany, the pathway of release of Cr (III) from the serpentinites and its oxidation to Cr (VI) is not assessed. RESPIRA project aims to characterize the Cr-bearing phases within serpentinites and serpentine soils (see Langone et al., FIST 2011) and to assess the processes of release and/or oxidation of Cr from rock to near-surface waters. Our multidisciplinary approach, that combines field, analytical and laboratory studies in solid and water samples, is also necessary to define whether or not serpentinites and serpentine soils are sources of non-anthropogenic Cr (VI).

Springs from serpentinite outcrops and from a serpentinite quarry in the coastal Tuscany were sampled for Cr (III) and Cr (VI) analysis, separating the two forms directly and immediately in the field using cation-exchange cartridges. All the spring waters are fed by Cr-rich ophiolite host rocks, however they exhibit different content in Cr (III) and Cr (VI). The study sites are far away from potentially anthropogenic pollution sources. The springs emerging directly from serpentinite quarry (Santa Luce) are Mg-bicarbonate and show alkaline pH values (8.1±0.1) as a consequence of the interaction with ultramafic rocks. The magnesium content in samples collected during dry season is higher than during rainy season when the discharge of the springs increases, indicating a different degree of interaction with the host rocks. The total chromium content is about 5 ppb and the prevailing form is Cr (III), even if slightly basic pH values indicate that the conditions are potentially favourable for both Cr (VI) and Cr (III) forms. Spring waters collected from the surroundings and circulating within ophiolites are Mg-bicarbonate with pH values around 7.5, while groundwaters circulating in carbonates and marls (sedimentary cover of ophiolites) are Ca-bicarbonate with slightly acid pH (6.8±0.2) and higher pCO₂ (from 2.3E-2 to 1.0E-1 atm). Differently, high Cr concentrations were measured in Querceto spring waters (50 ppb), almost entirely in the Cr (VI) form. As well, a spring in San Dalmazio site has about 15 ppb of Cr (VI). All the spring waters circulating in serpentinites are Mg-bicarbonate with pH values around 8. However Ca/Mg molar ratio in Querceto (0.7) is higher than in Santa Luce (0.03) and in San Dalmazio (0.06). In the same area Cr contents in serpentinite groundwaters are lower (less than 15 ppb), essentially in the form of Cr (III), and TIC content is higher. First results highlight differences in Cr (VI) and Cr (III) contents in spring waters discharging from serpentinites. It has been noticed that in Querceto and San Dalmazio Cu-Fe sulphide ores occur close to the springs. This point out that correlating the geochemistry of the water and the mineralogy of the serpentinites and their alteration products should be essential to evaluate distribution and concentration of Cr in waters. Further analyses of trace elements and organics (e.g. humic and fulvic acid, sulphides, ammonia and nitrate) should be fundamental to better understand oxidation and complexation pathway of Cr.

Presenter e-mail: elena.belluso@unito.it

Key terms: hydrology; hydrochemistry; waterborne asbestos fibres; Balangero mine; Piemonte - NW Italy

Water resources have been analyzed in terms of quantity and quality at the former mine of Balangero. The mine, set 30 km north-west of Turin, produced chrysotile since the 1920's and in the 1970's became the largest asbestos mine in Europe. In 1990 the mine was closed, although there were still over 18 million tons of asbestos to extract. The mine wasn't reopened because the Law 257/92 banned the extraction, import, export, marketing and production of asbestos, its products and products containing asbestos.

The study area covers a surface of about 7 km² in the nearby of the former mine and its two landfills of serpentinic coarse material, resulting from the rock extraction and processing. The former mine is set in the "Balangero Massif", a geological body mainly consisting of serpentinite. The research has been carried out in accordance with RSA Company, that deals with the rehabilitation and environmental development of the Balangero site, identified as National Interest Site for remediation by the Law 426/98.

A water balance for the years 2006 and 2007 has been calculated for 5 watersheds covering the whole study area. Precipitation and temperature data of seven meteorological stations have been utilized. In the study area, around 65-70% of precipitation is lost by evapotranspiration. The remaining water (water resources) flows principally as surface water rather than groundwater cause of the low permeability of metamorphic rocks. Infiltration is predominant only at the landfills (22% of the study area).

Also a qualitative characterization of some superficial water samples has been carried out in order to assess the influence of the wide landfill of mine rock residues on the water resources. The waters of the five watersheds have been sampled and analysed at the Turin University Laboratories (Dipartimento di Scienze della Terra and Dipartimento di Scienze Mineralogiche e Petrologiche). Water generally shows a magnesium-bicarbonate facies and secondarily a magnesium-sulphate facies. In some cases, the concentrations of sulphate and nickel exceed

the threshold defined by national law. According to literature data, such values are justified by the percolation of rainwater through the serpentinic materials of the landfill, relatively rich in nickel and sulphides. Regard to the suspended matter in water, only the breathable inorganic fibres (length > 5 µm, width < 3 µm, length/width > 3, as indicated by Italian law) have been researched and analyzed by SEM-EDS. Twenty-two mineral species have been found including three classified asbestos: chrysotile, tremolite-actinolite asbestos and anthophyllite asbestos. Cause of the high dispersion due to the reduced size of the fibres, the highest concentrations of asbestos were detected in samples that drain the landfills, while difficulties have been encountered in the other samples where a generalized low concentration of asbestos fibres probably occur. In order to obtain more accurate data for the other samples, analytical determinations by TEM-EDS have been recommended, as practiced in other countries for analysis of microfibrils in water.

Presenter e-mail: marroni@dst.unipi.it

Key terms: abbestos; ophiolites; risk assessment; Tuscan region

The six minerals grouped under the name of asbestos are universally recognized as dangerous for human health due to their fibrous shape. The asbestos minerals are generally found as common weathering products in peridotite, gabbro and basalt, typically associated in ophiolitic sequences. The circulation of fluids in these oceanic sequences cause a variably intense and penetrative hydrothermal weathering of pre-existing magmatic minerals such as olivine and pyroxene. No matter their peculiar chemical and physical characteristics, the industrial use of asbestos minerals has been completely eliminated from production and use in many countries. However, the asbestos fibres still represent an ubiquitous pollutant, not simply because of the number of industrial products still present in urban areas, but also because of the tendency, in asbestos-bearing rocks and soils, of fibres to be released naturally (landslides, erosion, weathering) or by human activities (mining, earthworks, excavations, tunnels).

Therefore, the control of the risk of environment contamination in areas where ophiolitic sequences crop out, still represents a relevant societal problem that require a precise estimate of the nature and abundance of fibrous minerals. This assessment can be performed with a multiscale and multidisciplinary geological study that allows a characterization of the asbestos from the mineralogical point of view (different degrees of risk for human health are related to different asbestos minerals).

We show here the main scientific and technical lines of a project of asbestos-related risk assessment developed by the Dipartimento di Scienze della Terra (Pisa University) and the Alitec s.n.c. and PivotConsulting s.p.a. companies, funded by the FSE (Fondo Sociale Europeo) through the Tuscany Region administration. The main goals of the CaMam (Caratterizzazione e Mappature Amianto) project is in fact the mapping and characterization of the asbestos-bearing ophiolitic rocks in the area of the Region of Tuscany.

The main phases of the project comprise a complete lithological and structural characterization of the outcrops with asbestos-bearing lithotypes as well as a qualitative and quantitative assessment of the amounts of these minerals.

All the collected field-based information will be stored and elaborated in a GIS (Geographic Information System) database. This database will contain a directory of areas where asbestos-bearing lithotypes are outcropping and the related qualitative and quantitative information. The database will be constructed starting from that already existing of the geological cartography, recently performed by the Tuscany region administration. The mineralogical characterization of asbestos phases will be performed by various techniques typically used in the context of fibrous minerals, such as XRD analyses, Raman spectroscopy and, where possible, TEM techniques. As much as possible an attempt will be made to check on possible relationships between the type of mineralizing phase and the structural, mineralogical and petrographical features of the lithotypes or fracture systems containing those phases.

In particular, with this project we aim to test a quantitative estimate of fibres by multi-scale image analyses of the outcrops and their mineralized fracture patterns. Thanks to the cooperation with PivotConsulting s.p.a. (c/o the Technology Centre of Navacchio (PI)) and Alitec s.n.c. companies, pilot studies in selected areas will be conducted to test the procedures for a quantitative assessment of content asbestos fibres and establish the background level of fibres resealed into the atmosphere. The companies will provide innovative techniques such as (i) the recognition of images through acquisition by drones (PivotConsulting s.p.a.), and (ii) acquisition of data on the concentration of micro and nano powders dispersed in the air using a portable detector (Alitec s.n.c.).

It's note the correlation between asbestos fibers and pleural mesothelioma which is called the "sentinel event" which highlights a particular exposure to those particular fibers. This case refers to a farmhand who, during his working life, has always worked in the municipality of Viggianello (PZ) Southern Italy - municipal road Cornaleto-Sant'Elena, where there are ophiolitic outcrops (known as green rocks). The woman has contracted a pleural mesothelioma. The survey carried out by means of leaves of particles of respirable fraction, as well as bulk samples of loose soil - the same type of work - and rock samples in place, has revealed the presence of chrysotile asbestos fiber type in soil. This presence appears to be in agreement with literature data. This paper illustrates the methods of

sampling carried out and the analytical results obtained by using optical microscopy (SEM) and phase contrast (PCOM).

Key terms: ophiolites; Classification; DM 14/05/1996

As it is widely known and studied in ophiolites (ultramafic rocks of intrusive magmatic origin, partially altered or metamorphosed) asbestos fibers may be found in the form of slow and small veins (those typical of alpine ophiolites, very rare in Apennines) and distributed within the fractures.

Mining, quarrying and processing could release a number of asbestos fibers into the environment, that needs to implement preventative measures of workers protection and local population.

The methods of control of the extracted materials are carried over from the Ministerial Decree (DM) 14/05/1996, which defines criteria for the classification and the use of "green stone" according to their content of asbestos. The excavation is allowed under a certain danger level as defined by the amount of asbestos released from the rocks, where the value of Release Index must be $Ir < 0.1$.

In addition to this law (exclusive to the ophiolites quarry sector) we can find the provisions of health and safety at work in Legislative Decree n. 81/2009. It stipulates specific analytical measures and controls over all work environments at risk for the presence of asbestos. The law identifies the permissible exposure limit (defined as "VL" Value Limit), beyond which they must take appropriate precautionary measures.

Various objections were raised over the correct application of the Ministerial Decree 5/14/1996, in particular relate to the real meaning of Ir (Release Index). The real ophiolitic danger is related to the chance of rocking crumbler during extraction and subsequent work phases since it is during these activities that rocks can more easily release asbestos fibers. These considerations were already included in the studies carried out by the Emilia-Romagna Region (Il Progetto Regionale Pietre Verdi - 2004). It proposes a new classification of the ophiolites deposits based on a simple but direct measurement of the release index (called AR "asbestos free or releasable") taken before and during the mining activities related to the types of products produced by the quarry.

Key terms: prima key word; seconda key word; terza key word

La tematica della cattura e stoccaggio del biossido di carbonio (CCS) rappresenta già da alcuni anni uno degli argomenti di maggiore interesse per il mondo scientifico e la ricerca. Su proposta della Commissione europea, il Parlamento europeo e il Consiglio dell'Unione europea, riconoscendo l'importanza di tali tecnologie, hanno emanato la direttiva 2009/31/EC del 23 aprile 2009. La direttiva considera la cattura e lo stoccaggio del biossido di carbonio come una tecnologia ponte che potrà contribuire a mitigare i cambiamenti climatici.

L'obiettivo indicato nella direttiva è quello di consentire il recepimento da parte di ogni Stato Membro entro il prossimo 25 giugno 2011.

A tale scopo il Ministero delle politiche europee, il Ministero dello sviluppo economico e il Ministero dell'Ambiente hanno costituito un gruppo di lavoro congiunto per la stesura dello schema di recepimento secondo i principi e criteri direttivi stabiliti dalla legge 4 giugno 2010, n.96 (legge "Comunitaria 2009"). Attente riflessioni, confronti, analisi degli aspetti tecnici, amministrativi e giuridici hanno portato nel marzo 2011 alla predisposizione finale dello schema di decreto legislativo, il cui testo è stato dapprima discusso e condiviso con le amministrazioni concorrenti (Ministero degli affari esteri, Ministero della giustizia, Ministero dell'economia e delle finanze) per poi essere sottoposto all'esame del Consiglio dei Ministri, che, in data 23 Marzo 2011, lo ha approvato in via preliminare.

Successivamente, in data 12 maggio 2011, il testo è stato discusso durante la Conferenza Stato-Regioni, dapprima per quanto concerne gli aspetti tecnici, mentre, in data 18 maggio 2011, per quanto concerne gli aspetti politici, riscontrando un parere favorevole, condizionato all'accoglimento di alcuni emendamenti.

Significativo per il raggiungimento di questi traguardi è stato l'apporto continuo e costruttivo delle regioni, degli enti di ricerca nazionali e delle associazioni di categoria degli operatori.

Le attività future, previste nei prossimi giorni, necessarie a concludere l'iter di recepimento riguarderanno la predisposizione del testo finale e l'invio alle varie commissioni parlamentari, chiamate a pronunciarsi in materia.

STRATEGIC USE OF UNDERGROUND FOR AN ENERGY MIX PLAN: THE EXAMPLE OF LATIUM REGION (CENTRAL ITALY)

PROCESI Monia¹, CANTUCCI Barbara¹, BUTTINELLI Mauro¹, QUATTROCCHI Fedora¹

1 - Istituto Nazionale di Geofisica e Vulcanologia, Via di Vigna Murata 605, 00143 Roma, Italy

Presenter e-mail: monia.procesi@ingv.it

Key terms: Mix energy plan; synergies in CO₂/natural gas storage; geothermal energy

The world-wide energy demand has been growing so much that there is the need to develop a strategic mix-energy plan to supply low GHG (GreenhouseGas) emissions energy and solve the problem of CO₂ emission increasing.

A study published in 2006 by the European Commission shows that if the existing trends continue, by 2050 anthropogenic CO₂ emissions will be unsustainably high: 900- 1000 parts per million by volume.

A first useful step to solve this problem can be to evaluate the synergies and/or conflicts between reliable technologies that can produce clean energy involving deep geological structures, namely:

1) clean coal combustion, jointed to CCS (Carbon Capture and Storage);
2) CH₄ storage in natural reservoirs;
3) renewable energies as geothermal energy;

These three technologies could coexist in a strategic use of the underground, especially in densely populated country as the Italian territory. In this framework, the preliminary underground screening for a strategic energy use must also consider the presence of potentially suitable areas addressed in the past by dedicated agency for instance to nuclear waste disposal. Selection of these sites is in fact based on more rigid criteria with respect to gas storage or geothermal energy. Therefore, areas selected for nuclear waste disposal represent a peculiar factor that should be taken into account for a correct energy plan evaluation.

CCS is considered one of the main technology able to stabilize and reduce the atmospheric concentration of anthropogenic CO₂. Nowadays CCS market is mainly developed in USA and Canada, but still less accounted in Europe. In Italy there aren't active CCS projects, even if potential areas have been already identified.

Traditionally, CH₄ has been a seasonal fuel. The demand of this gas is usually higher during the winter because used for heat spacing. Storing natural gas is actually strategic for two reasons: to fill the seasonal requirements and to have a strategic energy reserve. Many CH₄ storage sites are located in Northern America, while other are present also in Europe and Italy, but the number of sites is limited despite the huge underground potentiality.

Geothermal Energy is a renewable, clean and sustainable energy which can be used indirectly for power generation and directly for numerous applications such as: space and district heating, water heating aquaculture, horticulture and industrial processes.

In Italy the power generation from geothermal energy is about 5400 GWh/year. It comes exclusively from Tuscany (Larderello-Travale and Mt. Amiata geothermal fields) despite the already evaluated huge potentiality of other regions as Latium, Campania and Sicily. Nowadays, new technologies as EGS (Enhanced Geothermal Systems) and Binary Cycle Plants permit the development of the geothermal energy also in areas considered unproductive in the past, due to low underground temperatures and/or absence of fluids.

Here we present preliminary data concerning this work on the whole the Italian territory, starting from Lazio Region. Results show that in this area the three technologies can coexist despite the general complex geological setting.

Therefore we are developing a self-sustaining Dedicated Geographic Information Systems (D-GIS) necessary to organize and manage a reliable Mix-Energy plan relative to the entire Italian territory. It includes geological strategic data and also environmental and infrastructure information. The development of D-GIS can represent a useful planning tool to evaluate synergies and/or conflicts among different deep underground uses (500-5000 m depth) and correlated technologies. Products of this study can finally represent an useful tool not only for the scientific community but also for the policy makers to improve the guidelines for sites selection.

SUITABILITY OF DEEP SALINE AQUIFERS FOR UNDERGROUND STORAGE OF METHANE AND CARBON DIOXIDE

BENCINI Roberto¹, BIANCHI Elio¹, FANDINO Vladimir¹, RODRIGO Simone¹, VICO Giuseppe¹

1 - Independent Gas Management srl

Presenter e-mail: rbencini@ir-plc.com

Key terms: carbon capture and storage; underground gas storage; deep saline aquifers; naturally fractured carbonates; integrated multidisciplinary evaluation

Storage of Methane (CH₄) and Carbon Dioxide (CO₂) in deep saline

aquifers is a proven technique and a promising strategy to respectively address mitigation of climate change and energy security regarding additional Methane demand during cold weather. These themes are attracting growing interest within both scientific and industrial communities.

According to one of the leading scientific research bodies in geosciences in Italy "Deep saline aquifers offer the largest storage potential of all the geological CO₂ storage options, and are widely distributed throughout the Earth".

Moreover, according to the International Gas Union, "The sciences and technologies that UGS (Underground Gas Storage) operators use for Methane storage, specially for aquifers storage, are a solid basis for CO₂ sequestration projects", highlighting in an authoritative way the strong technical interconnection between these two industrial sectors.

In Italy, several storage projects in deep saline aquifers are underway. A major underground Methane storage site (Rivara Project) is being planned in a fractured carbonate reservoir in Italy's Po Valley. Rivara's working capacity is estimated at approximately 3.2 billion cubic metres (bcm), which would make it one of largest and potentially best performing gas storage facilities in Italy and in Europe.

Additionally, several sites in naturally fractured carbonate aquifers are being evaluated for potential CO₂ storage, among which a site offshore under the continental platform of the Tyrrhenian Sea. Major efforts are in progress to properly characterise these storage sites and to plan their safe operation ahead of the beginning of the construction phase, including reservoir and caprock stratigraphy and structure, geomechanics, reservoir engineering, geochemical and seismological monitoring.

An innovative, multidisciplinary and integrated work flow has been identified to document the suitability of these sites. The work programme is designed to determine the feasibility and the safety of the gas storage project, either CH₄ or CO₂. This includes two main phases, namely an Initial Phase, followed by the Appraisal Phase, which repeats the cycle in more details.

Each phase involves the following integrated sequential stages:

- ° Analysis of pre-existing data (wells, seismics, subsurface data, seismological data);
- ° 3D geologic modelling;
- ° 3D reservoir modelling;
- ° 3D geomechanic modelling.

The Initial Phase involves all the data gathering activities that can be implemented without a specific licence, while during the Appraisal Phase the activities include the acquisition of geophysical data and the drilling of wells, which require specific ministerial authorization and license. The key elements of the Appraisal Phase, in fact, are the acquisition of a new 3D reflection seismic campaign and the drilling of the necessary appraisal wells with the associated specialized activities (cores, logs, reservoir test). Before the beginning of the construction phase, it is also important to implement a multidisciplinary monitoring programme ante-operam, in order to have the basic elements for detecting any change that may occur after the beginning of the site operations.

While underground Methane storage (UGS) activities are fully regulated in Italy, and an aquifer specific European Standard (UNI-EN-1918-1) exists, underground storage of CO₂ is not yet currently regulated. Italy is however about to adopt European Directive 2009/31/CE of 23 April 2009 on the geological storage of carbon dioxide.

Independent Gas Management is a competent specialized operator for the safe development of suitable CH₄ and CO₂ underground storage sites in deep saline aquifers hosted in naturally fractured carbonate rocks.

Key terms: soil gas survey; shallow aquifer; flux measurement; natural gas storage; Po Plain

A geochemical survey in soils and shallow aquifers was carried out as part of the feasibility study of a potential natural gas (CH₄) storage site in a deep saline aquifer of Modena Province, Northern Italy.

This paper discusses the areal distribution of CO₂, CH₄ and other geo-gases (Rn, He, H₂, N₂) both in soils and shallow aquifers above the proposed storage reservoir.

Soil and dissolved gas, joined with isotopic analysis, allows to distinguish between shallow and deep origin fluids. This approach is used also to identify the presence of anomalous leakage of deep fluids towards surface, and therefore the presence of tectonic discontinuities by means distribution of pathfinder elements as ²²²Rn, He e H₂.

This methodology is based on the previous experience gathered in other projects aimed to i) water and soil gas surveys in active fault areas; ii) natural gas risk assessment and iii) CO₂ geological storage.

In particular, the goal of this survey is to characterize the composition, distribution and behavior of the geo-gas (CH₄, Rn, He, CO₂, H₂, etc...) in the geological layers closer to the surface, defining their baseline or background values, their origin, pathways and carrier roles.

The geochemical and isotopic characterization of the ground waters circulating in the first 200 meters has been carried out to investigate the origin of the circulating fluids, the gas-water-rock interaction processes, the amount of dissolved gases and/or their saturation status.

In the first 200 m, the presence of reducing waters enriched in CH₄ could be related to organic matter (peat) bearing strata which generate shallow-derived CH₄, as elsewhere in the Po Plain. No hints of thermogenic CH₄ gas leakage from deeper reservoirs have been envisaged.

The acquisition of pre-injection data is very important for the future natural gas storage development project and it is strategic as baseline for future monitoring during the gas injection period. Our study could be considered as a monitoring guideline applicable both to other gas storage sites before, during and after the injection and to natural analogues.

Key terms: carbon sequestration; natural analogue; geochemical modeling

Carbon capture and storage (CCS) is considered a valid option for reducing CO₂ concentration in atmosphere without a dramatic impact on the economy. The feasibility of many CCS projects worldwide it is still under evaluation, although others have already started (e.g. Weyburn pilot project in Canada; Cantucci et al., 2009 and reference therein). The injection of CO₂ underground allows to acquire useful experimental data to be used for geochemical modeling purposes as accurate data and chemical-physical constrains on rock and CO₂-rich fluid interactions are needed. Nevertheless understanding if CO₂ can safely be stored at depth for long times (thousands of years) can actually be evaluated only by geochemical modeling. Natural analogues are very useful for identifying key mechanisms and processes relevant to long-term stability and seepage mechanisms associated with CO₂ geological sequestration. Consequently, these systems are presently representing the easiest way to gather experimental data to be compared with those scenarios provided by geochemical models.

A high pCO₂ system was found located in San Cassiano Basin (Tiber Valley, Eastern Tuscany). Here, in correspondence of PSS1 borewell (Anelli et al., 1994), a relevant fraction (92,2% vol) of carbon dioxide is found at the depth of 3,800 m, presumably located at the top of the main fluid reservoir hosted in "andesitic" (?) volcanic rocks interbedded with the evaporitic Formation of Burano, at P-T conditions of nearly 700 bar (70 MPa) and 120 °C respectively, with a density of 860 kg/m³, univocally suggesting the presence of a supercritical fluid (Heinicke et al., 2006).

Fluid chemistry from the bore-well and that discharging at the surface from natural manifestations (bubbling mud pools, springs, stream waters, wells) were studied along with carbon (in CO₂) and helium isotopes.

Moreover extensive surveys on the altered volcanic rocks, likely corresponding to the top of the reservoir, and the hosted minerals were carried out. Qualitative and quantitative analyses were performed by means of SEM-EDS, XRD and EMP techniques. The mineral paragenesis consists of Quartz, Ca-Fe-Mg Carbonates, Na-K Illite, Fe-Mg Chlorite and accessory Apatite and Fe-Ti oxides. Fluid inclusion studies showed the presence of H₂O-rich and CO₂-rich phases. First-type inclusions provide information on the physical-chemical features of fluid responsible for hydrothermal alteration, whilst second-type inclusions indicate changes of CO₂ densities within the reservoir. Experimental runs at LLB (CEA-CNRs, Saclay, France) at SANS (Small Angle Neutron Scattering) diffractometer PAXE were conducted for retrieving data about the microstructure of porosity of the rocks. The mineral chemistry of Ca-Fe-Mg carbonates (Bicocchi et al., 2011) was studied by applying appropriate statistical methods.

The large chemical, physical and mineralogical dataset obtained in the present study will be employed to build up a conceptual model of the fluid-rock interaction processes that affected this geologically complex portion of the central-northern Apennines.

Key terms: Benthic fluxes; Early diagenesis; Benthic chambers; Dissolved inorganic carbon; Carbon sequestration

One of the most promising technological solutions in the CO₂ Capture and Storage (CCS) is the CO₂ injection in the sub-seabed deep saline aquifers. In the sub-seabed CCS a reliable monitoring of possible CO₂ seeps is required in order to assure safety, containment lifetime and biological impacts.

A useful CCS monitoring approach (the experimental biogeochemical approach) is to determine, before the geological storage, natural baseline levels and benthic fluxes of dissolved inorganic carbon species (pCO₂ and DIC) and of other connected parameters (alkalinity, pH and $\delta^{13}C_{DIC}$) in seawater in order to characterize the marine carbonate system from a chemically point of view and regarding its natural or anthropogenic origin. Furthermore, the study of the early diagenesis processes generating the observed benthic fluxes is a useful complementary aspect of the CCS biogeochemical monitoring approach.

The knowledge of the natural baseline levels and benthic fluxes, before the CO₂ injection, will allow the comparison with data obtained after the storage operations so that possible occurrences of unexpected leakages of the CO₂ injected in the geological formations under the sea bottom can be verified.

This approach could also be useful employed as an "early warning" system

in case of possible failure of the CO₂ storage.

The best method to determine dissolved benthic fluxes is the "in situ" measurement by benthic chamber deployments.

The biogeochemical approach is particularly sound in the northern and central Adriatic Sea where numerous previous DIC and other carbonate system connected chemical benthic flux data, various early diagenesis studies and also up to date and appropriate monitoring technologies (automated benthic chamber and on deck laboratory), able to measure "in situ" benthic fluxes, are available and where CO₂ sub-seabed storages can be carried out.

Previous researches allowed the definitions of nine different diagenetic environments in the northern and central Adriatic Sea; each environment is characterized by:

- 1) homogeneous particulate matter and dissolved nutrient continental inputs;
- 2) distances from main sediment sources;
- 3) bottom sediment composition;
- 4) organic matter;
- 5) depths;
- 6) oxygenation of water column.

In each diagenetic environment a natural background value of DIC, alkalinity and pH sediment-water fluxes has been assigned. These background values can be used as natural baseline in the CCS to monitoring possible seeps after the injection of CO₂ in depth. At present, various researches are in progress in the Adriatic Sea for the acquisition of new data of DIC and other dissolved chemical sediment-water fluxes and on early diagenesis studies, in order to increase the background knowledge in areas or seasons not covered by previous researches.

In particular, in fall 2010 and winter 2011 two cruises have been performed to measure benthic fluxes of dissolved inorganic carbon species and to determine the early diagenesis processes that origin the fluxes in the two extreme seasons in the central-western Adriatic Sea.

In these last cruises benthic fluxes have been measured "in situ" by deployments of the ISMAR-CNR and RSE "self-made" benthic chamber and using an on deck laboratory.

Furthermore, a technological development research is now being carried out by ISMAR-CNR and RSE for the set up of a full ocean depth (6000 m depth) Lander equipped with three benthic chambers and one micro-profiler.

CARBON DIOXIDE SEQUESTRATION VIA MINERALIZATION: THE STATE OF ART

DE VITO Caterina¹, MIGNARDI Silvano¹, FERRINI Vincenzo¹

1 - Sapienza Università di Roma

Presenter e-mail: silvano.mignardi@uniroma1.it

Key terms: carbon dioxide; reject brines; carbonation process; nesquehonite

Today a main challenge in environmental management is to consider some contaminants such as carbon dioxide (CO₂) and reject brines, instead of harmful and dangerous by-products, as valuable sources for several compounds to be involved in diverse industrial processes. The geological sequestration of CO₂ currently in vogue is considered the most promising method to trap and store this greenhouse gas. We propose alternatively the long-term sequestration of CO₂ in solid form through its mineral sequestering as hydroxycarbonate of magnesium, nesquehonite [MgCO₃·3H₂O], without any potential risks for the environment as it is stable at Earth surface conditions. Carbonation reactions are common in nature but the idea of developing this process for the disposal of CO₂ based on the chemical fixation of the carbon dioxide in the form of carbonate minerals was only proposed in 90s using calcium in brines, and then by carbonation of magnesium-bearing minerals from ultramafic igneous rocks. There are serious problems with that approach: the reaction kinetics for magnesium silicates tends to be too slow and environmental concerns are associated with mining and processing very large amounts of rocks.

Conversely, we developed an innovative and non-traditional use of CO₂ and brines in a process having a dual beneficial objective to reduce the volume of this greenhouse gas to be discharged and mitigate the negative effects of reject brines.

We recently described a carbonation process involving the reaction of gaseous CO₂ with a magnesium chloride solution producing nesquehonite. In order to evaluate the appropriateness of a reaction of CO₂ with Mg chloride solutions as a process for storing carbon dioxide and wastewater, the thermal behaviour of nesquehonite was investigated *in situ* using real-time parallel-beam X-ray powder diffraction. Nesquehonite appears to be stable up to 373 K suggesting that its storage as "sequestering medium of CO₂ and reject brines" remains stable under the temperature conditions that prevail at the Earth's surface. At temperature above 373 K the process of thermal decomposition of nesquehonite (*via* intermediate hydrated magnesium carbonate phases) ultimately produces magnesite in the range 423-483 K. This sequence involves the formation of carbonate minerals thermodynamically more stable than nesquehonite, assuring the stable storage of these hazardous materials for millions of years.

Our initial work on the carbonation process involved a relatively dilute solution of magnesium chloride, roughly 7 g L⁻¹ of Mg, at room temperature. The reaction rate was found to be rapid, the deposition of nesquehonite being virtually complete in about ten minutes. Nesquehonite removed about 80% of the CO₂ in solution. To test the efficiency of the carbonation process in more concentrated solutions, having salinity more close to that of the reject brines that are industrially available, further experiments have been carried out using solutions with different degree of salinity (16 and 32 g L⁻¹ of Mg). A comparison of the efficiency of the CO₂ mineralization process among sets of experiments at low and high salinity shows that in more concentrated solutions, the efficiency was reduced to about 65%. The results suggest that the goal of CO₂ sequestration and reject brines discharge seems to be realistically obtained also using the more common wastewater.

The sequestration of CO₂ and the disposal of reject brines *via* carbonation produces a solid material that can be utilized directly in many products such as acoustic panels, non structural panels, insulation, or agglomerated in concrete as a man made aggregate. Because nesquehonite growths as fibrous and acicular crystals, it improves the microstructures of manufacturing materials.

Key terms: CO₂ mineralogical sequestration; serpentinite; hydromagnesite; mine tailings; Tuscany

The Montecastelli copper mine, close to Pomarance (Tuscany, Italy), has been exploited since the Etruscan time, but it has been during the 19th century that Cu ores (bornite and calcopirite) were extensively cultivated. Copper minerals are mostly concentrated along a shear zone hosted by serpentinite. During exploitation, barren serpentinites as well as low grade ore material extracted in underground works were disposed in a mine dump in front of the entrance of the tunnels.

Field observations, and mineralogical investigations, indicate that specific layers of the dump were intensively carbonated. Carbonate precipitates are known from serpentinite mine dumps from many other localities (Wilson et al., 2006; and references therein). Such a low temperature alteration is a natural analogue of an induced carbon dioxide mineralogical sequestration, spontaneously developed in a very recent time. RESPIRA project, financed by EU and Tuscan Region, aims to study different type of carbonation processes, that led to natural analogues of CO₂ mineralogical sequestration. Here, we report the preliminary studies of the carbonation in Tuscany mine tailing, in order to give an estimate for the sequestration capacity of ultramafic mine tailings, and to provide a framework for the development of standard protocol of enhanced mineral sequestration at mine sites.

Dumps at Montecastelli mine are composed by a bottom incoherent layer, up to 4m thick, of medium to big size serpentinite clasts (up to 60 cm in diameter), randomly distributed and characterized by the presence of large voids between clasts. The intermediate layer, ranging from 10 cm to 1m in thickness, consists of small- medium-size serpentinite clasts encrusted by a very fine-grained whitish carbonate-rich material. A 15-40 cm of young soil with an initial accumulation of organic matter (litter, three roots, etc), alternating with serpentinite clasts, is on the top. On the distal part of the tailing, the bottom layer disappeared, prevailing a greenish serpentinite- and clay-rich layer very-fine grained and incoherent carbonate-rich layer intercalated to a greenish serpentinite- and clay-rich part.

The carbonate minerals are mainly represented by hydromagnesite, occurring as white coatings and crusts with the typical fibrous-radiating texture, and in veins or fracture fillings. Serpentinites are altered to friable mineral assemblage that consists mainly of clay and carbonates.

Provided that exploitation/exploration of the Cu ores at Montecastelli definitively stopped after the Second World War, spontaneous mineral carbonation of serpentinite clasts disposed in mine dumps has likely occurred during the last 60 years. Mineralogical, geochemical and isotopic (O, C, Sr) investigations will provide insights to the P,T conditions and fluid composition during carbonate precipitation in mine dumps at Montecastelli.

Presenter e-mail: andrea.orlando@igg.cnr.it

Key terms: mineral carbonation; high P-T experiments; acid attack; dissolution rate; sequestration of CO₂

Mineral trapping is a crucial process in a CO₂ sequestration perspective and it can be simplified as the sum of two consecutive processes: 1) dissolution of primary silicate minerals, such as olivine, serpentine, and pyroxenes, which are mainly found in igneous ultramafic rocks, variably affected by alteration processes, and 2) precipitation of carbonates as a consequence of reaction between solutions and CO₂. Several parameters, such as temperature, pressure, salinity of the solution, control the kinetics of the whole process. Thus, the realization of experimental tests taking into account these parameters is essential in either ex-situ or in situ CO₂ sequestration projects involving mineral trapping. An experimental study was performed within the ZEBU (Zero-Emission Biogas Use) project, aimed at increasing the CH₄ contents of biogas emitted from landfills through CO₂ separation and sequestration by serpentinite carbonation. Experiments in order to determine dissolution rates of a serpentinite sample mainly consisting of lizardite (with subordinate orthopyroxene, magnetite, and chromite) were performed under different P-T conditions (up to 30 MPa and 300 °C) in aqueous solutions at variable salinity. In particular, at 0.1 MPa and 70 °C, serpentinite was reacted with an acid solution (H₂SO₄ 2M) over different times (up to 24h). MgO extraction from the rock turned out to be efficient, varying between 82 to 97%, depending upon the reaction time. Calculated dissolution rates vary from 4.0 x10⁻⁹ to 8.5 x10⁻¹⁰ mole m⁻² s⁻¹. Carbonation tests were subsequently performed rising the pH of the solutions up to 9.5 (through addition of NH₃ solution) under a CO₂ flux, but they failed since Mg- and NH₄- bearing hydrated (or anhydrous) sulphates precipitated causing a considerable Mg depletion of the solutions. In contrast, precipitation of a Mg-hydrated carbonate, nesquehonite, occurred upon mixing a synthetic MgCl₂ solution (which simulates acid attack performed using HCl instead of H₂SO₄) with a solution of (NH₄)₂CO₃ obtained through absorption of CO₂ (from synthetic biogas) in ammonia.

At higher pressures, the serpentinite was reacted with a NaCl-bearing aqueous solution and supercritical CO₂ at 9-30 MPa and 250-300 °C, either in a stirred reactor or in externally heated pressure vessel. CO₂ was supplied from a tank (stirrer reactor) or produced from decomposition of oxalic acid or silver oxalate (pressure vessel). Serpentinite carbonation occurs after 24h at 30 MPa, 300 °C in 100 g L⁻¹ NaCl aqueous solutions. Under these conditions, Fe- and Ca- containing magnesite crystallized; its amount varies from 5 to 10 wt%. As regards the sequestration degree, CO₂ uptake attains a maximum of 16 mol% and possibly can be further enhanced by increasing the salinity of the aqueous solution. Assuming the

rock to be constituted only by pure lizardite, the calculated dissolution rates under these conditions range from 6.3×10^{-11} to 1.3×10^{-10} mole $m^{-2} s^{-1}$, and are roughly comparable to the value obtained through acid attack at 0.1 MPa and 70 °C for similar experimental duration. Overall, the results of the experiments indicate that single-step significant carbonation could be (quickly) attained at high P-T conditions avoiding acid attack. Under atmospheric conditions Mg is extracted very efficiently from serpentinite in acidic environment, but the pH of the obtained solution must be adjusted carefully, to avoid the precipitation of non carbonates Mg-containing solids.

Key terms: Reactive transport simulation; CO₂ Storage; saline aquifers

The fate of CO₂ once injected into a saline aquifer can be predicted by means of numerical modeling procedures of geochemical processes and fluid flow properties, these theoretical calculations being one of the few approaches for investigating the short-to-long-term consequences of CO₂ storage into a deep reservoir.

In this work the results of a methodological approach for the assessment of the CO₂ injection impact in the reservoir and the cap-rock stability in an offshore reservoir in the Tyrrhenian Sea are shown and discussed. The stratigraphic succession of the investigated area is constrained by a more than 3500 m deep well. It is characterized by: a thick marly-to-clayey cover succession overlying a calcareous fractured succession. The first geological sequence can be considered as an efficient cap-rock, whereas the last unit represents the reservoir of a huge regional deep aquifer. A re-interpretation of available seismic reflection dataset was performed to build a 3D geological model and to calculate its Gross Reservoir Volume.

3D simulations were performed by the TOUGHREACT code at the theoretical CO₂ injection pressure. In order to understand the nuances of this complex system, three different simulations were carried out. The first model is a stratigraphic column with a size of 0.11x0.11x4 km and a metric resolution in the injection/cap-rock area (total of 8,470 elements), with the goal to assess the geochemical evolution of the cap-rock and to ensure the sealing of the system. The second simulation is a horizontal model with a size of 99x11x11 m to study the fate of the displaced water at the plume front and the permeability variations as the injected CO₂ has started to promote geochemical reactions. The third simulation is at full scale (13.5x12.75x4 km) in order to predict the CO₂ path from the injection towards the spill point.

The most important effect evidenced in these runs is a barrier effect due to the flow of the CO₂-rich acidic water into the carbonate reservoir, originating a complex precipitation/dissolution surface that may have an effective impact on CO₂ sequestration due to the reduction of available storage volume reached by the CO₂ plume in 20 years and/or the enhancing of the required injection pressure.

Kinetic modeling suggests a rough dissolution of calcite of about 20% in volume close to the injection well, although precipitation occurs in the reservoir as soon as the effect of the CO₂ plume has disappeared. Basically, as the acidic saline fluid mixes with the alkaline formation waters calcite is precipitating. This implies that at the injection point the permeability increases and a sort of geochemical barrier is produced downstream along the fluid flow path. As a consequence, two key zones can be distinguished: i) inside and ii) outside the CO₂ plume. Calcite behavior may be regarded as "displacement" from the CO₂-rich water front to the downstream fluid path and this is likely the main cause of porosity/permeability reduction. This barrier diminishes the outflow velocity of the CO₂-displaced water, producing a lower CO₂ injectivity. The formation of secondary minerals occurs inside the plume where more acidic conditions are encountered, while the CO₂ plume grows as the injection proceeds up to roughly 1 km of radius after the injection of 30Mt of CO₂ in 20 years.

 3 - Tethys s.r.l., Milano, www.tethys-geco.it
 Presenter e-mail: ivana.lalicata@polimi.it

Key terms: Modflow; Trnvdstp; borehole heat exchanger; modelation

Simulation models can be applied for a more effective use of the subsol for geothermal purposes. In fact they are useful tools for the design of efficient systems which consider also the need to not create abnormal temperature distributions in soil and aquifers.

Aim of this study is to simulate a borehole heat exchanger through two computer codes: the first one often used in ground source heat pump design (TRNVDSTP, coupled to TRNSYS), the second one suitable for groundwater flow and transport models (MODFLOW/MT3D). The two software have been compared in terms of predicted heat exchange and temperature distribution in the aquifer. A geothermal system, consisting

of a 100 m U-pipe, located into a 200 m saturated sandy aquifer, assumed homogeneous for simplicity, has been implemented in the two programs. Simulations have been performed for a one year period representing winter and summer operation of a ground source heat pump.

Initial attempts with simplified simulations have shown the need to implement in Modflow the typical U-pipe geometry of a real borehole heat exchanger, although this implies strong grid refinement and extensive computational resources. Since TRNVDSTP is considered reliable if only thermal conduction is present, the first runs were performed without a groundwater flow. A good agreement has been observed between the results of the two software, both in relation to exchanged energies and temperature distribution into the model domain. In particular, the difference of exchanged energy, function of the fluid temperature inside the borehole heat exchanger, is less than 6%; also, in two observation points, located at a distance of 0.60 and 2.75 m from the centre of the U-pipe, the observed temperature differences are respectively lower than 1.06°C and 0.25°C. Thus, representing the real U-pipe geometry in Modflow, the program returns reliable results.

The simulated situation, which does not account for a groundwater flow, is not completely representative of the field conditions where groundwater heat exchangers are applied; thus some simulations considering the presence of the groundwater flow, and maintaining the U-pipe geometry, have been performed. In this latter case, the results in terms of exchanged energy differ of about 150%; in the two observation points the simulated temperature difference is less than 1.93°C and 0.78°C, respectively at the distance of 0.60 and 2.75 m. Therefore the two codes seem now to differently simulate the heat transfer between U-pipe and aquifer and then the impact of the geothermal system on groundwater. However Modflow seems suitable for being used also with technical purposes once the causes of the difference in the simulated temperature have been determined. The lack of experimental data and the difficulty in comparing the analyzed situation to the few modelation cases present in literature, have made difficult an exact evaluation of the accuracy of the observed results.

In next step of this research it could be useful to consider the results of some well-known analytic case in order to evaluate which one of the two codes better simulates the thermal exchange.

Anyway it is possible to conclude that the use of computer codes for geothermal systems design provides a positive support, also due to the availability of two reliable computer programs at least.

The comparison between the results obtained using Modflow and TRNVDSTP and those of the analytical solution could identify defects and strong points of the performed simulations; the efforts required to achieve a good match between simulations and analytical solution could also provide useful information for the improvement of the codes features in geothermal system simulations.

Key terms: low-enthalpy geothermal energy; monitoring; characterization

The importance of monitoring of hydrogeological parameters in areas of low-enthalpy resource exploitation covers two basic roles: the first one is related to the study of the thermal potential of the aquifers and their seasonal variations, the second concerns the study of physical and chemical changes of groundwater due to the plants in operation.

Two case studies located in the City of Rome are presented: the first relates to an area of the Tiber alluvial Valley, the second concerns the geological sequences of the "paleo-Tiber" the "F.so Crescenza" formation. In the first case, the study focused mainly in the definition of low enthalpy geothermal potential of waters of the two main aquifers of the alluvial Tiber deposits.

The second case focuses primarily on monitoring the chemical-physical and microbiological changes in the groundwater during the pre and post geothermal exchanger installation, and during the operation of the plant.

TIME-VARYING PROCESSES AFFECTING THE SURFACE HEAT FLOW IN THE WESTERN PO BASIN

PASQUALE Vincenzo¹, GOLA Gianluca¹, CHIOZZI Paolo¹, VERDOYA Massimo
 1 - Dipartimento per lo Studio del Territorio e delle sue Risorse, Settore di Geofisica, Università di Genova, Viale Benedetto XV 5, 16132 Genova, Italy

Presenter e-mail: pasquale@diptetis.unige.it

Key terms: Thermal geophysics; Terrestrial heat flow; Sedimentary basin

The thermal history of a sedimentary basin implies the superposition of different heat-transport mechanisms and geodynamic processes which cause changes in the structure and distribution of physical parameters. The thermal field is mirrored by the surface heat flow which is also a fundamental parameter for the evaluation of geothermal resources and their potential. This paper presents heat-flow data of the western Po Basin and surrounding areas, and analyzes the effects on the heat flow due to long-term climate change, radiogenic heat production, sedimentation and thrust faulting.

Thermal and stratigraphic data recovered from petroleum wells were used as basic information. The bottom-hole temperatures were processed for the cooling of the drilling mud and the in-situ vertical thermal conductivity was inferred by taking into account changes due to temperature, burial depth and anisotropy. Temperature data were corrected for the last Pleistocene glaciation, which has lasted over several ten thousand years and still affects the thermal regime to a few thousand meters.

Since the method chosen to determine the heat flow depends on the data quality and the precision required in the results, we utilized a technique based on the thermal resistance. High heat generation results in a decrease in heat flow with depth. Radioactive heat production was determined in the laboratory for a few rock samples. Moreover, as natural gamma-ray logs are available for a number of wells scattered in the basin, an empirical relation was used to convert logs into heat production. Heat

generation is lower in evaporites and carbonates, from low to medium in sandstones, higher in shale and siltstone. Calculations show that heat production should be taken into account in modeling the basin thermal evolution if the sediment layer is thick (>4 km) and if long time spans (>10 m.y.) are considered.

The heat flow is noticeably reduced when the rate and the duration of sedimentation are relatively high. As an initial condition, we assumed a horizontal depositional surface in thermal equilibrium with the underlying stratum of constant thermal properties. On the sea floor, sediment of the same conductivity is accumulated at a uniform rate. It turns out that for normal rates (of order to 0.001-0.01 mm/yr) the effect on the surface heat flow is negligible. With a Plio-Quaternary sedimentation rate as high as 0.1 mm/yr, the disturbance becomes significant in comparison with the measurement error.

Validation of the inferred surface heat flow was made by modeling the thermal state along a geological cross-section spanning from the buried thrusts of the Southern Alps to the Northern Apennines, through the undisturbed foredeep sector of the Po Basin. The model geometry and the petrophysical properties were based on depth-migrated seismic profiles and well information. A finite element approach was used to model the steady-state, purely conductive thermal regime. The measured heat flow is lower than the predicted one in correspondence of the Alps and Apennines buried thrusts. This can be accounted for by a still present transient thermal perturbation, which has been originated by thrusting and folding of the two orogenic belts. For estimating this effect, we use an overthrust model that combines friction heating along the thrust plane with the thermal effect due to relaxation of the thermal gradient. This model is valid if the solid state convection heat transport dominates conductive flow away from the thrust. If the thrust rate is relatively high (1-5 cm/yr) and the thrust sheets thick (>5 km), this process can yield an anomalously low heat flow.

GRAVITY SURVEYS FOR THE IDENTIFICATION OF THERMAL ANOMALIES A CASE HISTORY IN THE ARGENTERA MASSIF.

GUGLIEMMETTI Luca¹, COMINA Cesare¹, MANDRONE Giuseppe¹, ABDELFTAH Yassine², SCHILL Eva²

1 - Università degli Studi di Torino

Presenter e-mail: cesare.comina@unito.it

Key terms: Geothermal energy; Gravity methods; Geophysical exploration

The Argentera massif in Northern Italy provides an ideal site to investigate the potential of gravity measurements for geothermal resource assessment since the thermal anomalies reveal shallow surface manifestations such as hot springs. The geological and structural setting of the massif is, however, very complex and can be extrapolated to the subsurface only by structural investigations (Baietto, 2006) and geothermal potentiality could be addressed only by appropriate geochemical analysis to understand the circulation system (Guglielmetti, 2010). In this respect gravity data will be a fundamental aid in the comprehension of the geothermal system and in the location of the reservoir.

In this study, we will present the interpretation of a total of 384 gravity measurements collected during summer 2010 on the massif. One of the main goal of the campaign was to investigate the geological structures at depth in order to identify any natural gravity anomaly and figure out if it could be related to the circulation of hot waters or to the presence of a geothermal reservoir at depth.

From the geological point of view, the Argentera Massif, is the southernmost of the external crystalline massifs of the Alps. It is a pop-up structure cropping out owing both to its uplift and to the erosion of the Mesozoic sedimentary succession (Perello, 2001). The studied thermal springs are entirely located within the Malinvern Argentera Complex, which rocks, mainly constituted of quartz, K-feldspar, plagioclase, biotite, are highly milonitized and, as a result, the reservoir rock contains numerous microfractures (Michard, 1989). The structural setting of the Argentera Massif is the result brittle reactivation of pre-Alpine and early-Alpine ductile shear zones. A main NW-SE shear zone, the Valletta Shear Zone, crosscuts the massif dividing the two complexes and runs parallel to the corridor of the Bersezio Fault, a wide zone of fracturing and pervasive cataclases composed by several faults trending 150° and consisting of fractured protholith rocks, fault breccias, cataclases and gouges. In the central part of the massif, the Bersezio Fault connects to the Fremamorta Shear Zone, an E-W oriented milonitic corridor with a reverse sense of shear.

The gravity campaign was planned to cover as much as possible the Italian side of the Argentera Massif. Measures were carried out every 250m and high precision positions were collected using DGPS. Because of the highly mountainous region gravity data were collected both along trails and paved roads following the main valleys. Forward modeling and Inversion methods were applied on geological cross sections extracted from a preliminary 3D geological model. In particular two profiles crossing to the thermal areas locations have been studied. Gravity data inversions along these profiles have shown a very good fit with experimental data and are able to map with depth the faults superficially observed. Moreover the evidence of strong density anomalies near the hot spring locations has been observed.

Further studies are however suggested to collect gravity data also on the French side of the Argentera Massif increasing the density of the measuring stations; gravity results could moreover benefit from magnetotelluric measurements that could be carried out in some selected areas to highlight the resistivity anomalies at depth and compare them to the density distribution variations showed by gravity. A geomechanical study should be carried out to better understand the fracturation conditions of the cataclastic belts and fault zones to come out with more detailed 3D models that could be a useful tool to simulate thermal waters circulation and identify the presence of geothermal reservoirs that could be exploited for heat production and even power generation.

Key terms: Geophysical exploration; Magnetotellurics; Gravity; Geothermal field

A major problem in understanding the hydrothermal properties of geothermal reservoirs is to provide images of the subsurface structures, which can host geothermal fluids by means of appropriate geophysical techniques. Electrical resistivity/conductivity is a primary physical property strongly controlled by the hydrothermal processes occurring in geothermal reservoirs. Resistivity can be used to infer open fracture systems and horizons of increased permeability and filled with fluids, as well as high conductivity alteration minerals (clays, etc.) of hydrothermal origin. Aimed at the reconstruction of the subsurface and structural setting together with the identification of horizons, which could host geothermal reservoirs, this paper presents the results of a series of magnetotelluric and time domain electromagnetic soundings has been carried out, together with gravity measurements, in a geothermal area located in West Java (Indonesia).

Geochemical and thermal features at two sites located in this area, show different characters. The north-east site discharges fluids coming from a reservoir typical of volcanic-magmatic association, with temperatures ranging from 180-200 °C. Rainwater feeds the deep aquifer and the recharge area could be in principle situated not too far from the discharge site. The fluids discharged at the south-west zone are hosted in a geothermal reservoir with temperatures ranging from 140 to 160 °C. Rainwater feeds also this reservoir, which should be hosted in granitoid rocks.

Magnetotelluric survey has revealed significant differences in resistivity structure between these two geothermal zones. In the SW area, the conductive layer (clay cap) is rather discontinuous and shallow. The resistivity maintains relatively moderate, with values of 10-50 ohm m, to depth of about 2000 m below the surface. This agrees with a moderate alteration to large depth due to flow of fluid with relatively low temperatures. A possible explanation of this geoelectric setting is groundwater flow through discrete fractures zones scattered within a basement. The thermal manifestations might occur through a major fracture zone. The NE area presents a well discernible and thick (up to 500 m) conductive layer (<10 ohm m), interpretable as a cap rock. This layer is present next to the hot springs area and around it. Beneath the conductive layer, the resistivity increases with depth more rapidly than in the SW area. At depth of 1000-1500 m below the surface, resistivity shows average values larger than 50-100 ohm m. This resistivity pattern supports a hydraulic model through a diffuse flow of thermal groundwater. Sudden lateral changes in resistivity in correspondence of a valley in the NE site, support the presence of a near vertical fault, which might control the groundwater upflow. The Bouguer gravity anomaly is of relatively small magnitude, so that the presence of buried high-density bodies, which could act as heat sources for the hydrothermal systems, has to be excluded. The main positive anomaly, observed at the SW edge of the investigated area, could be related to an intrusive granodioritic body, also encountered by drilling, and the associated volcanic rocks cropping out, and it may reflect the border of an uplifted structure. In the above-mentioned NE site valley, the gravity map puts into evidence the possible presence of a fault roughly NNE/SSW directed.

In synthesis, the different resistivity structure between the two areas argues that the two main geothermal sites belong to geothermal systems which are hydraulically and thermally distinct. Also in relation to the reservoir temperatures estimated with geothermometers, the resistivity pattern appears more promising at and around the NE thermal area.

SPATIALLY CONSTRAINED INVERSION OF 3D MAGNETO TELLURIC DATA FOR GEOTHERMAL RESOURCE ASSESSMENT: THE TRAVALE CASE HISTORY.

STOCCO Stefano¹, COMINA Cesare², MANZELLA Adele³

1 - GAMUT SRL

2 - UNIVERSITA' DEGLI STUDI DI TORINO

3 - CNR-IGG

Presenter e-mail: stocco@gamutgeophysics.com

Key terms: magneto-telluric; geothermal resource; inversion; constraint; 3D model

The use of Magneto Telluric (MT) data for geothermal resource assessment is widely documented in scientific literature (Simpson and Bahr, 2005) because of its versatility, the significant depth of investigation that could be obtained and the potential relationships between the reconstructed electrical resistivity and the thermal properties of the fluids saturating the rock mass. However, MT data inversion approaches are often limited to the reconstruction of 3D structures from one-dimensional inversions of single investigation points or two-dimensional sections along a profile (Aragno et al., 2009; Strack et al., 2008; Azeez and Harinarayana, 2007; Newman et al., 2005).

In this paper, to overcome these limitations, an algorithm for the interpretation of 3D MT data based on a spatially constrained inversion process is proposed. The core of the algorithm consists in a least-squares inversion process in which all the MT sounding points are inverted globally for a complete representation of the investigated area. In this way a unique misfit function is used representing the whole dataset. Each MT sounding is inverted in terms of a one-dimensional resistivity profile but is linked to the closer profiles with appropriate spatial constraints. The structure of the algorithm has been developed on the basis of many similar literature works using analogous approaches for the interpretation of other geophysical data. In particular, the laterally constrained inversion (LCI) algorithm originally presented by Auken and Christiansen (2004) for the interpretation of resistivity data, which was successfully applied to the inversion of surface wave data (Socco et al., 2006). The spatial constraints can be considered as a priori information based on the geological variability of the investigated area: the smaller the expected variation of the model parameters, the more rigid will be the used constraints. In this way it is possible to obtain a subsoil model more or less regularized according to the intensity of the chosen constraints. A priori information on the geology of the site, deriving, for example, by other geophysical surveys or local drillings, could be moreover incorporated in the inversion process allowing for a more reliable model of the area.

An application to a real dataset of the spatially constrained inversion algorithm will be therefore presented to underlining the potentialities of the selected approach. In particular data from an extensive MT survey (a total of 55 soundings) carried out in the geothermal system of Travale

(Tuscany, Italy) will be presented. This last geothermal system is located at the eastern margin of a wide and homogeneous geothermal area, which include the Larderello site, in central Italy. The geological and structural setting of the Travale area involves, below a cover made of neogenic sediments and flysch facies formations, carbonate-anhydrite rocks of the Tuscan Nappe and the Metamorphic Basement. In the lower part of the metamorphic basement, contact metamorphic rocks (Skarn and Hornfels) are often met and represent the contact metamorphic aureole overlying granite intrusions. This aureole exhibits increased permeability due to the presence of fractures and is seismically characterized as a high amplitude seismic reflector (H Marker), that can constitute the potential target for deep wells (Bertini et al., 2006). The main geothermal reservoir is located in metamorphic, thermo-metamorphic and magmatic rocks up to 4000 m depth, characterized by a high degree of heterogeneity and anisotropy. The exploited fluid is superheated steam with temperature ranging up to 350 °C and pressure values around 6-7 MPa at production depth (about 3000 m). The spatially constrained inversion of MT data at this site has shed new light on the possibility of spatially describing the reservoir.

CONTRIBUTION OF FLUID INCLUSION STUDIES TO GEOTHERMAL RESEARCHES

RUGGIERI Giovanni¹
1 - IGG-CNR

Presenter e-mail: ruggieri@igg.cnr.it

Key terms: fluid inclusions; geothermal fields; Larderello (Italy); Berlin (El Salvador); Tendhau (Ethiopia)

Quantitative estimates of the physical-chemical conditions in active geothermal fields and their temporal evolution are of great importance for an optimal exploitation of geothermal resources. Much of the information on geothermal reservoirs characteristics comes from direct in-hole measurements, core samples and geochemical data on the reservoir fluids. Additional, and sometimes unique, information on the reservoir fluids can be obtained from studies of the fluid inclusions trapped within minerals formed during geothermal activity. As fluid inclusions record very local fluid circulation conditions, they represent the fluids present in well-defined zones of the geothermal reservoir. They are, moreover, the only direct evidence of the fluids that have circulated at different times through the reservoir rocks. The study of fluid inclusions, therefore, can provide important information on the local characteristics of the reservoir and on the time-space evolution of its geothermal fluids. The studies carried out on fluid inclusions in the last three decades by researchers of the International Institute for Geothermal Researches of CNR (Institute for Geosciences and Earth Resources (IGG-CNR) from 2002) have yielded important data on the fluids that have circulated in the geothermal fields of Southern Tuscany (Larderello-Travale-Montieri and Mt. Amiata), Ethiopia (Langano and Tendhau) and El Salvador (Berlin, Auachapan, Tortughero). These data provide useful information for both the evaluation of geothermal resources and in the geothermal exploration. For example, concerning the Larderello-Travale geothermal system, data on fluid inclusions trapped in samples from the deepest areas of the system (>2500 m below the ground level) provide information on physical-chemical nature of the fluids (i.e. aqueous-carbonic fluids at supra-hydrostatic pressure) that might be encountered by any drilling reaching the "K" seismic horizon. At Mt. Amiata, fluid inclusions trapped in deep samples of the Bagnore area show that the past geothermal fluids were enriched in CO₂ with respect to present-day fluids and that boiling processes depleted the CO₂ in the fluid. In the case of the Berlin geothermal field (El Salvador) fluid inclusion temperature data indicate a marked cooling process in the southern part of the field and confirm that the recorded temperature inversion in the deepest areas reached by the geothermal wells was not induced by geothermal drillings but it is a natural feature of this part of the system. Finally, studies on fluid inclusions of the Tendhau geothermal field instead showed different thermal histories (cooling, heating or substantial thermal equilibrium) depending on the location of the geothermal wells and on the sample depth.

GEOTHERMAL RESOURCE ASSESSMENT OF SOUTHERN ITALY, THE "VIGOR" AND "ATLANTE GEOTERMICO" CNR PROJECTS

MANZELLA Adele¹, MONTANARI Domenico¹
1 - CNR-IGG

Presenter e-mail: a.manzella@igg.cnr.it

Key terms: geothermal exploration; geothermal potential; atlas; assessment

A part of the session "D-9 Energia geotermica per lo sviluppo sostenibile: esplorazione e caratterizzazione delle risorse" is dedicated to the discussion of the preliminary results of the VIGOR and "Atlante Geotermico" projects carried out by the CNR. The project "Atlante geotermico", within the framework of the "Progetti Mezzogiorno" of CNR, represents a first level of geothermal data systematization, that will verify and locate conventional as well as unconventional geothermal resources for the regions of Southern Italy. The Southern Italy Geothermal Atlas, with a comparable format to that produced in the USA and prepared in other European countries, aims to provide the updating of the available information related to hydrothermal systems, including also the organization of different kind of information, which are the key point to produce an assessment of the geothermal resource, as well as the identification of the new types of resources, constituting a major opportunity to harness new sources of sustainable energy. At the same time, and starting from the results arisen from the Atlante Geotermico, the evaluation of the geothermal potential of Regions of Convergence -Campania, Puglia, Calabria, Sicilia- will be performed in the frame of the VIGOR Project. The VIGOR project was activated by the operative agreement between the MISE DGENRE (Directorate General for Nuclear Energy, Renewable Energy and Energy Efficiency) and the CNR DTA (National Research Council of Italy, Department of Earth and Environment) under the line of activity 1.4 of POI "Renewable Energy and Energy Conservation 2007-2013". The project marks an important step towards the broader goal of POI "Renewable Energy and Energy Conservation 2007-2013" to "Increase the proportion of energy produced by renewable sources and improving energy efficiency, fostering opportunities for local development".

These CNR Projects aim to provide analytical information useful to engage in exploration and exploitation for both high and low temperature resources, to broaden the knowledge of the natural potential and the real possibility of exploitation of geothermal resources in the Regions of Southern Italy. In these areas, the amount of energy produced from this sources is irrelevant today, despite the interesting perspectives, assessed in relation to new ways of widespread use of geothermal energy, with innovative technologies capable of triggering a thermal cycle even with small temperature differences. A main goal of the projects is also to provide the Ministry of Economic Development - DGENRE with feasibility studies to be used for the formulation of specific calls. This presentation will discuss in detail the characteristics of the projects and give the status of the ongoing activities.

Key terms: GEOEXCHANGE POTENTIAL; GIS MAPPING; GSHP; RENEWABLE ENERGY; SOUTH ITALY

The increasing interest in the direct utilization of shallow geothermal energy comes with the wish for better knowledge about the factors influencing its efficiency.

The project VIGOR (Evaluation of geothermal potential of Convergence Regions) aims to provide useful analytical information to initiate exploration and use of energy from geothermal sources, through the creation of a detailed reconnaissance operations, analysis and case studies to systematize and expand the knowledge of the natural potential and the potential for exploitation of geothermal resources in the territory of Campania, Calabria, Puglia and Sicily (Convergence regions).

The project is voted to extension and systematization of existing knowledge, it will produce all the necessary elements of knowledge (technical and economic feasibility) to carry out executive plans to use geothermal resources in the regions cited even for space conditioning and in other uses in the industrial, power production, agro-tourism and spa. It will also be taken care of the promotion of geothermal resources and its use and disclosure in order to develop an awareness of the population and develop the socio-economic and productive territories.

For this purposes we focused on the subsurface condition's influence on the use of borehole heat exchangers (BHEs) coupled with a heat pump for heating purposes, since this is the most popular heat-extracting technique. We created maps showing the potential for this technique provided by the thermal underground properties. Therefore, we established an underground model for two study areas in south-Italy (Puglia and Calabria) with different geological settings, by using a geographic information system (GIS). The subsurface has been divided into layers with similar thermal properties based on geological, hydrogeological and lithological information, in according to international existing properties database. For depths of 100 m, the weighted mean value of the specific thermal features were calculated and presented within maps. These maps point out how the heat exchange potential differs within and between the study areas and how it depends on local geological assessment.

Key terms: Geothermics; Campania; 3D Models

Within the framework of the VIGOR project, a characterization of medium enthalpy geothermal resources have been carried out in the Campania region (Southern Italy), with a focus on of "Guardia dei Lombardi" area (province of Avellino).

The VIGOR project has been developed based on an agreement between the Italian Ministry of Economic Development and the National Research Council, for the realization of innovative uses of geothermal sources in the so-called "regions of convergence" (Campania, Calabria, Puglia and Sicilia).

Thanks to the intense hydrocarbon exploration, carried out particularly during the 1956-1996 period, an extensive dataset made up by deep wells and seismic reflection profiles exists in the study area. The previous exploration demonstrated the presence of a fractured carbonate reservoir, mainly belonging to the Cretaceous section of the Apulian shallow water carbonate platform, which is deformed to shape a buried antiformal stack. The culmination of the uppermost thrust unit reaches a depth of about 200 m below sea level (i.e., about 1100 m below the ground level). The reservoir fluids are made up by a CO₂ gas cap, which rests above an accumulation of fresh water in the central and upper part of the culmination (e.g., Monte Forcuso 1 and 2 wells) and on salt water along the flank of the buried anticline (e.g., Bonito 1 Dir, Ciccone 1 wells). Medium enthalpy geothermal resources with a reservoir fluid up to 100°C have been estimated at depth of 2000 m below ground level by ENEL in previous assessments.

However, the presence of thermal springs (e.g. Terme di S. Teodoro) in the area suggest the presence of an active hydraulic circuit and provide further constraints about the geochemical characteristics of the reservoir waters and geothermometers which confirm a reservoir fluid temperature up to about 124 °C.

In this study, the overall reservoir/caprock system structural-stratigraphic setting has been defined based on the integrated interpretation of surface geology, public and available seismic reflection profiles, and composite well logs. In particular, a careful assessment of temperature field at depth has been carried out analyzing well logs through Horner plot construction. Where the data were scarce, a simplified approach has been applied. Moreover, based on well tests, cores and losses/absorptions the reservoir permeability was also re-estimated, confirming quite good permeability value for the fractured carbonate reservoir.

One of the main results of this research is the development of an integrated 3D geological model which provides the base for a detailed assessment of the possible geothermal exploitation of the carbonate reservoir. The preliminary results of our analysis suggest that the "Guardia dei Lombardi" site can be indicated as an interesting area for the geothermal medium enthalpy exploitation, although the presence of the CO₂ gas cap should be carefully evaluated.

Presenter e-mail: delia.bruno@ba.irsra.cnr.it

Key terms: environmental regulations; geological survey; aquifer; map; hydrothermal

Today, in the "Convergence Regions" (Puglia, Campania, Calabria, Sicilia) the amount of energy produced by geothermal resources is still negligible, despite the exciting opportunities to exploit even in the less significant geothermal potential areas, with considerable economy for the air-conditioned and the hot-water production. The "Vigor: evaluation of geothermal potential" project was started as from October 2010 with 24 months of life. The project's objectives are related to examination, identification and dissemination of all scientific and technical informations concerning the evaluation of geothermal potential in the Convergence Regions. Moreover, it aims to promote the optimum conditions in terms of regulations and administrative practices.

In fact, one of its objectives is to support the balanced development of the environmental compartment, preventing deficiencies and asymmetries with particular reference to other renewable resources affected by an initial legislation's delay. Therefore one of the activities is the informations collection of the bureaucratic procedures related to exploration and exploitation of geothermal resources in the four regions. Currently, while the plants for electric energy by renewable resources receive constant attention by the legislature, the geothermal potential exploitation is indirectly treated only. So, this research with connected applications, from the legal point of view, could incur into bureaucratic obstacles avoiding difficulties of interpretation.

Hence, the first step for these activities involved a review of existing regulations, through the drafting of a questionnaire submitted to the Regions offices. The evidences examination for the best regulative practices at national and international levels, with the informations described and discussed in the context analysis, will make certain assumptions of guidelines, protocols and authorizations of regulative instruments. The normatives uniformity will be evaluated and discussed with the scientific support of all researchers involved in VIGOR.

Presenter e-mail: maria.caputo@ba.irsra.cnr.it

Key terms: hydrological characterization; geothermal resource; low enthalpy

The interest in low enthalpy geothermal energy is growing in Italy in last years because the geothermal energy represents an important resource among the different kinds of green energies. However the exploitation of the geothermal resources concerns many issues related its environmental sustainability.

Particularly, the matter involves the open loop geothermal systems because of their direct use of groundwater. In the coastal areas, generally characterized by shallow aquifer, the installation of the geothermal systems is considered economically convenient because it doesn't need deep boreholes. Despite this positive aspect there are others negative ones also. Often these areas are affected by seawater intrusion and for this reason; the use of the coastal aquifer is ruled by restrictive laws aimed to protect the groundwater quality and quantity. This is a major problem for geothermal resources development, particularly in regions characterized for most of their territory from coasts. However, as the most of the population, the most important touristic destinations and the larger industrial sites are concentrated along the coast, the exploitation of geothermal resource in these areas is becoming more and more of interest.

This work deals with a hydrogeological characterization by means field tests and experimental measurements carried out in a coastal karst area of Apulia Region, located about 2 km far from the sea. Specifically, the study area extends for about 20 Km² and has been chosen within the VIGOR project as pilot site to study the influence of an open loop geothermal systems, on the sea water intrusion.

In the study area different tests, such as pumping tests, have been carried out in different times in order to determine the aquifer transmissivity; a wells monitoring network has been defined to monitor the depth and the hydraulic gradient of groundwater and its salinity and temperature.

All the data (geological, hydrogeological, geochemical and geophysical) and information collected during the exploration phase, allowed a detailed characterization of the fissured-karst aquifer.

The experimental approach utilized for this study represents a good effort to define a standard methodology, for hydraulic characterization of a coastal site, usefull for a feasibility study of an open loop geothermal system.

Key terms: Campania Region; Geothermal Exploration; Geothermal Resource Assessment

An organic organization and implementation of the available geothermal data in the southern Italian Regions (Campania, Calabria, Puglia and Sicily) useful to improve the exploration and exploitation of geothermal reservoirs, is the aim of the CNR project "Evaluation of Geothermal Potential in Convergence Regions" (VIGOR), financed by the Inter-Regional Operational Programme "Renewable Energy and Energy Conservation" POI 2007-2013.

In the Mondragone area hydrothermal evidences has been known since roman time, and this area has been chosen to further improve geothermal knowledge through new geophysical and geological exploration survey. From the geological point of view, the area is defined by an horst structure (Mt. Massico) elongate in NE-SW direction, characterized by a succession of Triassic-Cretaceous dolomitic limestone and Miocene terrigenous sediments. The Quaternary deposits are widespread in the adjacent plains , where the continental and marine sediments, interbedded with Roccamonfina and Campi Flegrei pyroclastic deposits, filling the Garigliano, to NW, and Volturno, to SE, graben, separated by the Mt. Massico horst through a NE-SW striking normal faults (Bergomi et al., 1969).

Field and seismic data indicate the study area is interested by deep normal NE-SW and N-S striking faults, although ESE-WNW to E-W strike-slip left-lateral faults are also present (Billi et al., 1997; Bruno et al., 2000). Probably these structural pattern plays an important role for the Mt. Massico groundwater circulation, partially confining such structure from the less permeable deposits of plains, and allowing the groundwater to flow primarily to the aquifer of the Garigliano plain (Allocca et al., 2005).

At the southeastern edge of the massif four sulfur hot springs with temperatures between 22°C and 50°C emerge. In particular two hot springs, ("La Calda" and "Della Salute", up to 50°C and 29°C respectively) are located at the foothill of the Miocene terrigenous succession of Mt. Pizzuto, closely to the coast (Bergomi et al., 1969, Corniello, 1988). While the other two ("S. Giuseppe" and "Mt. Petriolo solforosa" up to 22°C and 28°C respectively) are located at the foothill of the Mt. Petriolo carbonatic structure (Trumpy & Manzella, 2009).

According to some authors, the hot springs are fed by groundwater carbonate aquifer, where the water is heated and enriched of endogenous gas (CO₂, H₂S), rising along the extensive and deep tectonic discontinuity present, further testified by the morphological evidenced (sinkholes) found all along the southeastern edge of the Mt. Massico (Del Prete et al., 2004). Moreover the different temperatures and degrees of mineralization of the four springs are interpreted as closely linked to the rising speed and water-rock contact time (Corniello, 1988; Allocca et al., 2005).

A delimited area of 20 km² south-east of Mt. Massico has been chosen to be studied by means of geological and geophysical surveys and deep drilling to provide analytical information useful to develop an hydrogeological 3D model that will allows the application of technologies for direct exploitation of heat from geothermal source.

THE GEOTHERMAL POTENTIAL OF CAMPANIA VOLCANOES.

CARLINO Stefano¹, SOMMA Renato¹, TROISE Claudia¹, DE NATALE Giuseppe¹

1 - Istituto Nazionale di Geofisica e Vulcanologia - Osservatorio Vesuviano

Presenter e-mail: stefano.carlino@ov.ingv.it

Key terms: Geothermics; Volcanoes; Campi Flegrei; Ischia

Since 1939, many drilling finalized to the exploitation of the geothermal energy, were performed in volcanic district of Campania (Campi Flegrei, Ischia and Vesuvius), by SAFEN Company and subsequently, until 1985, by AGIP-ENEL joint venture. The attention to the geothermal energy exploration in Southern Italy was drawn by either the consolidate energy production of Larderello geothermal field (Tuscany) and by the oil crisis during the mid seventies. The results of the drilling were particularly interesting at Campi Flegrei and Ischia, where the high temperature (> 150°C) recorded at shallow depth (500 to 2000 m) and the occurrence of vigorous hot hydrothermal circulation, highlighted the possibility of geothermal exploitation also in the high enthalpy range. The project was abandoned at the end of 1970, probably due to technical problems related to the extraction of high salinity geothermal fluids, but also because the Italian Government preferred to comply with the oil economy. Nowadays, the advanced technology of geothermal plants (i.e. binary system) allows the solving of problems related to such harsh conditions.

The data obtained by drilling (down to 3 km of depth) and investigation between 1939 and 1985 allowed us to asses, by using the volume method, the geothermal resource for Campi Flegrei and Ischia, which correspond to a potential energy of about 6 and 11 GWy respectively. Such high values, together with the nowadays strong oil cost fluctuation and green energy policies, point out the needs to better define the actual possibility of geothermal exploitation in Campania volcanic district. In recent times, an important project (Campi Flegrei Deep Drilling Project, CFDDP) endorsed by the International Continental Drilling Program, is aimed to the understanding of the Campi Flegrei caldera dynamic and evaluate of the extractable geothermal resource, by two drillings located in the eastern sector of the caldera, the first (pilot hole) 500 m depth and

the second 3.5 km depth. The CFDDP will greatly improve scientific information of the eruptive history of the Campi Flegrei caldera, and knowledge of the related geothermal system. Thus, the project will represent a new starting point for the exploitation of geothermal resource in Southern Italy, where many areas are characterised by the presence of deep to shallow magma bodies, with high geothermal potential.

GEO.POWER: A PROJECT TO MANAGE THE GROWING DEMAND OF LOW-ENTHALPY GEOTHERMAL EXPLOITATION

GIAMBASTIANI Beatrice Maria Sole¹, MASTROCCICCO Micòl¹
1 - Earth Sciences Department, University of Ferrara

Presenter e-mail: gmbbrcc@unife.it

Key terms: Geothermal Energy; Renewable Energy Source; Ground-Coupled Heat Pump; Best Practice; Transferability

The European Union is committed to reducing its own greenhouse gas emissions by at least 20% by 2020 (compared with 1990 levels) by improving the use of renewable energy and decreasing energy consumption. Thus, the Commission in the Renewable Energy Road Map encourages the Member States and their local authorities to implement concrete measures within regional operational programmes in order to improve the yield of energy production and distribution, to facilitate investments in the green sector, and to encourage rational energy consumption behaviour.

Geothermal energy is one of the most environmental-friendly and cost-effective energy resources in use. Recent technological progress, cost variability, and the need to reduce the use of fossil fuels to cut pollution have made the exploitation of geothermal energy, especially low-enthalpy power generation utilizing Ground-Coupled Heat Pumps (GCHP), a feasible alternative. In this context, the GEO.POWER partners developed a project on geothermal energy, under the INTERREG IVC Programme, to fill their legislation gaps and in that way actively contribute to the EU "20-20-20" objective.

The general objective of the 2 year GEO.POWER project ("Geothermal energy to address energy performance strategies in residential and industrial buildings" <http://geopower-i4c.eu/>) is exchange best practices (BPs) related to low enthalpy energy supply and - after a technical and cost/benefit assessment to evaluate the potential of reproducibility - to prepare the ground to the transfer some of the selected best practices within the Mainstreaming Programmes of the regions participating into the project.

The partnership, coordinated by the Province of Ferrara (Italy) is composed by Ministries, Regions, Local Authorities, Universities of 9 Countries (Bulgaria, Hungary, Greece, Italy, Sweden, Estonia, Slovenia, United Kingdom and Belgium).

The project is basically divided in three phases:

° Phase 1 (January-May 2011) regards a review of the BPs achieved within GCHP sector and their possible application for the sustainable heating/cooling technology. Expertises are shared and exchanged within the partners and local deep delegations (composed by energy managers, technicians, stakeholders, urban planners, etc.) through the preparation of benchmarking reports and workshops.

° Phase 2 (July-December 2011) is based on an assessment for the reproducibility of the selected BPs in each recipient region. In this phase all partners go through a local technical analysis to estimate the weakness and potentialities for the application/adaptation of the identified GCHP practises in their own areas. This phase is addressed to design the optimum performance conditions for GCHP systems in terms of technical, economical and environmental point of view.

° Phase 3 (January-June 2012) consists in the elaboration of an action plan for each involved region to support policymakers' commitment. The action plan paves the way towards the transferability of the (adapted) BPs into the Mainstreaming Programmes and energy regulations plans. The main results of the project are the development of one action plan per each involved region, that provides an organized set of legal/regulatory, economical, and technical proposals. These proposals will include the regional operation programmes and address long-term investments strategy for GCHP application at wide scale. The project is still ongoing but preliminary results are now available (<http://geopower-i4c.eu/index.php?page=bpview>) consisting in a selection of best practices. Out of the 31 BPs initially screened, 12 BPs have been selected (4 in the public, 4 in the industry, 3 in private and 1 in the agriculture sector) according to the following criteria: field of application; type of systems; different hydrogeological setting; type of building; efficiency parameters; quality of the monitoring scheme; integration with other RES; benefits and level of supposed transferability.

Key terms: Geothermal energy; Geothermal heat exchanger; Hydrogeological properties

The correct design and performance of geothermal heat exchanger coupled with heat pump systems requires knowledge of the thermal properties of the subsurface rocks where the geology and especially the hydrogeology, play an important role. The accurate prediction of transient ground heat transfer is the key to establish the required borehole length and to determine the resulting fluid temperature. Moreover a correct dimensioning of geothermal heat exchanger system is essential for ensuring the sustainability of this technology.

The ground thermal properties can be measured in situ with a thermal response tests (TRT) where a heat transfer fluid flowing in a ground heat exchanger is heated and the resulting temperature perturbation is monitored. This method is largely approved in different countries for to determinate the thermal conductivity and the thermal resistance of the

whole borehole.

The vertical ground thermal property variations inside the borehole during a TRT and the resulting cooling after the test, allows correlating the subsurface thermal conductivity with stratigraphy. The logs of the evolution of the temperature recovery, combined with the hydrogeological data permit to discriminate the thermal exchange of each discrete layers. This methodology permits to obtain a distribute vertical thermal conductivity and thermal resistance of the subsol and provide an useful tool for a correct dimensioning of boreholes number, depth, spacing and geometrical arrays, take in account the entire heating and cooling seasonal cycle of the system.

EVALUATION OF THERMAL DISTURBANCE IN SHALLOW AQUIFER INDUCED BY OPEN-LOOP GEOTHERMAL PLANTS

STRINGARI Marco¹, DE LUCA Domenico Antonio¹

1 - Dipartimento di Scienze della Terra - Università degli Studi di Torino

Presenter e-mail: marco.stringari@unito.it

Key terms: Open-loop geothermal plants; Thermal alteration; Numerical model

Among the various systems of heat exchange with the subsurface it is possible to directly take the heat stored in the groundwater through the use of open-loop geothermal systems. The water is pumped to the surface through one or more wells and then it is generally pumped back into the groundwater (heated or cooled by the plant) through other wells.

The study of the thermal plume generated by the injection of heated or cooled water in the aquifer is very important. The study of propagation of the plume allows to assess the sustainability of the system in terms of heat and it avoids the possible influence / interference with existing plants and the involvement of sensitive areas such as wells for drinking water and rivers.

The thermal characteristics of the aquifer and the re-injection water temperature determine the intensity of the induced thermal disturbance. Hydrogeological characteristics of the area determine the extent of the thermal plume.

An aquifer is composed of a porous media, that is a solid matrix with interstitial spaces and water. The main hydro-geological characteristics that determine the groundwater flow (and the thermal propagation) are the hydraulic conductivity, the specific yield, the hydraulic gradient and the longitudinal dispersivity.

The finite-difference groundwater flow and transport code SEAWAT was used to realize numerical models, representing thermal plumes in typical hydrogeological conditions of Piemonte region. Specifically, the thermal effect caused by the re-injection of hot/cool water in the shallow aquifer was simulated.

SEAWAT is a MODFLOW/MT3DMS-based code designed to simulate three-dimensional variable-density groundwater flow coupled with multi-species solute and heat transport.

The simulations were made varying pumping rates in contexts characterized by different hydrogeological parameters. For each parametric variation was carried out a simulation and the possible propagation of the thermal plume was identified. The range of used hydrogeological parameters are typical of the aquifers of the Po river plain (Pianura Padana) and especially of the Piemonte plain.

The simulations were carried out in permanent regime, assuming either a continuous or intermittent operation of the system, in eating and cooling mode.

The choice of the " ΔT " parameter (the difference between the extraction and re-injection temperature from the groundwater) was based on temperature differences commonly founded in real plants, about 5 °C.

The natural temperatures of shallow aquifer are fairly constant during the year and they generally are between 13 and 16 °C in most of Piemonte plain. Seasonal variations usually oscillate around 1 °C. Since the goal of the survey was not the study of absolute temperature of the thermal plume, but the thermal variations in the aquifer, the undisturbed temperature in the simulations was considered constant and equal to an average value of 14,5 °C.

Comparing the different thermal plumes, it was possible to identify how different hydrogeological characteristics of an aquifer contribute to the expansion of the thermal plume.

For example it resulted that, under the same hydrogeological characteristics, the extent and intensity of the thermal plume increased significantly with increasing pumping rates of re-injection into groundwater. Dividing the same pumping rate between adjacent wells, the extent of the single plume decreases, but the thermal effects of individual wells may be combined with each other.

At constant pumping rates, the temperature changes and lateral extent of the plume are larger the lower the rate of groundwater flow. In the case of intermittent operation of the system, the time required for the disappearance of the plume is also inversely proportional to the groundwater flow.

PROCESSING OF THERMAL RESPONSE TESTS AND UNDERGROUND TEMPERATURE DATA IN BOREHOLE HEAT EXCHANGERS

VERDOYA Massimo¹, ORSI Marco¹, CHIOZZI Paolo¹, FERRETTI Gabriele¹

1 - Dipartimento Territorio e Risorse - Univ. di Genova

Presenter e-mail: verdoya@diptieris.unige.it

Key terms: Geothermal energy; low enthalpy; thermal conductivity

The use of geothermal heat pumps (GHPs) has been rapidly spreading in many countries, as a clean and efficient system for heating and cooling commercial and residential buildings. A typical GHP system mainly consists of a conventional heat pump unit coupled with a group of drillholes, which act as heat exchangers (BHEs). The thermal power that can be extracted with a BHE is site-specific and depends mainly on the thermal properties of the underground, and in particular, on the thermal conductivity. Laboratory measurements on thermophysical properties can be unfeasible as core samples are often unavailable in commercial holes. Thus, an in situ thermal response test (TRT) is carried out as an alternative investigation to obtain the actual heat-transfer performance between the underground and a BHE, as well as the ground thermal properties.

TRT experiment records the inlet and outlet temperature of a closed loop in a ready-to-operate BHE due to constant heating or cooling by the fluid

circulation. The change of outlet fluid temperature is directly related to thermal properties of the bulk rock surrounding the hole. Compared to lab determinations, the advantage offered by TRTs is that the underground thermal properties are integrated over the entire length of BHE, including groundwater and backfilling material. This provides the so-called "effective" thermal conductivity, which in some cases can be unrealistic for dimensioning purposes, especially in advection-dominated areas. We recently built a new TRT apparatus and performed some tests at selected sites in order to verify its performances under operating conditions. Our TRT apparatus is reversible, thus allowing both heat extraction and injection. Another peculiar feature is the automatic control of power supply. TRT records were performed in combination with conventional thermal logs aimed at the reconstruction of the undisturbed thermal profile prior to TRT and the analysis of the possible presence of groundwater movements.

The thermal test was carried out in "double U" BHEs, with hole diameter of 146 mm, drilled within alternating layers of silty sand and clay to about 100 m depth. The total test time was 72 hours. By processing the recorded temperatures versus time according to the infinite line source theory, an estimation of the effective thermal conductivity in the vicinity of the BHE was obtained.

The thermal properties results can be biased by different sources of errors. A preliminary analysis of the TRT time series showed that data are affected by well visible fluctuations. A first attempt to smooth these fluctuations was made by filtering the recorded signal with an exponential function which fits the temperature data. Then, TRT time series were further processed for their spectral characterization and denoising. A standard Fourier analysis allowed the recognition of a harmonic contribution with period of about twelve hours that can be ascribed to the daily air temperature change. In order to characterize the nature of the harmonic component, the thermal signal was filtered and compared with the data of air temperature change recorded at the test site, by analyzing the cross-correlation function and by estimating the coherency and the phase delay (through the cross-spectrum). The recorded data were then filtered to remove the disturbing spectral components associated to a non-optimal thermostatic behavior of the apparatus.

Finally, in order to investigate the advective heat transfer around the test site we applied some analytical thermal methods for inferring Darcy velocity from temperature-depth logs recorded prior to TRT. The analysis consisted in matching temperature and thermal gradient data with theoretical curves describing horizontal and vertical heat and water flow.

GEOLOGICAL-GEOPHYSICAL SURVEYS FOR THE ASSESSMENT OF A GEOEXCHANGE SYSTEM IN NORTH-WESTERN ITALY

BONETTO Sabrina¹; COMINA Cesare¹; DE LUCA Domenico Antonio¹; STRINGARI Marco¹

1 - Università degli Studi di Torino

Presenter e-mail: sabrina.bonetto@unito.it

Key terms: geothermal system; energy efficiency; geological survey

The present study focus on ground-side properties definition in an area of 7,000 square meters where a boreholes heat exchanger (BHE) system has to be designed for air conditioning and hot water production in the context of new residential buildings in the city of Tarvisio (Friuli Venezia Giulia, NW Italy). The study has been financed by the SATEA Society. Energy efficiency, environment cleanliness and economy of BHE systems are strictly related to the design and construction quality. In particular a proper knowledge of the local geology is essential for a correct dimensioning of the BHE system. Indeed the geological condition and the consequent plant dimensioning are site-specific, therefore in situ measurement and geological surveys are strictly necessary for its correct design. The larger is the system, the more is to gain on a proper estimation of the ground thermal conductivity and the temperature loss between the heat carrying fluid and the ground. In this context an underestimation of the BHE system will both reduce the efficiency and result in a progressive thermal depauperation of the ground, whereas its overestimation causes excessive and unnecessary costs. In order to optimize the costs and improve the efficiency of the BHE system, an integrated approach has been proposed combining different geological and geophysical investigation methodologies.

The study area is located in the southern side of the Bartolo Valley in front of the Tarvisio town centre at an altitude between 750 and 790 m a.s.l. Due to the limited number of outcrop evidences, a 100 meters investigation borehole has been drilled in order to obtain the local stratigraphy. A geothermal probe was installed in the borehole and a thermal response test was carried out in it. Direct data from the borehole have been integrated by means of different exploration pits, electrical and seismic tomographies and surface wave tests in order to extend the geological knowledge of the subsol to the whole area.

The investigation borehole has shown the presence of a coarse grained glacial deposits overlying the bedrock mainly composed by marly limestone and clayey marls beds. The results of the thermal response test attribute values of thermal conductivity of about 0,4 - 0,5 W/(m K) to the covers and 2 e 2,6 W/(m K) to the bedrock.

According to the observed geological features, glacial deposits and calcareous-marly bedrock both represent potential aquifers. The bedrock should be considered as a fractured aquifer with the presence of open fractures and faults; the glacial cover has a porous permeability due to the variable grain-size distribution depending on the abundance of silty and clay matrix. Local water stagnations have been observed in the glacial cover in presence of thin clay layer, while a significant water flow has been observed in correspondence of the contact with the underlying bedrock.

Geophysical investigations have shown the difference in grain-size, thickening and degree of humidity, between the covers, the altered bedrock and the sound bedrock; in particular they revealed a significantly different depth of the bedrock in the studied area. Contrary to the expectation based on stratigraphical drilling data, the lateral continuity of the surface contact between covers and calcareous bedrock is roughly cut off: in the western sector of the studied areas, bedrock is significantly deeper and the thickness of the covers is higher.

As a consequence, the horizontal equivalent thermal conductivity varies in the area because of the difference in the thickness of deposits which show higher thermal conductivity, in respect to the less conductive bedrock. The geological information obtained by the proposed integrated approach allowed to rectify the value of the thermal conductivity coefficient obtained with the only help of investigation drillings and thermal response tests which are not sufficient to realize the geological areal assessment and their variability

GEOPHYSICAL IMAGING OF THERMAL FLOWS IN GEOLOGIC MEDIA: LABORATORY EXPERIMENTS.

COMINA Cesare¹; GUGLIELMETTI Luca¹; MANDRONE Giuseppe¹

1 - Università degli Studi di Torino

Presenter e-mail: cesare.comina@unito.it

Key terms: Geophysical monitoring; Heat fluxes; Geothermal energy

In low enthalpy geothermal applications most of the studies use numerical models to simulate heat fluxes and temperature variations induced by heat exchangers into the ground. This requires a fundamental understanding of how soil moisture content and grain size affect the soil's thermal behavior. Very few experimental data showing the effects of these variations are however available and the relationships determined are only empirical. This work presents an economic but profitably way of simulating thermal fluxes at laboratory scale by the use of an instrumented thermal box giving also an insight of the potentiality of geophysical controls in imaging transient heat fluxes. Geophysical tests could indeed provide, even if extended from laboratory scale to the site scale, an indirect way of monitoring the variations induced in the soil during the heat production and of determining the relevant heat parameters to be used in the fluxes evaluation.

In this respect a boundary isolated box has been appropriately instrumented. Two electrical resistances, controlled by a thermometer, and a rheostat assure the desired heat flux from one side of the box.

Temperature measurements in different sections of the box are carried out to fathom the time necessary to the heat to propagate within the different types of soils tested until a thermal equilibrium is reached; soil moisture is measured at the same time.

Electrical measurements have been implemented to evaluate the effects of temperature on electrical resistivity and image the heat fluxes. In this respect a series of 16 electrodes have been placed equispaced along the central section of the box and a fast acquiring device (C.I.T. - Iridium-Italy) has been used to:

- ° measure locally (along the singles quadrupoles) the apparent electric resistivity in correspondence of the temperature sensors;
- ° obtain a tomographic reconstruction of the conductivity field inside the box;

In both ways a direct imaging and an indirect monitoring of heat fluxes is possible during tests. Indeed it will be shown, in the presented tests, that the apparent resistivities values confirm their potentialities in monitoring and quantifying the increase in temperature in correspondence of the measuring points by relating it to the electrical resistivity changes.

Moreover to obtain a 2D representation of the monitored phenomena differential tomographic images have been used. In particular: for each time step the difference between the reconstructed resistivity field at that time and the one before the start of heating has been evaluated. In this way it has been possible to obtain a representation of the heating front. Tests presented confirm the potentiality of geophysical tests to monitor heat fluxes and to provide important parameters that could be potentially adopted for a comparison with numerical simulations of the monitored phenomena.

4 - University of Parma, Department of Earth Sciences, Italy

Presenter e-mail: stenni@units.it

Key terms: water stable isotopes; Antarctica; ice cores; paleoclimate

Paleotemperature reconstructions from Antarctic ice cores rely mainly on δD

and $\delta^{18}O$ records and the main key factors controlling the observed

distribution of δD and $\delta^{18}O$ in Antarctic surface snow are mainly related to the condensation temperature of the precipitation and the origin of

moisture. The deuterium excess, $d = \delta D - 8 \cdot \delta^{18}O$, contains information about climate conditions prevailing in the source regions of precipitation and can be used as an integrated tracer of past hydrological cycle changes.

In the framework of the TALos Dome Ice CorE (TALDICE) project, a deep ice core (1620 m) has been drilled at Talos Dome, a peripheral dome of East Antarctica facing the Ross Sea, about 550 km north of Taylor Dome and 1100 km East from the EPICA Dome C drilling site. The TALDICE coring site (159°11'E 72°49'S; 2315 m; T -41°C; www.taldice.org) is located near the dome summit and is characterised by an annual snow accumulation rate of 80 mm water equivalent. Backtrajectory analyses suggest that Talos Dome is mainly influenced by air masses arriving both from the Pacific (Ross Sea) and Indian Ocean sectors. A preliminary dating based on an ice flow model and an inverse method suggests for the upper 1580 m an age of about 300,000 years BP.

The full TALDICE $\delta^{18}O$ record obtained from the bag samples as well as δD

and deuterium excess data are presented here. The $\delta^{18}O$ and δD measurements were carried out in Italy and France on a continuous basis of 1 m. These new records will be compared to the ones obtained from the EDC ice core as well as with other East Antarctic ice core records. In particular, we will focus on the whole isotopic profiles and on the last deglaciation. During Termination I the climatic changes at Talos Dome are in phase with the Antarctic plateau suggesting that the bipolar seesaw with Greenland temperature is also valid for this new coastal site facing the Ross Sea sector. At glacial-interglacial scale the full $\delta^{18}O$ record of

TALDICE is in good agreement with other inland deep ice cores but the deuterium excess record of TALDICE shows a larger Last Glacial Maximum - Holocene amplitude than the more inland sites. The $\delta^{18}O$ and deuterium excess records at TALDICE are in phase during deglaciations suggesting parallel variations of moisture source and Antarctic temperatures.

THE IMPACT OF GLOBAL CLIMATE CHANGE ON THE ADAMELLO GLACIER: RESULTS OF A REGIONAL HYDRO-CLIMATOLOGICAL STUDY

GROSSI Giovanna¹, CARONNA Paolo¹, RANZI Roberto¹
1 - DICATA - Università di Brescia

Presenter e-mail: giovanna.grossi@unibs.it

Key terms: glacier; mass balance; energy balance; climate change

This research aims at the evaluation of the mass balance of the Mandrone glacier, the widest hydrographic unit of the Adamello glacier, in the actual climatic conditions as well as in two climate scenarios foreseen for the 21st century by the IPCC. Since the Adamello glacier is one of the largest alpine glaciers, its representative role within the Great Alpine Region (GAR) is doubtless and the analysis of its response to climate variations can provide precious information regarding the future of other glacial areas. In fact the impact of climate change is expected to be stronger in the GAR with respect to other European areas, as the highest air temperature increase is going to be recorded at high altitude sites. The estimate of the yearly mass balance of the Mandrone glacier in the actual climate conditions was primarily supported by measurements of winter accumulation carried out through a snow water equivalent monitoring network in the areas around the glacier. The mass balance evaluation was also supported by the estimate of the energy balance in the melting season, provided by the run of the physically-based distributed model PDSLIM.

The reliability of this approach depends on the availability of high altitude precipitation measurements, which are seldom recorded nowadays.

Modern Italian meteorological networks mainly consist of gauges located at altitudes lower than 2000 m a.s.l., even in the alpine territory. For the Adamello region the spatial distribution of the annual precipitation cannot be properly described without the information provided by the high altitude precipitation gauges conducted until the 70s.

PDSLIM runs providing the estimate of the energy balance of the Mandrone glaciers were forced by the time series of hourly observations of six meteorological variables: air temperature, humidity and pressure, precipitation, global radiation and wind speed. Meteorological series were recorded between 1995 and 2009 through high altitude measurement gauges, close to the glacier.

Time series of meteorological observations were then modified according to emission scenarios B1 and A1B of the regional climate model COSMO-CLM (developed by Deutscher Wetterdienst) for two twenty-years periods, centered in 2050 and 2090, so that four different future climate scenarios were built and fitted to local climate characteristics. Further PDSLIM runs were performed using as input the modified meteorological series. The expected glacier mass balance for each of the four future scenarios was obtained. Results show intense ice melting, besides according to most pessimistic scenario and for the end of the century: the loss of specific mass of a few meters per year would occur in this scenario, when referred to the actual extension of the glacier. Even if uncertainties in both the climate model and the hydrological model cannot be left aside, a quasi-quantitative analysis of the most vulnerable glacier areas to climate change is attempted, providing a clue to understand the potential evolution of a little, but still fundamental, element of the hydrosphere. A serious concern on the fate of Italian glaciers, as the Adamello one, rises after our analysis.

Presenter e-mail: daniele.bocchiola@polimi.it

Key terms: climate change; Alpine catchments; glaciers

The presence of climate change introduces a quicker dynamics of the glacial and snow fed areas within the Alps. It is therefore necessary to unravel the mechanism of interaction between climate change and the hydrological cycle within the Alpine catchments, strongly depending upon snow and ice feeding. Once the ice and snow accumulation and melt processes have been modelled using physical schemes, it is possible to hypothesize future scenarios of the climate inputs and of the hydrological response of the catchments. Here, we carried out a study based upon this approach for a case study within the Adamello Lombardo (BS) Glacier, the greatest glacierized surface in Italy, covering 18.13 Km² in the Retiche Alps of Italy. First, we build a minimal hydrological model, semi-distributed with altitude belts, able to simulate daily flows within the Pantano catchment (10 km²), including the 2.15 Km² debris covered Venerocolo glacier, a Northern tongue of Adamello. The water from the catchment is exploited by the hydropower company ENEL. The model is validated during 2006-2009, by way of historical data climate and hydro data and field surveys upon the Venerocolo glacier. We then use climate scenarios from an IPCC model (CCSM3, IPCC A2, 2011-2100) to infer hydrological scenarios in the area. Such preliminary scenarios provide a first guess of the future glacier areas and hydrology therein, useful for planning exploitation strategies of water for hydropower, civil and cropping use.

DEBRIS-COVERED GLACIERS, A SPREADING GLACIER TYPOLOGY: DISTRIBUTION OF DEBRIS TEMPERATURE FROM DIRECT AND REMOTE SENSING DATA

SMIRAGLIA Claudio¹, MIHALCEA Claudia¹, DIOLAIUTI Guglielmina¹, D'AGATA Carlo¹

1 - UNIVERSITA' DI MILANO-DIPARTIMENTO SCIENZE DELLA TERRA

Presenter e-mail: claudio.smiraglia@unimi.it

Key terms: current glacier evolution; debris covered glacier; debris thickness and temperature

Debris cover is expanding over large areas in the ablation zone of many Alpine glaciers during the last decades. Then, the energy balance at glacier surface is modified and is impacting ice melt rate. Thermal conductive heat flux through debris is influenced by debris cover properties mainly: albedo, thickness and thermal conductivity. Debris distribution and pattern is driven by periglacial processes (rockfalls), redistribution of supra-glacial (moraines) and in-glacial (melt-out) debris, surface glacier morphology (slope, roughness) and dynamics (surface velocity, crevasse distribution). To study debris cover distribution over debris-covered glaciers, surface temperature from remote sensing and field-based data is the best solution. Also it is the most important parameter to quantify the energy available to melt ice in the surface energy balance. High temporal and spatial resolution measurements of debris temperature were performed at several debris covered glaciers on the Alps (Miage and Lys) and in Karakoram (Baltoro and Hinarche). An analysis of ground surface temperature measurements and Aster surface kinetic temperature data at Miage glacier yields high and significant correlation. Surface temperature distribution from Aster images is mainly influenced by debris thickness and elevation, which are inversely correlated. Longitudinal and cross temperature profiles highlight: crevassed areas, moraine deposits, vegetation areas outside the glacier, shadowed areas, continuous thick debris near the terminus, etc. There is a good correlation between meteorological data (incoming shortwave radiation and air temperature) from automatic weather stations and debris temperature. Surface temperature up to 45°C associated to thick debris and low surface albedo are measured on supra-glacial debris. Aster temperature maps at a pixel resolution of 90x90 m, present average temperature of 30-40 °C at 12:40 am local time. Temporal trends of temperature are analyzed from field-based data and spatial distribution maps are developed. Areas with stable, continuous and thick debris cover are mapped corresponding to positive energy balance and warmer conditions at the glacier surface.

MIAGE GLACIER INFLUENCE ON THE SHORT-TERM EVOLUTION OF SUPRAGLACIAL AND PROGLACIAL TREE VEGETATION

PELFINI Manuela¹, DIOLAIUTI Guglielmina¹, LEONELLI Giovanni¹, GARAVAGLIA Valentina¹

1 - Università degli Studi di Milano

Presenter e-mail: manuela.pelfini@unimi.it

Key terms: Miage debris-covered glacier; Italian Alps; supraglacial and proglacial tree vegetation; ice-cliff dynamics; backwasting and downwasting processes

The Miage Glacier (Mont Blanc Massif, Italian Alps) is the most important Italian debris-covered glacier with a well developed tree coverage growing on its debris layer and a continuous interaction also with the surrounding forest in the proglacial area.

Supraglacial debris cover allows vegetation to colonise glacier surface, and whenever it is enough stable and thick, also shrubs and trees can germinate and grow. Supraglacial tree growth and distribution patterns on the glacier are closely connected with the debris-covered glacier dynamics and evolution. The aim of this work was to evaluate tree age and tree spatial distribution on the glacier tongue and the influence of ice-cliff backwasting on tree loss close to glacier terminus. We analysed the fragile and fast changing environment that is present on the lower ablation sector of the Miage Glacier where ice cliffs are present and back and downwasting phenomena occur. Tree features and evolution were analysed with respect to glacier short-term variations (mainly surface displacements and ice ablation) and geometry changes of the two most representative ice cliffs. The supraglacial trees' life time resulted to be mainly controlled by rates and magnitude of ice flow, by glacier surface displacements and by the occurrence of backwasting and downwasting processes, whereas tree germination was associated with fine debris presence. These factors controlling plants' life and growth on the glacier, must be considered for reconstructing past environmental changes occurred on the glacier tongue by means of supraglacial trees. Moreover, we found that a large number of trees die under conditions of dominating backwasting phenomena (condition met especially on the northern glacier lobe), thus reducing the mean age of the whole plant population. Instead, in the case of prevalence of the downwasting phenomenon (as we mainly observed on the southern glacier lobe), trees more easily survive and flow downvalley transported by the glacier flux.

Information about glacial discharge in the proglacial area was obtained using tree rings, dating scars, compression wood and growth releases and reductions. We detected the presence of areas directly affected by glacial discharge and others characterized by boulders falling from the glacier front, highlighting the continuous remobilization of the debris performed by the glacial stream flow.

Therefore the integration of dendrogeomorphological and glaciologica data both from supraglacial and proglacial trees may contribute to better define the complex of biological and physical interactions at Miage Glacier.

Key terms: Glaciology; Global change; World War I; Archaeology; Ortles-Cevedale Group

Glaciers are relevant environmental indicators, natural sentinels very sensitive to temperature and precipitation changes. Like huge refrigerators, glaciers retain precious archives of environmental information, preserving a memory within their stratigraphy both of natural events and of the effects induced by human impact.

The recent period of retreat of alpine glaciers is characterized by a marked reduction in the thickness of the glaciers also at higher altitudes, where there are emerging not only large portions of the bedrock, but also trenches and military constructions of the "White War", as is happening in Punta Linke.

After the end of the Great War, the military structures were abandoned and progressively covered by snow and ice, thus preserving climatic-environmental information related to this site from the end of World War I to the present.

During the archaeological excavation campaign conducted in 2010, samples of ice have been collected from different contexts, for analysis at the CryoLab of the University of Milan-Bicocca. In particular, a detailed stratigraphic section of the snow and ice infill has been reconstructed and some thin sections of the sampled ice have been studied.

Particularly significant levels have been sampled to execute analysis aimed at the definition of the time and the modality of archeological structures burial.

The glaciological context of Punta Linke (made by the Italian Glaciological Committee in collaboration with the Provincia di Trento - Soprintendenza per i Beni Librari, Archivistici e Archeologici - Settore Beni Archeologici) includes also the reconstruction of the areal and volumetric variations of the glacial area near the archeological site, starting from the Holocene glacial maximum (Little Ice Age, culminated around the half of the 19th Century).

Moreover, in correspondence with the glaciated saddle between the Punta Linke site and the Mount Vioz, some high resolution geophysical surveys have been performed through a GPR working with 500 MHz and 200 MHz antennas. The GPR data allow us to reach the bedrock and enable us to reconstruct the thickness of the glacier as well as to identify some underlying structures.

The 8.26 m of ice core drilled in Focul Viu Ice Cave (Apuseni Mountains, Romania) represent one of the longest records from hypogean ice deposits. A sets of 8 radiocarbon dates were done on organic materials found in the ice cores at different depth, and estimate of the age at 6.84 m depth is of 198±66 A.D. (calibrated date). Some large nss-SO₄²⁻ (no-sea-salt sulphates) spikes were preliminary related with historical well known explosive volcanic events, with an improve of age/depth time scale. Using both 14C dates and volcanic spikes, were evaluate the variability of the accumulation rate of ice deposits, that show a mean values for the entire ice core of 34.8 cm/century of ice. Differences in accumulation rate will be related to change in snowfall, and especially the large increase during the Middle Age period (1100 to 1300 AD), probably related to an increase of the snowfall in the area. Interpolating the accumulation rate of for the deeper part of the ice core, were estimate the age of the bottom ice at 8,26 m depth of at around the Vft century A.C..

Key terms: sand wedge; permafrost; Last Glacial Maximum; Patagonian coast; Argentina

Conversely to the Terra del Fuego, in the Atlantic Patagonia coast evidence of soil wedging caused by frost cracking is sporadically described, and large sectors seems to be unaffected by this phenomenon. This is surprising because during the Last Glacial Maximum (LGM), we can expect that this coast was affected by permafrost conditions, even if not so intense as in the areas proximal to the LGM glacier margins. During a 3 years long lasting field work aimed at characterizing the coastal deposits in the St Jorge Gulf, several evidence of fossil wedges was individuated and analysed. The grain size of the material composing the fossil wedge, as well as that of the incorporating deposit, along with quartz grain characteristics at SEM analysis, allow to propose an aeolian sand infilling of the frost cracks, that should thus be classified as sand wedges. Some sand wedges intrude a complex soil/colluvial succession covering marine deposits supposed to be MIS5 in age on the base of palaeontological data and of their elevation above sea level, and postdate a pedogenic horizon dated at ca. 25 ka BP. A preliminary OSL age of infilling sand confirms this hypothesis. These chronological constraints individuate the LGM as the cold period of formation of the sand wedges, and allow to ameliorate the

knowledge of the extension of permafrost to the north of the Patagonia during this time. In some cases at least two generations of sand wedges were described, claiming to more than one cold phase during the LGM, separated by a phase of loess deposition and/or soil development (truncated soil with Bk or By horizons). This indicates significant environmental variability during the Last Glacial.

MIAGE GLACIER (MONT BLANC, ITALIAN ALPS): THE CONTRIBUTION OF A DEBRIS COVERED GLACIER TO THE HYDROLOGICAL BALANCE

SMIRAGLIA Claudio¹, MASETTI Marco¹, DIOLAIUTI Guglielmina¹, D'AGATA Carlo¹, MIHALCEA Claudia¹

1 - UNIVERSITA' DI MILANO - DIPARTIMENTO SCIENZE DELLA TERRA

Presenter e-mail: claudio.smiraglia@unimi.it

Key terms: debris covered glaciers; hydrological balance; glacier ablation; Miage Glacier

Miage Glacier is surely the most intensely studied debris covered glacier of the Italian Alps, also well known to the tourists as "the most Himalayan glacier of the Alps" and because of the presence of the homonymous ice contact lake on the West lateral side. Despite these facts, its hydrological balance has been seldom analyzed. Miage Glacier is located on the South West flank of Mont Blanc; it stretches from 1780 m at its terminus to Mount Blanc summit (4810 m asl) and with a surface area of 10.7 km² ranks as the third largest Italian glacier. The debris covered area is 2.9 km², while the debris free sector covers 7.8 km². Its hydrological basin is c. 24 km² wide and the ratio glacier surface/basin surface is 0.44.

The hydrological balance of Miage basin can be written as:

$$Wd - P - Sm = Ga$$

where:

Wd = volume of water discharged (water flowing through the studied sections + water flowing into the Miage lake + water losses through the bed of the Miage lake)

P = volume of basin precipitations

Sm = volume of snow melted

Ga = glacier ablation

To calculate the summer hydrological balance two different methods were applied: a glaciological approach (by measuring on the field ablation rates and by applying a degree day (DD) model) and a hydrological method founded on river discharge measurements. The DD model permitted to evaluate glacier ablation and meltwater production over the whole glacier area, thus showing the largest ablation (61%) to occur on the bare ice sector. The hydrological approach showed that a large part of the summer basin runoff was due to glacier ablation. The glacier ablation calculated by hydrological approach and the glacier ablation evaluated through DD model resulted in good agreement, the small discrepancies are probably due to the simplifications applied. The data elaborations indicate that the summer Miage basin hydrological balance depends mainly on the glacier ablation (52%) and then on precipitations (29%) and on snow melting (19%).

Key terms: glacier; Julian Alps; geomorphology; geodetic survey; geophysical investigations

The glaciers of the European Alps are currently affected by large mass losses, due to unfavorable climatic conditions. Glacier areas and volumes rapidly decrease and the bedrock tends to outcrop, causing morphological changes and fragmentation of most ice bodies. However, different glaciers are reacting in different ways to the same climatic forcing.

Investigations on small ice bodies have a particular significance in this context, since they largely contribute to the total loss of glacier area, due to their large number and rapid shrinkage. In addition, they can provide important insight into processes governing glacier wastage and into snow redistribution by wind and avalanches, since they allow detailed investigations.

In summer 2010 a specific field campaign was carried out on Montasio Occidentale Glacier (W.G.I. number I4L0003005), a 0.07 km² avalanche-fed ice body located in the Italian Julian Alps (Eastern European Alps). The "niche" glacier is exposed to north and its altitude averages 1940 m a.s.l., ranging from 2105 to 1880 m a.s.l.. The purpose was to assess its current status (surface topography, total area and volume, degree of activity and alimentation) and possible peculiarities in the reaction of this glacier to current climatic changes. Indeed, processes and feedbacks governing mass exchanges in this kind of low-altitude, avalanche-fed glaciers are still somewhat unknown. In addition, the Julian Alps are characterized by very high precipitation amounts and differences in climatic sensitivity are very likely to exist with respect to drier areas of the Alps.

The Montasio glacier was completely surveyed by a Terrestrial Laser Scanner in September 2010, obtaining a high resolution Digital Elevation Model (cell size 20 x 20 cm). Additional information like reflectivity and RGB values associated to the TLS survey allowed us to distinguish and map the different substrata (snow, firn, debris) which cover the ice body, and to automatically delineate the glaciated area and the surface features. Geophysical investigations were also performed, to investigate the internal structure of the glacier and its depth. Measurements were carried out along longitudinal and transversal transects using a radar system

equipped with a 75 MHz and a 200 MHz antennas. The EM image of the subsurface highlighted several reflecting surfaces within the glacier body and at the boundary between the ice and the underlying bedrock. Geomorphological investigations were performed in the glacier area and in its foreland, in order to make a detailed geomorphological map. The glacier is bordered by a prominent frontal moraine, cut to the right and left sides by meltwater gullies, almost inactive. Some other outer, minor moraine ridges are present at lower altitude; they formed during stadial phases and are currently covered by a soil. On the glacier, in a middle position, a squeeze moraine outcrops.

The first results of our observations confirm a peculiar behavior of Montasio glacier with respect to the most part of alpine glaciers. In particular, its mass seems to be stationary or slightly increasing in the latest years, in response to recent snowy winters and in spite of current warm summers. This first dataset will constitute the basis for future work. Our intention is to reconstruct the glacier evolution since the Little Ice Age and to continue the monitoring of this ice body to evaluate its behaviour in the coming years.

Key terms: Glaciology; Historic maps; Global Changes; Geomatics; Italian Alps

Frontal retreat, areal and volume reduction, accompanied by glacier surface lowering are among the fastest geological and geomorphological phenomena. Glacial shrinkage is sometimes so huge and rapid that it can be noticed by inexperienced observers. It is clear, however, that appropriate tools for the quantitative assessment of glacial changes are needed. In general, for an objective understanding of the glacial landscape, photography and, more usefully, the cartography should be used. Already in 19th Century, precursors of scientific studies on glaciers felt the need for accurate base map surveying. This need was emphasized by the Glaciological Commission in 1895 that became the "Italian Glaciological Committee" CGI. In 1914, CGI opened its first Bulletin volume with the publication of the complete Miage Glacier relief map, the first Italian application with "stereoautografo" Zeiss. The tradition of surveying and mapping brought on by the CGI was strengthened particularly between 1955 and 1975; since 1985 CGI produced thematic maps on the glacial geomorphology, of which F. Sacco was a forerunner (in the first half of the century).

Extremely useful maps were produced by terrestrial photogrammetry during the International Geophysical Year (1957-1958), serving as the base for comparison with subsequent surveys and for evaluating changes in recent displacement of some of the most important Italian glaciers. Nowadays geomatics, and in particular aerial and ground laser scanner (coupled with aerial photographs and satellite images) make possible to have very detailed and precise measurements of glacial and periglacial areas in a short time, and at relatively low cost.

The current extraordinary glacial environmental changes linked to global warming, make the cartographic products absolutely necessary to set the spatial and temporal evolution of glaciers and proglacial areas. The modern survey techniques are extremely important in order to provide a better understanding of geodynamic phenomena, environment planning (e.g. availability of water resources) and civil protection in case of glacial risk.

Presenter e-mail: alberto.carton@unipd.it

Key terms: periglacial; cryogenic landforms; solifluction; Dolomites

The studied area corresponds to the so-called Basin of Vauz, located between 1840 m and 2250 m of elevation. It lies between the Pordoi Pass (Dolomites) and the village of Arabba (BL). There are several landforms related to frost action and solifluction in this area, such as patterned ground, terracettes and lobes.

This research aims at i) studying the processes involved in the slow movement of the ground and in the development of the landforms of the area, and ii) understanding the role of water circulation inside the slope. Analogous phenomena are present in many areas of the Dolomites, especially on the passes and in several locations where pelitic and volcano-clastic formations crop out (i.e. S. Cassiano Fm. and Wengen Fm.). Indeed, the movements usually develop within the detrital deposits generated from the degradation of the two previously mentioned geological formations. The particle sizes of debris involved in the movements are between coarse sand and fine silt, with a predominance of medium sand and coarse silt (from 4mm to 0,002mm).

Measurements of the thermal state of the soil were recently undertaken in the study area, using thermometric probes (PB-5001-1M5; accuracy $\pm 0.2^\circ\text{C}$) connected to specific data loggers (TGP-4520 TINYTAG PLUS 2). They allow to store hourly minimum, maximum and average temperature. Measurements were collected at 1874 m, 1935 m, 2190 m and 2365 m of altitude, at sites exposed to the south and with an inclination of respectively 23° , 14° , 11° and 36° . In order to analyze the trend of temperature with depth, in one of the monitoring sites (at 1935 m) three thermometers were placed at different depth (5 cm, 25 cm and 50 cm from the ground level). Data on air temperatures and snow thickness are provided by the weather stations of Arabba and Passo Pordoi - Belvedere

(data supplied by the ARPAV Meteorological Centre of Arabba and Meteotrentino). Data series between November 2009 and September 2010 have been already collected, while a second set of data spanning from autumn 2010 to spring 2011 are going to be collected.

The first data show that in autumn 2009, in absence of snow cover, soil temperatures fluctuated in connection the daily air temperature cycles but the ground temperature remained above 0°C .

After the first snowfall, this connection weakened and the ground temperatures developed independently from the air temperature variations. The soil temperatures at the various monitoring sites reached stable values above 0°C during winter, until the snow cover disappeared. Thermometers placed at different depths show an attenuation of the thermal wave with increasing depth. The thermal cycles are visible at a depth of 5 cm, while at 25 cm depth they are more attenuated (only when snow cover is absent, e.g. autumn and late spring). Moreover, higher temperatures were recorded at 50 cm than at 5 cm and at 25 cm in autumn and in winter, the opposite in spring and in summer. During winter, with the presence of snow cover, generally an almost stable value of temperature is reached at every depth without temperature oscillations. The collected temperatures indicate the absence of freeze conditions during the full year at all the monitoring sites. Actually, soil temperatures never fell below 0°C , even if air temperatures reached values well below 0°C (-15° , -18°C). The lowest temperatures are not recorded at the highest monitoring sites, indicating that not only the altitude but also the steepness and the exposure of the slopes exert a strong control on the thermal regime of the soil.

The results obtained so far suggest that the thermal regime of the ground controls in a complicated way the solifluction phenomena affecting the slopes of this area.

Presenter e-mail: roberto.seppi@unipv.it

Key terms: permafrost; rock glacier; inventory; Alps

A number of rock glacier inventories were implemented in the framework of PermaNET (Permafrost long-term monitoring network), a project part of the European Territorial Cooperation and co-funded by the European Regional Development Fund (ERDF) in the scope of the Alpine Space Programme (www.alpine-space.eu). Rock glaciers are regarded as one of the most prominent permafrost-related landforms in the alpine territories. A new statistical model and a permafrost distribution map for the entire Alps are partly based on the rock glacier inventories carried out within the project and, in this framework, a new inventory was completed also in the province of Trento. This region is located in the southern part of the Alps and 20% of its territory lies above an altitude of 2000 m a.s.l. The rock glacier inventory is based on analyses carried out in a GIS using a recent (2006) orthophoto (resolution of 0.5m) and a DEM (grid resolution of 2m). First, the rock glaciers were identified using i) the orthophotos and ii) an hillshade derived from the DEM. Then, the outline of the landforms were digitized in the GIS as polygon shapes.

The characteristics of the rock glaciers were included in an attribute table linked to the shapes. Our database consist of several descriptive parameters, including that of the Permafrost Evidence Database (PED) of the PermaNET project. However, in agreement with other project partner (e.g. ARPA Valle d'Aosta), we used a number of supplementary parameters, in order to achieve a more complete description of the landforms.

The database was partially filled in during the landform digitalization, but most of the information (particularly the morphometric parameters) were obtained from analyses performed in the GIS. In summary, a first group of descriptive parameters of each rock glacier include: location (mountain group and coordinates), altitude (mean and range), slope, length, width, perimeter and area. Other parameters describe additional characteristics, such as: geometry (lobate or tongue shape); general morphology (simple, complex); surface morphology (presence of longitudinal and transverse ridges and furrows and/or hollows and pits); lithology of the feeding area; debris source (talus, till); degree of vegetation coverage, relationships with the local vegetation boundaries and with the glaciers/perennial snowfields located above the rock glacier.

Particular attention was paid to the definition of the activity status of the rock glaciers, that were classified as intact (active and inactive landforms containing frozen material) or relict (landforms without frozen material). The assessment was based on i) several evidences visible in the orthophotos and in the DEM, ii) direct field observations carried out in our previous works and iii) field data (i.e. topographic surveys). We used particularly restrictive criteria for classifying the activity status of the rock glaciers from the orthophotos, and this may have resulted in a slightly lower percentage of intact landforms compared to other inventories. Our inventory includes a total of 705 rock glaciers, 134 (19%) classified as intact, the others as relict. They are located at an average altitude 2280 m a.s.l., with a considerable distinction between relict (average altitude of 2190 m a.s.l.) and intact (average altitude of 2660 m a.s.l.) landforms. 50.3% of the rock glaciers face towards N, NE and NW, while 35.2% face towards S, SE and SW. The landforms density (n of rock glacier/km²) is notably different in the various mountain groups of the province, and this seems to be related to the different lithologies that characterize the region. The average surface of the rock glaciers is about 4.7 hectares (0,047 km²). The total area covered by the rock glaciers (33.3 km²) is 1.2% of the entire area of the province located above 1500 m a.s.l., indicating as these landforms are prominent in the periglacial environment of this region.

Presenter e-mail: renato.colucci@phd.units.it

Key terms: cryosphere; permafrost; ice caves; glaciers; periglacial geomorphology

The massif of Monte Canin, part of the Natural Park of the Julian Alps, represents a particular study case in terms of relationship between climate and environment. The heavy rainfall affecting the area throughout the year and the colder temperature are the main cause for the conditions normally found in much higher elevations in the Alps. The area is characterized by glacial and periglacial environments still less studied from a geomorphological and climatological point of view. Nevertheless general climatic information provided from weather stations located around (but never at altitudes above about 1800 m), and glaciological survey and mapping carried out by various geographers and researchers since the end of the '800 exists.

The glaciological reconstruction of the last 150 years is favored also by the important collection of maps and literature existing in Friuli Venezia Giulia.

Permafrost distribution is completely unknown except for the occurrence of some rock glaciers and protalus rampart where the permafrost presence is not investigated yet. Underground cryosphere is surely represented by the large number of karst caves in which it is reported the presence of snow and ice, often permanent and layered ice. Despite of the gap of knowledge also on the frozen karst caves they could provide a useful key to understand the permafrost distribution and/or the glaciological evolution of the landscape.

Key terms: GEOLOGY; UNDERGROUND; FIRENZE; UBSU; USCS

Large urban areas are already saturated and the private and collective mobility is affected by the difficulty in finding space for corridors of new infrastructures. Therefore, in order to allow a speedy crossing and connecting of down-town with the outskirts and the main suburban roads and highway it is necessary to develop the new infrastructures underground. The Florence area is currently affected by the planning, design and execution of major infrastructure projects: the urban penetration High-Speed Railway, the northern road bypass, the tramway in the city center. The chance of carrying out these works by minimizing the interference with the urban, social and economic concerns can only occur through a detailed knowledge of the underground 3D geological setting in terms of lithostratigraphy, geotechnics and hydrogeology. For years, the Department of Earth Sciences, University of Firenze and the Municipality of Firenze, Geological Office, have developed a synergistic collaboration that led to the creation of a geodatabase containing lithostratigraphic, geotechnical, hydrological and seismic data of over 2000 logs and wells. The computer aided management of that huge mass of data allowed to develop a 3D reconstruction of the Firenze underground following the of UBSU and USCS criteria, and to characterize the geological units in terms of seismic and geotechnical features, according to the most recent regulations. It was also possible to assign different ranges of permeability to each unit and reconstruct the trends of the groundwater over time. This highly detailed knowledge base can be mounted or the expected path of a work project or executive infrastructure underground in order to be able to conduct feasibility studies, identifying the various issues related to follow in monitoring progress and predict the potential developments in the course of the project. The degree of knowledge gained also allows to identify the bottom structure of the great monuments of Firenze, first of all the Cathedral, with Brunelleschi's Dome and Palazzo Vecchio, with the Tower of Arnolfo, but also the Uffizi, with its priceless collections. The body of these studies allow to public and private appropriate knowledge levels for a safety planning, design and execution of underground infrastructure, both for the environment and the cultural heritage and monuments. But all that must not be a point of arrival but a point of departure for further knowledge the Firenze underground and the protection of its monuments.

RECOMMENDATIONS FOR QUANTIFICATION OF THE REFERENCE GEOLOGICAL MODEL RELIABILITY APPLIED TO MAJOR CIVIL WORKS. GIVEN BY THE ITALIAN GROUP OF THE INTERNATIONAL ASSOCIATION FOR ENGINEERING GEOLOGY AND THE ENVIRONMENT

DEMATTEIS Antonio¹

1 - SEA Consulting s.r.l. - IAEG technical commission

Presenter e-mail: dematteis@seaconsult.eu

Key terms: reference geological model; quantification of reliability; major civil works

Geological structures are normally complex and for the major part cannot be directly observed, for these reasons in most cases, a fully reliable prediction of the geological, hydrogeological and geotechnical conditions is not possible. In the other hand, the knowledge of the complexity of subsurface geology is needed in any design and construction of major civil

engineering projects. For this purpose the Reference Geological Model is the particularly decision tool required to design, useful to reduce risk and optimize operational costs.

Reference Geological Model (RGM)

The definition of the RGM is a conceptual reconstruction of a given portion of the subsurface, describing the three-dimensional geometric situation and the evolution in time and space of geological events. It is a model derived from all the objective surface, subsurface and laboratory data available at the time it is formulated. But it is also subjective, as it is also derived from the interpretation given by the technicians concerned. The model is subject to change over time according to new data that is produced after its first formulation. The new data can be integrated in the model without major changes or, sometimes, imposing major revision up to the complete reformulation. The formulation process of the RGM must take into account the following aspects: (i) the area to be investigated should include all regional geological structures (e.g. folds, fault zones) relevant to the project, including all the aquifer recharge areas; (ii) the macro areas with various uncertainty degrees must be clearly highlighted in a dedicated geological chapter of the RGM, explaining the reasons for each causing the uncertainty. The criteria to guide this classification must at least take into account the following aspects: (a) availability and density of direct surveys (e.g. boreholes, etc.), indirect surveys (e.g. geophysics, aerial photo scales, etc.); (b) structural-geology complexity (e.g. deformed metamorphic complex or sedimentary structure not deformed); (c) percentage of outcropping of rock basement (the lower is the outcropping, the lower is the reliability of the geological map interpretation); (iii) finally, the possibility to interpret all the available data into one or more different models (e.g. the presence of different interpretations of the same sector).

All the stages of this process should be recorded in a suitable design report, distinguishing "facts", "interpretations" and "opinions".

Reliability quantification

The quantification of the reliability should be standardized in order to facilitate its correct use in civil works. This should follow into the following steps, listed in chronological order: (i) data collection and organization; (ii) data analysis; (iii) building of the RGM referred to the specific design phase; (iv) reliability quantification.

Generally speaking, the reliability quantification must be undertaken with the cooperation of the geologist, the designer and the customer. The process to be followed by those actors should be traceable and transparent to all those participating in the design (designer, constructor, owner, financiers, control institutions). It is recommended that:

- the reliability of a reference geological model must always be referred to the design phase in which it has been produced;

- to define the reliability it is crucial to use quantitative terms and check their coherence with all project documents;

- the elements that describe the reliability (or uncertainty) of a given geological element are three: existence, location and meaning (or impact on the project);

- the reliability of the Geotechnical Model, or Hydrogeological Model, must be related to the reliability of the Geological Model.

This document summarizes the recommendations written by the technical commission of the IAEG Italian Group, composed by Dematteis (Chairman), Kalamaras, Lombardi, Mandrone, Martinetti, Perello, Piana, Sapigni, Soldo.

PLANNING GREAT CONSTRUCTIONS IN DISTINCTIVE GEOLOGICAL AREAS: THE VIADOTTO SAN LEONARDO (SA-RC HIGHWAY).

SERANGELI Stefano¹, SCARANO Serena², MITTIGA Enrico¹

1 - ANAS s.p.A.

2 - Libero Professionista

Presenter e-mail: s.serangeli@stradeanas.it

Key terms: Great road infrastructures; Salerno - Reggio Calabria highway; lateral variability; pile foundations

During the early phases of the planning of great road infrastructures, a major part is played by the analysis of the influence of geology on the optimal positioning of the road axis in project, in order to minimize the existing urgencies and optimize costs and times of work.

Otherwise, when particular restrictions to the project do not allow to take decision with autonomy it is necessary to widen the work knowledge in order to cohabit with such geological peculiarities.

The Viadotto San Leonardo, on the highway A3 Salerno - Reggio Calabria in Calabria, is located in an area in which a lot of geological realities live together, linked by specific characteristics which offer a wide degree of lateral variability on the soil around them as well as by the tectonics, paleogeography and geomorphology of the area.

The project needs to foresee the adaptation to the ground of the infrastructure, with the resulting demolition and reconstruction of the viaduct over about the same right of way, requires to pay great attention to the solutions to be taken, above all to the piles foundation when dealing with grounds with different characteristics.

The work geological reference model, defined by the geological surface survey, the geotechnical site investigation, the seismic and geoelectric projections, has been further elaborated through several on-site research. At the same time, the geotechnical classification of the soil interested in the work has been improved.

The geological complexity of the area, which made it arduous to plan the foundations of the viaduct, lies in the presence of formations with clearly different geotechnical characteristics: on the one hand there are fine soils (blue-gray clays and clayey silt) and loose coarse soils (conglomerates and sand in yellowish-gray silt-sandy matrix), on the other there are rocks belonging to the carbonate complex (limestone and crystalline dolomitic limestone), which are in tectonic contact through a system of normal faults. This particular structural configuration influences the typological choice of some piles of the viaduct, which are set for a carriageway on the fine soils and the other on the limestone formation.

The total length of the viaduct, which comprehends 8 piles with a maximum height of about 33 meters each, will be 491.6 meters. Bored pile foundations are foreseen, as well as micropiles when altered rock layers are encountered at shallow depth.

10.1474/Epitome.04.0397.Geoitalia2011

THE ROLE OF GEOLOGICAL STUDIES IN THE DESIGN OF LARGE CIVIL WORKS: THE CASE OF THE "CALTANISSETTA" TUNNEL

CAPOZUCCA Flavio¹, MONACO Carmelo², BARRECA Giovanni², MARZELLI Matteo¹

1 - ANAS SpA
2 - Università di Catania

Presenter e-mail: f.capozucca@stradeanas.it

Key terms: geological model; tunnel; mud diapirism; high pressure fluids

The role of geological studies in the design of Large Civil Works is essential, especially in the Italian region that is locally characterized by a complicated geological framework. The "Caltanissetta" tunnel, which is the most important infrastructure in the Executive Project (EP) for the renovation and adaptation to B category of the SS 640 "di Porto Empedocle", provide an emblematic case regarding critical geological aspects that may condition design and realization decisions. The Palermo-Agrigento stretch is an important route for Sicily traffic and represents not only a penetration road for the internal areas, but also the roadway linking the south-western Sicily with the A19 Palermo-Catania Motorway. Therefore, it is the direct connection between the Agrigento Province and the main bypass of the island. The economically and socially strategic importance of this infrastructure required its inclusion in the "1st Strategic Infrastructure Program" of the "Legge Obiettivo" that requires the externalization to a General Contractor. The design of this 28.2 km long segment, which extends between the 44th km and the connection to the A19 Motorway, is currently at a final executive stage (ED) with a total economic investment of 990 Million Euro. Along this stretch, the "Caltanissetta" crossing is the main infrastructure and for its construction two parallel tunnels (4,052 and 4,044 m long) have been designed. These rods run in the underground beneath the Contrada S. Elia, a region recently affected by the south-westward urban expansion of the Caltanissetta town.

Based on the geological model proposed during the Definitive Design (DD) stage, the excavation of the tunnel was designed by using TBM EPB cutter, that will provide a final coating composed of a ring of seven segments; moreover, the machine should be able to operate soil consolidations during its advancement especially in rocks with poor geomechanical properties.

The choice of using the technology of mechanized excavation by TBM EPB has imposed, during ED stage, the review of the geological and hydrogeological model which will be used for the correct design of the cutter and its various components, as well as for the evaluation of time-advancement. The geological model consists of several stages of study that provide a continuous refinement of the model through the acquisition of new cognitive elements. The review process and the upgrade of the geological model will end only with the stage of building of the infrastructure, when the reliability of the hypothesized model will be checked.

The Reference Geological Model (RGM) for the "Caltanissetta" tunnel was defined through four stages of surveys (DD and ED stages), carried out following increasing quality standards and with the aim of i) validating the proposed model, ii) definition of the critical geological aspects that could interfere with the infrastructure and iii) evaluation of parameters necessary for the design of the TBM. In particular, the geological model of the area is characterized by the association of folds and thrust faults, involving the Messinian deposits of the "Serie gessoso-solfifera" and the lower Pliocene Trubi formation.

The occurrence of huge volumes of brecciate clays was interpreted as the result of mud diapirism related to high pressure fluids at depth. This sequence is unconformably covered by a Pliocene pelitic-sandy-arenaceous succession that is, in turn, deformed by compressive structures, accompanied by further diapirical intrusions of brecciate clays (that cause active mud volcanism) and extensional collapse structures.

The most recent studies are leading to a significant redefinition of the RGM geological model, with potential technical and economic implications that are currently under analysis.

A NON-LINEAR RELATIONSHIP BETWEEN GEOLOGICAL HAZARDS AND DESIGN CONTEXT: THE CASE OF A SMALL GEOLOGICAL BASIN IN THE APENNINES

MELISSA Paone¹, CAPOZUCCA Flavio¹, MARZELLI Matteo¹

1 - Direzione Centrale Progettazione ANAS, Roma

Presenter e-mail: me.paone@stradeanas.it

Key terms: geological hazard; design phase; Civitavecchia-Terni-Rieti; geological model; subsidence rates

The construction of a road infrastructure, as of any civil work, is closely related to the physical characteristics of the landscape and needs, therefore, an adequate geological characterization. The geological model is so an essential tool for the infrastructure design phase; the assessment of the work feasibility and the identification of geological critical issues would not be possible without a good and reliable geological model.

The model should be developed with a proven method, using from the beginning a multidisciplinary approach for the study of the geological context, e.g. in order to assess the right investigation volumes. Used with awareness, it allows to carefully evaluate the reliability degree, for the right geological risk assessment and a planning of investigations capable to minimize the residual risk.

ANAS has used this approach for the Definitive Design (DD) of the completion of the connection line Civitavecchia-Terni-Rieti, that represents, together with the Roma-L'Aquila-Teramo highway, an important transversal way between the ports of the Tyrrhenian and the Adriatic Sea. Even if the infrastructure has a limited extension, it is included in the Strategic Infrastructure Program because it represents the functional completion of the connection line, waited since the '50s, located between the last stretch in Umbria Region (at its executive phase) and the stretch in Lazio Region, completed during the '80s.

The area interested by the infrastructure, bordered on both sides from the calcareous massifs of Sabini mountains, relies on most of its length on Velino alluvial sediments, except from the sector where the Monte Lungo Maiolica limestones outcrop (Jurassic-Cretacic).

The limited extension of the infrastructure, the occurrence of topographical constraints and of environmental issues (e.g. the Ventina Lake is a SIC area, Site of Community Interest) led to a corridor geometrically forced. In summary, the project includes a main axis consisting of a very high embankment connected to the Umbrian side, a short artificial tunnel and a series of secondary reaches developing in artificial embankments and traffic roundabouts, in connection to the local road network.

The geological study of the Preliminary Design phase led to a basic

geological model that showed important geological hazards, related to the young age of alluvial sediments and to the very active neo-tectonic processes, that also induced high sedimentation rates, with high lateral and vertical heterogeneity. A 14-Carbon radiometric dating assessed sediments ages lower than 5,700 years.

As a consequence, the main construction problems interest essentially all the embankments reaches, particularly the higher ones.

The forecasting of subsidence rates of sediments assessed higher values than those ones measured in the adjacent Umbrian reach, where the 100 cm have been reached. The higher depth of the viaduct foundation elements (more than 50 m) asked for the evaluation of the best foundation solution.

Furthermore, the morpho-structural features of the area suggest an high probability of seismic amplification effects, while the geotechnical properties suggest a significant liquefiability risk of the fluvio-lacustrine sediments of the first 15 m, on which a dynamic characterization will be made by means of cyclic tests.

ACHIEVEMENT OF PREDICTIVE MODELS FOR SOIL BEHAVIOUR IN THE DESIGN OF UNDERGROUND WORKS: FROM MOUNTAIN PASS TUNNELS TO HIGH-SPEED RAILWAY LINK LINE TUNNELS

MARCHESE Francesco¹, PIGORINI Andrea¹, PENNA Giancarlo¹, RODANI Stefano¹, POLIMENI Santo¹

1 - Italferr S.p.A.

Presenter e-mail: f.marchese@italferr.it

Key terms: geological model; hydrogeological model; forecasting; tunnel; urban subway

In the arrangement of a reference geological and hydro geological model for the design of an underground work, great importance is given to the context where the work is placed, which can be crossing mountains for tens of kilometres covered by important tectonic structures or running underground high-density urban settlements and infrastructures.

This feature affects the objectives of the modelling, aimed at the identification and resolution during the design phase of possible while working troubles; it affects not only the choice of investigations and the importance of the results that should be attributed to them, but also the detail of the model itself, depending on the expected answers to the questions that the kind of work requires.

It will be shown some examples about important designs of infrastructural works in urban context.

10.1474/Epitome.04.0400.Geoitalia2011

SPATIAL ASSESSMENT OF GEOMECHANICAL ROCK MASS PROPERTIES BY GEOSTATISTICAL ANALYSES

FERRARI Federica¹, APUANI Tiziana¹, GIANI Gian Paolo¹

1 - Università degli Studi di Milano

Presenter e-mail: federica.ferrari@unimi.it

Key terms: rock masses; geostatistics; kriging; sequential simulation; San Giacomo Valley (SO)

The forecast of geomechanical rock mass properties can be an important goal in civil and mining engineering planning, especially when a wide area is involved. This work is a contribute in assessing how the geometrical and mechanical properties of the rock masses can be treated as regionalized variables. Indeed the present study deals with the reconstruction of main rock mass characteristics in an extended area, from punctual measurements of the rock mass features, through the use of different geostatistical techniques.

The research site is located in the Italian Central Alps, along the Chiavenna Valley (SO), which is composed by San Giacomo and Bregaglia valleys; it covers an area of about 200 km².

The regional geological setting is related to the Penninic Nappe arrangement, characterized by the emplacement of sub-horizontal gneissic bodies resulting from the Mesoalpine isoclinal folding of crystalline basements ("Tambò" and "Suretta" Units) emplaced through East and separated by metasedimentary cover units.

More than one hundred detailed structural and geomechanical field surveys, mainly located in San Giacomo Valley, unevenly distributed, were carried out in order to characterize the rock masses, in accordance with the I.S.R.M. suggested methods for the quantitative description of discontinuities in rock masses. The investigated lithologies belong to the "Tambò" Unit, to its meta-sedimentary cover and to the "Suretta" Unit. Geomechanical surveys allowed to identify the number of joint sets, their average orientations, spacing, persistence, roughness, aperture, presence and nature of filling, wall strength, weathering and moisture. From the collected data the rock mass quality indexes, such as the Rock Mass Rating and the Geological Strength Index, have been evaluated in each surveyed site.

The geomechanical parameters derived from the measurement stations are local data, therefore in order to know how they are distributed outside the measurement points, in the entire study area, different geostatistical techniques were applied. First of all, the field data of the main rock mass features, such as the intercept of discontinuities, fracture intensity and aperture, were analyzed, and the main statistical parameters were calculated. Then a procedure of Gaussian anamorphosis was performed when necessary. Afterward the correlation structures of the defined rock mass features were investigated, at different scales, by means of a semivariogram analysis, taking into account the occurrence of anisotropic correlations. Both kriging method and conditional simulation techniques were applied to estimate the geomechanical variables. The best results, supported by the validation process, are obtained by conditional simulation method, which respect local extreme values, compared with kriging technique which tends to produce smoothed distributions.

GEOLOGICAL AND GEOMECHANICAL STUDIES FOR HYDROELECTRIC POWER PLANTS IN THE ECUADORIAN ANDES - SOUTH AMERICA

VERZANI Lorenzo Paolo¹, SOLDI Luca¹, EUSEBIO Attilio¹, UTTINI Andrea¹, VENDRAMINI Mirko¹, RICCI Giovanni¹, ACCOTTO Cristina¹, PRINCIPI

Stefano¹; GROPELLI Gianluca²

1 - Geodata Engineering

2 - Università Milano

Presenter e-mail: lpv@geodata.it

Key terms: geology; geomechanics; investigation; hydroelectric power plants; ecuador

The Ecuador Government started a National Hydroelectric development Program to face both with short-term and long-term country electricity power and energy demand. Coca Codo Sinclair, Minas Union and Villadora Chontal are among the largest planned projects. The engineering geologists team, responsible for the design of the planned works must be able to make reliable predictions for suitable construction methods and how the dam and its foundation, the tunnels, etc. will perform, under every envisaged conditions. The Engineering Geologists supports the design activities from the very beginning phases of planning and interpretation of the investigations, studying and giving solutions for the engineering problems which may arise as the result of the interaction between geology and the planned works as well as to the prediction of and the development of measures for prevention or remediation of geological hazards. The predictions will usually involve both judgement and quantitative analyses, based on data collected by the site investigation team. This data is provided as a Geotechnical Model, which consists of:

- a sufficiently detailed model of the geological situation using the typical approaches of structural geology, geomorphology, hydrogeology and of the other Earth Sciences techniques;
- adopted values of parameters for the model, as required for the analysis.

The design of these large projects faced with Ecuador dramatically active geodynamic context, in terms of kinematics (displacements) and dynamics (forces) acting in the area, and finally with the resultant deformations (joint, faults, folds) at different scales, that, at project scale, means different geotechnical properties. Therefore, before all, a comprehensive geological based approach was used for understand the geotectonic and geomorphological project contexts strictly related with the complex subduction mechanisms and its impact along the arc and back-arc regions, in which the projects are placed.

In such, dramatically active context, the engineering solutions must be capable to work for example under frequent, heavy erosion and sedimentation processes, often catastrophic, sometimes related with active volcanic eruptions.

At the same time, unfortunately, the exceptional vegetation coverage and the thickness of weathering layer heavily mask the geological outcrops, all together with a limited amount of pre-existing data, particularly those regarding the seismic and landslide activities.

In such a context, if the field geological survey, performed by experts familiar with the context in which the work will be built, remains of paramount importance, the Geological Model must be based, more than usual, on remote sensing, boreholes (including some very long and inclined drilling) and geophysics data. Together with these classic investigation techniques the lithological and structural scenario was studied coupling an extensive 2D and 3D magneto-telluric (AMT) survey, giving a regional geological setting, almost continuous along works. The boreholes was scanned using imaging with acoustic and optical televiwers (OPTV, BHTV, Full Wave) that results in continuous and oriented 360° views of the borehole wall from which the character, relation, and orientation of lithological and structural planar features can be defined for hydrogeological and geomechanical studies. Furthermore borehole breakouts was used for the determination of the orientation and module of the natural stress field.

The collected data, was founded well fitting with the regional geodynamic context of the Andean Cordillera. The influence of the main, large scale, tectonic systems, was well detected, with related local scale tectonic structures. On this base it was created the Geotechnical Design Model starting from the geomechanical classes (or groups), then the geotechnical behaviour categories and technical classes of excavation predicted along the underground works and in the dam foundation area.

Presenter e-mail: marco.tallini@univaq.it

Key terms: tunnel boring project; geological characterization; karst hydrogeology; geophysical investigations; tunnel impact on groundwater

During the last decades the need to improve the long distance road system passing through Formia municipality, located between the coastal line of Southern Latium and the Aurunci Mts. reliefs at the back urgently rose. For this reason the definitive planning stage of the variation of the road SS 7 Appia, which will develop in the Formia municipality, through a natural piedmont tunnel 5 Km long, named "Costamezza" is being planned. The projected tunnel section is "B" category, dual carriageway. The project is commissioned to the grouped enterprises POLITECNICA-SATPI, with the participation of consulting societies and universities.

The Costamezza tunnel crosses the carbonate reliefs of Aurunci Mts., which are here strongly tectonized and karstified. Those reliefs host here an important karst aquifer which feeds the Mazzoccolo spring, located in the Formia municipality close to the eastern entrance of the tunnel, and many other springs located along the coast line. The Mazzoccolo spring (which discharge is around 600 l/s) is fundamental for the water supply of Formia district. For planning the variation, the geological and hydrogeological model has been studied in depth, for supporting the tunnel building and defining possible impacts on the aquifer, and on the spring water quality. The accuracy of the proposed geological-hydrogeological model is based on specific geological-structural and hydrogeological investigations, supported by field geological survey, borings and geophysical investigations (seismic reflection and geoelectrical

surveying for the eastern entrance).

The Costamezza tunnel, located at variable elevation between 30 and 100 m a.s.l., passes through mostly Mesozoic carbonate rocks, except at the entrances. In the western entrance, the tunnel path should cross a detritic complex made by blocks few meters wide, which is characterized by high permeability and instability. In the eastern entrance, the tunnel path should cross a low permeability complex, which is made by messinian clay with gypsum and chaotic flaky clays with rock blocks inside ("Sicilide unit" Aquitanian-Oligocene in age).

The hydrogeological studies evidences, in the internal part of the ridge, two main groundwater flow directions, one directed toward the coastal springs, and the other one toward the Mazzoccolo spring. For the entire Formia spring group, the recharge area is around 50 km², with an average discharge of 1500 l/s. The investigated regional hydrogeological context suggests that the basin feeding the springs is characterized by a wide karst system, allowing a fast and total infiltration of rainfalls which is around 1000 mm/y.

From the piezometric map it can be observed how the Mazzoccolo spring is mostly fed by the Mola Mt. and by the northernmost ridges, while Santa Maria Mt. and Costamezza reliefs feed the piedmont coastal aquifer which directly discharges towards the sea. In the area of Mola Mt., the tunnel elevation ranges between 65 and 75 m a.s.l., which is always above the water table. On the base of these considerations, any interference between the excavation works and the aquifer can be excluded.

For evaluating possible interferences between the gallery building activities, the existing tunnel and the Mazzoccolo spring, a monitoring activity of the aquifers feeding the spring and the springs at the base of the Aurunci Mts. has been performed. The drilling of 4 piezometers in the basal aquifer feeding the Mazzoccolo spring was proposed. The drilling of wells should have the following purposes:

- verify the real position of the piezometric level in many aquifer sectors and directly test the time variability.
- allow the withdrawal of significant water samples.
- allow the installation of measurement divers in the piezometric well, recording chemical and physical parameters
- allow to immediately identify possible polluting events that could rise during the excavation or during the tunnel's operating phase.

HYDROGEOLOGICAL STUDIES FOR DESIGN OF URBAN UNDERGROUND STRUCTURES: THE EXPERIENCE OF TURIN, ITALY

EUSEBIO Attilio¹, RICCI Giovanni¹, ENRIONE Riccardo¹, CROVA Riccardo²

1 - Geodata Engineering

2 - GTT

Presenter e-mail: aeu@geodata.it

Key terms: hydrogeology; interference; urban underground works; models; turin

Most of the world largest cities are located in alluvial plain areas. Urban tunnels runs commonly at shallow depth for functional and cost reasons. This gives rise to a series of consequences in terms of geology, sub-surface, and impacts. The sub-surface at shallow depth often consists of loose soils, alluvial deposits, or man made fills. The poor quality of the ground is one of the key factors for the tunnel design and construction control.

The presence of underground waters is one of the important elements that characterise the subsoil. A correct design procedure must carefully take into account the hydrogeological context, either for the construction phases or the entire work life. The study of groundwater is important from both technical and environmental points of view, using quantitative and qualitative approaches.

The technical analysis must include the intrinsic particularities of the permeated soils, that is, a study of the porous aquifer systems is necessary. Therefore the hydrogeological study must be based on a previous stratigraphic and sedimentological model.

After this, for the design scope, the aquifer system can be considered well defined when the relative hydrodynamic parameters (governing the groundwater flow), the geometric characteristics and the flow field are known.

The definition of a hydrostructure, and in particular of the water levels (with its variation during a period comparable with the expected work life, that means tens of years), should be based on historical data series (with more years of measurements) together with the results of the design in investigations.

The site investigations must measure the permeability and other hydrodynamic parameters of the aquifers, all together necessary for the quantitative assessment of the interference of the underground works with the aquifers.

This interference depends, apart from the geological and hydrogeological characteristics, also on the tunnel depth, with its layout and dimensions; it could be negative or positive, eventually permanent (dam effect).

The design should consider the quickly growing up tendency, for the use of the free aquifers for electricity production. The new buildings extensively adopt these power supply systems, sometimes with big plants, pumping and releasing a relevant quantity of underground waters.

Particularly where multiple underground works act together the hydrogeological consequences can be complexes and the importance of a detailed in situ investigation program which data can be analysed with appropriate numerical models, evaluating the interference during construction and life, must not be underestimated.

Some recent projects in Turin, the Linea 1 of Metro, the deep foundations of the skyscraper of Regione Piemonte and the underground relocation of railway lines Torino-Ceres with their potential interference with the free aquifer gave a significant result of experience, both during the design phase and during construction.

ROLE OF HYDROGEOLOGICAL MONITORING FOR THE EVALUATION OF THE NATURAL STATE OF A LONG AND DEEP TUNNEL IN ALPINE CONTEXT

PARISI Maria Elena¹, MONIN Nathalie¹, BRINO Lorenzo¹

1 - LTF SAS

Presenter e-mail: maria-elena.parisi@lft-sas.com

Key terms: underground civil; water environment; excavation; monitoring; knowledge

The construction of underground civil engineering infrastructure needs specific studies in order to define knowledge on which to base models, to make forecasts to determine the constructive elements, and then to produce a project, to build it and to put it in operation.

In the case of the new Lyon-Turin rail link, the studies involved for "the water environment" are taking on this way. The water component, precious resource, assumes in the conception study of an underground work a fundamental role.

The new Lyon-Turin railway is subdivided in 3 parts : a French part (Lyon - St Jean de Maurienne), an international part (St Jean de Maurienne - Chiusa San Michele) and an Italian part (Chiusa San Michele - Settimo-Torinese). The Lyon Turin Ferroviaria company (LTF) is responsible of the international part and is thus tasked with carrying out the pre-project studies and surveys in order to present the final details (location, costs and conditions for construction) of the engineering works to the French and Italian governments. This international part is running for more than 80 km and includes the major works of the future railway with a border tunnel, the Basis Tunnel, of about 57 km and a secondary tunnel of about 19 km, the Orsiera Tunnel.

The excavation of underground infrastructures may cause interferences on surface with the hydrological resource. In order to estimate the entity of these possible perturbations and to define the measures that allows containing them in acceptable limits, it is necessary evaluating the relationships among the superficial waters and the possible deep water slide intercepted by the tunnel, and then the exhaust flow in tunnel.

As regards the pre-project of the international part of the new Lyon-Turin railway, the studies conducted on the resource water in order to estimate the impacts of the project on the water component have had beginning in the half of 90-ies with the evaluation of the natural state (circulation, alimentation, quality) of the superficial and deep waters both in France and Italy. Monitoring of springs, wells, fountains, rivers have been realized and are still in progress. These monitoring are based on physical and chemical measures in order to have the knowledge of the hydrogeological resource before the beginning of any construction activity.

These monitoring have different aims. Obviously the first one concerns the pre-project of the tunnels with the modeling of the ante-operam natural state (identification of superficial or deep circulations, hot or cold circulations, mineralization, etc...). By crossing the different informations (hydrogeological complexes, structural elements, monitoring data, layout of the project), the potential water inflows in gallery and the potential impacts in surface can be precised. All these studies allow protecting the water component with the mitigation of the possible impact through proposals of adjusted excavation methods and the implementation of safeguard measures in case of really perturbations.

The second aim concerns the contribution of knowledge which is offered to the communes and the public administrations with the diffusion of the data.

Key terms: forecasting; hydrogeological impacts; numerical modeling; tunnel inflows; southern Alps

The project of a road tunnel through a sedimentary rock massif in the Southern Alps at Castion (BL) needed a detailed hydrogeological study in order to forecast the magnitude of water inflows inside the tunnel and the effects on surrounding groundwater flow conditions.

The geological succession crossed by the tunnel is completely represented by "Belluno Flysh", an Eocene turbiditic formation made by biogenic calcarenitic layers, alternated by arenitic and pelitic layers, with occasional inclusions of calcareous breccias. This formation is irregularly covered by fluvial and glacial deposits, that will be also drained by the tunnel.

The main critical issues related to geology are: the possible occurrence of calcarenitic layers interested by karst dissolution phenomena, as evidenced by open and karstified fractures founded in the preliminary geognostic investigations; the different rock mass fracturation degree, related to three main faults that cross the tunnel.

A three-dimensional groundwater flow model have been implemented at the steady state and calibrated using the ante-operam monitoring data on the available boreholes and the main springs in the area.

The numerical model has been used firstly to calculate the groundwater table distribution at the end of tunnel boring (steady state) and the final effects on springs flow at the surface. It also allowed to identify the most critical tunnel sectors in relation to groundwater inflows.

In order to forecast the tunnel effects during tunnel boring, three simulations, at three different time steps of the progressive tunnel advancement, have been set up.

A sensitivity analyses on the hydraulic conductivity of the rock mass has been finally made, in order to assess the effects of parameter uncertainties on the forecasted impacts.

The hydrological monitoring programmed during tunnel advancement will allow a post-audit process on the here presented groundwater model: particularly, groundwater inflows data (as a function of time and tunnel advancement) will allow to refine the calibration process, by means of transient simulations.

APPLICATION OF GROUNDWATER FLOW SIMULATION MODELS FOR DESIGN OF DEWATERING SYSTEM IN POROUS AQUIFERS

QUARANTA Nicola¹, MARENCO Luigi¹, COGO Elena¹

1 - GEOengineering s.r.l., Turin

Presenter e-mail: quaranta@geoengineering.torino.it

Key terms: Drainage system; aquifer modelling; Groundwater interference

The aim of the study is an hydrogeological survey on a stretch of artificial tunnel link, planned in an highway project, through the implementation of groundwater flow simulation models (MODFLOW).

In particular, the purpose of the model is to provide an initial assessment of the effects induced during construction and during operations, in respect of groundwater flow, and therefore optimize dewatering system during construction phase (well-points and deep wells).

The artificial tunnel in question is configured in the redevelopment of a section of SP 103 called "Cassanese", located between the cities of Brescia and Milan, south of the town of Pioltello (Milano district, Italy). The road section is part of the edge of urban areas with widespread presence of road infrastructure, technology networks and services.

The knowledge of the geological and hydrogeological conceptual model was supported both by sub-regional evaluations and boreholes drilled along the artificial tunnel position; geo-stratigraphical tunnel profile was produced as a synthesis of the local investigations, determining scenario's piezometric levels referred to the construction and operative phases.

It has been setup at first a two-dimensional simulation model of groundwater flow along 2 vertical cross sections of the tunnel axis of the gallery, representing the most severe conditions in the two phases of work, in term of lowering of groundwater levels to achieve, and then a three dimensional model in a zone of tunnel at great depth of excavation. The model was first calibrated in steady state, with reference to the current piezometric conditions, reproducing the natural groundwater flow and hydrogeological balance, and then it was extended in order by checking the changes in the flow field.

Estimated piezometric profile (upward-downward gradients) was determined both during the construction phase, appreciating effects due to introduction of piles and jet-grouting, both during the exercise phase, after the inclusion of a waterproof structure in the aquifer.

The interference with the groundwater flow with the construction of artificial tunnel Pioltello are limited, in terms of gradients induced by and planimetric extent of disruptions of the natural groundwater flow field.

Therefore the model was implemented in transient state and it allowed to obtain the following informations:

1. Initial flow rate needed to produce the piezometric depression in the share base of the excavation
2. Time interval after which the depression is achieved.
3. Flow amount that should be removed from the aquifer to maintain the level below excavations.
4. Lowering expected also in the area including the radius of influence characteristic of the aquifer.

Key terms: asbestos; risk; tunneling; structural geology; petrography

The new highway ring of the city of Genova, the so-called "Gronda di Ponente", aims to reduce road traffic along the existing A10 route, now absorbed by the urban fabric; the plan includes a double-tube main tunnel, by-pass and access tunnels for more than 50 km of underground works, to be excavated by means of both TBM and D&B technique.

In the project area three main Europe-vergent juxtaposed domains crop out, with the association of upper mantle and oceanic crust units (Sestri-Voltaggio Zone auct.), continental margin units (Voltri Group auct.) and Apenninic flysch units. The W to E decreasing metamorphic grade from eclogite facies to diagenesis and the complex tectonic setting testify a multi-phase deformation history.

The ophiolite units are mainly made of basic-ultrabasic rocks, the host rocks for the asbestos minerals typically growing in veins and joints. Thus, the risk related to the occurrence of natural asbestos is a major issue affecting the highway plan, which is expected to cross potentially asbestos-bearing rock units.

Among the minerals considered as "asbestos" by the Italian law, only actinolite, tremolite and chrysotile can be found in the Ligurian hinterland. Antigorite, another mineral of the serpentine group being the main component of metamorphic serpentinites, normally having a lamellar shape, was found to grow in veins with a fibrous habit.

The study was founded on detailed structural field surveys, borehole core analysis and laboratory mineralogical tests, aiming at identifying homogeneous petro-structural facies on the basis of meso- and macroscale structural, lithological and rheological criteria. Homogeneous litho-structural domains were mapped. Consequently a sampling campaign was planned where the choice of sampling criteria resulted as one of the most relevant issues, owing to the need of carrying out an exhaustive sampling as well as of determining the mineralogy and concentration of fibrous minerals for each rock type, vein type and structural context.

The laboratory analytical procedures included MicroRaman Spectrophotometry, X-Ray Diffraction and, especially for fibers concentration < 1%, Scanning Electron Microscope with Energy Dispersion System. The Polarizing Microscope has been also used to study the rocks in powders and in thin sections.

Different petro-structural facies with distinctive asbestos types and contents were defined, i.e.: (a) reaction rocks developed at contacts between different lithotypes, (b) rock volumes with bounded network of asbestos-bearing veins, (c) volumes with pervasive asbestos growth in veins/joints, (d) asbestos lacking rocks. The most critical asbestos-bearing rock types are (i) ductile shear zones with braided tremolite veins at the calc-schist-serpentinite contact and (ii) cataclastic serpentinites within brittle deformation zones. Minor asbestos concentrations were found in (iii) chlorite-tremolite schists at the calc-schist-metabasite contact, (iv) brecciated serpentinites with a stockwork of carbonate veins, (v) massive serpentinites and (vi) blueschist-facies metabasites with acicular amphibole. Fresh to slightly serpentinized peridotites commonly lack asbestos minerals.

Corresponding asbestos risk classes were defined on the basis of the critical 1000 mg/kg threshold as defined by the Italian law in force concerning asbestos concentration in soils. The main open issues concerning the asbestos risk analysis are finally dealt with: sampling representativeness, lack of certified methodological standards, gaps in the law, etc.

The geological reference model was analyzed in terms of global reliability, considering all variables affecting the geological predictions (e.g.: number of available boreholes, complexity of the tectonic setting, etc.). A geological section including a quantitative description of the asbestos-risk was finally drawn, allowing to define safety procedures for both underground works and muck spoil management.

Key terms: noble gases; groundwater; tunnel hydrogeological interferences; faults; groundwater flow systems

Noble gases (He, Ne, Ar, Kr, Xe) in groundwater are known as useful proxies to study the groundwater flow dynamics in aquifers. [Kipfer et al., 2002]. The atmosphere is the largest noble-gas reservoir on Earth.

Atmospheric noble gases enter the water cycle by gas partitioning at the air/water interface. Therefore, noble-gas concentrations in surface waters are often found at atmospheric equilibrium. In general, deviations from the expected equilibrium concentrations (e.g., due to the accumulation of radiogenic and terrigenous noble-gas isotopes) can be used to understand the transport dynamics within aquatic systems. For instance, the noble-gas concentrations and their isotope ratios have been used in groundwaters to determine residence times, mixing processes, and the origin of water [Mahara & Igarashi, 2003; Althaus et al., 2009]. Tunnel drilling offers a unique opportunity to sample and study deep waters that otherwise are hardly accessible. Understanding of the deep groundwater flow is of primary importance to assess possible negative impacts of tunneling on hydrogeological systems.

We sampled water for noble-gas analysis from tunnel inflows in the Monte Ceneri base tunnel (Canton Ticino, southern Switzerland) which passes through an area mainly characterized by metamorphic rocks (gneiss). Furthermore, we collected water samples from springs located in the same geological environment.

On the basis of the ⁴He, ³He, and ²²²Rn concentrations measured in the water samples, we identified the isotope signature of terrigenous helium for the studied region. The determined isotope composition for each sample allows for the distinction of old groundwaters strongly enriched in helium of crustal origin and more recent waters which are close to atmospheric equilibrium.

In the light of the available tritium measurements and geological logs, we elaborated a hydrogeological conceptual model. According to this model, different flow systems can be distinguished for water circulating through faults, that are generally filled by fine-grained, low permeable, material. One system seems to be separated from the surface and carries groundwater with a strong terrigenous He isotope signature of crustal origin. Other flow systems are a mixture of old and more recent waters close to atmospheric equilibrium. The water collected from more permeable faults shows a ³He enrichment most likely originating from the decay of tritium. Therefore this water seems to contain a fraction of recent recharge. The different types of water allow for the characterization of faults that may be critical for tunnel drilling due to their active hydrogeological role and to their influence on the rock's mechanics.

GEOLOGICAL AND HYDROGEOLOGICAL MODELS FOR THE DESIGN OF THE SOUTH PORTAL OF BEVERATE RAILWAY TUNNEL

SOLDO Luca¹, ENRIONE Riccardo¹, EUSEBIO Attilio¹, BINI Alfredo²

1 - Geodata Engineering

2 - Università Milano

Presenter e-mail: Iso@geodata.it

Key terms: hydrogeology; geomorphology; tunnel excavation; investigation; Beverate

Geological and geotechnical uncertainties and the resulting risks in construction of underground works are well understood. Both the design and construction phases are always characterized with a certain degree of uncertainty, particularly about the nature of the geological and geotechnical characteristics and their spatial variation. The level of knowledge of geological parameters which are the principal sources of the project risks is often not optimum due to geologic complexity, limits imposed on the investigations, etc.

The use of a step-wise investigation approach in reducing these risks has not received the deserved emphasis. In many designed works which met severe problems during construction it was found that often an inadequate model of ground conditions had been used, either because some

geological features had been missed or overlooked during investigation or because its significance had been underestimated.

In the paper a case history of an investigation campaign for the south portal of a railway tunnel focused on the base of a "geological perspective" is described, emphasizing the relevant advantages obtained in the design and construction phases. Site investigations, their follow up and their interpretation are highly specialistic tasks. They are typically following an hermeneutic approach along which the choice of the more adequate site investigation approaches is closely related with the necessary parameters for the design of the different engineering works, different for different geological environments. Also the site investigation phase typically must follow a step by step approach where additional investigations could arise because of the collected evidences.

In this case it is showed as the geotechnical and hydrogeological context was fully understood only on the basis of the contribution of this investigation approach, also supported by a specialistic contribution in sedimentology of glacial deposits.

The anamnesis-diagnosis and the prognosis phases are intimately related and they must be guided and interpreted, with wisdom, by the specialist "medician": does anybody could accept fully persuaded for an eyes disease the diagnosis of a luminary orthopedist?

Key terms: Rock mass classification; Roads plan; Sardinia; Ercinic basement

On the occasion of the planning of civil engineering infrastructures, involving rock masses, it's fundamental to collect information about the characteristics of the geomechanical quality, resistance and deformability of the rock mass.

These can be deduced from the usual methods of geomechanics classification of the cluster. Through the collection of field, survey and laboratory data, these methods allow to obtain useful parameters for the geomechanics quality indexes (RMR - Rock Mass Rating; GSI - Geological Strength Index, ecc), also providing geomechanical and geostructural classification of the rock mass under investigation.

During the ultimate planning phase of the first lot of the Tertenia - S. Priamo of new S.S. 125 section, this research methodology was applied. Along the way, the ground of the ercinic basement arises, like the formations of the San Vito Sandstones (ASV) and Monte S. Vittoria (MSV). The first is made up mostly by metarsandstones and quartz-mica metapelites, rarely metasandstones and thin levels of green/gray metaquartzsandstones, with intercalations of metapelites and gray metasiltstones; the second one is represented by metavulcanites, feldspar metarsandstones and metaconglomerates, and it can be divided into two kinds of litofacies: a) metaepiclastites and metarhyolites (MSVa); b) metagraywakes e metandesites (MSVb).

To analyse these formations we have classified the clusters from the proceeds of the data gathered during the geostructural and geomechanical study of rock mass, which was elaborated on linear stations according to ISRM standards. The measurement of each line helped to define the geological characteristics of the site, the classification of the different types of discontinuity and their geometrical and geomechanical features. All these informations have been collected with survey and geostructural synthesis forms and geomechanics classification tables showing the RMR and GSI Index.

The results collected through the field survey have been compared with those obtained by the extrapolation of the geognostic and laboratory data (recording of the RQD inside the borehole, Point Load Test and rock samples uniaxial compression) with the aim of having a more accurate assessment.

According to the performance obtained from the GSI index, the different lithologies have been included in the diagram "Geological Strength Index for Jointed Rocks" (Hoek & Marinos, 2000).

This comparison allowed us to notice a fair correspondence between the two data series and it has lead us to assign the geological parameters on the basis of which we have scaled the project operations.

3 - Dipartimento di Scienze della Terra e del Mare (DiSTeM) - Università di Palermo

Presenter e-mail: m.leta@libero.it

Key terms: public work; travertine; groundwater

Palermo city has been interested up till now by several geological investigations for carrying out a public project: the south east main sewer's finishing.

Preliminary and executive planning stages focused on: geological surveys about boreholes to core sampling, geotechnical laboratory testing and analysis, inspection of excavation face, groundwater management and control, performing of instrumental measures.

The trail of the sewer system crosses the city from the south east to the north west and intersects areas of high geological complexity, where morphology and structural have affected the appear today of the main Palermo plain litho-stratigraphic successions as regards the spatial relationship and the hydrodynamic configuration.

Continuous inspection of excavation face allows to store a detailed geological and litho-technical reconstruction on the spot investigation, improving knowledge about outcropping stratigraphic sequence and distribution of groundwater.

The analysis of stratigraphic data, coming from boreholes, and excavation sections have testified the presence of deposits ascribed to several marine and non marine sedimentary facies, from Pleistocene to Holocene in age. In the middle of Palermo plain near the west borderline of historic centre,

the tunnel excavations have revealed, for the first time, a travertine deposit. The travertine has a high historical meaningfulness in the evolving of depression Papireto and reaches an extension of about 6,000 square meters. Micropaleontology and facies analyses allowed to recognize a silty clays and sandy silt substratum Lower Pleistocene (Sicilian) in age underlying alluvial deposits passing upward to peat level followed by calcareous sand alternating to phytohermal and phytoclastic facies associations.

The areal and vertical development of these deposits, marked by discontinuity surfaces, shows changes in sedimentary environments and breaks the record related to groundwater fluctuations due to climatic/hydrology variations over time. In the early stage an instrumental monitoring started for supporting the public project that allowed us to locate the groundwater in the Calcarenitic deposits at an average depth of about 10 meters. The groundwater have been locally affected by changes correlated to the shape of this deposit. In some areas it was possible to record the presence of sub surface piezometric levels too. These were affected by specific local morphological conditions or due to the presence of deposits Holocene in age very sensitive to underlying aquifer fluctuations. The different instrumental sections have been showing in via Colonna Rotta a sudden recharge related to exceptional rainfall amplified by morphological structure and local stratigraphic sequence.

In November 2008 and February 2009 the exceptional meteoric events caused the flooding of the tunnel up to about 1 meter above the base of the excavation.

In some sections the plots show anomalous piezometric levels related to the public work. These piezometric profiles plotted for a time interval of about 5 years overlap perfectly to the different project phases, exhibiting a meaningful increases level (over 3 meters) on connecting to construction of hydraulic barrier, followed by protracted intervals of stabilization and sudden deflection that place the groundwater to a depth of about 5 meters definitely. On this area piezometric excursions involve a clear interfering between the works and the urban fabric above. This interfering needs continuous monitoring to prevent possible geological phenomena of local instability and protect the functionality of the sewer system.

Presenter e-mail: lucilia.gregori@gmail.com

Key terms: landscape; geomorphology; palaeogeography; art; Umbria

In the Umbria region the "landscapes of art" were made by Giotto, Perugino, Pintoricchio, Gozzoli They represent a sort of "widespread museum" on the territory and are unexpected resources and cultural opportunities. The usual vision and capture of the work of art may be increased by an "added value": the assessment of the geological and morphological characteristics of the landscapes, pictured behind the protagonists in the scenes and the comparison with the existing topographic model. The attention to the works background of some local artists, not only on Umbria landscape, offers interesting parallels with the local situations that must be interpreted. As a matter of fact the landscape represented in the painting corresponds to different climatic conditions. Due to this fact is possible to interpret the paleo-environmental characteristics of the area. That scene can be different or not from today, but the interesting challenge allows to recognize the features, compare them and reconstruct the paleo-landscape sometimes still recognizable. The correlation with the actual landscape is a fascinating cultural journey, and absolutely a new way to observe the paintings. (shared with other situations in the Marche region, Nesci, 2008). In Umbria region "Il Perugino" painted the Trasimeno lake landscape through the views through of Città della Pieve (his birthplace) or from Val di Chiana area. He characterizes a particular hydrological condition of the area, in a cross-section view related to the Chiana graben. The fresco paintings of Giotto, in the Upper Church in Assisi are an unusual review of St. Francis' life. They allow to do a "virtual walk" through the landscapes of the area around the Subasio or La Verna mountains. The scenarios, representing the outcropping lithologic complexes, describe the topographic characteristics of the reliefs, where thick sandstone benches influence with the morphology conditions identifying the Tuscan landscape. Also the calcareous bedrock on the Subasio mountain characterizes the landscape of that area. The "landscapes of art" are an addition to the emotions usually related to each painting. They can become an interesting comparison between the actual environment and the landscape observed from the artist.

Key terms: Cultural geomorphology; Cultural heritage; Natural resources; Landscape management; Montefeltro region

Cultural geomorphology is a field wherein a geomorphological approach is applied to the study of objects of cultural heritage. This interdisciplinary approach, which has already produced excellent results in the field of

Archaeology, is proving very effective in the study of historical and architectural landscapes and even in the analysis of pictorial representations. The Renaissance Views Project is based on this approach and aims to enhance the natural resources and cultural heritage of Montefeltro through scientific research, towards a cultural resource management of this territory. The idea was born from the discovery of the background landscapes in the works of Piero della Francesca (Nesci & Borchia, 2008, 2009, 2010). First, the landscapes in the diptych of the Duchess and Duke of Urbino by Piero della Francesca were studied utilizing geomorphological, cartographic and historical analysis. Then, other paintings by Piero della Francesca found in Valmarecchia region were studied. These studies increase the cultural value of an area already appreciated for its archaeological sites, historical records, ancient buildings, religious beliefs and practices. Therefore, it is necessary to develop a cultural project aimed at tourists by including parallel events of great prestige and potential visibility, such as courses of study, workshops, and collaborations with academic and cultural associations. THE REPRESENTATION OF THE LANDSCAPE IN RENAISSANCE MINIATURES AND MAPS OF THE ESTE COLLECTIONS IN THE BIBLIOTECA ESTENSE AND IN THE STATE ARCHIVES OF MODENA

BADIALI Federica¹

1 - PhD School in Earth System Sciences, Dipartimento di Scienze della Terra, Università degli Studi di Modena e Reggio Emilia

Presenter e-mail: federica.badiali@unimore.it

Key terms: Renaissance miniature; Renaissance maps; Anthropical landscape; Iconography

he study of the landscape representations in the miniatures of ancient manuscripts and maps of the Este, now kept at the Biblioteca Estense and at the State Archives of Modena, allows us to capture relevant such as unexpected information to reconstruct the Renaissance anthropic landscape, and to understand the value that contemporaries attributed to it.

In this way can be followed the evolution of relationships between man and environment, in a period when the human influence on the territory was almost exclusively linked to agricultural production and forestry. It presents a selection of some significant iconographic sources that were part of the rich collection of Este, which allow us to understand both the different degrees of adherence to the reality and of intentionality in the representation of landscape.

Often, the iconographic apparatus of these works follows a project of great complexity and elegance, in which there is clearly a choice to give priority each time man's work or elements of the landscape, but always with attention to details, demonstrating the importance of the agricultural landscape and large-scale country planning, topics always at the center of attention of Este dukes.

The ancient images of the landscape always go through the mediation of the will of the author, in turn susceptible to other external influences, which may be cultural, social or imposed by the client. In these images it is evident the strong subjective impression, both artists and the patrons, it emerges with great evidence in the representations of reality, in turn consequence of cultural conditioning that often lead to the adoption of conventional stylistic and symbolic modes, thus representing the landscape with highly variable levels of realism.

What is the motivation of these deviations from the reality? Were taken intentionally or unintentionally arising from the imagination of the artist? Were specifically requested by the commissioner, which wanted to represent their ideal model of landscape? Could be perceived by those who observe the image at that time?

Anyway you answer these questions should always be taken into due consideration the distance between the original idea, in whatever ways born, and the idea originated here and now in the mind of the observer who is immersed in the perception: that distance is simultaneously temporal and psychological.

Fortunately, our advantage in observing the ancient representations of the landscape is, or should be, to have the ability to capture what the observers of the past have not always see, that is the significance of the relationship between elements of fantasy and real issues. Perhaps the most lifelike images are the expression of the achievement of a stable relationship between environmental resources and agricultural production, that is between region's potential and citizens consumption, however, at the same time, alongside these representations of the landscape, we can observe others, in which the imagination produces images that fully belong to the sphere of wonder. Is clear, in these cases, the will of the artist, who consciously decides to use the representation of fantastic landscapes to describe the human soul's emotions.

Key terms: Integrated Quality Management System; Sustainability; geological heritage; Piemonte

The multidisciplinary research project "PROGEOPiemonte" aims to achieve a new conceptual and operational discipline in the management of the geological heritage of the Piemonte Region by means of the development of techniques for recognizing and managing its rich geodiversity at the

local and regional scale. After a systematic review of inventoried geosites, 9 strategic geothematic areas will be investigated to represent the geodiversity of Piemonte, each characterized by high potential for scientific studies, enhancement of public understanding of science, recreation activities and for economic support to local communities. Geological history, climate and environmental changes, natural hazards, soil processes and georesources will be popularized not only with geosites but also with museum collections, evidences of mining activity and quarrying, science exhibits and nature trails. The recognition of the economic value of geodiversity will lead to the production of regional guidelines for Geoconservation integrated quality management system, suitable for tourism and sustainable development strategies. In details, the integration model will be elaborated by the Department of Commodity Sciences, and will be based on the TIQMS (Territorial Integrated Quality Management System), a methodology developed by this Department and tested in a Comunità Montana near Turin. TIQMS allows the user to analyse a region by many points of view, regarding quality, landscape, environmental, occupational health and safety, and social accountability aspects.

All these features are managed on the basis of the European Landscape Convention adopted by Italy and the following international standards: ISO 9001:2008, ISO 14001:2004, OHSAS 18001:2007 and SAS800:2008. The methodology TIQMS was originally developed for the Public Administrations. Its flexible character allows it to be adaptable and for the implementation in new and different territorial contexts.

First of all a phase of research and analysis will take place; it is essential in order to build the next steps, which will mainly develop guides lines for the integrated management of the conversion and use of mining sites for touristic purposes.

It will be necessary to pick out, in agreement with the others agents involved, a number of indicators for quality estimation, environmental quality and landscape, occupational health and safety and social conditions.

For this and other goals, such as the management in real time of the data to calculate the indicators, it will be available a remote sensing system of the variables included in the project; it will be used Scato8TM, an hardware and software open source system elaborated by the Department of Commodity Sciences, able to gather, store and send data regarding the analysis of the natural components of the region, and others data necessary to analyse the landscape units that form the region, which are essential for its knowledge and description.

The implementation of the Scato8TM system has to be seen in an progression way. It is, indeed, able to adopt other noticeable variables, in order to fulfil the needs of the project.

The methodology will follow these steps:

1. Integrated territorial analyses on the region considered as the object of the study. This has the aim of detecting the beginning situation with an accent into the quality, environment, landscape, occupational health and safety, social responsibility aspects, and point out the indicators;
2. Build the plan for the Integrated Management System;
3. Define the procedures and the implementation of the integrated system; a guide for operators training and a documentary system will be arranged to check and improve the variables of the system;
4. Test the system and evaluation of a possible certification;
5. Elaboration of Guide Lines for the implementation of an integrated management system;
6. Elaboration of a Guide for touristic operators training.

THE GEO-CULTURAL HERITAGE OF THE MONUMENTAL COMPLEXITY OF THE MILAZZO PENINSULA (SE SICILY, ITALY)

Key terms: Milazzo Peninsula, Southern Italy; Geo-Cultural Heritage; Monumental Complexity; Historic evolution, Technical Construction, architectonic and ornamental materials; model of territorial management

This research aims to contribute to the knowledge and exploitation of the monumental complexity of the Milazzo Peninsula (NE Sicily), one of the most important territories in Southern Italy to be considered as Geo-cultural site.

Specifically, the purpose is to create a guidebook to document and illustrate the historic evolution, technical construction and natural materials used in the most important architectonic structures dating from the Archaic Period of Greek Art to the Rococo Period of Baroque Art. The Milazzo Peninsula leans out towards the Tyrrhenian Sea in a S-N direction, extending for about 7,5 km and reaching an altitude of 135 m (Trinità Mt.). It is characterized by the presence of the homonymous city which expands from the isthmus between the peninsula and the Milazzo-Barcellona Plain to the Milazzo Cape.

The city derived from the expansion of ancient settlements, unified over the course of centuries. It involves three areas: the High City, or the historic centre with its Medieval hamlet, castle and the most important monuments; the Low City, or the present urban centre, which extends from the port area to the archaeological ruins of the Greek Mylai (716 B.C.); the City of the Plain, which is the recent built-up area with several farmed areas.

Due to its strategic geographical position between the Messina Straits and the Aeolian Islands, Milazzo was a centre of important civilizations and the scene of famous historic events, from the Caio Duilio (260 B.C.) to the Corriolo (1860) Battles. The last was one of the most important battles for Garibaldi's Army, fought during the unification of Italy.

Several examples of evidence from the Bronze, Iron, Greek and Roman Ages are still preserved, both in the historical centre of the high city, and in the remaining areas. Under Arab domination the city was fortified with a very important castle (the Castrum) and its commercial and agricultural economy was reinforced. During the Norman, Suevian and Aragonese dominations the castle was enlarged and in the Aragonese and Spanish periods, it was enclosed by two different surrounding walls, transforming this architectonic complex into a Fortified Citadel. Other significant architectonic structures in Renaissance to Baroque Styles characterized Milazzo City.

The present study allowed the following to be analyzed:

- a Hellenistic mosaic of the 2nd century B.C., representing a "Kouros Siceliota" made up of polychrome tesserae, consisting of different types of limestones from Peloritani Mesozoic deposits;
- the Fortified Citadel, constructed by Mastio Federiciano (XI and XII

centuries), the Benedictine Monastery (XV century) and the Aragonese (XV century) and Spanish (XVI century) Surrounding Walls. The architectonic and ornamental materials used in these structures consist of dark Aeolian rhyolitic to basaltic volcanites; Peloritani polychrome metamorphic, plutonic and sedimentary rocks (Aspromonte Unit Pan-African and Variscan metamorphites and Late-Variscan plutonites; San Marco d'Alunzio Unit Mesozoic limestones and dolostones); - the Church of Saint Francis of Paola (XVI century), rebuilt on an old original 1464 structure. Its charming ornamental elements are made up of Sicilian polychrome marbles and limestones;
- the Church of Saint Antony of Padua (XVI-XVIII century), to dig into the rock (Miocene calcarenites), is rich in artistic mosaics made up of polychrome limestones and dolostones from Peloritani Mesozoic deposits (San Marco d'Alunzio and Longi-Taormina Units);
- the D'Amico Palace (XVIII century) is a notable testimony of the Messina Late-Baroque and Rococo Styles. The materials are sandstones and calcarenites from the Oligocene-Burdigalian Capo d'Orlando Flysch and of Burdigalian-Langhian Floresta Calcarenite deposits, respectively. This reconstructed geo-cultural system, which represent a very important heritage for sustainable tourism, is a promoter of innovative territorial conservation and management models.

The fifth geothematic area of PROGEOPIEMONTE PROJECT is represented by a sector of fluvial plain of in North - Eastern Piedmont (Po basin). Landforms, agents, processes and factors have been described and mapped for reconstructing the evolution of the fluvial plain. The change of Quaternary landscape and climate in the fluvial plain have been studied by pedological, geomorphological, paleoenvironmental and paleontological data. Waters (natural and artificial waters), are seen as an agent in both landscape evolution and anthropic land use. Geosites and nature trails will show relationships between landscape and anthropic activity.

SOME CRUCIAL KEY POINTS IN THE URBAN ENVIRONMENT DESIGN: ARE URBANISM AND PHYSICAL ENVIRONMENT DEFINITELY CONFLICTUAL?

GEORGIADIS Teodoro¹, ROSSI Federica¹

¹ - IBIMET CNR

Presenter e-mail: t.georgiadis@ibimet.cnr.it

Key terms: microclimate; physical quantities; urban design; wellness

In Italy, from year 1946 which constitute the origin of SVIMEZ (Association for the industry development of the Italian southern regions) a dispute, which is currently open, on the priority of urbanism as a guide and coordination of the urban development still pervades the political action. We saw that the concept of total freedom in managing the land-use and design gave rise to a long and complex series of unsolved problems related to the sustainability of cities as well as the effects on population wellness. Physical relationships between the built environment and microclimate was so poorly considered that the discipline is still not part of the academic cv's of architecture and engineering faculties. Environmental physics demonstrates that it is not quite possible to create a sustainable environment without considering at least elementary principles of human comfort. Thus, the still open question remains: it is possible to conciliate the environmental physical requirements with the urbanistic tools? A positive replay to the question the authors are confident should be possible by putting the human wellness at the centre of this system.

Presenter e-mail: luca.ghiraldi@regione.piemonte.it

Key terms: Valsesia; Cultural landscape; geosites

Landscape is a complex dynamic combination of landforms and processes. These elements are memories of the history of the Earth and enable us to understand the evolution of our world.

The paper describes first the conceptual framework and the methodology followed in order to investigate the relationships between landscape's geomorphological features, environmental dynamics and man in Valsesia (Northern sector of Piemonte Region, Italy), and then the suggestions for a program of appraisal and popularization of geoheritage.

Valsesia offers a wide variety of geological and geomorphological elements, and holds stories of different peoples, who founded their independence in the mountains environment by using the available local resources and even suffering the difficulties. There are traces of human activity starting from the Neanderthal man on the Fenera mountain; Waiser settlements in the upper part of the valley and several mines dated

back to period of Savoy. In this perspective, the physical landscape of Valsesia is an available resource for human activity and settlement; local community suffers, models, works, enhances and destroys part of the landscape, giving it a "personality", that can be defined as landscape culture. Culture is not intended only as "activities of human being" but as "the product of the interactions with the environment in which people lives".

In the transition between the physical and cultural landscape there is an increasingly request of information, curiosity and awareness by the observer, where the geomorphological aspects are evident, while the culture is hidden. For these reasons, the research project can be divided into four main parts: data collection, inventory and evaluation of geological heritage, valorisation of the landscape. These activities have been developed analyzing and linking the geological and geomorphological aspects with the cultural and historical ones.

The geological and geomorphological terrain survey and field data collection were performed by using geomatics tools: a pocket PC equipped with mobile-GIS software and GPS, allowing data collection on a dedicated inventory form properly set up for the Valsesia project. For the historical and cultural part, several local institutions were involved. They allowed a large collection of archival and bibliographic documentation.

The selection of 19 sites with the highest interest has been performed taking into account some peculiar features in order to achieve a wide audience: accessibility, potential dangerousness, educational value and scientific interest.

The popularization phase has been carried out through the production of didactic material (field guide), using simple languages, but at the same time scientific rigorously. Illustrations, pictures, and multimedia help the public to facilitate the comprehension of the natural processes.

Essential part of this work has been dedicated to highlighting the active role of humans being in the history of each site, focusing on the landscape's anthropogenic elements. Geosites described may, therefore, be proposed as elements of sustainable tourism, aware of local resources and respectful of local traditions. As different ingredients create a particular dish, so this project joined different and specific interests, in order to develop a valuable drama to tell different stories: glacialism and climate changes, religious sense and the environment, natural and human history of the valley, geological resources and mining activities.

Key terms: river evolution; historical drawings; Ausa creek

The Ausa creek, in the territory of Republic of San Marino, was strongly affected by human intervention, like artificial levees and flumes, and today it appears as a "urban river".

Seeking and digitizing various historical drawing (cadastral plans, technical and topographic maps) and through other documents it has been reconstructed the evolution of river morphology using a geographic information system.

The evolutionary hypothesis was then calibrated and compared with many geognostic data available in the area.

Finally the changes of the riverbed and channel pattern were reconstructed in the last 150 years, completed by the recognition of the areal extension and age of anthropogenic deposits.

Key terms: archeology; Mount Titano; nivation

Techniques and methods used in structural geology and geomorphology can offer a substantial contribution to archaeological investigation, especially in sites where the "stratigraphic" approach is difficult, and deposits aren't been in horizontal layers.

The site of "Tanaccia", located close to the cliffs bordering the eastern side of Mount Titano, near to the ridge, looks like "slope" archaeological area, and consists in a rock outcrop with a cave at the base (the Tanaccia). During excavations between 1990 and 1994, the finds of votive bronzes and pottery and coins, confirmed the existence of a medical sanctuary from the V century B.C. to the first century A. D.

The cave is probably a nivation hollow developed inside the rock along some interlayers and joints.

Geomorphological and structural analysis allowed to identify handmade expansions and their timeline.

Detailed survey of debris flow around the site provides insights for future archaeological investigations.

Key terms: Landslide-dammed lake; Geosite; Holocene; Montelago; Marche Apennines

Montelago is a hamlet placed approximately at 800 m a.s.l. near Sassoferrato (Ancona, Italy) within the Marche Apennines. Meso-Cenozoic calcareous-cherty-marly formations of the Umbria-Marche succession crop out in the watershed of Fosso del Lago, a NW-SE flowing tributary of Sentino river. The local toponyms "Montelago", "Fosso del Lago", "Il Lago" clearly hint at the presence of a former lake, at present dried out. The first attestation to Montelago appears in historical documents dated to the 13th-14th century, whereas the first cartographic representation accounted to the 19th century Gregorian Cadastre, where some water-ponds are distinctly represented. In this area, the first geological field-based evidence for the presence of an ancient lake was provided in 1960 by detecting blackish, laminated clays cropping out along the present channel of Fosso del Lago stream. In 2008, specifically addressed to a possible restoring and exploitation of the site as a geo-naturalistic attraction, two seismic tomographic profiles have been recorded and a continuous 26.5 m-deep core has been drilled in the area where laminated clays recovering 9 m of lacustrine peaty sediments cropped out. Detailed geomorphological surveys confirmed that the lake was generated by stream damming due to a large landslide failed from the left valley side.

Radiocarbon ages of peats and wood fragments, ranging from 8,180-8,040 cal B.P. (Atlantic) to 3,080-2,880 cal B.P. (Sub-Boreal), demonstrate that the lake persisted for several millennia. However, only a shrank pond survived throughout the entire time-span just in the place where the peaty-clays have been drilled, having been the upstream sector of the lake gradually filled by alluvial gravels. In any case, the youngest ages of the drilled sediments reasonably suggest that the extinction of the lake, by far, antedates the origin of local toponyms. Thus, a major problem arises about the local toponyms, as well as about nature and origin of the ponds represented in the 19th century Gregorian Cadastral maps, which are unlikely to represent relics of an old lake dried out almost three millennia before. Indeed, their very position does not allow regarding them as remnants of the former lake, since they both match the upstream portion of the former lacustrine trough and rest atop the alluvial fan-like bodies filling up this sector of the former landslide-related lake.

The Gregorian maps show a sharp upstream enlargement of the Fosso del Lago stream even to more than fourfold in width, suggesting the occurrence, at that time, of a narrow and elongated water impoundment, also stressed by a nearly horizontal valley-floor profile. This latter is bounded on both sides by 2-3 m-high scarps; a rough parallelism and straightness of the two scarps suggest a human intervention, most likely in enlarging an already entrenched channel to create (and/or to maintain) a small reservoir. Other unusual enlargements shown by Gregorian Cadastral maps on two rather steep (up to 15°-20°) tributaries of the Fosso del Lago stream match former soggy wetlands related to important springs at present dried-out, which evidence are small pot-like holes in the outflow points. It is also worth noticing that several dried-out springs marked by ground depressions and/or dried seepage-channels are apparent throughout the head-valley, thus stressing a recent lowering of the local ground-water level. Finally, long after the former landslide-dammed lake dried up, the Fosso del Lago has been modified by human intervention to create and/or to reshape and maintain a small reservoir supplied by still existing minor streams and by at least three important springs at present drought out. As a predisposing factor to such intervention, re-forming on the Fosso del Lago valley floor of some ponds and/or soggy wetlands because of local abundance in spring water cannot be ruled out.

GEOLOGICAL INVESTIGATIONS IN URBAN AREAS AND PLAINS: AN INVESTMENT.

MARTELLI Luca¹, ALBARELLO Dario²

1 - Regione Emilia-Romagna, Servizio geologico, sismico e dei suoli

2 - Università degli Studi di Siena, Dipartimento di Scienze della Terra

Presenter e-mail: lmartelli@regione.emilia-romagna.it

Key terms: urban areas; subsoil investigation; subsoil data base; geological mapping of the plains

Until a few years ago, geological mapping and research projects have focused mainly in mountain areas to the detriment of the urban areas and the plains. This is true also for the new Geological Map of Italy.

Perhaps this choice comes from the need to understand aspects not yet sufficiently clear in dynamics and evolution of complex chains as the Apennines and the difficulty of survey directly geological elements of the subsoil in urban areas and plains.

The increased urbanization, including the dissemination of infrastructure networks (roads, aqueducts, pipelines, etc.), has radically changed the context of the needs of geological knowledge and the role of the geologists in the society.

First, the urbanization of areas with geological hazards increased significantly the exposure to risk, the consumption of soil and the need for exploitation of subsoil resources.

Moreover, the need for research of renewable energy sources, such as geothermal energy, to reduce the emission of polluting gases into the atmosphere, requires geological knowledge especially near urban areas.

In urban areas, both because human works prevent direct observation and because they were developed mainly in valleys, plains and along the coast, it is often necessary to investigate the subsoil with drillings and geophysical surveys.

In situ tests often involves high costs, long time for authorization and execution and logistic difficulties (investigations in the historic centers not permitted, presence of underground utility networks, etc.).

Sparse available survey sites (drillings, seismic lines, etc.) are thus very precious points of observation, perhaps most valuable then outcrops in the chains.

It is therefore extremely important to organize all geological data of urban areas and plains in accessible databases, easy to update. So, geological investigations in urban areas and the related databases raise the meaning of a real investment, useful for urban planning and design of works.

Fortunately, the same data can be used for various purposes. For instance, the study of underground water reserves run in the 90s by the Emilia-Romagna Region and ENI, based on seismic lines and stratigraphic logs from oil wells (ENI data) and stratigraphic bore-holes and water wells (regional data base), integrated with studies on the main bodies of alluvial fan for hydrogeological purposes, have provided very important data also for studies of seismic microzonation and for the exploitation of underground heat, both for the ground coupled heat pumps (open loop and closed loop) and for the research and exploitation of thermal aquifers.

As test sites in the plains and urban areas are spotted, it is necessary to interpolate and correlate data, possibly with an appropriate number of checks distributed according to regular meshes. Moreover, in urban settings is often necessary to use non-invasive techniques. Of course it is also important that additional investigations are fast and low cost.

Measures of ambient vibrations allow quick and low cost checks throughout the territory and, in combination with stratigraphic investigations, allow the recognition of major stratigraphic discontinuities in the subsoil.

The investigation techniques and procedures mentioned above have been successfully tested in geological studies of large urban areas. We will briefly present some interesting results.

Finally, as after the new national seismic classification all Italian municipalities are classified seismic, the new technical standards for construction require detailed geological and geotechnical investigations for design, in particular for the calculation of the seismic force, in some regions the seismic microzonation is required for approval of the urban plans and geological information are used for civil protection plans (damage scenarios, test of strategic buildings, etc.) it is desirable that the official geological mapping will be completed at least in urban areas and in the plains.

Key terms: Urban geosciences; Geohazard assessment; Rome; Geological mapping; Susceptibility maps

The UrbisIT Project, led by the CNR-IGAG, Istituto di Geologia Ambientale e Geoingegneria, and commissioned by the Dipartimento della Protezione Civile, is aimed at the development of tools and products for geohazard assessment in urban areas, and of geological-technical models for seismic microzonation.

In particular, the project is organized into workpackages, and prefigures the specific procedure explained in the following steps.

- 1) Selection of study areas, in general few km² or tens of km² wide, with related data collection from scientific literature, public administrations and private companies. Data of interest concern the soil and subsoil of urban areas, and are of geological, hydrogeological, geophysical, geotechnical and remote sensing typology, along with related thematic maps.
 - 2) Definition, for each area, of three operational and study levels at different spatial scale, namely the broad, intermediate area, and site specific levels, to reach the detail specifically required for the scopes and expected products of the study.
 - 3) Analysis, selection and classification of collected data to be stored in a GIS supported database, which is projected for the three defined levels, and for different purposes such as, for instance, bi- and tri-dimensional geological reconstruction of urban subsoil, spatial hydrogeological and geotechnical, numerical modeling.
 - 4) Data elaboration and delivery of specific products for each level. At the 1st level, the broad area scale, Synthetic Geological Maps (SGM) (at 1:50.000-1:20.000 scale), and related stratigraphic schemes, are produced, which integrate basic geological cartographic data with the numerous and densely distributed, but not homogeneously detailed, borehole data. Large informal Basic Stratigraphic Units are introduced within the SGM, so as to characterize urban subsoils, and to provide a basic tool for preliminary Susceptibility Maps, related in particular to subsidence and sinkholes. At the 2nd level, the intermediate area scale, detailed Geological Maps (at 1:10.000 or broader scale), Susceptibility and local Geohazard Maps, Seismic Microzonation Maps are produced, along with specific studies on anthropogenic backfill deposits, on their geometrical characterization, and on their relations with the geological substratum. At the 3rd level, the site specific level, more detailed products, at 1:1.000-2.000 scale, such as Local Seismic Response or slope instability studies are expected.
- The city of Rome is one of the selected study areas where the above mentioned procedure and data elaborations have been tested. Synthetic Geological Maps of the entire urban area, and smaller scale Maps of the anthropogenic backfill deposits of the city centre, and Seismic Microzonation studies are here presented and discussed for this wide urban area.

Presenter e-mail: nardi@unina.it

Key terms: Tirana; Urban Geosciences; Underground model; GIS

The present work is focused on the reconstruction of a "geological underground model" in the center of Tirana. The obstacles in dealing with a geological study in urban areas are the shortage of outcrops and the widespread existence of underground utilities. These difficulties can be largely overcome with a multidisciplinary geological analysis based mostly on data from core surveys but also from new geophysical technologies. Tirana is situated in a flood-plain area actually crossed by the "Tirana" river, flowing in the northern part in his natural riverbed, and by the "Lana" river, flowing in artificial banks in the southern part. The whole plain is surrounded by low gradient hills whose directions reflect a structural control. The stratigraphic bedrock is made by a Tortonian silty mudstone on which can be found the recent alluvial-colluvial deposits. The study has been developed on a data set made by: continuous core surveys, laboratory/field geotechnical tests, digital terrain model, orthophotos, groundwater table levels and historical topographic maps. This data set via a multidisciplinary analysis, using also GIS and CAD software, allowed to develop geological sections (in lithological, depositional and hydrostratigraphic units), a morphological structures map, a 3D groundwater flow model, a chronology of recent events and a three-dimensional litho-stratigraphic arrangement. The digital image analysis together with continuous core wells stratigraphy allowed the recognition of surface and underground forms, the identification of sedimentary bodies and depositional facies and the reconstruction of geological processes that affected the topsoil and subsoil of Tirana. This study confirmed that a Quaternary continental floodplain system is set on a Tortonian marine transitional system. Moreover the present work shows that this continental system has been strongly affected by the fourth-order eustatic changes in Plio-Quaternary but also by tectonic activity linked to the formation of the range of hills skirting the urban area. This tectonic activity is the main cause of the subdivision of the study area in two domains with different fluvial hydrodynamics (erosional, depositional, etc.). Particularly the study of groundwater levels (derived from wells data), related to the subsurface geology, allowed to outline the morphology of the water table and the main groundwater elements. The 3D groundwater flow model developed shows the characteristics of the groundwater system composed by a confined shallow quaternary aquifer whose elements have E-W directions. Finally the GIS analysis allowed to compare the geological model outlined with the hydrostratigraphic one showing a good agreement between the two models. Indeed the morphology and position of the groundwater elements (such as watersheds or drain axes) matches largely the depositional facies defined in the geological model.

GEOHERITAGE: A WEBGIS CONCERNING PALERMO URBAN AREA

GIAMMARINARO Maria Stella¹, VALLONE Paola²

1 - Università di Palermo

2 - Regione Sicilia

Presenter e-mail: paola.vallone@regione.sicilia.it

Key terms: Palermo urban area; Urban geology; GIS application; Territorial planning

Palermo urban area is characterized by high variability of near surface geology and soil physical-mechanical properties on a very short distance scale, even few meters. So near territory portions can have a totally different hazard exposition.

GeoHeritage is a GIS application developed within Project 7T7, Cluster C 29, funded by MIUR, that manages a Geographic Information System concerning Palermo urban area. It includes: 1) a reliable high density stratigraphic - geotechnical database, assembled by means of a careful data reviewing process; 2) a database of some hundreds of lithotechnical sections, each carried out by using a high density of geotechnical and stratigraphical data; 3) the accelerograms database of the September 2002 seismic sequence, recorded by eight temporary digital seismic stations, located in correspondence of the main geological models recognized in Palermo urban area; 4) a damage census database, performed using the "AeDES" census damage card which codifies the damage suffered by structural elements in few features (damage class, typology and area of the damaged structural elements), set up by Civil Protection Regional Department - Sicily after the 6th September 2002 earthquake; 5) a macroseismic intensity database composed by intensity values estimated in 3000 different sites of the city by means of a macroseismic questionnaire dispensed during the 2002 earthquake; 6) a Palermo cultural heritage database.

GeoHeritage has all GIS functions and tools specifically dedicated to identify the zones interested by the main hazard factors. The possibility to display and simultaneously query the different database managed by GeoHeritage allows to easily highlight the buildings most exposed to hazard factors as soft foundation soils, shallow water table, ecc..., or vulnerability factors, as for example underground cavities. The tools equipped with GeoHeritage and the Geographic Information System elaborated for Palermo urban area can efficiently support territorial planning and management and correctly project interventions to assure safety conditions or in emergency situations.

For these reasons a website (www.ghgis.unipa.it) has been carried out, where GeoHeritage and the GIS concerning Palermo urban area have been implemented, setting up a permanent interface between those studying the territory properties and those preposing to make decisional choices concerning the territory.

Some cases of GeoHeritage utilizations are presented to highlight its reliability in territorial planning and heritage safeguard.

MULTIDISCIPLINARY GEOLOGICAL APPROACH FOR URBAN AREAS IN SICILY: EXAMPLES OF MESSINA AND CATANIA

CARBONE Serafina¹, LENTINI Fabio¹

1 - University of Catania

Presenter e-mail: lentinif38@gmail.com

Key terms: Urban geology; Neotectonics; Geomorphology; Geological hazard

In Sicily the geodynamic activity is testified by geomorphological evolution, uplift, volcanic and destructive earthquake events. In recent times the urban geology assumes particular importance, but the field

survey is hampered by roads and edifices and it needs detailed field mapping, integrated by subsurface data for reconstructing the stratigraphy and geometries of the geological bodies. The analysis must be supported by aerial photographs better of different times, and by historical documents.

In Eastern Sicily the Messina and Catania urban areas represent two examples of different geological aspects, but both are affected by geodynamics, which deeply influences the life of people. Messina is located on the western side of the Messina Straits, that shows morphological features strongly related to the structural setting. ENE-WSW oriented morphological escarpments, bordering the coast of the northern sector of the Straits, are clearly controlled by the Scilla System. Single channel seismic lines show faults affecting the sea-floor sediments. This area has been destroyed by the earthquakes of February 6th 1783, located in the offshore of Scilla village, and by the famous earthquake of December 28th 1908. The structure responsible of the last event is still not been recognized: more of ten different hypothesis have been presented in the literature. Recently a project to realize a bridge across the Straits produced a lots of subsurface geological data, that can permit a reconstruction of the geological features in the urban area. Catania is located on the southern flank of the Mount Etna volcano in front of the Ionian Sea. The town has been destroyed by two main earthquakes, occurred in 1169 and 1693. To define the complicate geological and morphological settings below the volcanic cover, as well as the structures responsible of the events, is fundamental the detailed analysis of the pre-volcanic morphology, of the stratigraphy of the volcanic products as well as the stratigraphy of the sedimentary basement. The study must be integrated with geophysical and stratigraphic analysis of the boreholes drilled in the urban area. This kind of study should be extended to a large area of the whole Eastern Sicily to recognize the regional seismogenic structures. The city was damaged by a lapilli fallout originated by a plinian eruption of 122 a.C. In 1381 it was threatened by lava flows originated by an eruptive fissure opened at 400 m a.s.l., and in 1669 the largest effusive eruption destroyed nine villages and reached the town. So that Catania represents another example of a city characterized by both volcanic and seismic high risks, and this should be a fundamental target of an urban geological multidisciplinary analysis.

THE GEOLOGY OF THE URBAN AREA OF BENEVENTO. THE PALAEOENVIRONMENTAL RECONSTRUCTION IMPORTANCE IN PREDICTING THE SEISMIC RESPONSE

SENATORE Maria Rosaria¹, BOSCAINO Modestino¹, PINTO Felice¹
1 - Università degli Studi del Sannio Benevento Italy

Presenter e-mail: senatore@unisannio.it

Key terms: STRATIGRAPHY; SEDIMENTOLOGY; SEISMIC RESPONSE; SEISMIC VULNERABILITY

Geological studies carried out between 2001 and 2003 in the city of Benevento were performed as part of a multidisciplinary project, coordinated by the National Group for Defense from Earthquakes (GNDDT), called Traiano Project, which was composed by ten research units with eight tasks developed in several stages. The Task 3 - geological characterization - has established the stratigraphic and structural framework to highlight the factors which influence the local amplification of the seismic signal. Since 2003, the data acquired with the Traiano Project have been continuously updated as soon as new boreholes and digs for the construction of building have become available. According to composition, texture, sedimentary structures of the sediments, and the depositional environment and the relative age, several stratigraphic units were recognized. The physical stratigraphy approach made possible to reconstruct with good approximation the spatial distribution of the units with their mutual geometrical relationships as they are not the result of a random geological evolution, but the result of a logical spatial and temporal development of depositional environments, arranged with the tectonic and morphological evolution of the area. Geological survey in the city, in digs for building construction, and in cuts along road was carried out; moreover 16 boreholes carried out for the purpose were analysed and about 400 stratigraphic logs archived and made available by several local public authorities were re-interpreted. The derived geological, stratigraphic and structural model is supported by the experimental geophysical data and has provided the base for the spatial extension of the data useful even to the geostatistic approach. The stratigraphic pattern is defined by: anthropogenic deposit: h, hl, h^o; mixed slope deposits: p-b2 (Late Pleistocene-Holocene), p-b4-7 (Late Pleistocene-Holocene) forming alluvial deposits: b, BN1 (Latest Pleistocene-Holocene), terraced alluvial deposits: BN2 (Late Pleistocene), BN3 (Middle-Late Pleistocene), bn4 (or Cretarossa alluvial deposits CR-bn4; Early Pleistocene); ancient alluvial deposits of Benevento Pacevecchia AABPV (Late Pliocene-Early Pleistocene): facies a silty and gravelly-sandy deposits (AABaPV); facies b: sand silty and gravelly deposits (AABbPV); facies c: silty sand and clayey-silt deposits (AABcPV); syn-orogenic units: Ariano group unit (UGA) (Early Middle Pliocene); pelitic-arenaceous facies (UGAPs); arenaceous pelitic facies (UGASp); Tufo Altavilla unit (UTA) (Late Messinian; Chiocchini & Chiocchini, 1996); pre-orogenic units: calcareous-pelitic Flysch Rosso succession (sfr) (Scandone, 1967; Early Cretaceous Burdigalian. A geological map (1:4.000 scale), demonstrating the validity of the classic geology investigation methods, updated and codified within the CAR.G project. The geological analysis and seismological data (Di Giulio et al., 2008) have made possible to distinguish at least three zones with different seismic response: 1) relatively low amplification (AF 1.1 +/- 0.1) along the Benevento hill, not considering the presence of covers, above AABaPV; 2) amplification of 1.5 +/- 0.2 related to the geological conditions of Rione Mellusi (in particular CR-bn4 above AABaPV or AABbPV), and in the rail station area (b and BN1 or BN2 and p-b2 on AABaPV) producing resonance phenomena with frequencies of 4 Hz; 3) amplification of 2.1 +/- 0.6 related to the geological conditions of the Sabato river plain (Triggio e Rione Libertà). This area was urbanized between 1940 and 1960 with inadequate buildings for seismic actions (Pecce et alii, 2004). The estimate damage for these buildings point out a large proportion of collapses in the case of a strong earthquake (about 40%, Cosenza et al., 2005).

A map of damage at the buildings carried out after an earthquake that struck Benevento in 1688, shows severe collapses in the area of the Triggio.

RECONSTRUCTION OF HYDRO-STRATIGRAPHIC MODEL BASED ON GEOLOGICAL-STRATIGRAPHIC MODEL IN THE BASEMENT OF THE URBAN AREA OF BAGNOLI; VALIDATION ON THE BASIS OF EXISTING IDROGEOLOGICAL DATA.

ALLOCCA Vincenzo¹, CAMMAROSANO Antonella¹, DELLI CARRI Diego², NARDI Giuseppe¹

1 - Università degli Studi di Napoli "Federico II"

2 - Romametropolitane

Presenter e-mail: anto.camm@hotmail.it

Key terms: Urban Geology; Underground Urbanism; Hydrogeology

The Plains of Coroglio and the Terrace of Bagnoli - Fuorigrotta represent a flat area that extends SW-NE direction from the Gulf of Pozzuoli to the central city area and is characterized by the presence of the volcanic edifice of St. Teresa. The basement of this area consists of a sequence of volcano-clastic deposits and transitional resting on a tuff substrate. Hydrogeological characteristics of the area are very unique compared to other areas of the city of Naples. In fact, it is characterized by the presence of an underground watershed that separates it from the rest of the groundwater flow system. It has in fact a drawing of the piezometric surface quite articulate, with a relatively high hydraulic gradient. A qualitative analysis of the trend of the piezometric surface does not identify in a comprehensive manner the geological causes that affect the hydrodynamic morphological elements (Celico et al., 2002). This work identifies these factors and test the existing patterns of the groundwater flow through the creation of hydrostratigraphic sections generated on the basis of a three-dimensional geological model of facies defined by survey data. These sections were made choosing for each depositional facies in the subsurface a particle size fraction, when homogeneous. In case of non-homogeneous particle size an average value has been assigned based on the relationship between thickness and grain sizes. The deposits were classified with respect to the relative permeability using values derived from laboratory data for pyroclastic soils that characterize the Neapolitan area (Cammarosano personal data) and canonical tables for transitional deposits. Taking into account the maximum and minimum value of relative permeability as defined, three classes of hydraulic conductivity were set up: High (K between 10-2 and 10-4 m / sec), medium (K between 10-4 and 10-6 m / sec) and low (K between 6.10 and 8.10 m / sec). Many sections representing the distribution of relative permeability in the subsurface were developed based on these three classes of hydraulic conductivity. Hydrostratigraphic sections, developed from the existing geological model, confirm the hydrogeological pattern established by Celico et al. 2002 (water table levels and watersheds obtained from hydrogeological data) and helped identify the geological causes that affect the hydrodynamic morphological elements.

These results validate the proposed methodology in the construction of hydrostratigraphic sections and lead to use advanced sedimentological analysis of stratigraphic data from wells in urban areas.

FROM DATA ACQUISITION TO URBAN MANAGEMENT: A GEOLOGICAL APPROACH FOR ADDRESSING GEOHAZARDS PREVENTION ACTIVITIES

URRU Giorgia¹

1 - CNR-IGAG, Università degli Studi "Roma Tre"

Presenter e-mail: urru@uniroma3.it

Key terms: Geohazards; G.I.S.; urban environment; Roma

A basic methodology to evaluate geohazards in urban environment is presented in this paper. The proposed methodology is useful for addressing urban planning and risk management before disaster, having a look at spatial data existents, easily consultable, flexible and dynamically connected.

Every day a natural catastrophe at least affects an area of the most populated region of the world where seismic, volcanic, cyclone, landslides, flood hazards are just a part of them. Actually the pervasive urbanization process and the increasing human needs (buildings, infrastructure, transport, energy pipe lines) have strongly modified the environment interacting with surface and underground earth properties, triggering man-made geohazards phenomena (cavities collapse, filling deposits instability, subsidence process). The civil protection authorities are mainly involved in the management of disaster events, but also in the prevention and prediction activities for reducing risks. By now the knowledge integration of environmental characteristics is mandatory to support the planning and the assessment of decision making process.

On this regard a methodological approach is suggested in this paper, based on geological data acquisition, from collecting topographic/thematic cartography to interpreting stratigraphic and geophysical logs, reviewing the pre-existent and new spatial (XYZ) and temporal information available. This semi-quantitative approach is focused on evaluating man-made geohazards, often interlocked to natural ones, giving a spatial tool for planning urban development, so to considerably reduce or mitigate the disaster risk.

The proposal methodology was developed in the city of Rome, a metropolitan area with huge amount of geological and historical information available. Rome is a strategic area for developing the proposed procedure, because of its geological-geodynamical/geomorphological settings and its vulnerability due to its World Heritage resources and its political role. Different geological hazards insist on the city with medium-low degree of impact. The complexity of alluvial deposits (Holocene), the variable thickness of man-made filling, the recent sprawl urban development are the main critical features.

Man-made deposits and seismic properties were principally investigated for Tiber's left bank tributaries. Two presently buried valleys (paleo-valleys), characterized by similar geology, but diachronous urban development, buildings typology, and infrastructure, were analyzed. The conceptual and logical model was implemented in a G.I.S., and the geological, geotechnical, hydrogeological, and stratigraphic data were stored in a RDMS. The comparison of the two valleys shows different seismic velocity profile respect to S-waves at the same depth, according to respective urbanization history and lithotype properties.

Finally, the proposed approach can give a relevant methodology to civil protection authorities, planning managers, and stakeholder for an aware and safe urban management, especially where surface data are rare and anthropic pressure on the local environment is high.

THE GEOHAZARD ASSESSMENT IN URBAN AREAS: THE RECONSTRUCTION OF THE ANTHROPIC BACKFILL GEOMETRY IN THE CENTRE OF ROME (URBISIT PROJECT).

STIGLIANO Francesco¹, CIOTOLI Giancarlo¹, DI SALVO Cristina¹, MANCINI Marco¹, MARCONI Fabrizio¹, MOSCATELLI Massimiliano¹, CAVINATO Gian Paolo¹

Presenter e-mail: francesco.stigliano@igag.cnr.it

Key terms: anthropic backfill mapping; geostatistics; flooding; geohazard; Rome

The anthropogenic deposits or "anthropic backfill unit" constitute one of the main and problematic geological feature of urban areas. Because of their anthropic origin they could not be referred to the natural processes originating the sedimentary formations; however, they could be considered as a true shallow and heterogeneous "geological body" due to their intrinsic characters, such as geometry, thickness, lithology, texture, and stratigraphic position above the natural geological substratum. Due to their geological/geotechnical characteristics these deposits can be linked to different geological hazards that affect urban areas. The presence of urban service networks and subsurface works excavated in the backfill units may increase the level of hazard. Furthermore, studies about the distribution of earthquake damages show a positive correlation between backfill thickness and seismic amplifications.

The backfill unit commonly hosts an important groundwater circulation fed by rainfall recharge, sewer leakage, buried ditch, and numerous springs localized at foothills. Furthermore, they often hide the original drainage network and could induce flooding phenomena. This study is aimed to reconstruct the bottom surface and the thickness maps of anthropic backfill of the city of Rome by using geostatistical interpolation techniques in order to develop a general tool to rapidly evaluate the flooding susceptibility of urban areas. The backfill elevation discrete values come from about 1400 boreholes located in the center of Rome and stored in the UrbisIT BDGT database (UrbisIT Project, CNR-IGAG-National Civil Protection Department).

As starting hypothesis the maximum thickness of anthropic backfill is thought to occur along the buried streams. An overlay between the map of the anthropic backfill thickness and the original drainage network (published by the Autorità di Bacino del Fiume Tevere) was performed in order to validate the initial hypothesis. The backfill thickness map was used to detect zones where the original drainage network filled by man-made deposits could involve flooding phenomena in case of heavy rainfall. Two variables were considered in the assessment of flooding susceptibility: the distance from the buried valley axes and the backfill thickness. These two variables have been represented as raster dataset and summed by using "map algebra" operation in GIS environment. More variables, like water main network and water table will be further considered in order to refine the risk analysis.

The application of probabilistic algorithm constitutes a reliable technique for the reconstruction of the backfill bottom surface and thickness maps in urban areas starting from stratigraphic boreholes. In particular, the results obtained by integrating the thickness of backfill units and the buried drainage network provides a rapid tool for the elaboration of preliminary maps of flooding susceptibility that can be used for risk evaluation and urban planning by public institutions.

Key terms: geohazard; seismic microzonation; Palatine hill; Rome

In 2009, after declaring the state of emergency for the central archaeological area of Rome following the adverse weather conditions of November and December 2008, the Commissario delegato (i.e., Government Commissioner, at present Roberto Cecchi, Ministry of Cultural Heritage and Activities) and the Dipartimento della Protezione Civile (i.e., Italian Civil Protection National Service, DPC) assigned the Istituto di Geologia Ambientale e Geingegneria (IGAG) of the Italian National Research Council (CNR) to evaluate the geohazard level affecting Palatine Hill, Roman Forum, and Coliseum. Research activities started up in February 2009 and were concluded in February 2011, with the valued contribution of the Soprintendenza Speciale per i Beni Archeologici di Roma (i.e., the archaeological Superintendence).

The first two phases of the project (between February and December 2009) were carried out mainly using available information from public Institutions and private companies. Three new thematic maps on a 1:1,000 scale were produced at the end of the second phase: (i) a geological and hydrogeological map with seven geological cross-sections, (ii) a susceptibility to instability map, and (iii) a seismic amplification susceptibility map. The third and final phase allowed to perform new field surveys and involved three CNR research Institutes (apart from IGAG, scientific coordinator) and one University department:

- o Istituto per l'Ambiente Marino Costiero (IAMC), CNR;
- o Istituto di Metodologie per l'Analisi Ambientale (IMAA), CNR;
- o Istituto per le Tecnologie Applicate ai Beni Culturali (ITABC), CNR;
- o Dipartimento di Ingegneria Strutturale e Geotecnica (DISG), SAPIENZA University of Rome.

The new surveys were planned to achieve two main goals:

- 1) the characterization of the archaeological layer, in order to (i) map the bottom surface of the anthropic covering, and (ii) typify the archaeological layer in terms of physical and mechanical properties.
- 2) the characterization of the underlying geological bedrock, aimed to (i) map the geological units and typify the recognized lithotypes in terms of

physical and mechanical properties, (ii) detect and monitor the water table position, and (iii) detect conditions potentially susceptible of instability (i.e., landslides, cavity or chamber collapse, seismically induced settlements);

Because almost no direct observation either of the geological bedrock or of the pre-anthropogenic/anthropogenic contact is possible due to the thousand-year-old anthropic covering, an extensive Electrical Resistivity Tomography (ERT) and Ground Penetrating Radar (GPR) survey was performed. Integration of the geophysical surveying methodologies with geotechnical boreholes allowed to define a very detailed geological model of the study area, in terms of buried topography, geometries of geological and anthropic bodies, and lithotype distribution. The geological and hydrogeological map, along with the geohazard susceptibility map were updated in the light of the new data. Moreover, geotechnical in situ and laboratory tests, active (Down-Hole, Cross-Hole, and MASW) and passive (noise measurements) geophysical surveys allowed to define a subsoil model aimed at 1D and 2D numerical evaluation of the seismic response of the area. The main results of this study lie in a seismic microzonation map on a 1:2,000 scale and site-specific response spectra to be used for seismic retrofitting of the monuments.

The main goals of the project were achieved at the end of the study. Results demonstrate how valued cooperation among Institution allow to accomplish prevention of risk related to local conditions of instability, both in terms of geological and seismic hazards. Finally, the proposed experience is a good example for managers, in order to develop site-specific guidelines for risk preparedness in heritage sites.

10.1474/Epitome.04.0433.Geoitalia2011

HAZARD ENDOGENOUS GAS EMISSIONS (CO₂, H₂S AND 222Rn) IN THE CAVE DEI SELCI (MARINO-ROME)

LUCCHETTI Carlo¹, CARAPEZZA Maria Luisa², BARBERI Franco¹, TUCCIMEI Paola¹, PAGLIUCA Nicola Mauro², TARCHINI Luca¹, RICCI Tullio², RANALDI Massimo¹, DE SIMONE Gabriele¹

1 - Università "Roma Tre"

2 - INGV (sezione Roma1)

Presenter e-mail: clucchetti@uniroma3.it

Key terms: Hazard endogenous gas; Soil radon concentration; Radon indoor; CO₂ flux; Alban Hills area

Many areas in the Alban Hills are at risk from endogenous gas emission mainly due to the presence of a quiescent volcano, active since 600000 years ago. The areas of gaseous emissions are located: in correspondence of structural highs of carbonate basement, along extensional faults with directions NW-SE (Cava dei Selci), on bottom of the Albano lake, and in areas where impermeable surface coverage is removed from excavations or perforated by wells. In the area of Cava dei Selci is a site of strong emission of endogenous gases (CO₂, H₂S and 222Rn are main) because anthropogenic excavations removed the surface sediment of low permeability, previously preventing the gas release. Since the year 2000, this area is monitored with flux measurements of CO₂ on a fixed grid. In this area since July 2009, 11 measurements of soil radon at 30 cm depth from ground level were made, having values between 1455 Bq/m³ and 69700 Bq/m³. Mainly the highest concentrations of soil radon were measured in correspondence of sites with higher CO₂ flux from soil (carrier effect). During the winter it was not possible to make measurements of soil radon because the area is covered by seasonal pool of water. Since 2010 concentration measurements of 222Rn and CO₂ in the soil (at 80 cm depth from ground level) were made along with measurements of CO₂ flux, in some home gardens around maximum degassing zone. Also in this case the highest values of soil radon were measured in correspondence of higher CO₂ flux. Since February 2010, radon indoor measurements were performed in some ground or underground rooms, selected for the presence of relevant CO₂ and H₂S air concentrations. In the underground level of some buildings, including three apartments in Maciocco street, at present evacuated, dangerous gas concentrations up to lethal levels (CO₂ 20,6-22 vol.%, H₂S >500 ppm) were observed. In one of these indoor environments, radon continuous measurement from February 26, 2011 to March 02, 2011, indicates 504 Bq/m³ as minimum value, 23500 Bq/m³ as maximum value and 7500 Bq/m³ as total average. During many radon indoor measurements it was possible to check carrier effect of CO₂. The measurements carry out in this area showed a strong release of gases from soils, not only in the main degassing site, but also in various parts of the urbanized area. This implies a widespread situation of danger for indoor concentrations of CO₂, H₂S, and 222Rn in some buildings. At regards these environmental issues, the introduction of constraints for excavation and drilling is recommended to prevent accidents to people and the high cost to restore security conditions.

RADON AND BUILDING: PREVENTIVE ACTION FOR RISK REDUCTION

CASTELLUCCIO Mauro¹, TUCCIMEI Paola¹, LUCCHETTI Carlo¹

1 - Università "Roma Tre"

Presenter e-mail: tuccimei@uniroma3.it

Key terms: soil radon concentration; soil intrinsic permeability; building protection; radon hazard mapping; urban planning

The World Health Organization identifies radon as the second cause of lung cancer in the general population, after smoking. Epidemiological studies have provided convincing evidence of an association between indoor radon exposure and lung cancer, even at the relatively low radon levels commonly found in residential buildings.

Radon is a natural gas produced from uranium and thorium decay; soil is generally the main source of radon accumulating in indoor environment. Thus the knowledge of gas potential release from soil is a powerful tool to make new buildings with low level of indoor radon: a preventive action with a specific field survey can be more effective and economic if compared with later mitigation practices.

The knowledge of potential radon emission from soil can have different addresses according to the investigation scale. If applied to large scale survey, it can provide useful data for urban planning and lead to a territory zoning, with location of areas where a significant proportion of homes exceed the reference level (radon-prone areas). In case of small scale investigation (construction site scale), it is possible to collect more detailed information on potential radon release from soil. Here, a protocol

for the evaluation of radon hazard factor is proposed in order to promote a practical approach to exploit in any single construction site. This protocol provides a set of indications whose core is the contemporaneous measurements of soil radon concentration and intrinsic permeability. Using these two parameters, a numerical index is calculated, whose value allows to characterise the site on the basis of hazard classes. Mapping soil radon and radon hazard can be a further investigation tool, useful to define the spatial distribution of parameters. Furthermore, the protocol provides suggestions on the protection degree of a new building, in terms of proper construction techniques to prevent gas transport from the soil to the indoor environment. It also gives indication on the permeability features of the ground surrounding the building with the aim of preventing a focused radon flow towards the building foundations. It is important to keep in mind that different methods can be used to measure the parameters. Consequently, it is useful and necessary to validate the method through intercomparison exercises in test-sites. Caffarella Valley (Rome) represents a well-consolidated reference site to study soil radon variability and intercomparison work took place there. Actually, this kind of events are regularly organised in different European countries with the participation of universities, research centres and private firms.

Key terms: POTENTIALLY TOXIC ELEMENTS; BIOGEOCHEMICAL INDICATORS; ISOTOPIC INDICATORS; ENVIRONMENTAL QUALITY; RAVENNA, ITALY

The final conclusions of a multidisciplinary study of Earth and Soil Sciences, carried out in the frame of Prin 2007 are presented. The study has dealt with a variety of natural materials, encompassing soils, waters, atmospheric depositions, the vegetation and the bottom sediments of a coastal lagoon, in the territory north of Ravenna, characterized by important agricultural and industrial activities. In particular, by chemical and isotopic methodologies and pedological survey, it has been studied the ecosystem of the San Vitale Pinewood and the Lagoon of Piasassa Baiona, both constituting the southernmost part of the Po river delta Park. The results obtained have shown that the Pinewood is affected by major salinization processes induced by local subsidence and concerning underground water and soils. This jeopardizes the vegetation's health, in particular, the pine trees that are the main characteristic species. Moreover, the proximity of the industrial zone of Ravenna to the Pinewood represents another threat to the environment, as it is a major pollution source by release of particulate matter with stacks. Therefore, potentially toxic elements may fallout onto the soils, waters and vegetation of the Pinewood, arising general concern on the preservation of the forest. The important traffic rolling on the road net contouring the Pinewood-Lagoon ecosystem is a further source of pollution, as indicated by the incoming diffusion of PGE on the topsoils bordering the roads. Lastly, the study of the bottom deposits of the Lagoon at the water-sediment interface has unveiled the diffuse presence of Hg with significant concentrations, derived from industrial wastewaters unloaded in the basin some decades ago. Luckily, Hg occurs in the element form and, thus, its mobility is very reduced, keeping so far the risk factor in the Lagoon low. As a whole, the Pinewood-Lagoon ecosystem is ailing due to incoming salinization processes and, subordinately, moderate pollution proceeding from the industrial zone and the traffic. Therefore, it is recommended to implement a monitoring survey of the study area on the ground of the parameters used in this research. In fact, they have been able to provide the local Administrations with punctual responses to the problem of degradation of the Pinewood-Lagoon ecosystem.

Presenter e-mail: balbi@geologiliguria.it

Key terms: Geology; Geomorphology; Geoarchaeology; Urban; Genova

Several complicated geological and geomorphological features, directly connected to the particular tectonic history of the area, have influenced over the centuries the development and expansion of the Genoese urban area. The city of Genova lies on a transitional zone between the Alps and the Apennines, whose extremely complicated tectonic history has left evident morphological traces. After the Tethys oceanic crust subduction, during the Paleogene, mountain building occurred due to several compressional phases that superimposed very different formations from the lithological, metamorphic and deformational point of view: cretaceous turbidites, jurassic mafic and ultramafic rocks from almost non-metamorphic to eclogites facies, dolomites, cherts, basalts, limestones etc. Some chain scale tectonic lines such as the Sestri-Voltaggio cross Genova and influence the morphology of one of the two important valleys that characterize the shape of the city. The north-east migration of the compressional front after the Oligocene left an extensional regime that caused the formation of the characteristic steep mountain slopes that face the sea along almost all of central and eastern Liguria as well as several graben structures that form the relatively less steep area occupied by the city of Genova. The Messinian-Pliocene sea level oscillations left evidences such as the submarine canyons that continue underwater the course of the two main waterways that cross the city, the Bisagno and Polcevera streams, and, on the other side, the thick marine deposits of overconsolidated shales along

the graben structures (Ortovero shales) as well as several marine terraces structures.

Despite the complicated morphological features, Genova has been populated since pre Roman times because of its position on the Mediterranean sea. The development of the town since its origins has been influenced by the peculiar morphology characterized by a few flat areas squeezed between the sea and the mountains (which can be as high as 800 m like mt Fasce) along an almost E-W direction, with the exception of the two larger valleys Bisagno and Polcevera that run northwards, giving the modern city the approximate aspect of a big upside down T. The morphology of the city has somehow influenced the human activities too, driving the ancient Genoese to sail the seas and develop commerce. The great subsoil lithological variety has allowed the development of several quarries in the urban area. They go from the small Antola marly limestone quarries which used to meet the need of local building material to those of the green opicalcites (Verde Polcevera), still very appreciated as decorative stones and the more recently opened quarries of basalts and dolomites used for the making of concrete, asphalts and steel making processes.

Several geomorphological and hydrogeological problems affect the city of Genova. The fast growth phase that followed World War II, characterized by a lack of proper planning, led to a quite indiscriminate urban sprawl towards the hills and the mountains. Since the 1960ies landslides and floods have periodically affected the city, leaving behind destruction and death as in the case of the landslide which occurred in Via Digione, a new area close to a hill, because of underestimation of geological data, or the 1970, 1992 and 2010 floods that interested various parts of the city. These natural phenomena could have made little or no damage if an appropriate town planning scheme had foreseen the possibility of these events.

Nowadays, in such geological and geomorphological contest lies a city of almost 700000 inhabitants, that tries to implement communication lines through its geologically and morphologically complicated inland to help the trade connected with its harbour grow and, at the same time, to solve its geomorphological and hydrogeological problems, planning a new growth without causing any further damage to its beautiful but difficult environment

INTEGRATED METHODOLOGIES WITHIN URBAN GEOLOGY STUDIES: THE EXAMPLE OF THE TOWN OF PAVIA (NORTHERN ITALY)

LIBERATI Monica¹, PILLA Giorgio¹, MEISINA Claudia¹, TORRESE Patrizio¹

- 1 - Università degli Studi di Pavia

Presenter e-mail: monica.liberati@unipv.it

Key terms: Urban geology; 3D underground modelling; Groundwater monitoring; Cultural heritage preservation

The town of Pavia is mostly located on the alluvial terrace and the terrace slope of the Ticino river. The ground morphology has been affected over the years by considerable anthropic modifications (ground reprofiling and made land laying). The river terrace is affected by secondary order streams erosion. One of these streams is the Vernavola canal, with its riverbed deepening toward the Ticino river that is the hydrological base level. Since 1985 the Vernavola valley constitutes the urban park of the Vernavola canal functioning as the lungs of the town.

It's worthy of remark that in ancient times, this geomorphological frame, the closeness to the river and the ground water resources supplying, led Roman people to settle in this area.

Nowadays, the town planning is focused on the ground use and does not concern the underground use. On the other hand, it should be necessary to manage the underground space as an urban resource with its limits of exploitation and pointing out that an incorrect use of it can lead implications regarding the environmental and the historical-cultural heritage protection. The urban underground has to be considered as a new usable space, considering the ever-growing utilization of the urban ground.

The authors propose for the town of Pavia an urban geology study dealing with different issues occurring in this area. As far as the urban area hydrogeology is concerned, a perched water table located at a depth of 5-6 m occurs in a first shallow sandy aquifer. This is linked to the occurrence of a likely continuous basal silty-clayey layer with a low hydraulic conductivity and a thickness ranging from 1 to a few meters. The perched water table gets also environmental importance, because it feeds several terrace springs, which are worthy of a touristic-environmental reappraisal. The springs are located along the fluvial terraces of the Ticino river and Vernavola stream. Rainfall inflows recharge the aquifer that consequently shows seasonal metric water table fluctuation according to the seasonal rainfall variation and the rice fields flooding. Since March 2008, the water table of the perched aquifer is already affected by a piezometric level continuous monitoring. In a short time other monitoring stations will be installed in different areas of the town. Indeed the monitoring of the seasonal fluctuations of the water table level is necessary to achieve the effect of the interference between the water table fluctuations and the foundations of the historical building and civil engineering constructions.

Actually, the historical centre of Pavia has a considerable historical and cultural heritage which need to be preserved, avoiding architectural losses as happened in 1989 with the collapse of the Civic Tower. It's worthy of remark that the urban underground still keeps the roman time sewer system. Given that this network overlaps with the layout of the main streets of the town some problems could rise cause of the interference with anthropic structures. Consequently, it appears necessary to carry out a suitable underground exploration survey including both drilling and geophysical not invasive investigation.

The preliminary collected data will concern the monitoring of the perched aquifer water table levels and the reconstruction of a 3D lithological model obtained by the processing of hundreds of wells and boreholes stratigraphies (and cone penetration tests). This modelling is necessary to get a suitable knowledge of the subsoil features, especially for the areas where monuments and historical buildings occur. Shallow geophysical exploration including 2D-3D ERT and GPR surveys will be carried out in the historical centre of the town, in order to reconstruct the map of the Roman sewer system and the different buried ancient canals. Finally, a hydrodynamic flow numerical modelling of the ground water will be carried out.

FLOODING EVENTS IN THE TOWN OF BARI (APULIA, SOUTHERN ITALY)CALDARA Massimo¹, MARSICO Antonella², PENNETTA Luigi², SIMONE Oronzo³

1 - Dipartimento di Scienze della Terra e Geoambientali

2 - idem

3 - Assessorato Ambiente - Regione Puglia

Presenter e-mail: lpennetta@geo.uniba.it

Key terms: historical flood events; hydraulic management; Bari (Apulia, south Italy)

The town of Bari developed at the end of a broad fossil drainage network set up on karstic terrains, in a wide depression called "Conca di Bari". During the past centuries, after strong rains that struck the hinterland, almost the whole town underwent to many ruinous floodings. These happened because of the peculiar hydro-geomorphological features of the catchments, widely developed inland up to the more elevated areas on the Murge hills, and the lack of an appropriate land management policy and urbanization plans. The first reported flooding occurred in 1567, when tons of mud struck Bari leaving traces nowadays still clearly evident. Other ruinous inundations occurred in 1827, 1905, 1915, and 1926. The risk of flooding in the "Conca di Bari" area has been reduced after the 1930s, when started interventions made in order to control the water regime of these ephemeral streams. Nowadays, after some tens of years since the last flooding, nothing or little things were done in order to clarify the causes and dynamics of those disastrous events. Therefore, in our research, one among the first contributors dealing with this calamity, we aimed at the understanding and recognizing the meteorological-environmental risk thresholds for the Bari area.

SOIL RADON CONCENTRATION SURVEY IN CAFFARELLA VALLEY TEST SITE (ROME)CASTELLUCCIO Mauro¹, TUCCIMEI Paola¹, LUCCHETTI Carlo¹

1 - Università "Roma Tre"

Presenter e-mail: tuccimei@uniroma3.it

Key terms: soil radon concentration; soil radon influence factors; soil radon variability; radon gas transport mechanism

Caffarella Valley, shaped by Almone River, covering approximately 200 ha, is one of the largest natural areas within the city of Rome and is the portion of the Appia Antica Regional Park (SE area of the city) closest to downtown. The valley represents a site particularly interesting for the soil radon survey related to indoor environment risk because of its features: it is a natural area easily accessible, close to urbanized territory and develops on a volcanic-derived background referred to the activity of Colli Albani district (the outcropping products are mainly Quaternary ignimbrites).

Since December 2007, a soil radon concentrations monitoring with simultaneous measurement of many related parameters is in progress, with the purpose of a better understanding of the influence factors that cause the radon spatial and temporal variability.

Investigation showed diffusion as main radon gas transport mechanism in the monitored control stations. Detected radon originates within few tenths of centimeters around the measurement point and its movement in soil is due to the concentration gradient. In this setting, main control parameters on the measured value of soil radon concentration are: geological background type, measurement depth below ground level, soil intrinsic permeability, topsoil conditions, sampling techniques. Specially, water content of the soil, related to rain events temporal distribution, has strong influence. Soil radon concentration shows a characteristic seasonal trend, with maximum values recorded during winter period, due to increased rainfall, and minimum values during July and August. Other geodynamic settings may have a predominant deep origin contribution to soil radon concentration, with transport due to advective fluxes (gas movement in soil caused by pressure gradient). Such settings may occur in volcanic or geothermal areas and generally where geological and structural discontinuities or cavities are present. In these cases, additional influence factors may further complicate the setting: movement dynamics linked to seasonal temperature and pressure gradients, presence of radon carrier gases, interaction with groundwater as a function of water temperature and gas solubility coefficient, etc. An example of a site characterized by predominant advective transport is Ficoncella Spa (Civitavecchia, Rome), a geothermal area with high permeability background (travertine) which promotes radon gas movement.

HAZARD FROM CAPABLE FAULTS AND THE ITHACA PROJECTCOMERCI Valerio¹, BLUMETTI Anna Maria¹, DI MANNA Pio¹, FIORENZA Domenico¹, GUERRIERI Luca¹, LUCARINI Mauro¹, SERVA Leonello¹, VITTORI Eutizio¹

1 - Geological Survey of Italy - ISPRA

Presenter e-mail: valerio.comerci@isprambiente.it

Key terms: Seismic hazard; Capable fault; ITHACA database

The importance of capable faults, namely the faults inducing significant deformation and/or dislocation at or near the ground surface, is well-acknowledged in the planning and siting of nuclear power plants and other high risk facilities. Indeed, while other natural hazards might be dealt with, the presence of capable faults is one of the basic exclusion criteria of a potential site for NPP: Where reliable evidence shows that there may be a capable fault ... an alternative site should be considered (IAEA, 2010).

In the Italian territory the presence of capable faults is a well established fact. Surface dislocations, for example, occurred during the 1915

(Avezzano, M 7.0) and the 1980 (Irpina, M 6.9) earthquakes with throw nearing one meter. Many other cases are known in historical times. Also recently, the Paganica fault, responsible of the 2009 L'Aquila earthquake (M 5.9, Mw 6.3) cut the surface with a throw of about 15 cm, severely damaging the water main of the Gran Sasso aqueduct (Vittori et al., 2011, and reference therein). In general, many Quaternary faults are being documented as capable, based on the paleoseismological studies of the last decades (e.g. Galli et al., 2008; McCalpin, 2009).

The ITHaCa (Italian Hazard from Capable faults) database, today available on the Portal of the Geological Survey of Italy

(<http://sg1.isprambiente.it/GeoMapView/index.html>), even if not exhaustive, represents a contribute to the detection and characterization of such tectonic structures on the national territory. The information in the database derives from the critical analysis of available scientific papers, technical reports, field surveys, and dedicated studies by ISPRA. The evidence of capability is: a) coseismic rupture in historical times; b) creep - tectonic deformation (detected by means of ground survey, GPS, remote sensing); c) paleoseismicity (possibly proved by absolute dating) of Holocene-late Pleistocene cut/deformed sediments and/or morphologies; d) cut/deformed sediments and/or morphologies belonging to middle or even lower Pleistocene, where sealing is not clearly proved and further investigation is therefore needed.

Mapping of capable faults is necessary for planning purposes and for building or retrofitting major critical and high-risk facilities, lifelines, etc. Today, apart from the obvious exclusion criterion, there are technological solutions which, if applied together with a targeted geological study, are even able to absorb large surface dislocations and ensure the operability of structures (typical example are the pipelines) after the earthquake. The contribution that geological sciences can offer to modern society in terms of hazard awareness and seismic risk reduction appears so far often underestimated and the need is evident to arise the collective perception that the present scientific knowledge of geological hazards is such that they can be appropriately faced.

E4-2 Invitato Burrato, Pierfrancesco

10.1474/Epitome.04.0441.Geoitalia2011

FROM SEISMOGENIC SOURCE TO GROUND SHAKING: APPLICATIONS OF THE DISS DATABASEBURRATO Pierfrancesco¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: pierfrancesco.burrato@ingv.it

Key terms: Seismogenic Sources; Seismic Hazard; DISS

There are three different categories of hazard associated with the activation of a seismogenic source: ground shaking, surface deformation and ground failure, and surface faulting. These three processes are the primary cause for damage to buildings and civil infrastructures, act at different scales, and their mitigation requires different approaches and level of details. Losses from ground shaking and ground failure are the most significant and largely outpace those caused by surface faulting. This is especially true for Italy, where few earthquakes caused unambiguous surface breaks (e.g. the Mw 7.0, 1915 Avezzano and the Mw 6.9, 1980 Irpinia earthquakes), and the associated losses have been negligible with respect to those induced by shaking. Risk mitigation programs at national and regional scale should hence concentrate on assessing the expected ground shaking with the best possible confidence. The construction of a reliable seismogenic source model is a necessary step in this strategy. Most of the emphasis should be placed on identifying a set of seismogenic sources that are: (1) defined in 3D and fully parameterized so as to allow their automatic elaboration, (2) obtained by merging geologic, tectonic and seismological data, spatially complete over the entire study region, and (3) checked for spatial, kinematic and dynamic consistency with the instrumental stress and strain records.

Active faulting data are an integral part in the construction of a reliable seismogenic source model and are the basis for assessing surface faulting hazard (i.e. hazard caused by capable faults). Since surface breaks at various scales represent the surface expression of seismogenic faulting at depth, information on active faulting is not alternative but rather complementary in the construction of a seismogenic source model.

The Database of Individual Seismogenic Sources (DISS, <http://diss.rm.ingv.it/diss/>) is a georeferenced repository of tectonic, fault and paleoseismological information for Italy and bordering countries. Seismogenic sources are fully parameterized for their geometry and kinematics and classified as (1) Individual (ISS), simplified 3D representations of fault planes, often associated with a historical or instrumental earthquake; (2) Composite (CSS), elongated fault systems containing an unspecified number of seismogenic sources that cannot be singled out; and (3) Debated (DSS), active faults that were proposed in the literature as potential seismogenic sources but were not considered reliable enough to be included in the database.

Individual Seismogenic Sources are assumed to exhibit "characteristic" behavior with respect to rupture length/width and expected magnitude, while Composite Seismogenic Sources are not associated with a specific set of earthquakes or earthquake distribution. They comprise two alternative seismic source models to choose from and are tested against independent geophysical data to assess their reliability.

The DISS database is expressly devoted and fully suitable for seismic hazard applications, such as Probabilistic Seismic Hazard Assessment (PSHA), Deterministic (Scenario earthquake) and High-Frequency Maximum Observed Shaking (HF-MOS) studies. We will present case histories and show how the use of basic geological, geophysical and tectonic data can be used for constraining the geometry and kinematics of the potential sources of strong ground shaking and will discuss how they are used as input in the planning of strategic installations and critical facilities. Identifying seismogenic sources is especially challenging in areas of blind or hidden faulting and slow deformation like the Po Plain, where

seismic hazard is relatively low but risk is high due to exposure. Investigating seismogenic sources in this critical part of Italy requires a fully multidisciplinary approach and demonstrates that seismogenic activity is an integral part of the recent local geological and geomorphological evolution.

CONTRIBUTION TO THE ANALYSIS OF THE SEISMIC HAZARD OF THE SITE OF THE NUCLEAR POWER PLANT IN KRSKO: MECHANISM OF THE LJUBLJANA, 1895 EARTHQUAKE FROM THE INVERSION OF ITS INTENSITIES.

SIROVICH Livio¹, COSTA Giovanni², PETTENATI Franco³, SUHADOLC Peter²
1 - O.G.S.
2 - University of Trieste
3 - O.G.S.

Presenter e-mail: sirovich@ogs.trieste.it

Key terms: Slovenia; Krsko; Seismotectonics; Ljubljana earthquake 1895; Nuclear Regulatory Commission

Depending on the countries and the construction periods, the nuclear power plants are built to resist earthquakes with a return period of 10.000<T<1.000.000 years (standard for home: T=475 years) with planning parameters not extrapolated only from the historical earthquake catalogues, but also from geologic-palaeoseismological estimates, with accuracy of the assessments in a dramatic decrease to the increase of T. Krsko, in Slovenia, is about 130 km in ENE from Trieste (direction of the dominant winds), planned at the end of the 70's with the "safe shut-down earthquake SSE" of the Regulatory Guide 1.60 of the U.S. Nuclear Regulatory Commission, anchored at PGA 0,30 g on the free field. It has been running since 1983.

The joining of the official hazard maps for T=475 Italian ("the Cornell's way") and Slovenian (with "smoothed seismicity"), considerably different, indicates open questions: belt of 0.275-0.300 g roughly east-west "led by" the Peri-Adriatic overthrust, in Italy; in areas, in Slovenia, with two high hazards apparently centered on Ljubljana, and Zagreb in Croatia. Other accredited "Cornell's way" studies have produced PGA>0,3g in Friuli. On the other side, in Slovenia the concentrations of intensity and hazard surrounding the two capitals could have been a spurious effect (historical sources concentrated in towns and convents); Krsko is found between these two concentrations, but the area is seismically active for the historical (completeness since 1870) and instrumental epicenters (good since 1999). In 1997, on "Nuclear Engineering and Design", Lapajne and Fajfar (Slovenian Geophysical Service; Civil Engineering Ljubljana University) have indicated only PGA(>0,3 g) of a quake with M=3.9 close to the plant.

In Slovenia and Croatia (joint owners of the plant) there are several seismo-tectonic models, but the matter is still in discussion and the palaeo-seismological and neo-tectonic knowledge could be improved. Three different regimes and tectonic schemes of the Krsko area are found in the Literature, all with the regional compression N-S and interaction of the Pannonian Basin. The first, with stronger asserted events produced by faults orthogonal to the geodynamic stress, with the ones considered more dangerous for the plant arranged in inverse/direct pairs [?]. The second has a lowered block (Krsko area) surrounded by 4 raised blocks (mountains) where the N-S compression alternatively would activate faults striking NE-SW and NW-SE. In the third scheme there is an interaction between three "masses at depth" [sic]: Adriatic, Central Alpine and Pannonic, with activation, on a regional scale, of inverse faults in the western sector and direct and transcurent elsewhere, whilst in the central area the maximum compression would be E-W and the minimum N-S, with strong earthquakes in the mid of the faulted areas.

In such articulated context, we show the automated geophysical inversion (KF) of the macroseismic field of the strongest Slovenian earthquake close to the plant, the Ljubljana 1895 one (degree V in Krsko). Achieved parameters: lat. 46.06°, long. 14.45°, strike 103°, rake 90°, dip 54°, depth 20Km (fixed), Vr/Vs=0.71 towards 103°, Vr/Vs=0.50 towards 283°, L=22km of which approx. 7km towards 103°, Mo=4.83·10¹⁸ Nm (Vr=rupture speed; Vs=speed of S waves fixed at 3.5 km/s; L=total length of the fault source; Mo=seismic moment); M=6.4 (from Mo). Note that, with pure dip-slip mechanism, the problem is bimodal and, thus, the plane could strike 103°+180° and dip towards NNE (KF also gives ambiguity of ±180° in the rake).

It would be necessary to gather good macro-seismic data and invert the source also of the event of Zagreb (1180, M~6.3, 60 km from Krsko). Conclusion: the difficult evaluation of the hazard asks for prudence and adequate safety factors. An international consent study is needed.

Tsunami Hazard (AND RISK) FOR THE COASTS OF SOUTHERN ITALY

LORITO Stefano¹, ROMANO Fabrizio¹, PIATANESI Alessio¹, KASTELIC Vanja¹, TIBERTI Mara Monica¹, ROBERTO Basilio¹, SELVA Jacopo¹, VALENSISE Gianluca¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: stefano.lorito@ingv.it

Key terms: tsunamis; hazard; earthquakes

Japan is one of the most advanced countries for seismic and tsunami risk mitigation. Even so, the Fukushima nuclear plant has been seriously damaged by the tsunami following the giant Mw 9.0, 11 March 2011, Tohoku earthquake. This dramatically recalled us that tsunamis are a too often underrated hazard. Mediterranean shorelines have been repeatedly struck by large tsunamis in the past. The current understanding of offshore seismogenic sources in southern Europe is indicative of a potentially destructive tsunami hazard, which is worsened by the concentration of population, infrastructures, and activities along European coastal plains. Nevertheless, for example as regards Italian coasts, official tsunami hazard and/or risk maps do not exist, nor their creation seems to be envisaged. Here, we briefly review some published and ongoing research in this context, with particular attention to a few existing infrastructures at coastal sites in Southern Italy.

E4-5 Invitato Carapezza, Maria Luisa

10.1474/Epitome.04.0444.Geoitalia2011

THE ROLE OF GEOTHERMAL ENERGY IN THE SUSTAINABLE DEVELOPMENT OF ITALY

CARAPEZZA Maria Luisa¹

1 - Istituto Nazionale di Geofisica e Vulcanologia - Roma

Presenter e-mail: marialuisa.carapezza@ingv.it

Key terms: Geothermal Energy; electric energy production; direct thermal uses

Italy has been the first country in the world to produce electric energy from high enthalpy natural geothermal steam and with its 843 MW of installed capacity is still the first producer in Europe of geothermal electric energy. However, Italy is presently only at the fifth rank in the world, quite distant from the first country (USA, 3093 MW). Because of its geodynamic setting and the presence of many recent or active volcanoes, wide zones of Italy are characterized by high anomalous heat flow and geothermal energy could significantly contribute to the sustainable development of the country. Besides further possible development of high enthalpy resources (T > 150 °C), electric energy could be generated by binary systems using medium enthalpy fluids (90 < T < 150 °C), a widespread resource as yet untapped in Italy. In addition, many volcanic areas of Italy contain at relatively shallow depth low-permeability, very hot rocks (T of 400 °C at 3000 m) that all look economically and technically much more attractive for the development of EGS (enhanced geothermal systems) than the European Soultz-sous-Forêts project (T of only 200 °C at 5000 m depth). Finally still in its infancy is in Italy the development of direct use of low enthalpy geothermal resources (hot waters with T < 90 °C). In particular, space heating and cooling can be conveniently generated using geothermal heat pump in soils or ground waters with only 15-20 °C with significant environmental benefits. Paradoxically we should follow the example of north European countries (e.g. Sweden), although being geologically cold with respect to Italy are much ahead in the utilization of geothermal heat pumps.

3 - GDP Consultants

4 - Regione Autonoma Valle d'Aosta, Dip. Difesa suolo e risorse idriche, Serv.Geol.

Presenter e-mail: f.piana@csg.to.cnr.it

Key terms: Seismic Microzoning; Alpine environment; Glacial deposits

Seismic microzoning can be defined as:

- the subdivision of a region that has relatively similar exposure to various earthquake related activities or
- the identification of individual areas having different potential for earthquake effects.

The goal of seismic microzoning is the determination of the degree to which seismic activity can affect the infrastructures. The determination takes into account the morphological, lithological and structural setting of particular land sectors in a seismically dangerous region. Such conditions include the physical and dynamic properties of the ground and basement rocks, the thickness of the surface deposits, the presence of permafrost, tectonic features and relief characteristics, and the spectral properties of seismic waves.

The damage pattern due to an earthquake depends largely on the local site condition and the social infrastructures of the region, with the most important condition being the intensity of ground shaking at the time of the earthquakes.

Contrasting seismic response is observed even within a short distance in response to small changes in the geology of the site. This fact is very crucial in the case of microzoning of Alpine environments (i.e narrow valleys with huge and very steep cliffs), where the surface deposits heterogeneities are great due to the presence of mixed alluvial, glacial and sub-aerial slope sediments, very sharp and irregular bedrock topography as well as marked lateral variability in local hydrostratigraphy or water-content of sediments. In these environment the risk definition in a given microzone can also be influenced by danger elements placed outside the microzone, affecting the reliability of the seismic risk evaluation. The "Gi-RES spin-off"

(<http://gdpconsultants.eu/geologia/index.cfm/gi-res-pagina.html>) working group, represented by CNR IGG Torino and GDP Consultants geologists is going to handle these problems in the frame of a seismic microzoning project in selected areas of the Valle d'Aosta Region, commissioned by the local Regional Administration in the frame of the EU Alcotra RiskNat Project (<http://www.risnat-alcotra.org/>).

A preliminary methodology has been defined to allow classification of the different geological and morphological settings of the study areas, that will be presented and discussed with respect to the recommendations and guidelines of the "Seismic Microzoning Working Group" of the Italian "Conferenze delle Regioni".

Presenter e-mail: pergalani@stru.polimi.it

Key terms: microzonation; amplification factors; response spectra; abacus

The earthquake of April 11th 2003 ($M_l = 4.7$), that struck the NW area of Piemonte, caused damages in several municipalities, fortunately without victims.

This event can be considered as representative of the expected seismicity level of the Region and, even if this level can be considered low in comparison to other Regions of Italy, it is necessary to take it into account for an accurate and safety urban planning.

So the government of the Piemonte, in the frame of the European Project RISKNET, decided to perform the seismic microzonation of the Sant'Agata Fossili (AL).

Starting from the recent guidelines "Indirizzi e Criteri per la Microzonazione Sismica (ICMS 2008)", a study regarding the level 1, able to point out the zones that can produce amplification effects, has been performed.

Then an analysis of seismic microzonation of level 3 (ICMS 2008) has been carried out. So a multidisciplinary group has been created, and the fundamental steps of the project have been:

1. geologic and geomorphologic analysis, through survey at scale 1:5,000 on an area about 0.2 Km², that has pointed out the presence of silty clay and marl (Gessoso-Solfifera Formation and Sant'Agata Marl);
2. geophysical characterization of the lithologic units and subsequently construction of the lithologic subsol model: particularly the HVSR survey (15 stations), that pointed out the presence of two sectors characterized by different behavior (the E sector without resonance and the W sector with resonance at 2-5 Hz); 2 Down-Hole (one in each sector); and in a test site different geophysical techniques (MASW, REMI, seismic refraction, passive MASW on 2D array, electrical resistivity tomography), that are necessary to obtain the accurate information for the application of the level 3;
3. geotechnical characterization through 2 geognostic drillings with SPT tests and collection of undisturbed samples to perform the dynamic and static laboratory tests;

4. individuation of the expected seismic inputs in term of accelerograms: particularly the 5 recorded accelerograms were selected from strong motion record databases (ITACA 2006), fixing the constraint of the geologic and seismologic characteristics of studied area, the expected magnitude-distance couple, the soil type of the registration station, the expected maximum horizontal acceleration (through the use of scaling) and the spectrum compatibility with the target spectrum (soil type A, "Norme Tecniche per le Costruzioni", NTC 2008);
5. numerical analysis, using a one-dimensional model, to point out the expected amplifications in term of amplification factors and elastic acceleration response spectra.

The results have been able to understand the geologic and geophysical differences of the municipality and consequently the different local seismic responses, that permit to better define the level of seismic protection of the buildings taking into account the expected amplification effects. In particular, the results in term of acceleration response spectra, in comparison with the corresponding spectra derived by the NTC, show, in some cases, significant differences, consequently the use of the calculated spectra is necessary during the building design project.

To detect, during the urban planning phase, the areas in which the application of the level 3 is necessary, an abacus can be used (level 2 of ICMS 2008). So the results in term of amplification factor, derived by the performed study, have been considered to perform a regional abacus for the silty clay lithology. Such regional abacus allows to have information of the expected amplification, known the average velocity of the shear waves and the correspondent thickness of a lithologic sequence. It permits to have more accurate results than the abacus of the ICMS, due to his regionalization in term of both expected seismic inputs and both geophysical and geotechnical characterization of the considered lithology.

SITE EFFECTS IN THE EASTERN PART OF L'AQUILA (CENTRAL ITALY) FOLLOWING THE 2009 SEISMIC SEQUENCE: ON THE USE OF EXPERIMENTAL AMPLIFICATION FACTORS FOR MICROZONATION STUDIES.

DE FERRARI Roberto¹, SPALLAROSSA Daniele¹, FERRETTI Gabriele¹, BARANI Simone¹, EVA Claudio¹

1 - DIP.TE.RIS. - UNIVERSITA' DI GENOVA

Presenter e-mail: deferrari@dipters.unige.it

Key terms: SEISMIC MONITORING; WEAK MOTION; AMPLIFICATION FACTOR

Following the disastrous earthquake ($M_w = 6.2$) occurred on the 6th April 2009 in central Italy, the Dip.Te.Ris - Genoa University carried out several experimental investigation on seismic response of different areas by passive seismic monitoring.

In order to investigate site amplification effects using an empirical approach, seismic temporary networks have been installed in some areas characterized by different geological conditions in the eastern part of L'Aquila.

The seismic networks operated in the period 20 April - 2 July and collected more than 800 weak motions earthquakes, with magnitude ranging between 1.5 and 4.2, at a distance range 5 - 30 km.

The recordings of 31 stations, located in Tempera, Paganica, Bazzano and S. Gregorio areas, were archived and analyzed.

The experimental study of amplification phenomena, has been carried out by using both standard spectral ratio techniques (HVSR and SSR) and different definition of amplification factor (FA) computed through PGA, PGV and Housner spectrum intensity (SI) ratios.

The results show complex and remarkable amplification site effects affecting both the horizontal and vertical component of the ground motion. In particular the Paganica and Tempera area is characterized by significant amplification effects at frequencies between 1.0 to 4.0 Hz and FA values ranging between 1.5 and 4.0. Indeed in some areas surrounding Bazzano village, fundamental frequencies lower than 3.0 Hz were observed. The San Gregorio area is characterized by fundamental frequency values between 2.0 and 3.0 Hz.

The main target of this study is the discussion about the usage of empirical amplification factors (FA) for quantifying seismic amplification phenomena in microzonation studies.

To this aim, a comparison between response spectra obtained from weak motion recordings of our stations and moderate to strong motion recordings of another temporary seismic network installed in Paganica (D'Alema et al., 2009) was carried out. This comparison has allowed us to verify the absence of outstanding variation of the amplification level and fundamental frequencies values with the respect to ground motion levels. Moreover in order to define the best proxy for the estimate of the seismic response of the investigated areas, the variability of the FA values has

been discussed as a function of the criteria adopted for the computation of FA (i.e. PGA, PGV, integration range of SI).

Finally we have compared the experimental amplification factor values with those obtained with numerical analysis carried out by other authors (Compagnoni et al., 2011) for this area. The results of this comparison show a quiet agreement between experimental and numerical amplification factors values and stress the reliability of passive seismic monitoring approach for microzonation studies especially in moderate to high seismicity areas.

Key terms: site effects; ambient noise; seismic array

Following the April 6th 2009, Mw 6.3 event, many studies were addressed to determine the site response in L'Aquila historical city center that suffered severe damage. The historical city is founded on a terrace that slopes down moving in the South-West direction, and raises about 50 meters above the Aterno River bed. The terrace is formed by alluvial Quaternary breccias (BrA) consisting of limestone clasts in a marly matrix. Toward north of the city the terrace is in contact with outcropping limestone, while moving toward South, it is superimposed to lacustrine sediments (LK) consisting mainly of silty and sandy layers and minor gravel beds. The thicknesses of BrA reach values of many tens of meters, while LK layer can be up to 200 meters thick below. Recent drilling data in the main square of L'Aquila report a thickness of 75-80 meters for BrA over more than 200 meters for LK. A deep borehole at the base of terrace along the Aterno River bank was recently drilled on a homogeneous sequence of LK unit with a thickness of about 195 meters overlying the meso-cenozoic limestone bedrock. Due to the high thickness of the sedimentary soft layer, in situ testing (dwn-hole, cross-hole and boreholes) due not allow a reliable characterizations of the deepest sediments. This outcome can be overcome by surface waves analysis based on large seismic arrays. We present the results of several 2D ambient noise arrays testing performed in the L'Aquila old town. The array dimensions and the instruments characteristics allowed us to investigate a wide range of frequencies and large depths. In order to verify the spatial stability of the site response we also performed a dense survey using single station HVNSR measurements. This last wide data set also consents to detect the variability in the soil characteristics of very shallow layers due to the present of local geological heterogeneities.

Key terms: Seismic microzonation; Seismic prospecting; Ambient Vibrations; HVSR; ESAC

Seismic microzonation represents a basic tool for the development of a correct prevention policy devoted to seismic risk reduction. To make this statement effective, three elements are necessary. The first one concerns the implementation of seismic microzonation in urban planning rules. To this purpose, advanced legislative interventions implementing this tool were provided by a number of regional administrations in Italy, that are going to be extended to the whole country also thanks to the "moral suasion" exerted by the national Dept. of Civil Protection. The second element is the definition of codified, up-to-date and scientifically well established experimental protocols and procedures that allows development of comparable microzonation maps. To this purpose, the "Guidelines for Seismic Microzonation" recently published in Italy by the "National Conference of Regional Administrations and Autonomous Provinces" and the Dept. of Civil Protection represented an important step towards and effective standardization of the field activities and map development. The third point, not less important than the previous ones, is the possibility provide cheap procedures that makes seismic microzonation feasible also in the absence of large funding that is in most cases unavailable for local administrations. To this purpose, the above cited guidelines suggests the possibility that three levels of seismic microzonation can be achieved, each characterized by a different level of outcomes (qualitative and exploratory in the first level up to strictly quantitative and very detailed in the third one) and costs. Anyway, in order to allow as many as possible local administrations to achieve at least a first or second level microzonation, the development of cheap experimental tools is mandatory. Ambient vibration measurements, both in the single station (HVSR approach) and array (ESAC approach) configurations may provide such a tool. Despite of the fact that these methodologies are exploratory in character, their extensive application where unevenly distributed complementary data are available (good geologic mapping, drillings, active seismic surveys, etc.) may allow quite reliable and cost effective results. In this view, on behalf of the Emilia-Romagna Regional

Administration and in strict cooperation with Rimini Provincial Administration and Rimini Municipality, an extensive passive seismic survey was developed in the whole Rimini urbanized area. The joint interpretation of ambient vibration measurements, geological reconstructions and borehole data, allowed the development of a "level 2" seismic microzonation map of the Town, where different seismic domains are clearly identified and characterized quantitatively in terms of an integral amplification parameters (FA factor). The most critical aspects of this experience will be discussed along with possible limitations and advantages of the adopted procedures and protocols.

Presenter e-mail: mike.difil@mclink.it

Key terms: gravity network; L'Aquila; earthquake april 2009; gravity changes

In 1989 a joint work was developed in co-operation with the University "Sapienza" of Rome and Servizio Geologico d'Italia (SGI) (today ISPRA). A gravity research started in the Aquila area aimed to realize a gravity network for high precise gravity measurements to detect gravity changes due to mass redistribution in the underground inferred by the geodynamic activity.

The gravity network has been designed so as to incorporate 17 stations, settled in 1989 and periodically reoccupied in 1990, 1992, 1995, 2005 and 2011. The local gravity network coincides with some benchmarks of the local leveling networks (L126, L197, L124 and L9) [Giuliani & Mattone, 2010] in order to remove the effect of the vertical ground movements and taking into account the spatial distribution of seismic events. High precision gravity combined with levelling benchmarks offers increasing potentialities for the study of time variations of the earth gravity field and crustal deformations related with geodynamic or tectonic processes. Presently, the network consists of 17 relative stations which are not destroyed during the earthquake. Gravity readings were made using two LaCoste & Romberg D model gravimeters (D-60 and D-138) at the same time. Presently, and similar to previous studies the new gravity data set has been referred to the Absolute gravity station established in 1977 at the Osservatorio Astronomico di Monte Porzio Catone [Cannizzo et al., 1978].

The gravity readings, for both gravimeters, are corrected for tidal effects, atmospheric loading and instrument drift. Later, as regard the gravity survey, the corrected and weighted gravity differences between each pair of stations are organized on joined loops and then adjusted according to the least square method; finally the gravity value at any station is computed relative to the local reference station (Fonte Cerreto-Assergi (4) station) and linked to the absolute gravity station.

During the time period covered by this study, six precise relative gravity surveys were also carried out at all stations of the network. Long-term spatial distribution of gravity changes performed before and repeated after earthquake is represented. Gravity changes have been observed on the whole area, before and after the earthquake period.

The gravity distribution shows different patterns in the eastern, central and western part of the seismic area. The gravity variation field is smoother in the central part of L'Aquila city and it shows a gravity decrease from the stations located in the northern part of the city. Qualitative gravity results are not totally in agreement with vertical changes measured by local leveling networks. It is possible to suppose that the observed gravity changes should indicate a mass variation in the underground, not in the shallow part but in depth.

Moreover, the results obtained from high precision gravity measurements show that, the most significant long-term observed gravity changes on Aquila area, were recorded not in the area corresponding to the seismogenic belt but in a largest zone. However gravity changes were observed in the same magnitude before and after the earthquake. CANNIZZO L., C. CERRUTTI & I. MARSON (1978): Absolute-Gravity measurements in Europe. EFFECTS OF A VELOCITY INVERSION IN A SOIL PROFILE: PARAMETRIC 1D ANALYSES AND COMPARISON WITH REAL CASES

QUADRIO Bruno¹, NASO Giuseppe¹, SABETTA Fabio¹, SANÒ Tito¹

1 - Dipartimento della Protezione Civile

Presenter e-mail: quadrio.b@gmail.com

Key terms: velocity inversion; local seismic response; NTC 2008; 1D analyses

According to Italian seismic regulations (NTC, 2008) there are two ways to define local seismic response, based on two different methods:
 - "specific analyses" (Local Seismic Response in chapter 7.11.3) that takes into account the specific earthquake that could occur in the site, the specific characterization of a subsoil model in terms of geotechnical and geophysical peculiarity, and the use of targeted calculation codes;
 - "simplified approach" (chapter 3.2.2) to use only in case on non applicability or non practicability of specific analyses, through the choice of a pre-defined class of subsoil (subsoil category), that enable the definition of an elastic spectra for engineering purposes.

Unfortunately, the specification of subsoil categories defined in "simplified approach" of NTC (2008) doesn't take into account a series of subsoil condition commonly found in nature (Vannucchi, 2009). For example there are no cases where softer strata of soil are contained by stiffer strata of

soil (and vice versa).

This subsoil condition is known in geotechnics as "velocity inversion" and is verified when the velocity of shear waves Vs doesn't increase monotonically with depth but soil strata with higher (or lower) velocity in respect of underlying or overlying soil strata are found.

This work, as general purpose, aims to provide ready-to-use information to professionals, about local seismic response of a site where a velocity inversion is present.

In particular we wanted to evaluate through 1D calculation codes and parametric analyses the effect (in terms of an amplification factor) of a stiffer strata between softer and vice versa, varying both seismic inputs applied to each model and every parameter of subsoil taken into account in the analyses (thickness and depth of stiffer/softer strata, depth of seismic bedrock, seismic impedance contrast). In previous works the problem was handled considering only a simpler situation based on a two-strata soil model (softer on a stiffer and vice versa) overlying a seismic bedrock (Aubeny et alii, 1986; Ding et alii, 2008, Sanò et alii, 2010).

Results will be provided through a comparison between amplification factors and, for most topic case, a comparison between elastic spectra will be shown.

Conclusion and comments will be addressed to define suggestions useful for seismic design and will be more specific when the presence of a velocity inversion cause remarkable differences in respect to an "homogeneous case" (where homogeneous means a model with the same thickness of soil overlying bedrock of the "inversion case", but with mean characteristic in terms of stiffness). Therefore, worse case in terms of safety will be highlighted.

Finally, to validate and verify results achieved, case based on models based on real situations extracted from Italian (ITACA) and foreign (KikNet) accelerometric database will be compared.

Presenter e-mail: francesco.fazio@fastwebnet.it

Key terms: seismic microzonation; planning; seismic risk

After the 6th April 2010 earthquake in a few Municipalities of L'Aquila Region, seismic microzonation (SM) maps have been produced, following Seismic Microzonation Guidelines (SMG), <http://www.urbit.it/indirizzi-e-criteri-per-la-microzonazione-sismica>.
A specific task group was formed to analyse the impact of SM on planning and to identify a methodology for risk mitigation GIS mapping. SMG, applied for the first time in a real case study, have been issued by Italian Civil Protection Department and Regions and Autonomous Provinces' Conference.

In this context, the application of SMG stands out because of complexity and richness of urban planning conditions.

These conditions concern the urban and environmental structure of L'Aquila Region, composed of a big urban centre included within a network of small and medium size centres, each one with its own morphological and functional characteristics and different accomplishment level of urban planning.

On one hand the research has been supported by a system of standards defined in SMG, included those for cartography and data base. On the other hand there has been several negative elements, such as very short working time, emergency condition given by post-earthquake reconstruction and not much financial and human resources. Firstly, the methodology has provided for a starting analysis of Municipality urban plans, identifying their structure and strategies, their main characteristics and aims, and therefore their different provisions and planning zones.

Secondly, urban plans have been standardized, georeferenced and geocoded. Then MS maps and urban plans have been overlaid and a few quantitative analyses have been processed.

Data comparing has lead to a first, rough description of several case-studies, outlining distinctive characteristics for each locality. A first set of observations and critical issues have been pointed out, tracing back to three, typologies: a) conditions needing further investigations; b) conditions giving operative instructions or rules; c) conditions involving choices in planning and, consequently, different methodological procedures.

This research can be considered the initial step to propose rules and guidelines in planning for the seismic risk mitigation.

SEISMIC MICROZONATION AND SEISMIC VULNERABILITY FOR SEISMIC EMERGENCY PLANNING

DOLCE Mauro¹, DI PASQUALE Giacomo¹, NASO Giuseppe¹, PERONACE Edoardo¹, QUADRIO Bruno¹, SPERANZA Elena¹

1 - Dipartimento della Protezione Civile, Ufficio Rischio Sismico

Presenter e-mail: mauro.dolce@protezionecivile.it

Key terms: seismic microzonation; seismic vulnerability; seismic emergency planning

SIGE is a specific software developed and used by the Italian Civil

Protection Department for processing speedy damage scenarios, related to a given return period T and hence to a seismic intensity. Hazard and seismic vulnerability distribution processed by the software are those provided by a CPD database available at national scale. Results provided by SIGE are relative to the whole territorial "administrative" extent of the Town Council on which the scenario is calculated, and consist in the total amount of losses in terms of collapsed and unusable buildings as far as people involved.

Starting from this operative tool, a new methodology, developed from previous studies by some of the authors (2007), has been developed in order to "distribute" over the urban area the losses resulting from SIGE, through minor information upgrades. The purpose of the method is to provide a geographic distribution of losses on the urban area so as to be more useful for developing or enhancing a seismic emergency plan. Basically, two main steps must be carried out to achieve the purpose: a local seismic hazard analysis and a seismic vulnerability assessment. Data required for the seismic hazard consist of a seismic microzonation sharing the urban territory into different areas featured by homogeneous seismic hazard.

Depending on the different settings and purposes, seismic microzonation can be carried out at different levels of analysis, with increasing complexity and required effort, according to three levels:

Level 1 is a basic knowledge level propaedeutical to the real seismic microzonation studies, as it consists of a collection of pre-existing data which are processed in order to classify the territory into homogenous microzones on a quality level;

Level 2 introduces quantitative information associated to the homogenous zones, by using further specific analyses, and leading to a real seismic microzonation map;

Level 3 develops a seismic microzonation map with detailed analyses on specific areas or subjects.

The methodology under exam uses as basic knowledge standard, the level 2 according to the following 5 tasks:

Task 1: collection, storage and data processing of existing data;

Task 2: definition of the technical-geological model of subsoil and individuation of possible co-seismic phenomena;

Task 3: geotechnical characterization of soils;

Task 4: numerical (amplification factor and susceptibility probabilities) characterization of each microzone;

Task 5: reports and maps elaboration;

The second step in the methodological framework is represented by the seismic vulnerability of the urban territory. This is assessed by outlining the main structural types characterising a given urban area, and then associating to each of them a seismic vulnerability class among those provided by the EMS 98 scale. In turn, the urban layout is divided into zones which can be assumed homogenous under the point of seismic vulnerability, and each of them is associated with the prevalent structural type (or types) and consequently to a given vulnerability class. The resulting product of this information level is a map showing different zones into which the urban area can be shared.

Finally, the intersection, governed by GIS and specific algorithms, between these two information levels (microzonation and vulnerability), provides a third information level consisting of a sub-zones map in which each sub-zone can be assumed homogenous both under the point of hazard and seismic vulnerability.

Seismic scenarios can be then processed and associated losses calculated and associated with each sub-zone. The final product of this process is represented by maps showing for each zone or sub-zones (depending on the purposes) the estimated losses in relation to a given return period of the earthquake.

These maps can be very helpful even for enhancing an existing emergency plan, as for checking the proper location of emergency areas or the accessibility to strategic and public buildings.

BASIN INDUCED SURFACE WAVES (RAYLEIGH) PROPAGATION IN A INTRAMOUNTAIN SEDIMENTARY BASIN: THE CASE STUDY OF NORCIA (PERUGIA, ITALY)

CAFFAGNI Enrico¹, PAROLAI Stefano², BINDI Dino³, CATTANEO Marco³

1 - University of Modena and Reggio Emilia

2 - GeoForschungsZentrum GFZ Potsdam

3 - Istituto Nazionale di Geofisica e Vulcanologia INGV

Presenter e-mail: enrico.caffagni@virgilio.it

Key terms: Site effects; Polarization; Basin induced Rayleigh waves; Norcia

We present the results of a study on the propagation of edge induced Rayleigh waves in the Norcia basin (Perugia, Umbria, Central Italy). The Norcia plain is a tectonic depression, created by normal and oblique faulting which affects the Apennines during the Quaternary. The seismicity of the area is strictly related to the activity of the normal faults, which induced several earthquakes in the past (very recently in 1997, Mw=6.0). Local site's effects might have occurred in the Norcia plain attributable to the impedance contrast between the bedrock and the lacustrine sediments (mono-dimensional, 1D) and/or to the diffraction of seismic waves at the basin border (2D or 3D dimensional), which generate local surface waves, Rayleigh and Love waves, observed as late arrivals in the seismic signals. In 2009 a seismic monitoring experiment was realized by Istituto Nazionale di Geofisica e Vulcanologia (INGV, Milano and Roma) and the GeoForschungsZentrum (GFZ, Potsdam, Germany), installing a temporary seismic network of 15 stations from January to May. In this work 12 local earthquakes were analyzed, whose epicenters occurred all around the Norcia basin, with MI range 2.0 - 3.8, recorded before the L'Aquila sequence. All seismic signals were windowed (12 sec. before P-wave arrival and 68 sec. after), and denoised using a denoising procedure following Parolai (2009). In order to detect Rayleigh waves, instantaneous polarization attributes, instantaneous reciprocal signed ellipticity (ellipticity) and instantaneous tilt angle from the major axis of polarization, on the three components of each signal are determined using the Renè et al (1986) method, but using the S-Transform (Stockwell, 1996) values of the signals (the S-Transform is a time-frequency representation of the amplitude spectrum). The two horizontal components of the signals were rotated between 0° and 180° (with step by 9°) and the value of the angle (we called it Theta_max) that led to a maximum of the S-Transform for each point in the time-frequency plane was saved. A comparison between energy on the horizontal plane and the vertical directions helped us to identify some Rayleigh arrivals, characterized by an elliptical polarization, (with absolute values of the signed ellipticity greater than 0.125, following Renè (1986)). Finally we reconstructed, for every event, chronology maps of Rayleigh waves

directions (with step by 2 sec), evaluating the most likely values of ellipticity (absolute values) and Theta_max. We found that first Rayleigh arrivals generally in high frequencies, $f > 5$ Hz, and in some cases immediately after the S-wave arrivals, are responsible of 2D or 3D site's effects, in form of wave trains at low values of ellipticity (even < 0.4), but with high energy, while late arrivals, like scattered energy from the edge basin, showed lower energy with higher values of ellipticity (> 0.6).

PROBABILISTIC RIVER FLOOD MODEL: THE ROLE OF THE SPATIAL CORRELATION

MARTINA Mario Lloyd Virgilio¹, DOTTORI Francesco¹, TODINI Ezio¹

1 - University of Bologna

Presenter e-mail: mlvmartina@gmail.com

Key terms: flood; hazard; insurance; spatial correlation; model

The aim of the research is to develop an innovative approach that accounts for the spatial correlation of floods. The methodology proposed is to generate continuous long time series of flows in the different locations from which one can derive a flood event catalogue. The results of this new approach are compared with the ones deriving from the more traditional use of flood data.

The study provides interesting ideas on the benefits that may derive from the setting up of a probabilistic river model which could be used in the feasibility study.

The assessment of the spatio-temporal distribution of flood extremes requires to: (1) extract and reproduce the statistical spatio-temporal distribution of precipitation, (2) model correctly the hydrological processes at point and catchment scales

Therefore the results of the approach is derived by using a cascade of models. The first one is a stochastic rainfall generator, which must be used to increase the size of the historical precipitation and discharge records, while the second one is a distributed hydrological model that converts the rainfall in river flow at a wide number of locations.

It is presented the Po river basin as the case study. The Po river basin (70.000 km²) in Italy is well suited for testing the new methodological approach. Daily precipitation and discharge records are available for research purposes from 1939 for a large number of rain and river gauges. Continuous records of rainfall and discharge are also available for hundreds of gauges over the basin since the beginning of the '90s. Detailed spatial geographical and geomorphological data are also available for the catchment, while the main river network is described by thousands of cross sections.

10.1474/Epitome.04.0456.Geoitalia2011

THE ROLE OF THE INSURANCE INDUSTRY IN THE NATURAL DISASTER EVENTS

COVIELLO Antonio¹

1 - National Research Council and Second University of Naples

Presenter e-mail: A.COVIELLO@IRAT.CNR.IT

Key terms: Insurance; natural disaster; reimbursement

The purpose of this research is to propose the creation of a national insurance fund which provides for damages in the event of natural disasters and the method of reimbursement in such cases.

More than half the Italian population lives in areas subject to natural disasters such as, floods, volcanic activity and above all, earthquakes. According to official data collected by the Ministry of Environment, 89% of the communities in Umbria are at an elevated risk followed by 87% in Basilicata, 86% in Molise, 71% in Liguria and Valle d'Aosta, 68% in Abruzzo and 44% in Lombardia.

Between 1994 and 2004, the Italian government spent over 20 billion euros, about 2 billion a year to repair damages caused by floods, earthquakes and dangerous landslides to which another billion and a half for less serious damages. On the whole, 50% of the damages to homes were caused by earthquake activity and 6.5% for flood and landslide.

An adequate insurance coverage would instead provide for these types of private damages via a payout via companies in the affected areas. Thus the heaviest expenses would be left to the federal government (and repair costs) to reconstruct public infrastructure. This would create a system which already exists in 21 other countries that provide a public system (and also partially privatized) to help in times of natural calamities. The following are example countries: The United States, The United Kingdom, Australia, France, Germany, Japan, Spain, Mexico, Turkey and Romania. For example "Catastrophe cover" policies could be created which would be supported by an obligatory European pool of insurance which would then take on the role of monitoring the risks by a team of experts.

The cost of the policies would be based on the statistical geographical data of the area in question and also on the probability of a natural disaster. Earthquakes in particular would be taken into consideration given Italy's seismic history.

The purpose of my study is to propose the creation of 4 levels of insurance compensation: the first level concerns small damages in which private citizens would assume responsibility for the damages; in the second level the insurance company would pay based on their role in a particular policy. In the 3rd level we have multinational insurance companies (re-insurance company) which share the risks as a group on an international level. In the 4th and last level, and only in the last level, a government intervention is foreseen in the case of a natural disaster, which would also accept aid coming from international help groups.

FLOOD DAMAGE ASSESSMENT WITH PURPOSES OF INSURANCE: THE CASE STUDY OF ALESSANDRIA (PIEDMONT)

GUFFANTI Valeria¹; DE AMICIS Mattia Giovanni¹; LUINO Fabio²
 1 - Dipartimento Scienze dell'Ambiente e del Territorio, Università di Milano - Bicocca
 2 - CNR IRPI Torino

Presenter e-mail: mattia.deamicis@unimib.it

Key terms: insurance; flood assesment; flood damages

The last census of the Italian Ministry of Environment shows that areas exposed to "highest potential geo-hydrological risk" are 7.1% of the total surface, but relates 5,553 municipalities, representing 68.8% of the total. Annually there are many damages to property in consequence of natural instability processes. For these damages the Italian State annually spends more than 3,000 million of Euros. Periodically, always just after severe geo-hydrological events, the public and the scientific community are debating the possibility to insure damages to environment, structures and infrastructures, but the legislature has never yet defined guidelines. This paper examines the flood event occurred on 5-7 November 1994, which affected the course of the Tanaro River provoking remarkable damages in the city of Alessandria (Piedmont). The aim of this research is to determine a criterion for assessing the damage for insurance purposes. In the first step hundreds of documents collected in the technical office of Alessandria municipality were analyzed. These documents are damage appraisal attached to claims submitted by private citizens. Particular attention has been paid to define the cadastral data of the buildings in order to make a proper georeferencing practices.

With all the information gathered it was created a database containing:
 a) the market value of residential buildings (obtained by the Banca dati delle quotazioni immobiliari, published by the Osservatorio del Mercato Immobiliare dell'Agenzia del Territorio) related to the 1994 and to the second half of 2009.
 b) the building degree of damage related to 1994 and to the second half of 2009, calculated on the basis of "normal value" of buildings. First of all the relationship between the height of floodwaters and the degree of damage has been analysed thanks to the observation of the height water distribution, grouping the buildings by area (eg. Orti district, town center, left bank); thereafter it has also studied the relationship between the distance (Euclidean) from the River Tanaro and the damage. The damage in the town center and in the Orti district have the trend awaited. It is growing in relation to the increase of the waterflood height and it is decreasing when the distance of the building from the river is increasing.

The left bank has another kind of situation. It was affected by particular dynamics of the flood that are associated with the urban characteristics of the territory.

There is a railway embankment that during the flood event played the role of a dam. When it breached the surrounding areas were flooded with violence. On this bank there is also the Cittadella, a sturdy military fortification that protected the buildings located near the bank closer to the river. The presence of this large building diverted waterfloods that bypassed it and then dived back in the Tanaro riverbed.

Sixteen years after the severe event, moreover, the real estate value of the town center has suffered a slight decline: this may be due both to the loss of the area value because of its proximity to the river and to the higher cost of renovations due to the constraints that are normally in force for the buildings in that area. In the Orti district, on the contrary, the trend has proved the opposite: the value has increased probably because it is a growing residential area.

The flood is not just a problem in "terms of water", but especially a problem at "human level". In this sector it would therefore require a holistic approach to identifying problems of urban planning, socio-economic, development and management, in order to prevent and, secondarily, to quantify the hydraulic risk.

AN INSURANCE MODEL FOR FLOODING RISK AREAS: A CASE STUDY IN LOMBARDY REGION

LUINO Fabio¹, BIDDOCU Marcella², CIRIO Chiara Giorgia³, NIGRELLI

Guido¹, CHIARLE Marta¹

1 - CNR IRPI UOS Torino

2 - CNR IMAMOTER Torino

3 - freelance - Torino

Presenter e-mail: fabio.luino@irpi.cnr.it

Key terms: FLOOD; INSURANCE; RISK; LOMBARDY; ITALY

Floods are very common in Italy. Annually floods occur in different parts of the peninsula and cause severe damage and sometimes result in injuries or fatalities. Researching historical floods gives evidence of the frequency, magnitude, impacts, areas involved and types of damages. In spite of this wealth of information, town-and-country planning rarely takes into account these lessons of the past.

Italy has no single agency with a specific mandate to systematically collect flood data much less to analyze and validate it. There are two agencies that have documentation on the extent of flood-related economic loss: the prefectures and the chambers of commerce. They have collected flood claims filed by public bodies, private citizens and businesses.

In the aftermath of a flood, specifically in the early post-emergency phase, disaster aid and relief is provided by numerous local public and private agencies. Additionally, there is assistance to flood areas provided by other sources. However, data about disaster relief rarely flow into a single database. Consequently, a true estimate of the monetary costs incurred by a particular flood event is nearly impossible to make and all estimates are highly approximate. At best, it is suggested that between 1955 and 2000, the Ministry of Public Works spent between 4500 million euros and 100 million euros annually for flood-related work. Similarly, since their establishment, the regional governments have spent about 700 million euros per year.

This paper presents the use of a model quantifying potential losses suitable for planning and insurance against flood. The model is derived from a methodology for flood damage estimation developed in a small town in Varese province. It simulates event scenarios and evaluates expected economic losses. Potential economic loss assessment implies knowledge of the event, exposed asset values and the degree of damage. Following a widely shared simplifying assumption, flood water level was taken as the only factor indicating event magnitude.

The model incorporates the following steps: a) event description: definition of flood parameters (flooded area and water level), utilizing real-time measurements or data from event simulation with a hydraulic model; b) asset damage and identification of the affected population; c) evaluation of the degree of damage as a function of event magnitude; d) attribution of an economic value to different exposed assets; e)

quantification of economic loss by multiplying economic losses and damage severity.

An insurance bonus has been associated to each building, taking into account the economic loss occurred during the most severe documented event, and the frequency of floods from the Second World War till today. This pilot effort can be useful for land administration bodies and insurance companies in demonstrating the benefit of systematic acquisition and management of flood-related damage data.

SESSIONE F1

Lo sviluppo sostenibile nel territorio attraverso la musealizzazione:

F1-1 Orale Preite, Massimo

10.1474/Epitome.04.0460.Geoitalia2011

THE MASTERPLAN OF THE MINING PARK OF THE COLLINE METALLIFERE

PREITE Massimo¹

1 - University of Florence, AIPAI Vicepresident, TICCIH Board Membre

Presenter e-mail: agaka@libero.it

Key terms: Industrial Heritage; Mining Park; Mining Museums; Mining Landscape; Cultural Landscapes

The strategic objective of the Masterplan of the National Technological and Archeological Park of the Colline Metallifere has very few precedents, insofar as the conceptual project is geared not so much towards the conservation of a few isolated remains, but to the development and promotion of a large-scale area, with a history of mining and metal-working spanning many centuries. Thus, conservation is extended to an assortment of many different objects (extraction and smelting sites, quarries, inhabited sites, transportation and storage facilities, slag heaps etc) which exist in relation to each other, but also with a wider environmental system which supplied the resources needed for them to work. Successfully embracing this complex system of relationships has been the real challenge for the Masterplan. Accordingly, the goal of heritage conservation has been attained on a scale requiring "conservation projects in the landscape": it is landscape which gives meaning and significance to disused machinery and facilities which, otherwise, viewed individually, convey very little ability to explain their function within the wider context of the complex relationship between man and his environment, which arises in each and every occupational process. The landscape dimension unquestionably adds a series of limitations in terms of morphology and the environment; but at the same time proves to be the scale best suited per deducing, from the overall pattern, the margins of transformation on which to base a coherent project to safeguard the heritage, and the margins for ascribing (to that same heritage) an active role in our modern society. From wide-ranging surveys of mining and metallurgical remains in the Colline Metallifere area (survey work which is well covered by this publication), there emerge all the features of originality and innovation of the Technological and Archeological Park, which was set up in 2002. First, its interdisciplinary nature, linked to a multiple supply of attractive elements, ranging from Etruscan and medieval archeology to industrial archeology, the natural and environmental heritage, the historical and architectural heritage (old town centres, castles etc) and the landscape. At the same time, stress should be laid on the twin aim of the Masterplan. It was drawn up as a tool designed to achieve both cultural and economic goals. While heritage protection remains an inalienable objective, the Masterplan does not hesitate to explore the opportunities for development which the Colline Metallifere can benefit from, via innovative enhancement and reuse of the industrial heritage.

10.1474/Epitome.04.0461.Geoitalia2011

A THEATRE IN THE PARK. THE TEATRO DELLE ROCCE PROJECT IN THE PARCO NAZIONALE DELLE COLLINE METALLIFERE GROSSETANE

CASINI Alessandra¹, AGRESTI Luca¹

1 - PARCO NAZIONALE DELLE COLLINE METALLIFERE GROSSETANE (TUSCANY)

Presenter e-mail: parcominerario@comune.gavorrano.gr.it

Key terms: MINING PARK; INDUSTRIAL HERITAGE; THEATRE; CULTURAL PROJECT

The Parco Nazionale delle Colline Metallifere Grossetane is located in northern sector of the Grosseto province in Tuscany, central Italy. The TM Geopark coincides with the territory of the Colline Metallifere

(Metalliferous Hills), the most important mining district in Italy together with some zones of Sardinia.

The area of the park extends on a whole surface of 1087 km² and includes the territories of seven municipalities: Follonica, Gavorrano, Massa Marittima, Monterotondo Marittimo, Montieri, Roccastrada and Scarlino.

The Park area has a relatively low human presence as the resident population is of 53.549 people) with a density of 49.3 people/km² against a level of 198.8 people/km² for the whole Italian territory (ISTAT data of 31 December 2007).

The most densely-populated municipality is Follonica (21.761 inhabitants), while in the others population ranges from 1.221 people (Montieri municipality) to 8.681 people (Gavorrano municipality).

The territory in question is characterized by hilly slopes with frequent outcrops of limestone, and red clayey soils deriving from the action of external agents on the limestone. Of particular note is the presence of various phenomena such as: Karst formations, geothermal phenomena thermal springs; and, finally, the large-scale mining and ore-processing areas of copper, lead, silver, lignite and pyrite.

The areas with the steepest hills, and the more hilly upland country in and around Massa Marittima, Monterotondo Marittimo and Montieri, are rich in mineral, geothermal and thermal resources, the exploitation of which has left a great deal of evidence relating to the various historical periods. This evidence has created a unique and unrepeatable landscape, a distinctive feature of which are the pipelines for steam generated by geothermal activity, and the natural, endogenous manifestations of naturalistic and geological value.

Large-scale morphological and ecological alterations of the landscape (stone quarries) are also a product of the demand for material for use as filler in the mines (Gavorrano), and for stones for ornamental use and for gypsum. However, these are now a characteristic feature of the mining and industrial landscape of the Colline Metallifere, also marked by examples of cultural development (the Teatro delle Rocce theatre, built inside an abandoned quarry connected with the Gavorrano Mine).

Intensive working by mining industry have left significant marks on the landscape in and around Gavorrano.

The Teatro delle Rocce is an open air theatre, it is a part of this project, as the conversion of a quarry which was used by the mine to fill in the underground tunnels. In fact, one of the main aspects of the project is to save the mining factories to give it a new "cultural" function. It was a real process of returning to the community of a lost and abandoned heritage with the closing of mining activities.

The presence of the Teatro delle Rocce has allowed to take an interesting cultural project in the park by organizing a festival of theater and music that in a few years it has become one of the most important events of the Province of Grosseto and allowed to transform a degraded place in a vital center frequented by many visitors, creating quality cultural offer and many reasons for return of visitors.

This allowed to undertake projects with theatre companies in collaboration with the Tuscany Region and the Province of Grosseto, in particular, the company KATZENMACHER of Alfonso Santagata with the project "La Miniera del Teatro" is creating in the park a real permanent workshop about the theatre in the territory.

F1-3 Invitato Sbrilli, Luca

10.1474/Epitome.04.0462.Geoitalia2011

A CULTURAL ENTERPRISE FOR ARCHEOLOGICAL, MINING AND NATURAL PARKS

SBRILLI Luca¹

1 - PARCHI VAL DI CORNIA SpA

Presenter e-mail: SBRILLI@PARCHIVALDICORNIA.IT

Key terms: Val di Cornia, archaeological-Mineral Park; Mine district; Rocca San Silvestro; Coordinated territorial planning; Management of the cultural and natural heritage

The Parchi Val di Cornia SpA is a public company with a shareholding owned by the municipalities of Piombino, Campiglia M.ma, San Vincenzo, Sasseta and Suvereto, along with the Province of Livorno. It is a cultural enterprise holding some 350 sq.km that has, by statute, the aim of creating an integrated management system for the cultural and historical heritage and the environment of the territory.

Important and original work in coordinated territorial planning between the 5 shareholder towns has, since the '80s, led to the current structure for the protected areas. Important legal battles over ten years against illegal development, degradation and abandonment, permitted the creation of the entire park system.

Parchi Val di Cornia SpA saw the light as a public-private company, using an original tool for the management of the cultural and natural heritage in Italy: the limited company.

Since its establishment in 1993, the company has grown and today includes three museum complexes, an archaeological park, an archaeological-mineral park and 4 natural parks. Now a solid reality, the company has more than 30 full-time employees, a figure which reaches between 70 and 80 during the spring and summer. The work the company has carried out in valorising the historical and environmental heritage has aided the development of sustainable cultural tourism and contributed substantially to an ongoing process that sees tourism as a new force for the local economy, alongside existing industry. It is instructive to consider that in the year 2000 the tourist presence in the Val di Cornia numbered around 1,100,000. In 2009 this figure exceeded 2 million. The development of cultural resources brought about by the company, together with local government, has allowed a new image of the area to arise, one no longer linked to the steel industry.

The company, through the sale of tickets and income from concessions and parking has, in the last five years, been more than 94% self-financing.

The San Silvestro Archaeological-Mineral park is located near Campiglia Marittima and it covers 450 Hectares. This is an old mine district and a very important geological area, in particular for the skarn complex and its mineralization.

This park saw the light in 1996, it was founded in order to valorise a vast mining territory which has always been characterised by the close rapport between man and resources, settlement and extraction activity, archaeology and the landscape. It was the first mining park of Tuscany. San Silvestro Park is an open air history book for the story of mining, from Etruscan times until to the 1970s. The activity of extraction and mine working had left behind a lot of structures and plant that are amongst the most important European examples of industrial archaeology.

These structures are today the museum and hostels for visitors. The park takes its name from the Rocca di San Silvestro, an old and unique medieval mine village. Five years ago, an old mine joining two valleys was

restored, one kilometer used by a mine train transporting visitors.

After 15 years of activity, the results have become important for the culture and economy of the territory. In our country however, there are some legal problems regarding the management of these particular parks, so we hope a new regional law will resolve this. We will work for this objectives together with the all the other Tuscan mine parks. Tuscany has one the richest historical mining and geological heritages in the world.

F1-4 Invitato Mantengoli, Patrizia

10.1474/Epitome.04.0463.Geoitalia2011

THE ABBADIA SAN SALVATORE MINING DISTRICT (SIENA, CENTRAL ITALY) AND THE MUSEUM MINING PARK

MANTENGOLI Patrizia¹

1 - Assessore/Vice Sindaco - Comune di Abbadia San Salvatore (Si)

Presenter e-mail: cultura@comune.abbadia.siena.it

Key terms: Mercury; cinnabar; Abbadia San Salvatore; Museum Mining Park

The Abbadia San Salvatore mining district (ASSMD) has a long-standing history during which different events have interlaced: a) a small village that in a few years turned to be in an important mining center; b) a company (the Monte Amiata) that became at world level one of the main actors in the mining market and c) a peculiar metal (mercury): the only metal that is liquid at standard PT conditions) whose commercial decline has determined the financial collapse of the producing companies.

Since 1800, the Abbadia San Salvatore mines along with those from Almaden (Spain) and Idrija (Slovenia) have exploited the most important mercury ore deposits worldwide. The mining activity in the ASSMD has lasted for at least one century during which it has suffered ups and downs that can be summarized in four main stages: i) the pioneering exploration when the Hg-bearing mineral (cinnabar) was searched in the Mt. Amiata (the youngest, about 200 ka, and largest volcanic complex in Tuscany, central Italy) area; ii) the build-up of the metallurgical plant with the financial and technological support of foreign companies; iii) the passage of the Hg district from private to public investors; iv) the workers' fights and the closure of the mining activity in the eighties.

Currently, the local museum, hosted in the historical building of Torre dell'Orologio, contains numerous documents, objects, photos and reproductions that allow the visitor to travel back in the past when the mining activity was the heart and the core business of the municipality of Abbadia San Salvatore. In the museum, the technical-scientific instruments are exposed in their original environment in chronological order. Thus, the visitor can appreciate how the mineral was worked for the extraction of mercury and how the technology has implemented since the XIX century. The perception of both the functional structure and the morphological organization of the mining complex is highlighted thanks to a peculiar sequence of the metal that has controlled and determined the fate of Abbadia San Salvatore: the extraction, the metallurgy and the memory. The documentary-exposive organization is in the Study Center and the Archive located in the Torre dell'Orologio, the documentary museum is in the former mechanical workshop that also hosts the machinery museum, temporary exhibitions and conferences and meetings. The museum of Abbadia San Salvatore is included in the network of the Musei Senesi and represents the first step of a larger project aimed to build the Museum Mining Park.

Abbadia San Salvatore is located in the heart of one of the most important districts worldwide by a natural, historical and artistic point of view: the Orcia Valley, Pienza Montepulciano, the thermal resorts of Chianciano, the Bolsena Lake, the Grosseto Maremma, Sovana, Sorano, Pitigliano and so forth. Abbadia is few kilometers away from the important railway and highway nodes of Chiusi from which Mt. Amiata can be reached in about 30 minutes by car or by bus. The Museum Mining Park will thus benefit of exceptionally favorable accessibility conditions from historical centers that have a strong tourist appeal.

F1-5 Invitato Ottelli, Luciano

10.1474/Epitome.04.0464.Geoitalia2011

GEOLOGICAL MINING PARK OF SARDINIA

OTTELLI Luciano¹

1 - Parco Geominerario Storico e Ambientale della Sardegna

Presenter e-mail: direttore@parcogeominerario.sardegna.it

Key terms: Geological Mining Park; cultural resources; Charta of Cagliari

The Geological Mining Park of Sardinia is located in the centre of the western basin of the Mediterranean sea. It has been proclaimed the first Geological Mining Park in the world, an emblematic example of the new global network of Geosites-Geoparks established by UNESCO. Therefore, it is identified as a theme Park and it is part of a very special territorial context, namely the island of Sardinia, considered a small, but complete continent, because of its environmental and geological features. The Park includes eight different areas of interest situated all over the regional territory, covering a surface area of 3455 km². Clearly visible within its area there are signs of the material culture and of the settlements built around the mining activities which created new and original forms of landscape and social and cultural environments, able to characterize huge areas with a precise identity of universal value, unique and representative of the whole Mediterranean geological and cultural region.

The Origin Of The Park

The creation of the Geological Mining Park is a result of the realization of ideas, contributions, individual innovations and a united strength of purpose which established themselves during the last decades of the twentieth century in the Sulcis- Iglesiente- Guspinese territory. 1996 was the year of change in the Park's history: the compilation of the dossier to be presented to the UNESCO commission gave full recognition of the international value of historical, geological and environmental peculiarities of the Park. The General Conference of UNESCO in Paris recognised the island's first Park in the network of Geosites and Geoparks. After two years, on September 30th 1998, before the highest authorities of UNESCO and of the Italian Government, the Charta of Cagliari was signed. This is a document containing the working guidelines of the Park. After various difficulties and demonstrations, on October 16th 2001 the Italian government signed the constitutive decree of the Park. From that moment on, the Park became institutionally recognized. In 2007, UNESCO recognition and membership of the Geoparks European network was confirmed.

Mission

The Park was established because of the desire to create an organisation able to enhance its historical and cultural resources, linked to the common

mining tradition, within a context which adds to the preservation of abandoned archaeological industrial and mining sites, the extraordinary naturalistic and landscape resources of the territory. Therefore, the multi-theme peculiarities create an environment able to offer a "Geological Mining Park cultural product" package, linking the coastal areas of the island to the inland areas on a homogeneous sustainable development programme which represents a chance for social and economic rewards, ensuring at the same time a rich offering of topics and interests, made unique by the universal values within the Park territories.

Geology
Sardinia is one of the most geologically complete regions of the European and Mediterranean area. Therefore, its geological history is part of that of Western Europe and strongly differs from that of the Italian peninsula. It has one of the most ancient coastlines in Europe: high sea-cliffs, sandy beaches and impressive dunes. Inside the Geological Mining Park of Sardinia there are many karsts, unique in the whole world, inside of which there are many grottoes, some of them monumental, crossed by underground rivers. Inland and on the coasts we can see the changes of the landscape due to mining activity, carried out since remote ages.

History
The historical course of Sardinia and of its Park is strictly connected to mines. Nuraghes and small bronzes, as well as lead metallurgy are evidence of the exploitation of the mines by Punic, Romans, Pisans and Piedmonteses. The history of its mineral codes and of the whole Sardinian mining district is proof of a close relationship between man and the exploitation of the huge geological resources that both Sardinia and the Geological Mining Park still have. Mining villages and small towns and centuries of mining companies' history, represent, together with miners' struggles and the closure of the mines, a historical continuum which is nowadays guaranteed by the Geological Mining Park and which projects its territories towards a future of reconversion of its resources and memory recovery.

F1-6 Orale Fornaro, Mauro

10.1474/Epitome.04.0465.Geoitalia2011

THE ENHANCEMENT OF COGNE MINE: A VERY IMPORTANT CHANCE FOR THE VALLE D'AOSTA GEOMINING PARK

BARAL Gino¹, FORNARO Mauro², GIULIANI Andrea³, ROSTAGNOTTO Angelo¹, SAVOCA Domenico³, SERTORIO Marco¹

¹ - Libero Professionista

² - Università di Torino - Dipartimento di Scienze della Terra

³ - Regione Lombardia - Assessorato Qualità dell'Ambiente

Presenter e-mail: mauro.fornaro@unito.it

Key terms: Dismissed mining site; Geomining park; Territorial Rehabilitation; Industrial Heritage; Environmental Remediation

The Region of Valle d'Aosta, on the basis of two Regional Laws, foresaw the preservation and valorization of dismissed mining sites (L. 5/2008 Art. 21) and the creation of a Geomining Park (L. 12/2008 - Art. 5) in its territory: it includes different dismissed mining areas.

The increasing interest from local administrations toward "abandoned mining sites" is both motivated by cultural and economic considerations. Several initiatives are related to these two main topics.

Most of them are private and "voluntary", but also public, thanks to "co-financing" and aim to preserve the historical memory and to reintegrate the abandoned structures into the original territory (D.Lgs 42/2004).

The Earth Science Dept. of University of Turin is the coordinator of a group of expertise - Researchers and Consulting Technicians - which carried out a multidisciplinary feasibility study, concerning also the old St. Marcel and Brusson mines. Those mining sites were interested, during the past months, by a public tender for their valorization in a touristic and museum context.

The preparatory study, carried out by Earth Science Dept., was initially based on the works concerning Cogne Magnetite Mine, which was frozen because of administrative difficulties, coming from the same mining claim. For this mine, different studies have helped to identify main points of interest and critical elements, indicating the priorities for intervention in a mining context, perhaps even too "rich" and complex in terms of tourism. The outdoor heritage is composed by the structures, buildings and plants of Colonna Village and the cableway of Costa del Pino that are difficult to preserve or refurbish.

On the other hand, the underground is very well-preserved, equipped with an inclined shaft (skip) and train, that could be easily used.

If the Mine Company would like to renounce to the mining concession, it has to think about the onerous works caused by mine rehabilitation, which are, by law, charged on the last Mine Society.

The preliminary technical investigation of the Department of Earth Sciences has however allowed the priority identification of the interventions of remediation, for the safety and the restoration of some mining structures, that are considered worthy of preservation.

This gave a way to report on the technical results already available, summarizing the operational criteria and giving to the competent Administration some objective elements of evaluation for the planning choices.

In this regard, it should be noted that the recent Italian government approval of the contested law on "Federalismo demaniale (state property federalism)" (D.lgs. 28-05-2010, n. 85) seems to confer the ore deposits to the provincial (or regional) heritage, even if already covered by the existing Mining Law (RD 1443/1927).

The controversial political decision to consider these assets in "availability of the competent authorities (then alienable!) could then put the same Municipality of Cogne in the conditions to acquire - like an historical nemesis - "its" ore-body, as desired in the nineteenth century by the worthy Dr. Grappein! The mine of Cogne has been certainly deserving of all this.

Through the Valle d'Aosta Region, will nevertheless be necessary to make requests for the financing for new Operative Regional Projects (POR), taking advantage of the European Structural Funds (FES).

For the Mining Park of Valle d'Aosta, in addition to the strengthening of the renewed Mining Museum of Cogne and the realization of specific "info points" in other historical mining sites, it may be optimal to identify the well-recovered Bard Fortress facility as the "Gateway Park".

F1-7 Invitato Bergamini, Massimo

10.1474/Epitome.04.0466.Geoitalia2011

REQUALIFICATION PROJECTS FOR BALANGERO AND CORIO MINING SITE

BERGAMINI Massimo¹

1 - R.S.A. Srl

Presenter e-mail: bergamini@rsa-srl.it

Key terms: asbesto mine; requalification; projects; memory preservation; Ecomuseum

R.S.A. Srl - Public Company for reclamation and environmental development of Balangero and Corio asbestos mine.

The asbestos mine of Balangero and Corio is "a reclamation intervention site of national interest" as defined by the law n° 426/98 art. 1

The surface area to be reclaimed is a mountain region of about 400 ha situated 30 km far from the north-west of Turin. The area covered by the factories have a surface of about 40.000 sq metres. Inside the asbestos open pit there is a cultivation basin with a volume of about 2 million cubic metres.

The exploitation of asbestos serpentine sediment, consisting most of chrysotile, begun in 1920 and become, by 1970, one of the main international manufacture with a production average between 130.000 to 160.000 ton/year, sending to exportation more than 60% of material. The mining industry, carried out with steps cultivation system, has caused a significant transformation of the rock area involved placed on the borderline between Balangero and Corio.

This activity has caused the heaping of more than 45 million cubic metres of mining tailings, that has re-profiled and completely filled up the valley, as well as the production of 60.000 cubic metres of mud containing asbestos stocked in sedimentation basins all along main streams. Balangero Asbestos Mining Company become insolvent and stopped the activity just before it was issued the Law n° 257/1992, containing regulations about prohibition of asbestos excavation, trade and use. According to art. n° 11 of the Law, it was provided for environmental remediation of the asbestos mine of Balangero and Corio, including execution conditions.

Remediation in progress is carried on with particular care to the environmental setting in order to develop opportunities to recover the site by an economical requalification of territories involved.

Hydro-geological and environmental setting is done by naturalistic engineering techniques in support of environmental restore of the involved territories.

The recovering area take care to ecological sustainable solutions: one of the project, that will be carry out in a short term, is a photovoltaic setting in those territories that will not be any more available to public use because of permanent remediation.

In a long term, when the asbestos mine reclamation will be completed, besides the production of alternative energy sources, the development plan foresees to set up a Mining Park with the purpose of environmental and historical memory preservation and valorization.

By now, R.S.A. Srl has submitted the Ecomuseum Project to the value and approval procedure by the Regional Administration Committee.

Since some years this purpose has already been carried on by a partnership between R.S.A. Srl and the local Government according to the same intention not only to preserve the historical memory of Balangero and Corio Asbestos Mine as an unrepeatable case of industrial archeology, but also for the development of environmental training activities referred to students of territorial different level schools.

Furthermore the future Ecomuseum exhibition area could be used to display on going requalification projects, to organize shared activities with local associations and become, moreover, a study and research centre with the purpose to spur on local business activities.

That is why an European Project Idea Contest, financed by funds of Piedmont Region, has been called in October 2010. Many project professionals have taken part to the competition, this has given us the chance to collect very interesting and peculiar ideas for the mining park. Last 20th of April the Selection Committee has selected the winner between the projects submitted and afterwards, R.S.A. Srl has already scheduled to arrange for exhibition and some events in order to show all projects.

MINERALOGICAL MUSEUMS IN THE MORAINIC AMPHITHEATRE OF IVREA (AMI)

CANAVESE Giuliano¹

1 - Ecomuseo AMI

Presenter e-mail: presidente@ecomuseoami.it

Key terms: AMI Museum Network; Brossio; Traversella; Zubiena - Bessa; Salussola

As part of its efforts to promote the variety of cultural riches of the Morainic Amphitheatre of Ivrea (Anfiteatro Morenico di Ivrea - AMI), the AMI Ecomuseum has designed and created the AMI Museum Network, with financial support from the 'Compagnia di San Paolo' foundation, the Provinces of Turin and Biella, from the 15 municipalities of the Morainic Amphitheatre of Ivrea and from the Ecomuseum of the Elvo and Serra Valley, as well as by employing its own financial resources.

The AMI Museum Network unites 11 of the 19 museums present and active in Morainic Amphitheatre of Ivrea area. A structure of service and support, managed and controlled by the Ecomuseum of the Morainic Amphitheatre of Ivrea, which aims to:

- o acquaint an audience extending beyond the local area with these museums, through activities directed at informing and promoting, with the support of the Provincial Tourist Agencies and a set of unified and coordinated tools and promotional channels;
- o keep the museums open on an ongoing and certain basis for a significant period of the year, prolonging traditional opening times to the public during village festivals and fairs;
- o provide these museums (which are often managed by volunteers) with human resources that possess university level education and training and that have been properly instructed on how to present each individual museum correctly and how to relate with the public, as well as how to interpret their role as 'museum professionals'.

Museums with different characteristics, but representative, as a whole, of the economic and cultural history of the area of the amphitheatre form the AMI Museum Network.

Among these, two groups of museums dedicated to mining activities prevail, which until the recent past, were of economic importance. In Valchiusella, on the western side of the Morainic Amphitheatre of Ivrea, iron and pyrite mines, as well as stone quarries, were cultivated and exploited, even before the Roman conquest (II Century A.C.) according to historians. During the eighteenth century, Valchiusella was the largest producer of iron in the Savoy state.

The two mineralogical museums devoted to this theme are located in Traversella, where FIAT was the last owner of the mines, and in Brosso, where mining activities were last managed by Montecatini. Both areas concluded their mining activities in the early years after World War II. The eastern side of the Morainic Amphitheatre of Ivrea witnessed gold mining activities even before the Roman conquest. Gold mining probably reached its peak with the Romans, if - as claimed by Plinio - 5,000 men were employed to search for gold in the territory of the Bessa, located in the municipality of Zubiena. Gold hunting activities subsequently declined and are now practised for educational purposes or as a sport or hobby. Both the Gold and Bessa Museum in Zubiena, and the Gold and Stone Laboratory Museum in Salussola exhibit materials, instruments and examples of these mining activities.

THE MINING INDUSTRIAL HERITAGE OF THE ALPS AND CENTRAL ITALY: AN ANALYSIS OF RECOVERY AND VALORISATION INITIATIVES IN A MINERAL DEPOSITS GEOLOGY KEY

CASTELLANO Antonella Maria¹; RODEGHIERO Franco¹

1 - Università degli Studi di Milano - Bicocca, Dipartimento di Scienze Geologiche e Geotecnologie

Presenter e-mail: a.castellano@hotmail.it

Key terms: mining industrial heritage; mining sites improvement initiatives; mineral deposits geology; Alps and Central Italy

Nowadays there is a great number of recovery initiatives of abandoned mining sites in a belt that runs from the Eastern Alps through Liguria, Emilia-Romagna up to Tuscany in Italy and in cross-boundary areas. This study involves their census and their characterization focusing on mineral deposits geology aspects.

During the last decade we have seen an increasing interest in these initiatives by the Scientific Community, by the Government (ISPRA) and Territorial Bodies (Tuscany and Lombardy).

In the 1980s and 1990s the closing of the majority of the Italian mines, most of which metalliferous, carried out to a sensible reduction in Italy in the scientific production on the ore deposits geology.

Forty-five improvement initiatives of mining sites (ore and industrial minerals mines and ornamental stone quarries) have been identified. For each site a monographic paper has been produced after direct surveys in situ. A critical comparison between what is offered and what is really accessible by users has also been realized.

The data synthesis yielded a thematic map of the situation of the recovery and improvement initiatives of abandoned mining sites from the Alps to Tuscany updated to 2010.

The recovery initiatives have been divided in three categories which include "Mines and Quarries", "Parks and Museums", "Projects". The first group enables visitors to see the ore deposit with their own eyes, as it proposes to people a visit of underground mining stopes and levels; the second group offers external paths and/or museum exhibitions, sometimes with artificial reconstructions of mining tunnels; at last the third group is made up of the initiatives at a stage of feasibility study. From this study it appears that at present the Italian regions with the largest number of recovery initiatives are Trentino - Alto Adige, Lombardy and Tuscany.

Most of these sites involve ore deposits, mainly base metals sulphides; deposits of industrial minerals, indeed, are incompletely represented by talc, fluorite, salt and sulphur and coal mining sites; a remaining small part is made up of ornamental stones quarries, all underground.

From the Alps to Tuscany today it is possible to have a recovered mining heritage that potentially enables to carry out live observations on mineral deposits geology topics about the following important categories of deposits:

- polymetallic and talc deposits (stratiform and vein-type) in the Crystalline Basements;
- iron, lead - zinc (Ag, Cu) "MVT or carbonate-hosted", coal, salt, and sulphur stratiform deposits in the Mesozoic and Tertiary sedimentary cover;
- polymetallic vein-type pyrite, gold and talc deposits;
- Sed-Ex type copper, pyrite and manganese deposits in the alpine and appenninic ophiolites and meta-ophiolites and in their covers;
- polymetallic skarn type deposits connected to Tertiary plutonism;
- gold-bearing placer deposits in Quaternary fluvio-glacial sediments;
- ornamental stones quarries (marbles) in the Paleozoic (Alps) and in the Mesozoic (Appennines).

All the recovered mining sites are different for types and settings of deposits, mineral substance, geological domain, metallogenic context and age and they are present in a defined geographic neighborhood: from the Alps to Tuscany.

The in situ surveys have pointed out that the mineral deposits geology basic elements of these recovery initiatives are often incomplete or lacking, while great emphasis is given to historic information, together with mining industrial archeology.

This heritage, indeed, covers not only industrial archaeology and/or tourism topics, but also important geological and mineral deposits aspects. The local geology of mineral deposits is indispensable condition for the opening of quarries and mines. Therefore it is also necessary to pass to the wide public this important cultural aspect.

Besides this heritage would be available to the scientific community and to Italian and transalpine universities for didactic and cultural aims.

F1-10 Orale Patane, Agata

10.1474/Epitome.04.0469.Geoitalia2011

THE NATIONAL DAY OF MINES A NETWORK FOR ECO-MUSEUMS MINING IN ITALY

PATANE Agata¹

1 - ISPRA

Presenter e-mail: agata.patane@isprambiente.it

Key terms: dismissed mining sites; mines, territory; database; mineralogical collections

The National Day of Mines, now in its third edition, is a national initiative that involves many Italian mines aiming to promote the use of geological and mining heritage and create a museum network.

The institutions and associations sponsoring the event are: ISPRA, Italian National Institute for Environmental Protection and Research (<http://www.isprambiente.gov.it/site/it-IT/>); AIPAI, Italian Association for

industrial archaeological heritage (www.patrimoniindustriale.it); ANIM, National Association of mining engineers (www.anim-gallerie.it); Italian Mining Association for mining and oil extraction (www.assomineraria.org); National Association of Geology and Tourism G&T (www.geologiaetourismo.it), sponsoring the G&T day.

The National Day of Mines represents an opportunity to study the dismissed mining sites and their cultural enhancement; the memory of the thousands of workers who were employed in mining, the relationship between rural life and industry, folk tradition and modernization, which is a particular characteristic of the communities associated with mining. The third edition includes the participation of many Italian regions. The calendar of events is available on the ISPRA and AIPAI websites. Initiatives are typically guided tours and geological tourist routes, seminars and conferences.

The comprehensive purpose is to reflect the value of the mining heritage in the Italian countryside, to affirm the historical significance, and to keep the memory alive. In addition, these initiatives are an opportunity to highlight the value of recovering these territories for sustainable development.

The "Italian Directory of Earth Sciences" ISPRA has registered approximately one hundred eco-mining museums, which will be part of the future museum network, supported by the AIPAI Mines Commission. All of these sites are included in a database, which will be available soon on <http://www.museo.isprambiente.it/Regioni.page> site.

ISPRA researches work on the territory concerning the cultural enhancement of the mining sites of geological interest, through the Museum Service Institute, which inherited the Litomineralogical Collections from the former Italian Geological Survey. The Litomineralogical Collections are the result of 150 years of survey activities related to the Geological Map of Italy, mining explorations, and samples acquired by purchase or donation. The whole litomineralogical heritage is currently preserved in a database - GEODOC Project - waiting to receive funding for the purpose of cataloging according to national standards of the Central Institute for Catalogue and Documentation.

The Litomineralogical Collections began with the unification of Italy after the establishment of the Geological Committee, (the new Office and then Geological Survey) under the Royal Corps of Mines, for the purpose of studying soil and subsoil of the Kingdom, of knowing and using of domestic raw materials. The Litomineralogical Collections demonstrate the determination by the rulers of the Kingdom of Italy in order to know its territory in order to plan properly.

The Litomineralogical Collections (currently belonging to ISPRA) were hosted for more than 100 years in a building of great prestige, the "Agricoltura Geological Museum" in largo santa susanna, [built for this purpose in 1875 up to three levels of exhibition space (2700m²), and it was abandoned (because of needed repair work) by the Geological Service in 1995]. Currently the Collections lie mostly in storage rooms (excluding the exhibition space of 270 m² hosted at the ISPRA office in Via Curtatone), it is waiting for public funding that could restore the original and necessary places for the exhibition.

F1-11 Orale Paganoni, Anna

10.1474/Epitome.04.0470.Geoitalia2011

THE GEOLOGY BUILTS THE LANDSCAPE

PAGANONI Anna¹

1 - Museo Civico di Scienze Naturali - Geologia, Bergamo

Presenter e-mail: apaganoni@comune.bg.it

Key terms: Museums; Tourism; Geological gardens; Via Geoalpina

Often the subjects of geology are intertwined with those of culture and management of land, its conservation and enhancement. This process is no stranger to transformations taking place, they include the reorganization of the urbanized area, the conversion of raw materials to production areas and the increase in residual areas.

Geologists have a new opportunity to broaden their skills, communicate with other professionals involved in land management, become active participants in defining aspects of cultural value unknown to most speakers. Problem areas, sometimes considered only for material suggestions neglecting the Geological Value reveal important opportunity to achieve users in search of novelty and excitement. Obviously the process does not go through a traditional musealization, aimed at conservation purposes excluding innovative methods and techniques.

Examples of this can be considered in cases of conversion of underground caves of Vicenza stone, temporarily used for cultural events. Massive pillars supporting the ceiling emerge from the water, marks of the blocks draw the walls and the ceiling with their massive size. But also Gavronano mines or quarries in many Italian regions are transformed after the discovery of extraordinary paleontological deposits, all are examples which demonstrate a change in sensitivity to the world of geology and the approach of a new audience. The search for cultural events such as concerts, or art installations leads to the search and discovery of quality sites, and the nature of the materials carried by insights and accomplishments in quality. This method has long pursued by museums for public awareness by involving them in new locations or purposes that are more engaging than the individual paths or guided tours in the exhibition halls.

Today, the inventory of geological heritage, the musealization spread in situ, the recovery of abandoned areas are issues that have assumed a central role in the economic and social debate after years of quiescence in fact, are common examples of its conversion and development of the territory. Abandoned land have become "geological gardens" where large blocks are carefully collected and described to demonstrate unusual geological features. Near the Geological Survey of Regione Emilia Romagna, for example, has been set up this kind of installation, but similar cases are offered in other sites. After a careful selection of geological sequences belonging to a limited geographical area to facilitate the understanding of rocks visible along hiking trails, bicycle paths or recognized in floods. This methodology is particularly suited to convey the basic concepts of geology also at a disadvantage from a public limited mobility.

Is also growing a new type of musealization particularly recommended as it does not alter the environment, it moves along existing routes by offering support guide proposes a context of geological processes and issues in any broader cultural context. Emblematic of this is the experience of Via Geoalpina, symbol project of Planet Earth TYPE, who made trips described in a geological perspective and tourism throughout the Alps. The Italian pathways are described by members of G & T Associazione Italiana di Geologia Turismo. They are available through a dedicated website, free downloadable, computer readable and planned for a user friendly approach to geology.

The process is not without difficulties and contradictions, achievements

banal or difficult to manage, but the excitement that is linked to this type of museum routes documents a new impetus of geological disciplines lowered into a new culture of the landscape.

10.1474/Epitome.04.0471.Geoitalia2011

SUSTAINABLE EXPLOITATION AND UNDERSTANDING OF THE RELATIONSHIPS BETWEEN MAN AND LANDSCAPE IN THE ECOMUSEUM OF HILL AND WINE OF CASTELLO DI SERRAVALLE (BOLOGNA, ITALY)

BADIALI Federica¹

¹ - PhD School in Earth System Sciences, Dip. di Scienze della Terra, Università degli Studi di Modena e Reggio Emilia

Presenter e-mail: federica.badiali@unimore.it

Key terms: cultural heritage; tourism; agriculture; sustainable exploitation; involvement

The landscape of the Apennine areas has preserved many important traces of the mutual relationship between man and environment, continuously during the centuries; in this way, a great value heritage has been created, which deserves to be emphasized and protected, and in which we can find also human activities now almost forgotten. For this reason these areas are ideal to a sustainable enhancement, which could be carried out by means of an Ecomuseum, because "don't exist marginal or insignificant areas, on the contrary only places that have not found the correct convergence between potentiality and initiatives yet" (Piacente & Poli, 2003).

An Ecomuseum refers to a new holistic idea of Cultural Heritage, until now mainly related to specific items and objects, performed by traditional Museums; in other words, an Ecomuseum is an "agreement by which a community is committed to taking care of a territory" (Maggi, 2002). In fact, in a traditional Museum it keeps and shows works of art, ancient objects or scientific attestations. On the contrary, an Ecomuseum involves all the land surrounding it and has, as its main task, the increasing in values and the preservation of either the historical and cultural heritage or the natural and environmental one.

Therefore the Ecomuseum doesn't focus its attention just on objects, historical buildings or landscape elements but lets to discover direct the local heritage and the inhabitants activities: the representation of the local community.

It is presented the case of the Ecomuseum of Hill and Wine (Castello di Serravalle, Bologna, Italy), opened in 2004. In this territory, near the border between Modena and Bologna, 325 m sea level, in a hilly zone of wines DOP and DOCG production, the landscape alternates intensive vineyards, cultivated fields and geomorphological elements of great interest, beside charming features such as the fortified medieval village of Serravalle, in whose walls you can see the use of local rocks and re-used Roman bricks. Nowadays, in this area, the most important expression of the interaction between man and landscape is mainly represented by the viticulture; but we shouldn't forget the archaeo-botanical proofs, ensuring the grapevine-growing in the Roman Age and probably even earlier. The Ecomuseum of Hill and Wine, opened in 2004, covers the entire municipality of Castello di Serravalle; the seat is in the medieval Casa del Capitano, here are educational panels and some objects, however the information given by panels are brief and the exposed objects are few, so that the attention of the visitors is not focused inside the Casa del Capitano, but outside, where the real Ecomuseum headquarter is located. All the Ecomuseum routes on the territory are marked with arrows and the points of interest are illustrated by information panels. The Ecomuseum is divided and organized in nine Systems, which represent the main topics in the man-environment relationship: each one has its own colour and is explained inside and outside the seat by didactical panels and meaningful objects.

During the first years of activity, the Ecomuseum of Hill and Wine has created four important educational tools: the map-guide, the interactive totem with touch screen system for the virtual tour, the audio-guide for the visit in the castle and the web-site; particularly, the audio-guide and the totem can be used by persons with disabilities, too. In this way visitors can independently create their own itinerary, based on personal needs and interests.

Ecomuseums can be effective tools both for a sustainable tourist exploitation and for spreading knowledge and awareness of the local cultural patrimony among the residents, although the involvement of the citizens remains a critical issue.

Finally, the archaeo-environmental study, which aims to reconstruct the past landscape, result of a non-destructive environmental use, will be useful as a beginning for next studies about the future landscapes.

10.1474/Epitome.04.0472.Geoitalia2011

THE POLITICAL AND SOCIAL ROLE OF FIVE SCIENTIFIC-TERRITORIAL MUSEA OF REGGIO CALABRIA AND MESSINA PROVINCES (SOUTHERN ITALY)

MESSINA Antonia¹, BONANNO Rosa¹, PROCOPIO Smeralda¹, MAZZITELLI Maria¹

¹ - Dipartimento di Scienze degli Alimenti e dell'Ambiente - Sezione Scienze della Terra, Università di Messina - Messina (Italy).

Presenter e-mail: rbonanno@unime.it

Key terms: Scientific-Territorial Musea; Research; Conservation; Scientific and Cultural divulgation; Political and Social role

To be able to "read" our Territory, with eyes which understand the significance of each small and large thing, cheering its beauty, proud to know its value and role in the living equilibrium of the Earth's System, is the privilege of a chosen few. But these people, as the chosen few, have a duty to keenly take part in the fight against the indiscriminate use of Nature and its resources. This also means teaching others, not just specialists, the characteristics, peculiarities and wholeness which make this territory important for its environmental aspects and which have to be safeguarded and exploited in the best way possible.

Even today, in spite of natural and anthropic degradation, Sicily and Calabria (Southern Italy), exhibit an high naturalistic-environmental value, testified by the wealth of Natural Reserves and Parks, which constitute a very important system for safeguarding their natural characters, peculiar from place to place and, sometimes, unique. These, according to their geographical positions and geological features, are different from area to area, and responsible for different historical-artistic-anthropological systems. All these elements constitute a

natural-cultural system of high value, and are promoters of innovative territorial management models.

That being so, in the last fifteen years the Petrology and Crystalline Geology team and the Doctorate in Tourism, Territory and Environment of Messina University has organized five scientific-territorial Musea in the Messina and Reggio Calabria Provinces (Southern Italy), under the patronage of Athenaeum and of relevant Municipality. These structures have been set up by researchers prompted by the need to spread capillary scientific-historical-cultural knowledge, so that each visitor can take note of the importance in safeguarding the defined Territory.

With the aim of defining the political and social role of these structures, an examination of them will be carried out in this work, focusing early on their typology and museal itinerary and, subsequently, they will be incorporated into their specific roles.

The structures in object are: the Earth Science Museum - Petrography and Cartography Sections of the Calabria and Sicily Regions (Messina University, Messina); The Natural History Museum of the Messina Straits in the Mediterranean (Villa San Giovanni, Reggio Calabria); the Territorial Museum of Novara di Sicilia (Novara di Sicilia, Messina); the Memory and Emigration Museum of Limina (Limina, Messina); the Historic Museum of Mathematic, Physic and Natural Sciences (Messina University, Messina). The Musea are open to the public and gather up, order, catalogue, conserve and preserve collections and single objects, very important of the scientific and/or technologic and/or cultural point of view. The elements of this heritage, pick up directly in the field if mineral, rock, fossil, and biotic specie, or acquired in different way if thematic map, instrument or historical and anthropological find, originally have not evocative value. For to assume significance of good responsible for a link between the territorial community and its history, the materials have been contextualized through a scientific analysis that allowed them to assume a specific function in the context of scientific and/or historic evolution of the Territory, in addition to the possibility to divulge the significances which they have been loaded.

These Musea have a role of research and popular scientific structures. Its social and political role consist that the displayed natural objects and historical materials testified the evolution of the Territory and of its community. They are the memory of natural and anthropic events which allow to immortalize both community and Territory. This political and social role is the most important function of these Musea, that justified their creation, their status of public institution, and which permit them a continue develop, preventing their destruction.

10.1474/Epitome.04.0473.Geoitalia2011

THE VOLCANO ETNA AND THE GRAND TOUR: THE PLANNING OF A NATURAL MUSEUM TO ENHANCE THE AREA

RAPISARDA Carmine¹, MESSINA Antonia¹

¹ - UNIVERSITY OF MESSINA

Presenter e-mail: rapisardac@libero.it

Key terms: THE VOLCANO ETNA; THE GRAND TOUR; THE PLANNING OF A NATURAL MUSEUM; TO ENHANCE THE AREA

Man was always fascinated by volcano Etna, especially during the eruptive phase, when fear and attraction come together in front of the spectacular natural phenomenon.

In the past, the great mountain has been seen as part of the underworld, where Hephaestus placed his domain. Even in Christianity it was considered as a demonic place, where the fire has been seen as a purifier of souls and in Middle Age the volcano was imagined a gate to communicate with the afterlife; belief that continued in folk traditions until the eighteenth century.

The aim of this work is to consider how the Etna Natural History Museum, to be known for its aspects abiotic, biotic, historical and cultural and for its uniqueness.

This museum will be interactive with a past reconstructed through the memories of the foreign travelers.

Therefore, we have defined routes that lead from the slopes of the volcano to the summit. They relate elements, shapes, colors, sounds and smells of nature to preserve an important area and stimulate a qualified management.

The routes reconstruct, document and illustrate paths that follow in the footsteps of great travelers. The illustrations will make use of documents and maps, a rich iconographic comparing past and present and between the "visible and invisible".

The first scientific approaches to the study of the volcano begin during the humanist period, with Bembo (1493) in particular. But the travelers of the Grand Tour also developed a deep interest in Etna. The first ascents followed a similar route that lasted almost until the 1800's:

After leaving Nicolosi, going through the woods and crossing the desert region they arrived at the only natural refuge, called the "Cave of Capriole". In 1810 Gemmellaro built the first shelter, it was called "The House of the British". The travelers usually setting off around midnight reached the base of the crater, then they walked and reaches the summit at dawn. Obviously, like Houel (1777) and Bartels (1786), not all reached the crater, so instead they saw the show from the ruins of the mysterious "Tower of the Philosopher".

Among the most significant scientific contributions was the work of Déodat de Dolomieu (1781) cataloging materials and making comparative studies with Vesuvius and the Aeolian Islands. His following correspondence with Gioeni makes up a lively and intense debate about the nature of the rocks. The territory of Etna was observed with increasing interest not only from the scientific point of view but also from a social historical perspective: observations of its distributions appear very important in some travel stories, from landing in Sicily the volcano remains the "topos". All travelers aspire to scale it and often follow the classic route, the one made by Fazello (1558) in the sixteenth century, which remain unchanged until the eighteenth century.

From the memoirs of travelers in addition to the varied excursions have been testimonies of some natural lava stone monuments and/or built by human hands, in particular, we include: the cave of goats, the snow cave (grotte à la neige) and the Grotto of Palombe. The first was a stopping place for travelers until 1810, when the first shelter was built by Gemmellaro: "The house of the English", then transformed into an observatory and later destroyed by a lava flow.

Among the monuments of man wanted to mention:

- 1) the aqueduct, interesting for the description and pictures left by Jean Houel, it brings water from a cistern near S. M. di Licodia to Catania.
- 2) castles - would include Paternò was visited by Denon (1778) The materials cataloged and analyzed are the basis for the planning of a natural museum of Etna, designed to promote the territory and its memories: it should be supplemented with historical-cultural and real or

virtual.

The Natural History Museum of Etna was therefore designed to promote the territory and its memories, as a cultural space and as a model for innovative tourism.

SESSIONE F2

10.1474/Epitome.04.0474.Geoitalia2011

DOLOMITES: FROM THE UNESCO WORLD HERITAGE LIST TO A MANAGEMENT STRATEGY

PANIZZA Mario¹, PIACENTE Sandra¹

1 - Università degli Studi di Modena e Reggio Emilia, Dipartimento di Scienze della Terra

Presenter e-mail: mario.panizza@unimore.it

Key terms: Dolomites; UNESCO World Heritage List; Geomorphology; Management strategy; Geopark

In the collective imagination, the Dolomites are a spectacular area to study and to enjoy. In art, particularly in painting, the shapes of these mountains have inspired many visions, generating emblematic artistic images and also evoking fascinating ideas. Some examples of this will be illustrated.

In order to obtain a geomorphological understanding of these mountains, with reference to their inclusion in the UNESCO World Heritage List, an original interpretation has been introduced, that is, "geomorphodiversity" (Panizza, 2009): "the critical and specific assessment of the geomorphological features of a territory, by comparing them in a way that is both extrinsic (with other territories) and intrinsic (with the territory itself). It takes into account the level of their scientific quality, the scale of investigation and the purpose of the research". Some typical situations are presented concerning the spectacular and attractive landscape and its morphotectodynamics, morphotectostatics, morpholithology, morphoclimatology and mass wasting.

This geomorphological key of interpretation can also be used to define the more general "values" of the Dolomites, referring to "geological" values in a broad sense, subdividing them into extrinsic and intrinsic values.

In the evaluation of the "livableness" of the Dolomites, problems concerning "environmental criticism" must also be taken into account in terms of risk and impact. so as to achieve a correct and sustainable enjoyment of this mountain territory.

As for the appraisal of the Dolomites, particularly regarding Earth Sciences, a conceptual path is illustrated, following the phases of scientific interpretation, communication, knowledge and awareness. The idea is "not planning in order to protect and protecting in order to manage but planning in order to educate, educating to develop awareness and developing awareness in order to appraise and self protect. (Panizza & Piacente, 2003).

Finally, appraisal and enhancement must be linked to a network of all the physical, biological and cultural elements of the territory. A "network" which cannot only be understood as being of "spatial significance" (a network of places, communities etc.), that is a group of sites bounded by territorial limits, but an "open network" system in its cultural significance, which therefore, exists apart from limitations of space, time and concepts.

CONSERVATION AND VALORIZATION OF GEOLOGICAL HERITAGE: WHICH OPPORTUNITIES FOR GEOLOGISTS?

GRAZIANO Gian Vito¹, TORRE Fabio², TORRE Alessandro²

1 - Consiglio Nazionale Geologi

2 - Haliotis Association

Presenter e-mail: presidente@consigliozionalegeologi.it

Key terms: Geological heritage; alternative job; geotourism activities

Geoparks and geosites directly lead on professional figure of geologists, who usually are not very involved in environmental conservation and valorization politics.

Nevertheless a development of nature conservation systems in geological way must connect with a jobbing outlet for geologists: it's real that census, characterization and interpretation of geological heritage are objectives of recent date, but it's how true that opportunity by the terms of alternative job for geologists must be yet matured.

The occupational outlet is relative to present demand of job for geotourism activities, but it's necessary from now get ready for that will be the future demand, in probably supposition of a strong increment of geoconservation politics in next years.

F2-3 Orale Amato, Vincenzo

10.1474/Epitome.04.0476.Geoitalia2011

GEOTOURISM IN THE PARKS AND IN THE PROTECTED AREAS OF THE CAMPANIA REGION (SOUTH ITALY).

AMATO Vincenzo¹, BENEDETTO Lorenzo², CAMPANELLI Luciano², CIARCA Sabatino³, PELLINO Roberto⁴

1 - Università del Molise

2 - Ordine Geologi Campania

3 - Università del Sannio

4 - Geologo, Ass. Lerka Minerka

Presenter e-mail: vincenzo.amato@unimol.it

Key terms: geodiversity; geological heritage; geosites

The Campania Region is one of the areas with the highest index of geodiversity (landscapes and rock types) of the Italian peninsula. Along the Tyrrhenian margin are present typically coastal landscapes alternating low and high rocky coasts, and, in the Neapolitan areas, typically volcanic landscapes, too. The inner part of the Region is characterized by typically mountain landscapes alternating high and rugged mountains (up to 2000 m a.s.l.) and gentle hills. This part is characterized too by typically fluvial landscapes, alternating broad fluvial-marshy valleys. From the coastal

area to the inner part of the region there are sand and clayey silt alluvial-coastal deposits of Quaternary ages, volcanoclastic (lavas and pyroclasts) deposits of Late Quaternary ages, carbonatic deposits of Meso-Cenozoic ages (Matese, Picentini, Lattari Mountains, ecc.) and terrigenous deposits of Cenozoic ages (Sannio and Cilento Mountains). This geodiversity was generated by the outcropping rock types variability and by their complex deformational and evolutionary history, both ancient and recent.

In very recent times, the environments and the geodiversity of the region are suffering many scratching attacks, sometimes irreversibly devastating, which have heavily depleted the geological and environmental heritage. Nevertheless the geodiversity must not only be presented in the form of risky events but also in the form of resource, often of exceptional natural value. Indeed many of the regional areas covered by this slow process of environmental wasting are subject to protection (2 National Parks, 8 Regional Parks, 6 Protected Marine Areas, 5 National Natural Reserves, 4 Regional Natural Reserves, and 7 Protected Areas, in add to many Local Reserves and protected areas). In these areas the geological heritage presents specific characteristics that can be easily connected to the most natural places that contain them. In fact, here, the Campania Region Offices identified and surveyed the most important geosites. Unfortunately, there are no enterprises to enhance and promote the geological heritage, aimed at a geotourism sustainable use. The efforts to network the sites representative of the geological and geomorphological complexity of the Region are totally lacking, especially regard to geotouristic paths and itineraries, educational materials, etc., with the exception of the Cilento and Vallo di Diano Park, that, recently, became Geopark.

With the aim to promote the geological heritage of the parks and protected areas in the Region, the Italian Association of Geology and Tourism, the Geological Regional Order, the Lerka Minerka Trekking Association, supported by FIST and by some local administration, organized, for the 2011 year, a calendar of geotouristic itineraries and events (see www.geologiaetourismo.it and www.geologi.campania.it). The geotouristic events want to involve mainly the geologists, with the aim of raising awareness the professional responsible for the enhancement of the geological heritage, and, in secondly, the geotourists and trekking sportsman, with the aim of broadcast widely the importance and the value of the geological heritage.

These events may be a proposal and an added value to the tourism, that the Campania region, offers to the visitors of the parks and protected areas, and at the same time, may be represent an opportunity to increase the presence of tourists, attracted not only by natural features but also by geological features that these areas contain. The main geotouristic events interest the territory of the Matese, the Taburno-Camposauro, Lattari M., Picentini M., Roccamonfina regional parks, of the Cilento and Vallo di Diano National Park, of the Elea-Velia, Paestum, Ercolano and Cuma Archaeological Parks, and of the Naples urban and hilly area.

THE ADAMELLO BRENTA GEOPARK

AVANZINI Marco¹, GRASSI Chiara², MASÈ Vajollet²

1 - Museo Tridentino di Scienze Naturali

2 - Parco Naturale Adamello Brenta

Presenter e-mail: avanzini@mtsn.tn.it

Key terms: geopark; landscape; geological heritage; geotourism; sustainable development

The Adamello Brenta Natural Park expand on an area of 620.5 square km between 477 and 3,558 m above sea level. It is the largest protected area in the Trentino region and one of the largest in the Alps. Besides an exceptional wealth of flora and fauna, in which the brown bear is the emblem of an untouched nature, the Adamello-Brenta contains a priceless landscape and geological heritage.

Separated by the Rendena valley, two mountain chains, differing for their geology, characterize the Park. On the eastern side are the Dolomiti di Brenta group; Majestic cathedrals of limestone where the water flows along networks of karst conduits, wells and galleries towards beautiful waterfalls, and springs. On the western side, the Adamello - Presanella massif, is constituted by magmatic rocks and shaped by the action of the water in all its forms, above all, the Adamello glacier: the largest glacier of the Italian Alps.

Thanks to the sustainable development strategy adopted (European Charter for Sustainable Tourism since 2006) and the outreach activities proposed, on the 26th of June, 2008, the Natural Park Adamello Brenta is joined to the European and Global Geopark Network under the auspices of UNESCO.

Exactly one year later, on the 26th of June, 2009, the Brenta Dolomites, with 8 other geographical sectors belonging to 5 different provinces, are inscribed in the list of UNESCO World Heritage Sites because of their beauty and unique landscape and their "scientific importance in geology and geomorphology".

The Adamello Brenta Geopark is characterized by an high geodiversity, and constitute an open-air laboratory where the secrets of the Earth's history can be learned in 61 different Geosites.

In line with the broader and more complex strategy for the conservation and enhancement of natural, historical and cultural heritage, the Adamello Brenta has powered its many initiatives through the development of a new Action Plan.

Besides protecting and promoting the geological heritage, the Plan will ensure an important role in the development of socio-economic fabric of the area for the Geopark. New activities have in particular been turned to Geotourism: from education and communication, to training and route mapping. Special attention has been given to the high altitude mountain refuges, raising residents awareness on scientific research, and on the historical and cultural aspects of the development of productive activities. With Park guides or guidebooks, tourists, residents or alumni can discover the power of the ancient glaciers, explore the old mines of quartz, or walk across the beautiful landscape of the Dolomites, trace the Vallesinella waterfalls to their karst springs or walk on a moraine of the Little Ice Age and directly measure glacier retreat in the last 150 years.

Protecting and promoting geological heritage lead us to improve our understanding of landscape changes over time and space and our responsibility towards nature.

GEOPARKS IN ITALY: INNOVATIVE TOOLS FOR

GEOCONSERVATION AND LOCAL SUSTAINABLE DEVELOPMENTBURLANDO Maurizio¹

1 - National Forum of Italian Geoparks

Presenter e-mail: direttore@parcobeigua.it

Key terms: Geoparks; Geoconservation; Sustainable development; Geoheritage

Within the whole international system of Geoparks specifically identified to safeguard and promote the geological heritage of Planet Earth - the European Geoparks Network (EGN) and the Global Geoparks Network (GGN) under the auspices of UNESCO - Italy is well represented by seven territories of particular value.

This is the Madonie Nature Park in Sicily (recognized in 2001), Rocca di Cerere Cultural Park always in Sicily (2001), the Beigua Nature Park in Liguria (2005), the Sardinia Geomining Park (2007), the Adamello Brenta Nature Park in Trentino (2008), the Cilento and Vallo di Diano National Park in Campania (2010) and the Colline Metallifere Geomining Park in Tuscany (2010).

To coordinate and to develop that geoparks system the National Forum of Italian Geoparks was inaugurated on 17th February 2010 in the Adamello Brenta Geopark.

The National Forum of Italian Geoparks consists of:

- one representative from each recognized Geopark (5 at the moment)
 - one representative from the UNESCO Italian National Commission
 - one representative from the National Geological Survey (at ISPRA - Superior Institute for Protection and Environmental Research))
 - one representative from the Italian Federation of Earth Sciences Associations (GeoItalia FIST, which gathers all the scientific associations which deal with Earth Sciences in Italy)
 - one representative from the Italian Federation of Parks and Nature Reserves (Federparchi, which constitutes also the Italian Section of EUROPARC Federation and has also the function of General Secretariat of Italian Committee of IUCN)
 - one representative from the National Council of Professional Geologists.
- The forum could also invite in some circumstances: representatives from National Tourism Organisations and representatives from Universities involved in Geoconservation and Geotourism.
- During the first meeting a proper regulation about the functioning of the National Forum has been approved and the aims of the Forum has been defined:

- to best coordinate the Italian Geoparks' initiatives;
- to promote the development of new Italian Geoparks;
- to promote new projects for the valorisation of the geological heritage at a national level;
- to provide information and popularize the International Network of Geoparks (EGN/GGN) through the various communication tools (website, newsletters, newspapers, etc.);
- to create new opportunity of integration between the many national activities direct to the growing of geological heritage's policy and to the development of geotourism;
- to provide a technical and scientific support to the territories who want to submit to the EGN/GGN;
- to organize an annual workshop in order to exchange best practices and to popularize the various projects and activities of the Geoparks, the geological heritage conservation and the realization of virtuous actions for the sustainable development.

Following the interest from several areas of Italy of Geoparks concept and with the main aims to enhance the geological heritage, to develop geological tourism, to raise public awareness about the Earth Sciences, the National Forum of Italian Geoparks intend to consolidate its first activities working at a large-scale, supporting common projects and initiatives at a national level, serving the European Geoparks Network and the Global Geoparks Network under the auspices of UNESCO in their actions at an international level

10.1474/Epitome.04.0479.Geoitalia2011

GEOTHERMAL AREA IN THE PARCO NAZIONALE DELLE COLLINE METALLIFERE GROSSETANE. A "SUSTAINABLE" GEOSITE.CASINI Alessandra¹, CINELLI Riccardo¹

1 - PARCO NAZIONALE DELLE COLLINE METALLIFERE GROSSETANE

Presenter e-mail: parcominerario@comune.gavorrano.gr.it

Key terms: GEOSITE; GEOTHERMAL AREA; SUSTAINABLE DEVELOPMENT

Geothermal area of the Tuscan Mining Geopark is a complex landscape where there are a geological heritage of international significance and the remains of the first industrial production of electricity through the heat of the earth. A modern system of geothermal power plants allows the production of energy with low environmental impact and the creation of many agricultural activities that take advantage of this resource.

Geothermal landscape
In this area there are important evidences of recent and present geothermal and hydrothermal activities occur. These evidences have created a unique and unrepeatable landscape, a distinctive feature of which are the pipelines for steam generated by geothermal activity, and the natural, endogenous manifestations of naturalistic and geological value, together with the ancient alum quarries. One of the most interesting is certainly the geological site of Biancane, which has a footpath network with information panels that allow reaching and observing the geological and naturalistic peculiarities of this area.

Industrial Heritage
Geothermal area has also industrial relevance, in fact in this area for the first time in history boric acid was extracted from geothermal fluids. In 1777 Hoeffler, director of the "Farmacie granducali", discovered the presence of boric acid in waters of a thermal pool and carried out some experimentation to extract boric acid. Since 1818 the Count De Lardarel increased the industrial process for the production of boric acid by introducing extraction procedure. At present the signs of this activities for acid boric production are represented by the remains of some decantation pools built in early 19th century. In this area for the first time in the world the geothermal fluids were utilized to produce electrical energy.

The sustainability
At present in the Geopark there are five geothermal power stations which cover 70% of the energy requirements of the Province of Grosseto. Close to the geothermal power station, some cheese factories use geothermal power to produce high quality cheese.

10.1474/Epitome.04.0480.Geoitalia2011

A CONCRETE PERSPECTIVE FOR GEOTOURISM IN MOLISE REGION (ITALY): FROM THE INVENTORY TO THE TOURISTIC PROMOTION OF GEOSITESFILOCAMO Francesca¹, BARANELLO Sergio², DI PAOLA Gianluigi¹, GIANNANTONIO Olga², IAROSSEI Mario², MONACO Rossella², RELVINI Maria³, ROSSKOPF Carmen Maria¹

1 - Dipartimento S.T.A.T., Università degli Studi del Molise

2 - Servizio Geologico Regionale, Direzione Generale IV, Regione Molise

3 - Servizio Turismo, Industria Albergghiera, Direzione Generale II, Regione Molise

Presenter e-mail: frafilo@yahoo.com

Key terms: Geosites; Inventory; Molise; Geotourism

The Molise region, albeit of limited extension, is characterized by a high geodiversity. Its geological history, the long-term climatic influences and the geomorphological dynamics that characterize in an unique way its mountainous, hilly and coastal areas, have given rise to numerous sites of geological interest. These sites have been examined, assessed and inventoried in the research project "The Geosites Inventory in Molise region", carried out by the University of Molise in partnership and on behalf of the Molise Region with the main purposes to contribute both to the preservation and valorisation of the regional geological heritage and the implementation of the Italian Geosites Inventory in progress by the National Institute for the Protection and Environmental Research (ISPRA). The inventory we carried out in Molise region has allowed to identify and select over 80 geosites of various scientific interest (geomorphological, stratigraphical, paleontological, etc.). The selected geosites, most of which are of regional interest and of high scientific and didactic value, well represent the geodiversity of Molise region and allow to understand the various steps of its geological evolution. Many of them are located within protected areas (National, Regional and Natural parks, Sites of Community Importance, etc.) which extend over ca. 34% of the regional territory.

In order to enhance and promote the inventoried geosites and to provide a contribution to the development of sustainable tourism within the Molise territory, we have started a series of further activities aimed at the disclosure of the geological heritage to a non-scientific audience. In particular, in addition to the specific catalogue card, a synthetic descriptive card was produced for each geosite which is designed to ease disclosure especially to non-specialist audiences such as excursionists and tourists. This descriptive card, in addition to the data concerning the identification and the assessment of the geosite, contains a section dedicated to the landscape and the territorial context, allowing the reader to deepen the salient features of the physiographic unit in which the geological site is located. The descriptive cards of ca. 20 geosites along with a photo gallery have already been published on the website of the Servizio Turismo, Industria Albergghiera of Molise Region.

Furthermore, the material for a book on the Geosites of the Alto Molise physiographic unit, well-known for its specific geological-geomorphological features and its rich cultural to archaeological heritage, has been produced. This book will contain an introductory section on the Alto Molise physiographic unit, illustrating its geologic-geomorphological, naturalistic, cultural and historical-archaeological aspects, which is followed by a detailed description of the 16 selected geosites, including their descriptive cards, which allows to connect them to the territory. It will also include a map illustrating the location of geosites, protected areas, main streets and main sites of archaeological interest.

What we are currently working on is the development of geo-touristic itineraries aimed to promote both the geosites and the natural and/or cultural heritage of certain areas. In particular, we are working on the illustration of specific geological-naturalistic contexts such as those characterizing for example the "Le Mainarde Itinerary" which interests the Molise portion of the area of the Abruzzo, Lazio e Molise National Park and offers geosites of great scenic impact, and on itineraries combining the visit of geosites with those of historical monuments and/or archaeological sites, as for instance the Geo-archaeological itinerary which links the archaeological site of Sepinum to the surrounding geological heritage. The progress of our research project envisages the realization of an Atlas of the geosites selected in Molise region to further promote the regional geological heritage.

10.1474/Epitome.04.0481.Geoitalia2011

THE GEOLOGICAL HERITAGE OF CILENTO AND VALLO DI DIANO GEOPARK: A SOURCE OF SUSTAINABLE DEVELOPMENTVALENTE Alessio¹, GUIDA Domenico², ALOIA Aniello³

1 - Università degli Studi del Sannio, Benevento

2 - Università degli Studi di Salerno

3 - Parco Nazionale del Cilento e Vallo di Diano

Presenter e-mail: valente@unisannio.it

Key terms: Geological heritage; Geopark; Sustainable development; Cilento and Vallo di Diano

The Cilento and Vallo di Diano Geopark extends for more than 1800 km² in the southern Italy. Its great number of geological appearances, with different degree of importance and interest (stratigraphical, geomorphological, hydrogeological, etc.), can be integrated in a variety of ecosystems, already inserted into the "Man and Biosphere" programme of UNESCO, as well as to exceptional and unique archaeological sites as Paestum, Velia and Padula, recognised as World Heritage by UNESCO. However, this territory is considered less economically developed than other surrounding areas, so the geological heritage can be a great opportunity, especially for tourism purposes, in changing this situation.

Moreover, a net difference is observable between the coastal area of the Geopark, which present numerous kind of accommodation and attractions, and the inner one, poorly known and inadequately framed. For instance, in the relieves of Cilento and Vallo di Diano Geopark, belonging to Apennines, are well exposed the successions involved by the former thrust, occurring in the Miocene. The most of these succession, that permit to see, along the inner mountain sides, sedimentary and structural features, uniqueness and scientifically relevant, for different reasons are neglected from tourists, which generally frequent the coastal areas. Besides a more diffusive promotion of the entire geological heritage of the Geopark to the public with publications and events, the improvement of the access of the geological appearances in the inner area. Such improvement require the adjustment of the viability in order to reach trails, also practicable by cycle or by horse. These activity could involve young people in work cooperatives, and provide a system of structures and infrastructure.

The role of water in Cilento and Vallo di Diano Geopark is considerable for the suggestive springs and falls as well as for superficial and underground forms widespread in the territory. About water and its processes a long

term program of education must be realized in the schools of the area. Such program of education can help the young generation to understand the values of the territory in which they live and the necessary actions for the correct maintenance and fruition. The planning of this program foresees moments of popularization in the classrooms integrated by excursions on the territory for the direct knowledge of the natural beauties and particularly of the geodiversity present.

Also along the coast of the Geopark can be focused some geological appearances able to developed tourism activity. In particular, along the more eastern cliffs of the Cilentò, reachable only from the sea, the occurrence of terraces, sea notches and caves, representing traces of paleosealevel, can become the basic elements for a new pathway in the sea. Such pathway, carried out by a fitted boat, could help tourists to discover the changing of sea level in the late Quaternary through these traces. The pathway can be integrated from the evidences of prehistoric settlements, which cover a wide chronological range since 500.000 years ago. This particular cruise, like the first example, promote a particular tourism in which the geological heritage could be represent a way to develop employment and enhance knowledge.

This strategy in geotourism is becoming a reality, as revealed by some institutions that already develop several activity about the geological heritage in accordance with the Geopark authority, such as: the Foundation MIDA (Museums Integrated to the environment), which operate for the exploitation of the environmental resources and the local cultural assets, and manages the famous caves of the Angel of Pertosa (geosite) and the Municipality of Morigerati, which operate in collaboration with the WWF in the Oasis of Morigerati in order to valorise the geologic uniqueness (e.g. karstic cave of the river Bussento) and to safeguard the high biodiversity.

10.1474/Epitome.04.0482.Geoitalia2011

GEOLOGICAL TRAILS AND SELF-DIRECTED LEARNING: AN EXPERIENCE IN THE SARNTAL ALPS (SOUTH TYROL, ITALY)

BENCIO LINI Luca¹, MERCI Alessandro¹, ROBAZZA Monica¹, ZORZENON Marco¹

¹ - Università di Udine

Presenter e-mail: luca.benciolini@uniud.it

Key terms: self-directed learning; Sarntal Alps; field geology

Since the nineties, both public understanding and teaching activities of Sciences have been progressively shifted from unidirectional communications (books, ex cathedra lessons and so on) toward participatory experiences, as for example them parks, science festivals or didactic curricula based on hands-on laboratory. In spite of this evolution, Earth Sciences represent today a critical subject for science communication. As an example, plate tectonics is a multidisciplinary subject and is very difficult for teaching in scientifically rigorous terms. This is commonly given in didactic curricula postulating a kinematic models more than giving evidences, as an axiom instead of a theory explaining data and phenomena.

On the other hand, geotourism has the task of capture the audience with spectacular geologic phenomena often explained in terms of Plate Tectonics. In this case, because of the knowledge deficit, scientific explanations for the public must be fascinating and surprising more than rigorous. Furthermore, both public understanding and teaching reverse logical connections among data and theories and tell geology to the public in a magical perspective more than as a scientific discipline. Changing this science communication model is possible?

The Sulzspitz area in the Sarntal Alps compounds five metamorphic lithologies, all with a well developed crystalline structure, implying a 200 Ma geological evolution from the Hercynian chain to the opening of the Tethys ocean. Spectacular objects are not available for making such a long and fascinating story attractive for the tourist. A main question is: has this geology filed any interest for geotouristic activities?

A group of tourists has been accompanied in the Sulzspitz area; each tourist was equipped by a field notebook and a geology hammer. The travel guide gave a general stimulation on the geology field work especially on observing, drawing, writing impressions with no any idea on the geological evolution of the area. We infer that: i) these basic field geology activities do not imply a specific knowledge deficit, ii) these activities are possible tools for a free exploration of reality, iii) nature may represents an exhaustive laboratory that does not need a strategic story for communicating emotions. Our approach shifts the public understanding from theories and scientific results to the scientific research. As a strategy, we choose to provide only basic informations as a tool for rocks description, including::

- 1) Rocks are heterogeneous materials
 - 2) Rocks are composed by minerals
 - 3) Any domain homogeneous in colour, form and shine is a single mineral
 - 4) Rocks have to be broken with the hammer in order to evaluate their actual color.
- This activity may provide us the answer to some questions on the public stakeholder:
- Which is the reaction to a self-directed learning proposal ?
 - Which subjects are selected ?
 - Which descriptive strategies are spontaneously chosen ?
- We suggest that this activity may represent in the future a permanent communication channel among researchers and public in order to promote geology as a scientific issue of personal contemplation of Nature.

PEOPLE ENJOY METAMORPHIC ROCKS: CASE HISTORIES FROM TOLLEGNO AND FONTAINEMORE, WESTERN ALPS (ITALY)

MAFFEO Stefano¹, BRAGA Roberto²

¹ - Equipe Arc-en-Ciel Ambiente e Cultura , La Salle, Aosta - Italy (info@eaec.it)

² - Dipartimento di Scienze della Terra e Geologico-Ambientali - Università di Bologna (Italy), Piazza di Porta San Donato 1, 40126 Bologna - Italy (r.braga@unibo.it)

Presenter e-mail: r.braga@unibo.it

Key terms: Geological Heritage; Geosites; Geotourism; Tollegno; Fontainemore

In this contribution we present two case histories in which basic field and petrographic knowledge coupled with scientific marketing strategies have proven to be successful in promoting the geological heritage of

Fontainemore and Tollegno villages.

The key requirements are: (1) easily accessible outcrops; (2) coarse-grained rocks where minerals can be identified with the unaided eye and (3) readily distinguishable cross-cutting relations among different rock types. In addition, some weathering patterns such as differential erosion can help in recognizing different rock types. Outcrop can be replaced, in favorable circumstances, by an exhibition of meter-sized boulders (the so-called Rock Garden), previously collected from local stream/river and successively located in a portion of public area, e.g. a promenade along the river.

The effort to promote basement rocks requires: (1) to support local communities during the evaluation of the geological heritage potential; (2) the financial and logistic support from local communities; (3) the design and implementation of an Opening Act, generally two-three days culminating into the visit to the outcrops and/or Rock Garden; (4) the organization of activities related to the opening act (e.g. brief seminars, open-air activities organized jointly with local social and educational realities) and, more importantly, (5) to make all the activities go viral on the local media (newspapers, newsletters, informative flyers, postcards) and the internet. All the above practical aspects have been implemented at Tollegno (near Biella, Italy) where high-grade metamorphic rocks and clinopyroxene-bearing calc-silicates cut by andesitic and granitoid dikes occur along the Cervo stream, and Fontainemore (Aosta Valley) where a rock garden of eclogite-facies boulders has been made in a public garden along the Lys stream.

Basement rocks can represent an attraction for people interested in the Natural heritage of their territory.

THE UPPER CARBONIFEROUS SAN GIORGIO BASIN (SOUTH WESTERN SARDINIA)

RIZZO Roberto¹, MUNTONI Francesco¹

¹ - Geological Mining Park of Sardinia

Presenter e-mail: francescomuntoni@parcogeominerario.sardegna.it

Key terms: Mining; Park; Geosites; Educational; Sardinia

The need to have a better knowledge and preservation of geosites is at present compared to that concerning the flora, fauna and the landscapes diversity; in fact they represents an inestimable natural and cultural heritage testifying the history of Earth. The Upper Carboniferous deposits of the so called "San Giorgio Basin" have been restudied keeping in mind these assumption, especially because of it shows at the same time an elevated scientific value, peculiar in the Sardinian geological context, and, unfortunately, an example of destruction caused by human activities. These outcrops, already known at the end of the Nineteenth Century with an extension of about 3 sqkm, cover at the moment a surface not exceeding 0.3 sqkm.

The Authors propose as protection and exploitation actions, both a project of a thematic itinerary reaching the most interesting outcrops, with educational characteristics.

The geological site is situated in South-Western Sardinia at a few kilometres SW from the down-town of Iglesias and about 50 km from Cagliari within an area characterized by the presence of several important abandoned mines (Campo Pisano, Monteponi, San Giovanni, Genna Luas etc.).

The area containing the Carboniferous sediments, although of little extension, is particularly important from a scientific and teaching point of view. The best exposed outcrops are located in the neighbourhood and partially surrounded by mining dumps originated from the closest mentioned mines since the first half of the Seventies and later for some decades. The geosite is made up of a geological body deposited in a continental environment after the Hercynian Orogeny and assigned to the Upper Carboniferous (Westphalian-Stephanian) after the study of several taxa belonging to macroflora and palynomorphs, of very rare microsaurian trace fossils, arachnoids and blattoids.

ABOUT THE INEXPRESSED POTENTIAL OF GOOD LEVEL EARTH SCIENCES OUTREACH IN ITALY

GOSSO Guido¹, LARDEAUX Jean Marc², ROSSI Patrizia³, SPALLA Maria Iole¹

¹ - Dipartimento di Scienze della Terra "A. Desio" Università degli Studi di Milano and C.N.R. - I.D.P.A., Milano, Italy

² - Université de Nice Sophia Antipolis, GéAzur, Parc Valrose, Nice.

³ - Parco Naturale Alpi Marittime, Valdieri (CN)

Presenter e-mail: guido.gosso@unimi.it

Key terms: Parco Naturale Alpi Marittime; Parc National du Mercantour; Natural Sciences; scientific outreach

If we digit on the web of Earth Sciences the word Alps, the rewarding number of about 24.000 scientific papers will appear on our screen and this is only an example of what may happen to words as Glacier, Volcano, Apennines or Sea Floor. In Italy, a country sharing a half of the whole Alpine belt with Europe, displaying over 3.000 km of Mediterranean shoreline, disposing of glaciers, volcanoes, forests and plains immersed in the Mediterranean climate, such wealth of knowledge and Nature is all but speculantly flanked by an adequate diffusion of even elementary notions capable of making basics of Earth behavior popular. Information about Science is not a privilege, but a current civil right in many countries; in our case, on Italian TV programs, cooking Italian food is of course at the top! But TV channels are doing good job popularizing basics in Medical Sciences and irradiate a reasonable level of outreach in Zoology, much less in Botany, very little in Astrophysics and Cosmology and modern Biology, although the latter two are recently of great appeal to high school students on the way to choose for their further career. Italian Parks developed a wealth of activities directed to some levels of schools for guided visits, or to tourist groups or solitaires. In the open Nature the level of the offer of commented trips is in many cases adequate, but a higher standard would attract more fascinated visitors. This may be gained if forestry, mineralogy, geology, geomorphology, zoology and botany would be commented during walks in alternance during excursions, following the level of posed questions, and not giving the impression of school-style teaching, but rather that of fulfilling wishes and imagination of participants; there is no pre-cooked package of information that may be displayed by field guides that will not bore even the most curious trekker. Young Ph.D. students may serve as field guides in Italian Parks during summer, periodically; they do have the scientific level requested to follow

a short scientific communication course, and become adequate to explaining in different European languages the beauties of Italian Nature in any season. It is just matter of organization and communication of the offer of well-commented scientific entertainment trips in the Nature. The market for this exists; the offer is not sufficiently diffused! The unexpressed potential is that of young high level Ph.D. science students that would spread enthusiasm for a week or two during summer, or whenever, to the people of Park visitors. Experiments are going on already in many European sites, including Italy and France, and should be diffused into others.

10.1474/Epitome.04.0486.Geoitalia2011

PROGEO-PIEMONTE: A MULTIDISCIPLINARY RESEARCH PROJECT FOR DEVELOPING A PROACTIVE MANAGEMENT OF GEOLOGICAL HERITAGE IN THE PIEMONTE REGION.

GIARDINO Marco¹, PROGEO-PIEMONTE Research Team²

1 - Università degli Studi di Torino
2 - Interdisciplinary research team from Università degli Studi di Torino, Politecnico di Torino, CNR-IGG, Museo Regionale di Scienze Naturali di Torino, Comitato Glaciologico

Presenter e-mail: marco.giardino@unito.it

Key terms: geological heritage; Piemonte; geosites; geodiversity management

"Geoheritage" is a generic but descriptive term applied to sites or areas of geologic features with significant scientific, educational, cultural, or aesthetic value. By presenting a project in the framework of the initiative "Progetti di ricerca di Ateneo 2011" (by Università degli Studi di Torino and Compagnia di San Paolo bank foundation), the large, multidisciplinary research team of "ProGEO-Piemonte" (41 senior researchers, 8 fellows and PhD students, 5 technical staff from 5 different departments) aims to achieve a new conceptual and operational discipline in the management of the geological heritage of the Piemonte Region by means of the development of techniques for recognizing and managing its rich geodiversity at the local and regional scales.

The ProGEO-Piemonte assumption is that geoheritage sites ("geosites") can serve both the public and private interests. After a systematic review of inventoried geosites by the "Centro di documentazione sulla Geodiversità e la Geoconservazione" (by Università degli Studi di Torino and Museo Regionale di Scienze Naturali, Torino), 9 strategic geothematic areas will be investigated by specialized research teams to represent the geodiversity of Piemonte:

1. The Monviso massif and the Cottian Alps as symbols of the Alpine chain (coord. F. Rolfo)
2. Pages of the Earth history book recorded in the successions of the Marquais area (coord. A. d'Atri)
3. Climate variability and past environmental changes: lessons from the Messinian record of the Tertiary Piedmont Basin (coord. F. Dela Pierre)
4. Interaction of geological processes and human activities in the Monferrato hills (coord. L. Masciocco)
5. Natural and artificial waters of NE Piemonte (coord. R. Ajassa)
6. Glaciation and deglaciation: geomorphic signatures on Morainic Amphitheatres of Ivrea and Belvedere (coord. M.G. Forno)
7. Geomaterials as a resource for mankind development: the Traversella and Brozzo Mining areas (coord. E. Costa)
8. Geoenvironmental dynamics and risks: the Cassas landslides and the large slope instabilities of the Middle Susa valley (coord. M. Giardino)
9. Turin: the foundation stones of geological heritage in the Piemonte Region (coord. A. Borghi)

Since each geothematic area is characterized by high potential for scientific studies, enhancement of public understanding of science, recreational activities and for economic support to local communities, four interdisciplinary research teams (A-D) will cover the aspects of:

- A. It applications for geoheritage data management (coord. L. Ghiraldi);
- B. visual representation of geological processes and evolution (V. Lombardo);
- C. geodiversity action plans for dissemination activities (coord. E. Ferrero);
- D. tool integrated management of geosites by application of TIQ (Territorial Integrated Quality; coord. R. Beltramo)

Scientific concepts will be coupled with geodiffusion interests: geosites within the thematic areas will be accommodated along with elements such as museum collections, evidences of mining activity and quarrying, science exhibits and nature trails. Action plans will be developed with local partners to determine management requirements for the different geodiversity elements.

Outcomes of the project will include didactic tools for educators, schools and public in general, such as real and virtual geological tracks, interactive websites and training courses for geonaturalistic guides. The recognition of the economic value of geodiversity will lead to the production of Geoconservation guidelines for the Regione Piemonte, including planning considerations, and tourism and sustainable development strategies in general.

Key terms: geotourism; geological travel; history of geology

Between the 18th and the 19th century, the science of geology, not yet institutionalized, was essentially a practice realized in the field. So, the geological travel became a tool for studying and observing nature. There were many scholars (De Saussure, Dolomieu, Fortis, Arduino, De Luc, von Buch and so on) that made different types of trips (mineralogical, lithological, paleontological) in order to understand the formation of our planet and the stratigraphical shape of the Earth's crust. The main destination of these travels were the Alps and the Prealps that, in those years, were studied in great detail.

The participation to the working group, "Geological travels in the

mountains of Northern Italy. The fieldwork in the stratigraphic locations of historical importance in the 18th century-PRIN 2007" coordinated by Prof. E. Vaccari (Università degli Studi dell'Insubria, Varese, Italy), provided the opportunity to reconstruct and follow in the field a trip made from one of these scholars-travelers, through the study of his letters and diaries. In the summer of 1797, Carlo Amoretti, an eclectic polygraph, explored a wide area from the Piedmont banks of Lago Maggiore to the surrounding mountains observing some aspects of great mineralogical and lithological interest for that historical period: traps, granite, kaolin, fossil fuels and different rock-types.

This cultural heritage of geo-mineralogical knowledge about the practice of travel is a real source to be used today both by geologists for their studies, as a matter of confrontation, and by local authorities, for the territorial enhancement and development of the so-called Geo-tourism. In this context, a geo-historical digital path of the 1797 Amoretti's trip has been planned for the users of the net. Indeed, through the use of Google Earth application, it can be possible to compare the historical maps with the current ones, tracing the path followed by the scientist-traveller, identifying places and points of interest litho-geo-mineralogical and so on. This interactive tour could be enriched by a number of other geological and cultural information. To this end, a collaboration with experts in different fields of geological sciences would be desirable. The final application could provide its users with a complete picture of the necessary information to explore directly on the field the geo-historical routes of interest.

Such use of historical sources has been placed as a key element within a proposal for a recent European project. The "HistGeoAlp" project, presented by Prof. E. Vaccari (University of Insubria), with a network of other 11 partners from Italy, Austria, Slovenia, Germany and Switzerland, has not been activated yet, but if it will meet the interest of the scientific community it will start soon in the future. The main aim of this project is to provide the tool to create a network between different types of existing and new geo-sites and geo-routes (also within geoparks), through multimedia database, a virtual museum on the history of geological travels and information points.

To date some financed projects only partially met the increasing need of territorial improvement, such as the projects concerning the mountain routes (Via Alpina, Via Adventure, Iron Route, Via Geoalpina) and many web-sites concerning the geo-tourism.

The added feature of the "HistGeoAlp" project is the integration of different geo-sites and skills (historical, geological, cartographic, administrative and based on computer science) able to link the net with the territory and promote geo-tourism.

With the cooperation of other historians and geoscientists it will be possible to plan other geo-historical paths and give, in this way, the opportunity to create a network such as the one proposed by the "HistGeoAlp" project.

Key terms: Geotourism; Geological Heritage; Historical Mining; Metallurgy Iron Technology; Mineralogical Collection

The multidisciplinary research project PROGEOPIEMONTE (PROactive management of GEOlogical heritage in the PIEMONTE region: innovative methods and functional guidelines for promoting geodiversity knowledge and supporting geoconservation activities (PROGEO-Piemonte - coord. M. Giardino), aims to achieve a new conceptual and operational discipline in the management of the geological heritage of the Piemonte Region by means of the development of techniques for recognizing and managing its rich geodiversity at the local and regional scale. After a systematic review of inventoried geosites, 9 strategic geothematic areas will be investigated to represent the geodiversity of Piemonte. Geological history, climate and environmental changes, natural hazards, soil processes and georesources will be popularized not only with geosites but also with museum collections, evidences of mining activity and quarrying, science exhibits and nature trails. The recognition of the economic value of geodiversity will lead to the production of regional guidelines for Geoconservation integrated quality management system, suitable for tourism and sustainable development strategies.

One of the nine chosen geosites is the Brozzo and Traversella mining area. These locations are two of the most important iron mines in the Piemonte area since ancient time. Iron mining activity in Traversella was very important until the end of the second world war, whereas in the Brozzo mine production was focussed on pyrite extraction for sulphuric acid manufacturing until the beginning of '900. Not only these sites are of primary scientific importance, (the Brozzo-Traversella mining district represents the only skarn-type mineralization in the Alps), but also for science passionate, mineralogist and collectors, these two localities are of the highest interest, and outstanding mineralogical samples coming from these two mines are displayed in the most famous museum all over the world.

Among the scientific research actions that our team want to carry out on the site, we will obtain the reconstruction of the mineralogical features of the Traversella and Brozzo mines, by performing mineralogical, petrological and ore deposits studies. We will acquire information from every kind of historical sources. In order to achieve these objectives, we will need to coordinate a study of historical mineralogical samples and of recent findings in these sites. Such a study will be carried on by optical microscopy, SEM-EDS microanalysis, microXRF, XRD, focussing on the field observation and mapping, and the study of historical documentation about mining and metallurgic processes before the XIX century. We will cooperate with the existing organization as well as the Museum of the Mineralogical Group Valchiusella, the Museum of Brozzo Mine, the Comune di Traversella and Comune di Brozzo, the Comunità Montana, the Piemonte Region and the Turin Provincia, and last but not least the Museum of Natural Science of Turin.

With these actions we would like to put on view the extraordinary importance of the Traversella mine from a scientific point of view, but also we want emphasize the role of the site from the point of view of the industrial development in Piemonte Region. We will illustrate the impact

on the surrounding region from a sociological and environmental point of view, investigating the lifestyle of people living and working, during centuries, in this small mining region. As expected results, the team would obtain a new series of books and booklets relative to historical background of mining extraction, metallurgical dressing, mineralogical richness in the area, scientific importance of the samples in various museums in the world, itineraries in the area for a better comprehension of the interaction between mines and geological environment.

Key terms: geotourism; geological heritage; sedimentary environments; Marguareis Massif; Permian-Cenozoic history

The multidisciplinary research project "PROGEO-Piemonte" aims to achieve a new conceptual and operational discipline in the management of the geological heritage of the Piemonte Region by means of the development of techniques for recognizing and managing its rich geodiversity at the local and regional scale. Nine strategic geothematic areas will be investigated to represent the geodiversity of Piemonte, each characterized by high potential for scientific studies, enhancement of public understanding of science, recreation activities and for economic support to local communities.

One of these nine geothematic areas concerns the record of deep geological time as stratigraphic successions. In the Piemonte sector of the Alpine chain, sedimentary successions are best exposed in the area comprised between the Marguareis Massif and the Colle di Tenda (Western Ligurian Alps) where altitude and the mainly carbonate rock composition concur to provide superb geological exposures. This sector is particularly complex as it appears as a mosaic of different units, pertaining to the European Mesozoic passive continental margin of the Alpine Tethys, that however consist of sedimentary rocks deposited in different depositional environments and affected by prolonged gaps in sedimentation. These units were juxtaposed and superposed by tectonic processes during Alpine orogenesis. In a relatively restricted area, rocks of very different age (from Permian to Eocene for a total time span of over 200 million years), nature (volcanic and sedimentary), and depositional environment (from carbonate tidal flats to deep sea turbidite basins) are exposed. On the whole, they record the main stages of the geological evolution of the European margin related to the opening and closure of the Alpine Tethys ocean and consequent genesis of the Alpine chain. All these features, moreover, are exposed in a protected mountain area (Parco della Alta Valle Pesio), easily visitable through untarred roads and well indicated trails, that also bears an historical added value related to the presence of military fortresses of the XIX century.

The geological knowledge of these successions and their evolutionary model is quite well established on the basis of both existing scientific literature (Carraro et al., 1970; Gosso et al., 1983; Lanteaume et al., 1990) and original data published by the proponents (Piana et al., 2009; Bertok et al., 2011).

We propose to project a series of itineraries, developed in a GIS environment, aimed to illustrate, in a scientifically correct, but accessible to a large public of non-specialists, way the most significant steps in the geological evolution through time of the rock successions exposed in the area, with particular emphasis on the past environmental factors that have determined the observable lithological changes.

Key terms: Ivrea Morainic Amphitheatre; Belvedere Glacier; geological heritage; geosites; Piedmont

A study of the Ivrea and Belvedere morainic amphitheatres is included in the Project "Proactive management of geological heritage in the Piedmont Region: innovative methods and functional guidelines for promoting knowledge and supporting geoconservation activities (PROGEO-Piemonte - coord. M. Giardino)" proposed by the Earth Sciences Department of Turin. This multidisciplinary research aims to achieve a new conceptual and operational discipline in the management of the geological heritage of the Piemonte Region by means of the development of techniques for recognizing and managing its rich geodiversity at the local and regional scale.

The Ivrea Morainic Amphitheatre (IMA) is the main product of the Aosta

Valley glacialism at the outlet of the Dora Baltea Valley. It is one of the widest (505 km²) amphitheatres of the Italian Alps and the first to be studied (since 1844). The IMA consists of a branched complex of lateral and end moraines and kame terraces, dated from the end of the Early Pleistocene to the end of the Late Pleistocene (900±20 ky BP). This succession is partible into ten stratigraphic units, potentially correlable to the whole sequence of the main Quaternary glaciations registered in the marine oxygen isotope stratigraphy. The IMA shows remarkable evidence of the glacial sedimentation and erosion: above all the Serra d'Ivrea lateral moraine and the Colli d'Ivrea bedrock outcrop area.

The present Belvedere Glacier (9 km²) is the biggest of the Piedmont, placed below the eastern face of the Monte Rosa in the uppermost Anzasca Valley. This debris covered glacier is well-known because of its supraglacial "ephemeral lake", but it is also notable for the Holocene morainic apparatus essentially referable to the Little Ice Age. The following scientific research actions will be developed with the aim to improve the already available data:

- 1) Surveys about sedimentologic, stratigraphical and morphological features of the Serra d'Ivrea moraine.
 - 2) Investigation of the relations between glacial activity and bedrock features responsible for the modelling of the Colli d'Ivrea subglacial landforms.
 - 3) Climatic significance of the Lateglacial-Holocene sequences of the Terre Ballerine and Tomalino peaty records in the Colli d'Ivrea sector.
 - 4) Stratigraphy of the Late Pleistocene sequence of the Andrate glaciolacustrine plain.
 - 5) Reconstruction of the T. Chiussella fluvial deviations related to the IMA right lateral sector edification.
 - 6) Geological study of the gold placers and the ancient mines distributed at the IMA outer edge, including the Bessa Roman auriferodinae.
 - 7) Survey of the IMA erratic blocks, according to the Piedmont regional law about the protection of erratics.
 - 8) Research on the Holocene climatic changes derived from the stratigraphy of the Belvedere morainic complex.
- Research methods will consist of geological survey, photointerpretation and borehole execution, supported by radiocarbon dating, pedological, petrographic and palinological analyses and SEM-EDS gold microanalyses. The IMA geomorphologic exemplarity makes it excellent for scientific education, mainly geologic, geomorphologic and palaeoclimatic. In spite of its remarkable human settlement (93 communes), the IMA preserves wide expanse of country and woody land. The soil protection and the agricultural and natural landscape preservation have to be supported by the diffusion of a scientific knowledge of the territory. Actually a 2% of this valuable land is under the protection of two parks: the Bessa and Barage Regional Park at the eastern edge of the IMA and the Candia Lake Provincial Park into its internal depression. Also the suggestion of further parks and geosites must be documented and well-founded. So an important aim of the project is the popularization of the results by a coordinate output of brochures, posters and geologic itineraries books, as well as lectures, workshop and short courses for teachers and naturalist guides.

Key terms: Monviso Massif; Cottian Alps; Piemonte; geological heritage; geotourism

The multidisciplinary research project "PROGEOPIemonte" (PROactive management of GEOlogical heritage in the PIEMONTE region) aims to achieve a new conceptual and operational discipline in the management of the geological heritage of the Piemonte Region. Within the project, 9 strategic geothematic areas will be investigated to represent the geodiversity of Piemonte, each one of them being characterized by high potential for scientific studies, enhancement of public understanding of science, recreation activities and for economic support to local communities (see Giardino & the ProGeo team, 2011, this abstracts volume).

In the framework of the "PROGEOPIemonte", the Monviso Massif (MM) geothematic area may well be considered as one of the most outstanding symbols of the Alps in general, and of the Cottian Alps in particular. Its peculiar shape above the Piedmont basin already impressed the ancient Romans more than 20 centuries ago. Moreover, the Monviso bottom at Pian del Re gives birth to the Po river, the historically most important source of life and welfare in northern Italy.

From the geological point of view, the MM is a very well preserved composite ophiolite nappe, which represents the remnants of a former ocean that disappeared during the powerful orogenic processes due to the Africa-Europe collision, which eventually led to the building of the Alps. This will be a great starting point for a comprehensive study involving the MM area itself together with nearby, geologically related areas. More specifically, a number of different geological topics involving different expertises and some additional non-geological disciplines will be usefully considered:

- 1) A WHOLE OCEAN IN A SMALL PEBBLE: some of the best preserved ophiolites in the Alps at the Monviso and the associated Cu-Fe mineralizations (e.g. Castelli & Lombardo, 2007, Ofioliti, 32, 1-14).
- 2) THE GEOLOGICAL ARCHITECTURE OF THE COTTIAN ALPS: lithostratigraphic units of the Dora-Maira Unit and Piemonte domain from Susa to Varaita Valley (e.g. Borghi, Cadoppi et al., 1984, Boll. Mus. Reg. Sci. Nat. Torino).
- 3) PETROGRAPHY TOGETHER WITH PREHISTORY: the first primary source of jade in the Alps at Punta Rasciassa in the MM, and its importance in

terms of Neolithic to Bronze-age polished stone implements (e.g. Compagnoni, Rolfo *et al.*, 2007, *Period. Mineral.*, 76, 79-89).

4) **TYPE LOCALITIES FOR NEW MINERALS:** the Carlotouranite first found and described at Sampyre, Val Varaita (e.g. Compagnoni, Ferraris, Mellini, 1985, *Amer. Mineral.*, 70, 767-772) and other minerals as for instance the Ellembergerite, Bearthite, Mg-staurolite, Mg-dumortierite in lower Val Varaita (e.g. Compagnoni & Rolfo, 2003, *EMU Notes in Mineralogy*, 5, 13-49).

5) **A GEOMORPHOLOGIC AID TO RECONSTRUCTIVE GEORCHEOLOGY:** the area, now buried under a debris flow, where Hannibal is thought to have regrouped his army while crossing the Alps in the upper Po valley, below Col de la Traversette in the Cottian Alps north of MM (e.g. Mahaney *et al.*, 2010, *Geology Today*, 26/6, 209-215).

6) **THE ROCK-DWELLING ORGANISMS ON THE OPHIOLITIC ROCKS:** the biodiversity of lichens, microfungi and cyanobacteria colonizing the ophiolites, which can give additional value for the environmental assessment and valorization of the MM outcrops (e.g. Favero-Longo *et al.*, 2005, *Int. Biodet. Biodegr.*, 56, 17-27.)

Key terms: Piedmont; Geological heritage; Messinian; Climate change; Paleoenvironmental change

The multidisciplinary research project "PROGEOPIEMONTE" (PROactive management of GEOlogical heritage in the PIEMONTE region: innovative methods and functional guidelines for promoting geodiversity knowledge and supporting geoconservation activities) aims to achieve a new conceptual and operational discipline in the management of the geological heritage of Piemonte by means of the development of techniques for recognizing and managing its rich geodiversity at the local and regional scale. After a systematic review of inventoried geosites, 9 strategic geothematic areas will be investigated to represent the geodiversity of Piemonte, each characterized by high potential for scientific studies, enhancement of public understanding of science, recreation activities and for economic support to local communities. The recognition of the economic value of geodiversity will lead to the production of regional guidelines for Geoconservation integrated quality management system, suitable for tourism and sustainable development strategies. In this framework, the climate and environmental change subject will be addressed studying the record of the Messinian time slice, a crucial interval for the geological history of the Piemonte region (Tertiary Piedmont Basin, TPB) and of the Mediterranean basin. During the Messinian the Mediterranean sea became the largest saline basin in the Earth history, with dramatic impact on both marine and terrestrial ecosystems. This event, known as the Messinian salinity crisis (MSC) led to the deposition of sedimentary rocks testifying fluctuating salinity from hypersaline (evaporitic rocks) to hyposaline (continental and lacustrine rocks). Nowadays evaporitic rocks (gypsum, anhydrite and halite) form because of severe evaporation of the sea water under arid climate conditions and in relatively shallow water and silled basins. In this sense, ancient evaporitic successions are useful paleoclimatic and paleobathymetric indicators. In the early '70s the discovery of thick sequences of evaporitic rocks buried under the Mediterranean sea bottom resulted in the formulation of the theory of the desiccation of the Mediterranean, according to which, following the closure of the Gibraltar strait, the communication between the Atlantic ocean and the Mediterranean sea was suddenly interrupted. The negative hydrologic balance and the severe evaporation of the sea water led to a dramatic sea level drop (of the order of 1000 m); as a result, the Mediterranean was completely desiccated and thick sequences of shallow water evaporitic rocks were deposited abruptly on deep water muds and marls. Since then, innovative researches, devoted to the reconstruction of the complex MSC events, were carried out by international teams; but the Messinian succession of the TPB, one of the reference succession for the deep desiccated model, has been overlooked. New researches are now in progress, devoted to the integration of physical stratigraphic, biomagnetostratigraphic and cyclostratigraphic data, and focused to the reconstruction of a reliable chronostratigraphic framework for the paleoenvironmental, paleoclimate and paleohydrologic changes occurred during the MSC and the characterization of the large suite of evaporite gypsum facies that crop out in the TPB. The scientific results of this theme will be disseminated to a non specialist public through the preparation of several itineraries, especially in the Langhe region, showing the most significant steps of the MSC in Piedmont, the paleoenvironmental modifications that occurred and their deep impact on ecosystems. The advancing knowledge on the MSC will greatly help to improve people awareness of environmental modification and past climate variability suffered by the Earth through geological time, and to address the crucial question whether it could happen again in the future.

Key terms: geotourism; geosites; climbing sites; scientific value

The climbing sites around the Alps are peculiar geomorphological emergencies. Several are the shapes of climbing cliffs that reflect both

lithotypes and structures and a lot are the examples especially in the Italian side of Alps, where the great geodiversity in lithotypes makes possible to find out a climbing site for different geological and geomorphological situations. In this sense, the scientific and additional values of climbing sites are usually high and they can be considered geosites, ideal situation for divulging Earth Sciences among general public. From the academic point of view, these geomorphological emergencies have been investigated by scientists in virtue of the well exposure of lithologies and structures and so the geological and geomorphological information at disposal are abundant. The potential for use (accessibility, services, actual use of the site) is usually high especially because of the possibility of involving the mountain haunTERS, in particular climbers, in being confident with Earth sciences topics. For this reasons an approach to assessment and valorization of these sites is herein proposed. The project involves specialist of divulgation and geotourism, and researchers expert on geology of the investigated area.

The two selected sites are easily accessible and famous among the climbers communities. They are located in a restricted region along the SS26, about 22 Km straddling the border between Piemonte and Valle D'Aosta, with two different lithological and structural situations. Montestrutto is a geomorphological relief modeled in the Eclogitic Micaschist Complex of the Sesia Lanzo Zone and it derives its name because it constitutes an obstruction along the valley (Mons Obstructus). The Arnad "Gruvieria" sector is an evident cliff constituted by the rocks of the Gneiss Minuti Complex and once again the toponym reflects the alveolar morphology of particular layers, distributed regularly in the cliff. In addition, the selected region is characterized by a lot of cultural elements (Montestrutto Castle, Via Francigena) whose settlement was strictly influenced by the presence of the geomorphological elements. The fieldwork activity has the main aim of reconstructing the geological and geomorphological evolution of the cliffs and it has been specifically addressed to individuation and measurement of structures of the rock (foliations, axial planes, mineral lineation, fractures) highlighting which are the minerals marking which structures. The main aim is to correlate them with the typology of climbing that changes in function of the micro and macro morphologies of the wall. Even in the same climbing site the cliff may assume different geographical orientation, exposing differently the structures. The deriving climbing modalities are singular and reflected in the difficulty grade of the route. This is the topic to play on in order to arouse interests in climber in trying to understand why they climb in a such way and which natural elements can help their vertical progression. In addition, all the obtained information can be useful in order to deepen the investigations about the quality of the rock mass of the cliff to determine the hazardous processes (rock falls mainly) that combined with vulnerability (climbers and tourists in general) may be source of risks. Education of mountaineers to risk and individuation of hazards represent another positive implication of these project. Since the selected sites are easily accessible by other kinds of public, a further step may be the finding of additional viewpoint also for non-climbers in order to make the spectacular geomorphosites and related topics usable by a wider audience. In this sense all the information can be inserted in a whole cultural context including ecologic and historical information in order to provide a complete framework to climbers and general public.

Key terms: Geomorphosites; Gressoney High Valley; Local Communities; Protected areas

Geomorphosites could be defined as locations strategically relevant, often unique, in order to track the signs of landscape evolution across time (Marchetti, 1999). These sites may serve either to increase knowledge for future projects and have a didactic, historical, and cultural value. The decay or damage of these sites by human activities, would mean the loss of a historical and scientific patrimony.

These locations are deeply linked to local communities. Therefore they require some kind of protection in order to preserve and making them accessible to visitors, becoming a destination and an incentive for tourism. Gressoney Valley (or Lys Valley) is located along the Lys river, and constitutes a connection between Lys glacier, belonging to Rosa Mountain chain, and Valle d'Aosta. On its edge the valley resemble a glacial and periglacial environment, extending upward in front of the glacier. In this portion, the typical features of a landscape modeled by a retreating glacier can be found: moraines, sheepbacks, erratic boulders, lakes, peat bogs, solifluxion, and glacial erosion morphologies.

On these bare substrates, which have been recently released by ice, the first type of plant associations begin to appear, modifying the scenery. This environment is extremely sensitive to any climatic change and the typical elements of glacial alpine landscape are quite visible but vulnerable to ongoing changes. In order to analyze and classify the relevant landscape elements of this site of interest we plan to perform a historical and bibliographic survey; a geomorphologic and glaciologic studies by ground and aerial survey, in order to create a geomorphologic map 1:10.000 of Late Quaternary deposits (glacial, fluvial, periglacial, flooding, lake, marsh, of peat bogs and of mountainside). In this way, past and current processes which produced the deposits can be explored.

In a second stage, we will select those elements which can be recognized as sites of interest on the basis of five scientific properties: example of geomorphologic evolution, naturalistic rarity, paleogeomorphologic mark, ecological value (Carton *et al.*, 1994). The score relative to their intrinsic value and their vulnerability will be assigned, finally creating an appropriate informative and geographic support.

This final product will be useful to define the areas and elements which need protection, according what is provided by the Italian law 394/91 (Law on protected areas) and by regional norms of Valle d'Aosta.

The forms of protections provided by the law could be applied to single elements (natural monuments) or broader areas (natural parks); the latter could be administered by the local community, larger community (local park of supra-municipal interest) or regional administration (regional park).

 Presenter e-mail: direttore@parcobeigua.it

Key terms: Paleontological heritage; Oligocene; Geoparks

Inside the territory of the Beigua Geopark two sites are of particular interest from the point of view of fossil remains: the geosites of Stella S. Giustina and Sassello-Maddalena. The well preserved fossil content of these sites highlights the geological history of the territory, referring in particular to the pre-transgressive and transgressive depositional phases of the Tertiary Piedmont Basin (TPB) on the inner margin of the Ligurian Alps chain before the opening of the modern Ligurian Sea. The S. Giustina silicoclastic deposits records the transition from continental (alluvial plane with flood areas, meanders and small lakes) to brackish (Cerithium facies) environments linked to the pre-transgressive phase of the TPB evolution (30 Mya). In the basal levels, the diversified and well preserved fossil flora is mainly composed of Pteridophytes, Gymnosperms and Angiosperms. This association can be compared to tropical basal and pre-montane altitudinal belts in the today Tropical Western Hemisphere.

The Maddalena succession starts with marine sediments, laying on the metapelites of the Voltri Unit, which testifies the early stage of the Oligocene (28 Mya) transgression of the TPB. This event is here characterized by the development of a small reef of corals and red algae (Corallinales). The reefal build-up is suffocated by coarse to medium grained silicoclastic sediments, that exhibit a rich larger foraminifera assemblage (Nummulites and lepidocyclinids). A new coral and red algae reefal settlement overlies these deposits that are, finally, overlain by mollusk-rich sandstones and pelites, linked to a deepening phase of the basin. The abundant, well preserved, in living position, large coral colonies are the most valuable element of this site. During Miocene the area underwent shallow and deep sea phases until the Messinian (7.2-5.3 Mya), when the deposition of evaporites closed the history of the TPB. Meanwhile, at the beginning of the Miocene the modern Ligurian Sea was opening southward, changing therefore the paleogeography of the entire area.

To promote the high value paleontological heritage the Beigua Geopark authority has set up a dedicated visitor centre in Sassello. The Visitor Center is housed in the wonderful frame of Palazzo Gervino, a historical building in Sassello town center. Through modern multimedia equipment, the Visitor Center provides information both on the features of Beigua Geopark and the Geopark international networks (the European Geopark Network and the Global Geopark Network supported by UNESCO). The Visitor Center - thanks to the collaboration with the Culture Councilorship of the Municipality of Savona - offers the possibility to observe a display of rare fossil finds of Anthracotherium, an Artiodactyl mammal widespread in Europe, Asia and probably Africa between the Eocene and Oligocene periods (50-23 million years ago). It was a big-size animal (about 2 m long and 1.5 m high at the shoulder) living in subtropical climate areas, marshy or lagoon habitats.

Finally some rooms introduce the visitors to the discovery of the Oligocene epoch, a fantastic trip back in the time to investigate the geological environments and species that lived in Beigua territory: the tropical forest in Stella Santa Giustina site with a rich exhibition of fossils about terrestrial higher plants and form of leaves logs; the tropical sea in Sassello with fossil collections found in the area of Ponte Prina - Maddalena.

THE ROUTE OF THE OLD SILVER MINES IN THE SARRABUS (SE SARDINIA)

RIZZO Roberto¹, MUNTONI Francesco¹

1 - Geological Mining Park of Sardinia

Presenter e-mail: francescomuntoni@parcogeominerario.sardegna.it

Key terms: Mining; Park; Sardinia

Starting in 1869 with the creation of joint-stock company in Genoa Mining Lanusei, region Sarrabus (SE Sardinia) we began a rational exploitation of large mineral deposits of silver, although the prospecting in this region date back to 1600. In 1860, the noted French engineer Leon Gouin, in its report on mining in Sardinia, presented at the World Fair in Paris, wrote that the mine at Mount Narba, then still being explored, it was of considerable interest for its rich silver, especially the native state in the fluorite scattered visible to the naked eye, the only example of its kind in Sardinia.

In 1870 there were only four active grants (Gibbas, Perd'Arba, Peddie Attu, on Cadillonargiu) more than 24 exploration permits for silver galena. In the following twenty years in the territory of Sarrabus there was a real race to silver as the most legendary gold in America and Australia. In fact, the enhancement of research brought to light the full extent of the reservoir known as the "silver-vein, whose total length is about 30 km roughly in EW direction by up to Burcei Muravera. With these assumptions, the Company was formed in 1869 to Lanusei who commissioned the construction management engineer GB That extended across the highly profitable crops Baccu Arrodas, Giuanni Bonu, and Masaloni Tuviolis. In the same year, realizing westward continuation of the current silver-Leon Gouin Tacconis Sarrabus formed the Society for the exploitation of the mine Tacconis, and the Societe Francaise des Mines du Rio Ollastu for the exploitation of mines Nicola Secchi, Serra S'Illixi and S'Arcilloni.

To connect all these mines and therefore all transactions facilitate transport of the ore was carried out by the same company a road along the tortuous path from the town of Rio Ollastu Burcei who came to the mine director S'Arcilloni connecting to SS 125 'height of Mount Cantoniera Acutzu. Another road, the height of the previous incrociante Fasson, instead linking the mine Masaloni and continued eastward, joining the other mines of Monte Narba, and Giuanni Bonu Baccu Arrodas. The great peculiarity of the mines of Sarrabus it was the richness of native silver and a parade of accessory minerals and gangue beautifully crystallized some of whom discovered for the first time in Italy during his cultivation of these mines. Ullmann, Stefanie, Breithaupt, and antimony pirargirite native was first discovered here in Italy. G.B. Traverso gave

some 170 collections of minerals Sarrabus to Italian and foreign museums. For beauty and elegance of these mineral samples were compared to those found in much more famous and ancient mines of Norway, Saxony and Bohemia. If today we can enjoy this heritage identity fortunately not been lost in manufacturing, we owe exclusively to GB Across one of the greatest figures in the field of view 800 Geomining.

THE UPPER ANIENE VALLEY BETWEEN GEOLOGY, NATURE, HISTORY AND RELIGION

PICHEZZI Rita Maria¹, D'OREFICE Maurizio¹, PANTALONI Marco¹
 1 - ISPRA

Presenter e-mail: rita.pichezzi@isprambiente.it

Key terms: geology; geomorphology; environmental protection

The upper Aniene River valley, located in central-eastern Lazio region, is an area characterized by peculiar geological and geomorphological aspects, and by a rich historical, artistic and cultural heritage.

The Aniene River originates in Fiumata, in Frosinone province, near the border between Lazio and Abruzzo, in the Regional Natural Park of Simbruini Mountains.

It collects the waters of numerous springs that flow into the massive beech forest located on the southeastern side of Tarino Mount (1959 m). The highest of these springs is Riglioso (or Capo Aniene), located at an altitude of 1203 m, with a water flow lower than the Pertuso Caves spring, between Trevi nel Lazio and Filetino.

Shortly after the Trevi Falls, the Aniene collect the Simbrivio River and, once in Agosta, thanks to the Acqua Claudia spring and later, in the territory of Arsoli and Marano Equo with the contribution of Acqua Marcia springs, the river flow increase significantly.

Continuing its run toward the sea, the Aniene forms the powerful Tivoli Falls, 160 meters high, and reaches the Tiber River at Ponte Salario, after covering 99 km, bringing a quantity of water of 35 m³/s.

With its plenty of water the river has been exploited since ancient times to feed the aqueducts that brought water into the city of Rome; the first of these aqueducts was built in the year 312 BC by the censor Appio Claudio Cieco, and was called Appio aqueduct in his honor. Subsequently, in 272 BC, was realized the second aqueduct, called Anius vetus, by the censors Manio Curio Dentato and Fulvio Flacco. In 52 AD the Emperor Claudio exploited the mid-valley area springs, realizing a new aqueduct, called Anius novus.

The interconnection of the hydrological Aniene circuit with the hydrogeological Simbruini system, fed by abundant rains and snow, combined with the karst environment, create the conditions for a foothills springs system from which up-to-date is taken drinkable water used to supply part of Rome urban area, the Colli Albani area and some municipalities of the Sacco Valley.

The Aniene Valley, originally inhabited by Equi population which, allied to Volsci, long defended their independence from the Romans, had considerable importance during the Roman Empire inducing the Emperor Nerone to build his sumptuous Villa and Termae near Subiaco and the Emperor Traiano in the Highlands of Arcinazzo. During the Middle Age were built castles, hermitages and monasteries; of particular interest are the most important settlements of medieval monasticism, the Sacro Speco di San Benedetto and the Monastery of Santa Scolastica in Subiaco, splendid examples of monastic art and architecture and cradle of the Italian engraving.

The Aniene Valley sums many of the geomorphological features of the Italian territory: the austerity of the high mountain areas with large karstic plateau, dolines, swallow holes and caves, the narrow gorges carved by water, the green hills, and an extensive meandering system in a typical alluvial plain.

The rocks that build up the main ridges are composed mainly of limestones in carbonate platform facies ranging from Triassic to Cretaceous age. Limestones and marly-limestones Miocene deposits crops out on the edge of the ridges and forms the relief of the Ruffi Mountains. After the Subiaco town, the Aniene Valley is developed into Miocene silicoclastic deposits.

The area crossed by the river has a traditional agricultural economy, unfortunately now in steep decline, connected with the livestock activities, small industrial with handcraft activities.

The touristic potential of the area is very important, but little or nothing valued. Beyond the Valley can be visited shrines, ancient villages, castles and museums, a sign of spirituality and rural life.

This territory represents an important example of a high interest geo-archaeological area, therefore suitable to be subjected to environmental protection, thereby contributing to the socio-economic development of the valley.

THE ANCIENT SANDSTONE QUARRIES ALONG THE COASTS OF SARDINIA: STUDIES FOR QUALIFICATION AND CULTURAL VALORIZATION

NAITZA Stefano¹, MILESI Alessandra¹, BALLETTTO Ginevra¹

1 - Università di Cagliari

Presenter e-mail: snaitza@unica.it

Key terms: Geosites; Ancient quarries; Sardinia; Cultural valorization

Mediterranean ancient coastal quarries are geosites of multidisciplinary relevance. As a matter of fact, they may be seen as: 1) historical-archaeological sites, showing evidences of past mining techniques; 2) sources of the original stone materials used for ancient building, potentially employable in cultural heritage conservation/restoration; 3) sites of geological/geomorphological interest, often retaining important stratigraphic sections and frequently associated with significant coastal landforms. These sites are also interesting for paleoclimatological and climate change researches as markers of secular changes in sea level. Our studies are focused on the punic-roman coastal sandstone quarries occurring along the Southern and Western coasts of Sardinia. They exploited Quaternary marine and continental (aeolian) deposits. The former (marine conglomerates and carbonate sandstones) are commonly attributed to the marine sea level highstands of the MIS 5 (late Pleistocene), while the aeolianites (sandstones and sands) have been referred to ages varying from middle Pleistocene to Holocene. Carbonate sandstones were an easy-to cut material, well suitable for shaping stone blocks destined to harbours, military and civil works (city walls,

aqueducts), and for civil and religious buildings. In Sardinia, a general inventory and documentation of the ancient coastal quarries is still lacking, as well as projects of qualification of these sites, often characterized by singular and suggestive landscapes. The ongoing research, also funded by the Geo-mineral, Historical and Environmental Park of Sardinia, is aimed to provide systematic, multidisciplinary studies on the sites, and to establish possible guidelines for their qualification, with the possible inclusion in the network of historical mining sites managed by the Park. The study comprises field surveys and mapping of the quarries, including 1) the geological features of the deposits and the geomorphological aspects of the quarry landscapes, and 2) all the features related to past quarrying activities (layout and structure of the quarries, extraction fronts, spoil heaps, working areas, paths of transport of stone blocks; loading and harbouring facilities, etc.). Study of quarries is coupled with mineralogical and petrographical studies of the stones, essential for further reconstructions of their diffusion at a regional scale. Surveys include systematic observations of the state of conservation of the quarries, and the assessment of site degradation deriving from natural and anthropogenic factors. This large set of heterogeneous data will be organized in a database implemented in a GIS. Until now, 11 main localities and many minor sites have been identified, including several well-preserved quarry landscapes. In some cases the sites may be defined as real quarry complexes, formed by multiple quarries, as in the localities of San Giovanni di Sinis, Piscinnu, and Nora. These latter are of great interest for the intents of this research, since they often preserve important records of extraction activities and quarry organization. In the aims of our research, the systematic documentation of the Sardinian coastal quarries in all their aspects will improve the public understanding of their importance as geohistorical sites of great cultural, historical and scientific relevance. This will allow to delineate appropriate guidelines for their conservation and sustainable management. From this point of view, the Geo-mineral, Historical and Environmental Park of Sardinia, established by UNESCO in 1997 and included in the worldwide geoparks network, is the most considerable resource now present in Sardinia. Sardinian ancient coastal quarries have all the features and values for a future inclusion in the Park, possibly forming a specific thematic area, in order to ensure the protection of sites and, at the same time, promote their fruition within a network of tourist and cultural routes.

MINING, GEOLOGICAL AND MINERALOGICAL HERITAGE OF THE ABANDONED GREAT MONTEVECCHIO MINE (SW SARDINIA, ITALY)

RIZZO Roberto¹, MUNTONI Francesco¹, CADONI Efisio²

1 - Parco Geominerario Storico e Ambientale della Sardegna, Via Monteverdi 16, 09016 Iglesias (CI)

2 - Geologo, Montevecchio 09030 Guspini (VS)

Presenter e-mail: robertorizzo@parcogeominerario.sardegna.it

Key terms: Sardinia; mining heritage; Montevecchio mine

The great Montevecchio mine is located a few miles NW of Arbus and Guspini villages in SW Sardinia.

All mining works are set into the thick Cambro-Ordovician volcanic and sedimentary formations (Arenarie di San Vito and acid to intermediate metavolcanics). These Paleozoic terranes suffered the intrusion effects of the late Paleozoic Arburese granitic pluton that transformed the wall rock in hornfels for over 300 m from the contact. In addition, the cooling collapse of the pluton has produced in the surrounding area an impressive field of fractures with parallel and perpendicular direction to the pluton axis.

These two fracture systems are place of hydrothermal Pb-Zn-Fe sulphide vein deposits with gangue of quartz and calcite. Based on their relation to the granitic body are recognized peripheral and radial or crossing vein deposits. The former are more tickest, better mineralized and always parallel to the contact granite-metamorphic rocks. Those radials sink into the granite for many km but they stops abruptly against the peripheral veins.

The great Montevecchio mine exploited the richer and very large peripheral mineralized bundle of whole area, that is known for approximately 10 km in length and 600 m in depth, with maximum thicknesses for the individual veins from 1.5 to 7-8 m. The useful mineralization include galena, sphalerite and cerussite, with subordinate acanthite, pyrite, chalcopyrite and arsenopyrite, in gangue of quartz, ankerite and siderite, and more rare calcite and baryte. Secondary minerals are cerussite, anglesite, pyromorphite, smithsonite and brochantite. In particular, the emerald green in colour anglesite is the mine's hallmark mineral. The most important rare metals are cadmium, gallium, germanium, indium, which were recovered at the production of zinc in Porto Marghera, while lead, silver and copper were recovered in the Foundry of San Gavino Monreale.

In 143 years of industrial activity the great Montevecchio mine developed in five mining concessions referred to as Genna Sciria, Piccalinna, Montevecchio I, II Montevecchio, Montevecchio III. According to their geographical position respect to the homonymous village, built to the development of the mining life, an eastern and western zone is distinguished, where the mineralized bundle took the names of S. Antonio, Piccalinna, Sanna, Telle and Casargiu derived from the mines that were prepared for the ore deposit exploitation.

The irregularity of the mineralization, the variability of the tenor of the ore and the instability of wall rock characterized the Montevecchio mine for problems of exploitation. In addition to industrial production, mining has been also experimentation and technological research of high level. The wise management and the technical and scientific experience of managers and technicians has allowed the creation of structures, systems and machines that have revolutionized the mining operation by improving productivity and safety of the workplace.

The exploitation systems, the art of arming the gallery, the continue research have made Montevecchio a school and a training ground. It was culture and technology, and exported worldwide mining technology.

The whole Arburese lode system is of worldwide size, one of the most impressive in Europe, certainly the finest example in Sardinia and Italy of its kind (hydrothermal veins related with plutons). Together with the other neighboring Ingurtosu and Gennamari mines Montevecchio boasted the richest concentration of lead and zinc minerals in Sardinia, having produced over 1,700,000 t of lead metal and about 1,200,000 t of zinc metal as well as silver, bismuth, antimony, copper, cadmium and germanium.

Presenter e-mail: presidente@consigliozionalegeologi.it

Key terms: Knowledge; social, cultural, economic and territorial contexts; landscape expression of geology

Territorial and environmental problems, ever more delicate and dramatic in our country, require, now more than ever, the constant presence of the geologist in all the social, cultural, economic and territorial contexts. It's necessary to act with greater authority, and involve the society, making the public aware of the real status of the land: how the territory can be both a source of risk or a resource. Knowledge is the key tool: the diffusion of scientific heritage, using topics well known and appreciated, more accessible to the public, may represent one of the new goals for the geologist. Only through the sharing of knowledge, it is possible to reach the common aim of territorial safety and a shared well-being. The wine, well appreciated in our culture, take its roots in the landscape and the landscape is an expression of geology: so it could become a "medium" to communicate the earth sciences to the whole society.

"THE LANDSCAPES OF THE WINE": A BALANCE OF THE EXPERIENCE OF COMMUNICATION AROUND THE "GEOLOGY OF THE WINE"

GREGORI Lucilia¹

1 - Department of Earth Sciences, University of Perugia

Presenter e-mail: lucilia.gregori@gmail.com

Key terms: landscape; wine; geomorphology; palaeogeography; communication

The experience of the "Landscapes of wine" workshop started since 2004 is a new and innovative approach with the aim to put together the wine-oenographic expertise, the knowledge of the wines and their geological reasons. Usually the wine world is enclosed in the tasting experience. On the contrary study of "terroirs" and in particular, their geological and geomorphological context is not still well appreciated. There are still two separated worlds: the first is related to the experts (entrepreneurs, sommeliers, oenologists, etc.). The other grouped the researchers of the wine geology, these two worlds do not still communicate despite of they are both important.

The sedimentary sequences, that represent the vineyards lithological substrate, are the result of different morphogenetic processes. The knowledge of these physical processes is fundamental to comprehend the peculiar characteristics of a wine. After several international conference on this issue now there is an increasing interest around this new approach.

The types of deposits, the mineralogical and petrographic characteristics and the relationships with other disciplines (art, myth, philosophy, geology, etc.) can offer new points of view. Also the review of the "Goethe's Travel in Italy" is another cultural implication. This approach aimed to compare, around a glass of wine, all the interested people. The geology of wine so it is not a "gambling culture" but is a opportunity that opens new perspectives for research and employment.

WINE AND TERRITORY: A GEO-ENVIRONMENTAL PATH

LUGERI Francesca Romana¹, AMADIO Vittorio², GIANNELLA Gianluigi³

1 - Istituto Superiore Protezione e Ricerca Ambientale - ROMA

2 - Università Mediterranea Reggio Calabria

3 - Ordine dei Geologi del Lazio

Presenter e-mail: francesca.lugeri@isprambiente.it

Key terms: Landscape; Wine; Geomorphology; Environment; Culture

The social-economical scenario of an area is strictly linked to the geological one: even at different scales, the endogenous and exogenous processes, and the rocks, as elements of the landscape, condition the evolution of environment and form the base of spatial-temporal development of a region.

By integrating different information about the geo-morphological arrangement and the land use of a region, it is possible to study the territory and the link between landscapes and wine production areas. Wine production is in fact one of the most important activities in the Italian economy and culture and, at the same time, is an expression of the landscape: in this way it could be a "medium" to communicate the landscape, its origin, its history.

In this work a new approach is purposed, aiming to integrate the complex

aspects of the landscapes, and to share the scientific heritage with the whole society. The goal is to provide a complete knowledge of an area (useful for environmental planning as well as for informative/educational programs and, last but not least, for new purposes of eco-touristic development) highlighting the richness of different landscapes. Wines, as well as other cultural expressions, are strictly linked to the territory: the popularization of the geo-environmental heritage walks on the same paths of tourism. A special attention should be devoted to an original link (already performed in some other countries) between landscapes, eno-tourism and sports: a new field for new actions, in order to promote a sustainable development in Italy, as well as a more sensible culture of responsible wine consumption. The modern technology offers new powerful tools: the GIS are able to synthesize, manage and represent a large amount of data; thanks to GIS it's almost easy to reach an evaluation of the state of the studied landscapes, referring to the dual risk/resource which characterizes our country. A further interesting opportunity is to discover, through this process, agricultural wine areas of special geological, environmental and cultural value, which in some cases can be considered geosites.

Presenter e-mail: abollati@uniroma3.it

Key terms: Viticulture zonation; Cesanese wine; geographical traceability; isotopic analysis

In this paper we present the first results of an on-going methodological research aiming at the definition of the capability of a territory to wine production, as well as the geographical traceability of typical wines (monocultivar). The main focus is to define an integrated geological-chemical methodology for the characterization of the product, the definition of links between wine composition (and its organoleptic characteristics) and the nature of its substratum, with the aim of valorization of autochthonous vines and the correspondent wines on the grounds of their original environment.

The study area includes two DOC and one DOCG areas, located in the Cesanese wine production zone, in the Frosinone and Rome provinces. The research is being conducted considering the geological, morphological, soil and climate characteristics in wine production aptitude. As for wine zonation, a GIS was used for the implementation of a data base and the realization of thematic layers (lithology, altitude, slope, exposition). First results show that in the study area outcrop mostly volcanic formations (33%) and sandstones (28%); vineyards are more widespread on soils deriving from volcanites and in a lesser percentage on sandy and alluvial soils.

The study vine sites are mostly located on SE, S and SW slopes, secondarily on W and E slopes, pending between 0 and 10%; additionally 92% of vineyard stands at altitudes ranging between 200 and 400 m a.s.l. Temperature, precipitation and humidity data of the study area have been compared to the references for vine-growing and show that the area is climatically suitable for wine production; moreover bio-climate indices are comprised in the typical range for the production of superior quality wine or high alcoholic grade.

In order to verify the geographical traceability of wines, the earth-alkaline metal strontium (Sr) has been considered, and specifically the ⁸⁷Sr/⁸⁶Sr isotopic ratio, whose value depends on the Rb and Sr content of the substratum rock and on the time elapsed since its formation.

For the isotopic analysis we have selected red wines coming from diverse substratum, and from different wine-making farms, chosen on the grounds of wine quality, the reliability of wine provenance from well defined areas, on the mono variety of the cultivar and the wine making process. For each farm, one or more small area with "Cesanese comune" or "Cesanese di Affile" vines variety, on a homogeneous substratum, were selected; the latter is the most widespread in the study area and is one of the few varieties in Latium able to produce superior quality wines. For each vineyard we sampled the rock substratum, soil, grapes, must (with or without yeast) and wine.

First results show that the ⁸⁷Sr/⁸⁶Sr isotopic ratio of the examined must and wines (also of different years) of each farm does not change and that a good correspondence exists between values of different wines and musts when vineyard are placed on soils originated from the same volcanic substratum. On the contrary, there is no correspondence between these values and those of wines and musts coming from farms whose vineyards are placed on substratum of different origin and age. In order to confirm these results samples of musts of 2010 and wine of 2009 are being analyzed, to confirm the repeatability of results in different climate and atmospheric conditions.

Key terms: TERROIR; WINE; LANDSCAPE; WEBGIS; CARTOGRAPHY

Wines and landscapes are deeply linked by a lot of geological elements (soils, rocks, morphological arrangement, climate and so on). This concept is well known, but not so shared as due. All the information about the complex themes about wine are usually summarized in the

French term Terroir, but in these last years new questions need new answers. An original model of web site about wine, GIS based, is able to show to the web surfers all the information about wine, landscapes and territory, following both of scientific and cultural way. One of the most important roles of Internet consists in providing an important source of information and knowledge to a potentially enormous public. Trade journals within the sector were indeed the first to offer blogs and forums on their sites. The vastness and dispersal of the information represents an obstacle to the accessing of this knowledge in particular in Italy. WineGIS, a modern geographic information system based on the internet, aims to make easier the access to information about wine and territory. Through the use of technologically advanced solutions, WineGIS offers, following an integrated approach, scientific and technical instruments able to represent in a unified way, a complex and rich view of Italian wine production areas.

GIS technologies, wide ranges of information, new ways of dialogues: these goals will become the tools for a modern development planning of the wine production areas.

WineGIS can contribute greatly to a richer understanding of the culture of Italian wines and aid to the appreciation of this important "fruit of our earth".

Presenter e-mail: umberto.aviani@phd.units.it

Key terms: food safety; stable isotopes; plant-soil interaction

The realization of models of traceability that allow to go back to the origin of a product, protecting food safety, is an issue that has been affecting the wine production sector and the scientific community for a long time. This work aims at defining a reliable and repeatable operating protocol at a regional scale, that allows to confirm the geographic and varietal origin of grape and wine Prosecco CDO (QWPSR) in order to preserve their uniqueness and quality that underlie success recognized by all.

Analysis of stable isotope abundance ratios proved to be quite successful in determining the geographical origin of agricultural products; in particular, the Sr isotopic systematics is increasing applications to verify the authenticity of wines, since every isotopic fractionation occurring during the biological transfer from soil to plant and grapes is in-run corrected during mass-spectrometry data acquisition. The ⁸⁷Sr/⁸⁶Sr ratio in grapes hence reflects the isotopic signature of soils from the different geological environment of growth and can also discriminate wines from different origins, provided that no changes occur during vinification.

In the viticultural areas of Controlled Denomination of Origin, of the provinces of Treviso, Padova, Vicenza, Belluno and Venezia, some zones characterized by homogeneous pedo-climatic environment have been identified: clayey soils and climatic variables comparable with the exception of rainfalls that show a positive gradient of 150 mm, by moving from south to north of the entire area selected.

In each of these areas more vineyards planted with Prosecco were selected, differing by type of conduction and pruning systems adopted, as Guyot, Sylvoz, spur pruned cordon, Geneva Double Curtain (GDC) and pergola, in order to check possible interference of these factors on the dynamics of absorption in addition to the role of soil composition.

To this aim, from each site a representative number of soil samples was collected, 3 depths for each site, interesting a total thickness of 60cm, corresponding to the soil layer more explored by roots; moreover, at the ripening, samples of grape consisting of a significant number of bunches have been taken.

The production activity, recorded over a significant number of vines, and in each vineyard, was assessed through the quantity of grapes per plant, number of bunches per vine and the average bunch weight; on obtained musts, conventional qualitative parameters such as, soluble solids content (° Brix), total titratable acidity and real acidity (pH) were evaluated. Successively, on wines obtained from every vineyard under investigation, the main aromatic precursors will be analyzed.

Samples of vineyard soil were dried in oven and the Sr isotope-ratio was measured on the exchangeable fraction of Sr, the carbonate fraction and by the total soil digestion. The Sr isotopic composition was also measured on crushed and homogenized grape skins, seeds and grape stalks and on carefully extracted grape juice by both nitric acid and hydrogen peroxide and oxidative calcination procedures, to highlight possible experimental bias. Sr was separated from the chemical matrix by ion-exchange and the isotopic composition determined by TIMS. The results indicate Sr-isotopic equilibrium between grape stalk, seeds and juice, supporting the hypothesis that the isotopic signature is not altered during biochemical reactions in the plant. A slightly lower isotopic composition is observed for grape skin, possibly reflecting the effects of an aerosol component.

Grape juices from the different provinces are readily distinguishable on the basis of the different Sr isotopic composition, ranging in the large span between 0.70706 and 0.71215 depending on the lithologic composition of the area. The major correspondence with the juice isotopic signature has been observed for the exchangeable fraction of Sr in soils.

TACING THE GEOGRAPHICAL ORIGIN OF WINES USING SR-ISOTOPE AS CRUCIAL GEOCHEMICAL TRACER

TOMMASINI Simone¹, BRASCHI Eleonora¹, MARCHIONNI Sara¹, BUCELLI Puerluigi², PRIORI Simone³, BOLLATI Andrea³, COSTANTINI Edoardo², MATTEI Massimo³, CONTICELLI Sandro⁴

1 - Università degli Studi di Firenze

2 - CRA Firenze

3 - Università di Roma Tre

4 - Università degli Studi di Firenze; Istituto di Geoscienze e Georisorse

Presenter e-mail: eleonora.braschi@unifi.it

Key terms: Microvinification; Sr-isotope; Terroir; Substratum

The Department of Earth Sciences of the University of Firenze has been involved in the research project ISSUOVINO with the aim to define a geochemical marker suitable to associate the wine to its grape harvest terroir. Following this research guideline, we have determined Sr isotope ratios ($87\text{Sr}/86\text{Sr}$) in a number of microvinifications on single grapevines belonging to the "Azienda Barone Ricasoli S.p.A." at Brolio, and, in order to make a comparison, in other high-quality wines of the Italian territory, namely: other wines of the Chianti Classico Consortium (Tuscany) along with wines of the Cesanese (Latium), Aglianico del Sannio (Campania), and Aglianico del Vulture (Basilicata) Consortia.

The $87\text{Sr}/86\text{Sr}$ measurements on wines have been normalised to the $87\text{Sr}/86\text{Sr}$ of sea-water, resulting in the definition of a parameter called Indice di Provenienza Controllata (IPC). Wines of each farm have distinct IPC values that can be related to the lithologies of the geological substratum underneath each vineyard. The vineyards of the Chianti Classico Consortium are located on geological substrata belonging to both Pliocene marine sediments and Tertiary Carbonate Flysch ($-1.6 < \text{IPC} < -0.2$), and Oligo-Miocene sandstones and pelites of the Tuscan Nappe ($\text{IPC} > 2.0$). The vineyards of the Cesanese, Aglianico del Sannio, and Aglianico del Vulture Consortia are mainly located on Pleistocene volcanic deposits with IPC values from $+0.5$ to -2.0 .

In the context of the microvinifications of the Azienda Barone Ricasoli, we have collected grapes in 11 sampling points, for a total of 62 analyses, during the 2008 and 2009 grape harvest. The results demonstrate an excellent reproducibility of the IPC values of each sampling point in the two harvesting years. This suggests that the Sr uptake process from the grapevine roots to its final product, the wine, is time independent. Another result obtained during the pilot study is related to the small-scale, albeit detectable, variability of IPC values observed among the different sampling points. This variability is due to both the heterogeneity of the geological substratum of the vineyard, and the isotopic change of the leachable Sr fraction, hence bio-available, from the soil. These small-scale IPC value differences can allow to further select the cultivation suitability of single cru apt to yield wines of the best quality.

In conclusion, the results obtained during the research project ISSUOVINO led to the definition of the extremely promising isotope-geochemical tracer called Indice di Provenienza Controllata. Wines inherit their inorganic element inventory from the geological substratum on which each vineyard is embedded, hence the IPC value can safely represent a meaningful parameter in the analysis procedure to guarantee the geographic origin and the production terroir of wines. It is noteworthy that the certificate of guarantee of geographic origin of products of the agricultural food chain has been recently established in the law issued on January 2011 by the Agriculture Committee of the Italian Camera dei Deputati.

SR ISOTOPES AND ITALIAN WINES : AN ATTEMPT TO CHARACTERIZE TRACEABILITY FOR THE WINE ORIGIN AND MARKETING

CASTORINA Francesca¹, MASI Umberto¹

1 - Università di Roma "La Sapienza"

Presenter e-mail: francesca.castorina@uniroma1.it

Key terms: Italian wines; Sr isotopes; traceability; origin

The assignment of geographical origin of highly valuable products such as wine, is of considerable importance within the European Union.

Conventional chemical methods of analysis are not always able to evaluate unambiguously the regional provenance of wine. Therefore, stable isotope ratio of bioelements such as C, N, O, S and isotope ratios of heavy elements (Pb and Sr) have been also applied to provide additional information of wine regional origin. The application of Sr isotopes to the characterization of wine dates as back as the '90s (Horns et al., 1993). In these two decades, however, no clear-cut evidence has been achieved on the thoroughly usefulness of Sr isotopes for wine characterization. In fact, isotopic ambiguity has been found for wines from certain areas throughout the world (e.g. Vorster et al., 2010). The first data of Sr-isotope ratios of Italian wines were carried out by Wolff-Bönisch et al. (1998), who reported analyses of wines from the Vesuvius and Etna volcanic districts, finding obvious differences. Recently, Mercurio et al. (2011) have determined the isotopic composition of wines from the Phlegrean Fields area, and Castorina and Masi (2011) have carried out a study of wines from Romagna.

In this work, we present the Sr isotopic composition of several Italian wines aimed at evaluating the potential of this geochemical tracer of provenance. Although a larger database is needed, nevertheless, the results obtained with this study confirm that Sr isotopes can be used as a valuable tool for constraining the geographical origin of wine, at least combined with the application of other isotopic systematics and/or multi-element analysis.

WINE AND FOOD TOUR THROUGH THE UNESCO SITES FROM CERVETERI (RM) TO TARQUINIA (VT): A PATH FOR FEELING THE TERRITORY

DI LORETO Eugenio¹, LIPERI Lorenzo¹

1 - Lazio Region - Regional Environment Directorate

Presenter e-mail: eugenio.diloreto@consigliozionalegeologi.it

Key terms: UNESCO; heritage; geology; archaeology; wine and food

In 2004, the UNESCO has recognized the Etruscan necropolis of Cerveteri and Tarquinia as World Heritage sites. In order to promote and enhance these archaeological sites, a special program for cultural-tourist paths should be developed, aiming to improve both of the cultural and the natural evidences: archaeological monuments, traditional local production of food and wines and, last but not least, the natural features, including the highly specific ones from a geological point of view (geosites). The proposed route offers representative aspects of this area, between the hills stretching inwards from the northern coast of Lazio, between the towns of Cerveteri and Tarquinia. The landscape is differently shaped by the presence of different geological formations: volcanic domes and lava domes of Ceriti reliefs; ignimbrites and pyroclastic flows "Tufo Rosso a scorie nere," referring to the Sabatini Volcanic District and (in part) to the Vicano one; sedimentary deposits as the Tolfa Flysch and Plio-Pleistocene Clays; the so called "Macco" (yellow sandy limestone). The presence of the different rocks characterizes the morphology of the district: lava domes are observed, related to the Cerite acid volcanism, and the gorge landscape, on the main rivers. Thermal and mineral springs with gaseous manifestations testify the volcanic activity in the area. The tour presents further naturalistic features: the "Natural Reserve of Caldara di Manziara", the "Monterano Nature Reserve" and "Suburban Park Marturanum". Well known and famous in all the world for their archaeological value are the Etruscan necropolis of Cerveteri and Tarquinia and Barbarano Romano (VT). Soil fertility also allows a significant agricultural production and livestock farming: these factors give rise to a large and tasty assortment of food and wines (DOC wines of Cerveteri and Tarquinia). The food and wine stops in the presented route, allow to enjoy the local cuisine specialties (Tozzetti Attozzata, Acqua Cotta), as well as indicate the festivals and events of the land.

THE GIS TECHNOLOGY APPLIED TO THE ANALYSIS OF THE "TERROIR"

FARABOLLINI Piero¹, ANGELINI Serafino²

1 - Università Camerino

2 - LAC Firenze

Presenter e-mail: piero.farabollini@consigliozionalegeologi.it

Key terms: GIS; terroir; geomorphology

The term "terroir" reveals more than one meaning. From a geological point of view, it involves many of the landscape's morphological components such as bedrock, soil composition, slope shape, steepness, exposure, weather conditions. An integrated study that would enable the analysis of these factors and their synthesis in a series of meaningful information, is possible thanks to GIS, already successfully used in environmental studies aimed at the exploitation of the territory. The different informative layers for the various components that enable a complete reading of the territory, are integrated into the GIS. These instruments, so flexible and easy to update, are useful in suggesting new strategies and logical processes aimed at solve the environmental contrasts, and in supplying new and complete answers to the various needs of knowledge. In this case, the study of the most important Italian wine's "terroir", can be performed analyzing the territory of production, using the GIS technology: this approach is interesting also in terms of popularization, considering the link between nature and culture symbolized by the wine in the Italian culture.

GEOLOGISTS AND SOMMELIERS: A NEW WAY TO DISCOVER AND COMMUNICATE THE TERRITORY

GIANNELLA Gianluigi¹, LUGERI Francesca Romana²

1 - Ordine Geologi Lazio

2 - ISPPA

Presenter e-mail: g.giannella@libero.it

Key terms: geologist; sommelier; wine; landforms

In the last years the fields of science and communication became closer, revealing many interesting shared themes, very useful in order to reach and divulge a complete knowledge of a land. The economic and social components that activate the mechanisms of marketing, in the field of food and wine, are investing new energies in this direction, focusing the attention on new image of wine. In this context, however, the territorial contextualization appears not enough exhaustive, referring to the link between the environment in the places of production and the characteristics of each wine: we need something more than the geographical origin or the simple DOC.

The wines are a significant sign of the landscape and the role of the "geologist sommelier" can offer new ways to learn about the wines, studying the natural arrangement of the territory of origin, and the history of production.

The organoleptic analysis may be related to the landscape elements in an integrated approach. In the proposed suggestion, some Italian wines are

analyzed linking their tastes with the landscape settings of the places where the wines are produced.

ITALIAN REGIONS: LANDSCAPES AND GREAT WINES. SUGGESTIONS FOR A SUSTAINABLE TOURISM

TESTA Bruno¹, DI GREGORIO Felice², ALDIGHERI Barbara¹, LUGERI Francesca Romana³

1 - CNR IDPA

2 - Università Cagliari

3 - ISPRA

Presenter e-mail: bruno.testa@idpa.cnr.it

Key terms: Wines; landscapes; geology; tourism

The landscapes of Italy are well-known and appreciated around the world: the geological arrangement in our land can be "read" through the landforms.

In the Italian territory, full of different land settings, the geologic and geomorphologic system influences the land use, each region shows its own special association of landforms that corresponds to a characteristic cultural arrangement. The vineyards cultivation and the wine production are very important in many cultures, and play a determinant role in local as well as in global economic development. Particularly, in the Italian culture the wine production represents an activity full of significance; the DOC areas, although identified at the administrative level of municipality, testify the vocation of the corresponding territory. By integrating different information about the environmental components, analyzing the geo-morphological, lithological and biological/vegetational data, we tried to investigate the distribution of the most renowned wine production areas in the different landscape settings. Following this approach it is possible to perform new ways in the local development, combining the social/economical requirements with the environmental planning policies, in terms of sustainable tourism. The Italian wines tell us about the natural and cultural history of their own places of origin, accompanying the passengers in a path of knowledge.

BEGINNING AND DEVELOPMENT OF THE GEOLOGICAL MAPS OF ITALY BEFORE ITS NATIONAL UNITY

LAURETI Lamberto¹

1 - Dipartimento di Scienze della Terra e dell'Ambiente - Università di Pavia (Italy)

Presenter e-mail: laureti@unipv.it

Key terms: history of geology; italian geology; geological maps

The aim of this paper is to show a review of the geological representations of the Italian territory issued before its political unity. Starting from the half of the XVIII century, the development of the geodetic studies allowed the surveying of topographic maps suitable to include thematic items about the lithological characters of the terrain, the location of ore bodies and fossiliferous sites with other aspects referring to the Earth Sciences. By this regard the paper considers the maps produced both by Italian and foreigner researchers.

As starting point of an evolution developed across a century, a significant event can be represented by the project of a work on the physical aspects of Tuscany (1754) by the Florentine Giovanni Targioni Tozzetti, consisting in a "carta oreografica" with the main tectonic lines, and a "carta icnografica" showing the various lithological formations, each one identified by a specific colour. However technical obstacles and other difficulties compromised the project's development.

One must not forget that the geo-political subdivision of the Italian territory, kept till over the half of the XIX century, if didn't encourage a systematic and wide geological survey, nevertheless didn't prevent detailed observations concerning particularly regions characterized by very impressive natural features (as the volcanic areas of Phlegrean Fields, Vesuvius and Etna). In this regard many observations and drawings were made mainly after the violent volcanic eruption of the Monte Nuovo (1539) near Pozzuoli, or after the Vesuvius one (1631). In the same times among the numerous ones, we can mention the Etna representation by Giuseppe Recupero (1779), with the drawing of the lava flows. Another significant map was drawn by Eliseo della Concezione, after the calamitous earthquake that struck the Calabria region in 1783.

Among the naturalistic representations made in the second half of the XVIII century, a particular attention must be given to the mineralogical maps, generally made on a topographical or geographical basis, by the insertion, nearby the mine sites, of letters or symbols relative to chemical elements (copper, silver, lead, etc.). Typical models are the maps drawn by: Nicolis de Robilant for the Sardinia Kingdom (1784-85); Ermenegildo Pini and Domenico Vandelli for the Lombardy; P. M. Cermelli (1782) and Giuseppe Morozzo (1791) for the Latium.

But only in the first quarter of the XIX century the geological mapping of Italy shows some very interesting realizations as the splendidly coloured Carta fisica del suolo di Roma, drawn by G. B. Brocchi (1820). Also Scipione Breislak (1798-1801), drew other maps relative to the volcanic areas of the Campania region, with yet simple geological colours, while later the botanist Michele Tenore will draw a real geological coloured map of the same region (1827).

Besides the Italian contribution, a very important hand coloured geological map series was realized by foreigner scientists: South Tyrol (1822) and Lombard lakes (1829) by L. von Buch, the lake of Como by H. T. de La Beche (1830), the surroundings of Rome by F. Ch. L. Sickler (1816-21) and G. H. Westphal (1824-28), the Sicily by Ch. Daubeny (1825).

As recently referred by Hugh Torrens (2006) it is necessary to recall a first attempt to draw a geological map of the entire Italian territory by G. Watt in 1804. A real map of the Italian territory was realized later (1844) by H. de Collegno thanks to the numerous local and regional maps meanwhile issued by the same Collegno (Piedmont and Lombardy), Sismonda (Savoy and Piedmont), Da Rio (Euganei Hills), Pasini (Lombard-Venetian

Kingdom), Hoffmann (Sicily), Giuli (Tuscany), Abich (Neapolis Kingdom), Philippi (Calabria), Sartorius (Etna), Gemmellaro (Sicily) and many others.

10.1474/Epitome.04.0515.Geoitalia2011

GEOLOGY, CARTOGRAPHY AND KNOWLEDGE OF THE TERRITORY IN THE TRAVELS OF ALBERTO FERRERO DELLA MARMORA (1789-1863)

VACCARI Ezio¹

1 - Università dell'Insubria (Varese)

Presenter e-mail: ezio.vaccari@uninsubria.it

Key terms: history of geology; cartography; 19th century; Sardinia

The Piedmontise count Alberto Ferrero Della Marmora, also known as La Marmora (1789-1863), was a military officer and mining inspector who developed a specific expertise on the geological, mineralogical and paleontological features of Sardinia. Between 1819 and 1855 La Marmora spent about 13 years in Sardinia, where he undertook several scientific travels, as shown by his main work, "Voyage en Sardaigne" (1826), later enlarged in a second edition in three volumes: physical and human geography (1839), archaeology (1840), geology and paleontology (1857), the atlas with a geological map.

Indispensable sources for understanding this fieldwork are also the publication "Itinéraire de l'île de la Sardaigne" (1860; Italian edition, 1868), as well as the unpublished notebooks and papers conserved in the Archives Alberti La Marmora of the Centro Studi Generazioni e Luoghi di Biella.

La Marmora also worked for some years on the administration of the Sardinian territory, when he was "Commissario Reale Plenipotenziario" and later, between 1849 and 1851, General Commander of Sardinia for the Savoy Monarchy. His work in the field of the Earth Sciences, both in Sardinia and in North-Western Italy, greatly benefited from the use of travel as an "epistemological tool", allowing to describe and analyze a combination of cultural, social, geographical, anthropological, economical, technical and scientific elements. The purpose of this paper is to reconstruct and evaluate the extent of the impressive scientific contribution of La Marmora, still little known within the context of the Italian geology before and after the unification of Italy, using published and unpublished sources. This work is part of a potential research project, which is currently discussed by Oxford University, Università dell'Insubria, Fondazione Sella and Centro Generazioni e Luoghi - Archivi Alberti La Marmora. It is based on a comparative study of the role of La Marmora and Quintino Sella (1827-1884) in the knowledge of the territory of the united Italy. They put particular attention to the survey for mineral and agricultural resources improving the geological mapping as well as the state-controlled construction and management of infrastructures.

F4-3 Invitato Vai, Gian Battista

10.1474/Epitome.04.0516.Geoitalia2011

GEOLOGISTS' "OUR ITALY"

VAI Gian Battista¹

1 - Museo Geologico Giovanni Capellini, Università di Bologna

Presenter e-mail: giambattista.vai@unibo.it

Key terms: pioneers; patriots; geological community; lights and shadows; past and present

Luigi Ferdinando Marsili, the most European and cosmopolitan Italian scientist of the late 17th to early 18th century, making reference to his relations with the Duke of Modena, the Venetian Republic, and the Grand Duke of Tuscany during 1681, in his Autobiografia writes "They promised to give always signs of friendship and esteem to His Highness for his well founded desire, the accomplishment of which would result also profitable to the constitution of Italy". Marsili indeed cared about the concepts of a Bolognese "fatherland", an Italian "nation" whose correlative political unitarian "state" was to be pursued, and a European "theater" in which he was an actor of a sharp conflict between Christianity and the Muslim Empire. The dream of a united nation, rooted in the awareness that modern science and the new arts were born in Italy during the Renaissance, was part of Marsili's legacy.

All Italian naturalist geologists of the late 18th and 19th centuries have profited of Marsili's legacy so much that one can safely state that they unanimously supported the national unity without distinction of party, religion, ideology, institutional link and country of origin. Following Marsili, this case history was punctuated by scientists such as Arduino, Spallanzani, Brocchi, Tondi, Pilla, Della Marmora, Scarabelli, Sella, Sismonda, Omboni, Gastaldi, Scacchi, Palmieri, Pareto, Gemmellaro, Capellini, Stoppani, Taramelli, to quote a little sampling. They contributed greatly to the origin of the new Italian state, obtaining back a quite inadequate recognition. A country like Italy having so many priority needs of protection from geological risks did not exploit the skills of its geologists who succeeded in completing Italy's Geological Map at 1:100,000 only a century after the national unification. This fact shows how the unity was needed, and how much the process was punctuated by shadows and gaps. A celebration is useful if, beyond rhetoric, the past is frankly re-evaluated to understand the present and prepare a better future. In this sense we may look for the reasons why that category of geologists favored so much the Italian unity. Was it depending on the historical evolution of geology or was it linked more or less to the geopolitical setting of Italy at that time?

F4-4 Invitato D'Andrea, Myriam

10.1474/Epitome.04.0517.Geoitalia2011

THE COLLECTION OF RELIEF-MAPS BY THE GEOLOGICAL SURVEY OF ITALY

D'ANDREA Myriam¹, FULLONI Sabina¹, CAPITANIO Flavio¹

1 - Italian National Institute for Environmental Protection and Research (ISPRA)

Presenter e-mail: miriam.dandrea@isprambiente.it

Key terms: cultural heritage; relief maps; Geological Survey of Italy; ISPRA Geological and historic Collections; ICCD "OA" standards

The Italian National Institute for Environmental Protection and Research

(ISPR) preserves the Paleontological and lithomineralogical Collections, inherited from the Geological Survey of Italy. These conspicuous historic-scientific Collections strictly belong to the cultural heritage of Italy and they have indeed a high cultural and economic value. The Collections include more than 100,000 paleontological finds and more than 50,000 mineral and rock samples, as well as relief-maps, busts, portraits and scientific equipment. This unique heritage testifies the geological survey and mapping of the entire territory, since the beginning of the Geological Map of Italy in the last fourth of the XIXth century, up to the 70s of the XXth century.

Among the others, in support of the Geological Map of Italy, the Collection of historic geological relief-maps was commissioned by the Royal Geological Survey, to specialized artists which used various techniques and materials, such as wood, galvanic alloy, gypsum and oil painting. The 17 existing works, realized from 1877 to 1920, are now described in a Catalogue for the first time, directly compared with the contemporary geological maps drawn on the same area. Therefore, one century after their production, it is important to study the connections between politics, economy, science, and art, in the period ranging from the last fourth of the XIXth century (when Italy became a united nation) and the first twenty years of the XXth century (till the World War I).

In fact, the relief-maps witness a new way to represent the geological data considering the whole Italian territory after its unification. It is not possible to approach the history of the geological mapping in Italy without taking account of the great contribution given by these handcrafts, which illustrate many areas of strategic importance for mining industry (Isola d'Elba, Massa Marittima, Alpi Apuane, Montecatini-Val di Cecina), geological risk (Vulcano Laziale, Provincia di Napoli, Campi Flegrei, Monte Vesuvio, Isola d'Ischia, Monte Etna) or for geomorphology in itself (Monte Bianco, Argentario, Monte Soratte).

Who asks himself why such models - so detailed and realistic, but also heavy and cumbersome and expensive - were realized, should think about the use of the relief-maps by architects and planners as well as geologists. There was (and there is still today) the need to immediately identify and understand the strategic sites, in all their multiple and complex aspects, that goes well beyond the mere geological setting. A geological relief, more than a multi-layer cartography, could be suitable to illustrate and to discuss not only geological problems, but also land planning with local and international stakeholders and sponsors.

All the 17 relief-maps have been studied and classified in a Pre-catalogue format as "Objects of Art", following the standards of the Central Institute for Cataloguing and Documentation (ICCD). First of all, this pioneer work aimed at reconstructing the historic, scientific, and technical outline of these real works of art. Furthermore, it has given also the opportunity to test the ICCD standards on this topic, offering in the meantime a service to other institutions, which preserve similar heritage and are interested to improve their cataloguing activity. In fact, the studies led to investigate analogous collections preserved by other institutions (Istituto Geografico Militare, Firenze; Museo Regionale di Scienze Naturali, Torino; Museo Mineralogico e Geologico Estense "Gemma", University of Modena; Museo "G. Capellini", University of Bologna; Museo Storico dell'Architettura Militare - within the Museo dell'Arma del Genio, Roma). Starting from the Collection of historic geological relief-maps of ISPR, the complete census of these handcrafts in Italy will require joint research programs with other institutions dealing with collections and single items localized not only in Italy but also abroad.

F4-5 Orale Procopio, Fabio

10.1474/Epitome.04.0518.Geoitalia2011

IMPORTANCE OF THE POST-UNITARY GEOLOGIC CARTOGRAPHY IN CALABRIA (1861-1889)

MARABINI Stefano¹, PROCOPIO Fabio²

1 - Museo geologico "G. Capellini", Via Zamboni 63, 40127 Bologna, Italy
2 - Ordine dei Geologi della Calabria, via Stromboli, 23 Catanzaro, Italy

Presenter e-mail: fabioprocopio@libero.it

Key terms: SGI congress; large scale geological map; Catanzaro; Southern Italy

The eighth "Adunanza Generale della Società Geologica Italiana" was opened on September 23, 1889 in the City Hall of Catanzaro, Calabria. At the time, the event was also additionally called "1° Congresso Geologico dell'Italia Meridionale", as to underline the National Geological Unity reached almost thirty years after the political unity of Italy.

It may appear unusual the choice to objectively celebrate this first south Italian geological congress in a region such as Calabria devoid of a university centre, in a small city such as Catanzaro, instead of centers important and known for their geological research such as Naples, Palermo, Catania, Messina and Cagliari.

Although on one hand the choice of Catanzaro was favored in some way by the authoritative president of the SGI Giovanni Capellini (1833-1922) following the withdrawal of Vicenza, on the other hand it was absolutely not casual. Still before 1861, the Liceo Galluppi in Catanzaro, a former Jesuit college, hosted a Gabinetto di Storia Naturale including a rich geological collection. Teachers at the Galluppi school were both Domenico Lovisato (1842-1916) who had produced geological maps of Northern Calabria at 1:250,000 and 1:50,000 scale that were presented at the 1878 Universal Exhibition in Paris, and Antonio Neviani (1857-1946) who was Capellini's student in Bologna and later also became president of the SGI.

An additional Capellini's student, Vincenzo Rambotti (1845-1878), had been intensively active in Calabria. He died prematurely of malaria and his maps were partly published posthumously by Neviani. Moreover, Emilio Cortese (1856-1939) had been active in Calabria for a decade on behalf of the Royal Ufficio Geologico. Neviani and Cortese were asked by Capellini to organize the general assembly of the GSI and prepare two-day field trips on carriages and horse-back to the Tertiary and Recent surroundings of Catanzaro, the Mesozoic of the Tirolo mountains, and the schists and granites of the Gimigliano zone.

Both organizers and participants to the Catanzaro congress were well aware that the geological mapping and researches made in Calabria in the first three decades after the unity of Italy were most important, and the geological anomaly of this area in the national frame had already appeared. To emphasize this point, the opportunity was taken by the Royal Ufficio Geologico to present at the congress members gathering in the Catanzaro City Hall the "Carta Geologica del Catanzarese" at 1:10,000 scale (in 12 sheets); the scale selected and the exceptional level of details for the time showed the possibility of an immediate practical implementation of the map.

It is known that the expectations of the first post-unity geologists were to a large extent unfulfilled. Nevertheless, the quality of the publications and the cartography produced by the geologists operating in Calabria in those

years represented a solid and internationally recognized basis for the geology of the 20th century. The point is best witnessed by the French Maurice Gignoux (1881-1955) and his worldwide famous stratigraphical work on the Calabrian and the Quaternary just starting from the surroundings of Catanzaro, the main place of the 1889 SGI congress.

THE FOUNDERS OF SEISMOLOGY IN ITALY BY THE MID-NINETEENTH CENTURY

LUONGO Giuseppe¹, CUBELLIS Elena², OBRIZZO Francesco²

1 - Università di Napoli "Federico II"
2 - Istituto Nazionale di Geofisica e Vulcanologia - Sezione di Napoli, Osservatorio Vesuviano

Presenter e-mail: giuseppe.luongo@unina.it

Key terms: Earthquakes and volcanism; Seismic source; Intensity Scale; National Geodynamic Service; Seismograph

The scientific study of earthquakes received a critical stimulus in 1755, when a disastrous earthquake struck Lisbon on November 1. A significant contribution to this evolution comes from Italy, where by the mid-nineteenth century many scientists operated to record, localize and classify the intensity of the earthquakes. During that time two disastrous earthquakes occurred, the Neapolitan earthquake of 1857 and the Ischian earthquake of 1883. Believing that earthquakes were produced from volcanic sources, they drew attention to the nearness of volcanoes to the stricken areas.

The firm foundations of modern seismology were laid by Robert Mallet (1810-1881). The earthquake of December 16, 1857, in Southern Italy (Two Sicily Kingdom) provided Mallet with the opportunity to study seismic effects extensively and to establish much of the basis of observational field seismology. To ascertain the surface position and depth of seismic focus Mallet measured the direction and inclination of fissures in buildings, the direction of the fall of columns and the projection of detached masses of masonry.

To overcome the imperfect record of the features of an earthquake afforded by broken walls, fissured roofs and overturned objects due to a variety of causes, seismologists aimed their activity to construct instruments for registering the complex movements of an earthquake to exclude some errors coming from non homogeneity of structures. Luigi Palmieri (1807-1896) operated in this direction with the invention of his electro-magnetic seismograph in 1855. In the following year, one instrument was placed in the Vesuvius Observatory and a second in a building of the University of Naples. During the eruption at Mt. Vesuvius that began on 8 December, 1861, the first eruption after the Unit of Italy (17 march 1861), two clusters of shocks were recorded by Palmieri's seismograph.

Italian seismology is deeply indebted to Michele Stefano de Rossi (1834-1898) for its advance. He was the founder of the "Bullettino del Vulcanismo Italiano" in 1874, the first journal devoted to the study of volcanoes and earthquakes. His chief object was to encourage the spread of regular observations of endogenous phenomena made at various stations in Italy; it was the de Rossi's journal helped to create in Italy the public interest that made the national seismic service possible. In 1874 de Rossi introduced a scale for comparing intensities of different earthquakes that met with general approval. Moreover he studied the earthquakes which damaged Casamicciola in 1881 and ruined it in 1883. For the last de Rossi proposed an original mechanism for the seismic energy release: the earthquake was caused by sudden slip taking place along a fracture in the upper part of the crust and subsequent vibrations of its opposing faces. Giuseppe Mercalli (1850-1914) investigated several great earthquakes and studied the phenomena of the Italian volcanoes in original way. As an investigator of earthquakes Mercalli soon realized a usefulness scale of intensity which contains the germs of MCS and MM Scales. The violent earthquake that destroyed Casamicciola in 1883 was studied by Mercalli employing the method devised by Mallet. He concluded that this earthquake was a true volcanic earthquake, an unsuccessful attempt to force an eruption.

Henry James Johnston-Lavis (1856-1914) lived in Naples from 1879 to 1894. During his residence in Naples, on 4 March 1881 and 28 July 1883, two destructive earthquakes occurred in the nearby island of Ischia. Johnston-Lavis classified the two ischian earthquakes as events of volcanic origin. On each occasion he was directly inspired by Mallet's investigation of the Neapolitan earthquake.

After the destruction of Casamicciola, the Government established in 1887 a National Geodynamic Service placed under the charge of Pietro Tacchini (1838-1905) and founded the Geodynamic Observatory of Ischia, the director being Giulio Grablovitz (1846-1928).

THE STOPPANI AND TARAMELLI'S PROJECT FOR A POST-UNITARIAN GEOLOGICAL CARTOGRAPHY IN THE EASTERN ALPS

MAGNANI Stefano¹, MARABINI Stefano², ZANONI Elena³

1 - Università degli Studi di Udine
2 - Museo geologico "G. Capellini", Bologna
3 - università degli Studi di Verona

Presenter e-mail: stefano.magnani@uniud.it

Key terms: Stoppani; Taramelli; Sella; Geology; Cartography

Antonio Stoppani (1824-1891), geologist and paleontologist, author of the scientific bestseller *Il bel Paese* (1876), and his pupil Torquato Taramelli (1845-1922), in his time regarded as a preeminent exponent of the <<new>> geology, having reinstated the Italian Earth Sciences within the European context, had a crucial role in relation in the realization of the geological map of Italy.

In fact, in the aftermath of the unification of Italy, the peninsula was in need of an exhaustive knowledge of the territory under a physical, geographical and geological aspect so to boost its industrial development. Only this kind of knowledge would have allowed an evaluation of the energetic resources that Italy had at its disposal. It was also necessary to have an in-depth study of the geological structure, of the soil's composition and of the morphology of the territory for the execution of drainage works, for the laying of the railroads and of other industrial infrastructures. In this perspective, during those years, the project for the geological map of the peninsula became a priority.

Stoppani, very close friend with one of the main promoters of the project,

Quintino Sella (1827-1884), was strongly committed to this project undertaking it since its beginning in 1861. With Taramelli's support, he upheld the need to assign the direction of the Geological Survey to a national geological institute designed on the German and English models. Within this institute, geologists, paleontologists and academics would have played a prevailing role. In doing so, he opposed those who considered opportune to entrust the project to a special section of the Mine Corps based on a French model, extending a public service centered on the engineer figure, a professional with technical and operative skills, to the whole peninsula.

Although they didn't disregard the practical aims of this undertaking, Stoppani and Taramelli understood that the realization of a geological map based on stratigraphical and paleontological studies, chemical and microscopic analyses, carried out by scholars provided with a deep knowledge of lithology and topography, was crucial. They found a good occasion to put into effect their ideas when Taramelli, thanks to the support of Stoppani and Sella, obtained the Natural Sciences chair at the Istituto Tecnico in Udine (1866-1874). During those years, he dedicated himself to a systematic study of the Eastern Alps. He was especially animated by the will to deepen the knowledge of those territories and to demonstrate their full belonging to the Italian peninsula, not only from the historical and cultural point of view but also from the geographical and geological one. These studies culminated in the realization of the geological map of Friuli, presented at the 2nd International Geological Congress held in Bologna in 1881.

The recent discovery of the diaries regarding the reconnaissances, carried out between 1871 and 1874, provides an extraordinary documentation that allows us to understand Taramelli's approach, showing a different perspective compared with the official publications.

These diaries show the coexistence of two aspects: a <<naturalistic>> consciousness of a geology consistent with the scientific method and, at the same time, a deep humanistic tradition able to perceive the "art" of nature.

Beyond the struggle between geologists and mine engineers that made the work for the geological map difficult until the end of the century, the analysis of the positions held by the two Lombardian geologists and of their sharing views within the Geological Committee (officially constituted in 1867), contributes nowadays to clarify the backstage of one of the founding moments of the modern Italian geology.

F4-8 Invitato Sella, Mattia

10.1474/Epitome.04.0521.Geoitalia2011

QUINTINO SELLA, BETWEEN SCIENCE, MOUNTAINEERING AND CULTURE. FROM VALENTINO CASTLE TO PALAZZO CORSINI

SELLA Mattia¹

1 - Dip. Scienze della Terra "Ardito Desio" Univ. Milano

Presenter e-mail: mattia_sella@fastwebnet.it

Key terms: Quintino Sella; Geology; Corpo Reale delle Miniere; Geological Map of Italy; Geological Society

Quintino Sella, scientist and promoter of science, must be contextualized within the history of Earth Sciences and the evolution of ideas and theories which developed in the nineteenth century when the first geological maps appeared through the work of William Smith, Coquebert de Montbret, d'Ormalus d'Halley, Alberto della Marmora, Giuseppe Scarabelli, Giacinto Ottavio Provana Collegno. But in Italy the real Geological mapping enterprise starts in 1861, thanks to Quintino Sella and Felice Giordano. Sella, born in 1827, graduated in 1847 in Hydraulic Engineering at the University of Turin, right after he was sent by minister Des Ambrois together with Giordano to specialize in Paris at the Ecole des Mines.

Between 1850-52 he traveled around Europe to gain work experience in mining districts. In 1852 he was appointed professor of applied geometry at the University of Turin and from 1854 to 1861 he devoted himself to studies in theoretical and morphological crystallography. In 1856 he was appointed "second class engineer" in the Corpo Reale delle Miniere, the Royal Corp of Mining Engineers, in Turin, and undertook an intense career at this important institution of the Kingdom. In 1860 he was appointed professor of crystallography at the Scuola di Applicazione per Ingegneri, (the Royal Technical School for Engineers founded at the Valentino Castle in 1859, thanks to the commitment of Sella himself). 1860 was a turning point for Sella's life that became a politician. Since that year, he reduces the effort devoted to scientific study but became a promoter of science and culture regarded as key tools for building the new Nation. Sella scientist is best known as crystallographer and mining engineer, but he was also involved in geology. Since 1861 he supported the project of the making of the Geological Map of Italy, and he was one of the makers of the foundation of the Comitato Geologico; during the Congress of Naturalists, in Biella (1864), he presented the "large-scale geological map of the Biellese", made in collaboration with Gastaldi and Berruti; in 1881, together with Capellini, he organized in Bologna the 2nd International Congress of Geology, during which the Italian Geological Society was founded. Sella intended to promote science also through the Italian Alpine Club, born in 1863 at the Valentino Castle. Even the decision to establish this association in the Scuola di Applicazione per gli Ingegneri, which was the technical-scientific and academic seat in Turin, capital of the Kingdom, suggests the aim to promote science in the Italian society. In 1869 the Commission of Inquiry on mining of Sardinia sent Sella to this island and in 1871 he presented to the government the "Relazione sulle condizioni dell'industria mineraria in Sardegna". Sella used La Marmora's geological map to build the "Carta mineraria dell'Isola di Sardegna". In 1870 Rome became the capital of Italy and "the Science must move to Rome", in 1874 Sella, President of the Accademia dei Lincei, organized the reconstruction of this national science institution, in the just bought Palazzo Corsini. He believed that education and training of young people was the prior task for a strong and democratic development of a Nation and became involved in the renovation of Universities, research centers, laboratories and Academies. Sella promoted the establishment of several technical and mining schools. In addition to being a professor of geometry, mathematics and mineralogy, he was a member of the Higher Council of Education, of the Commission for the reorganization of the educational legislation. In 1861 he was appointed Secretary General of the Ministry of Education, ministry who he held ad interim for a few months in 1872. Within the building of the new Nation he also considered the importance of "the mines, the quarrying industry, the construction of underground railways" and he has been also engaged in the construction of rail tunnels (Frejus, San Gottardo).

F4-9 Invitato Dal Piaz, Giorgio

10.1474/Epitome.04.0522.Geoitalia2011

FELICE GIORDANO AND THE GEOLOGY OF THE MATTERHORN

DAL PIAZ Giorgio¹

1 - Accademia delle Scienze di Torino

Presenter e-mail: giorgio.dalpiazz@uniud.it

Key terms: Felice Giordano; Matterhorn; Geology; Tectonics

The Matterhorn (Monte Cervino, Cervin) is famous in its own right, not only from a climber's point of view. The mysterious spell of this great pyramid, standing out in isolation from its surrounding glaciers, has bewitched numerous generations of naturalists and geologists since the heroic age of Horace B. de Saussure (1740-1799) and other distinguished explorers of the Swiss-Italian Alps in the XIX century (B. Studer, H. Gerlach), who gave the first lithological descriptions of the "inaccessible peak". On behalf of Quintino Sella, in the 1865 Felice Giordano promoted and supported Carrel's Italian team in the unlucky race to the Matterhorn conquest, tragically won by Eduard Whymper. Three years later, Giordano was the first geologist to climb the Matterhorn and to give a direct and accurate description of its lithology and structural setting, shown in two profile profiles across the Western Valais-Monte Rosa area. Discussing protoliths, structure and the age of the Matterhorn metamorphic rocks, Giordano was not far from the mobilist nappe theory, an interpretation which he evaluated in opposition to the fan-mushroom or double-fold fixist models, but which he later rejected, mainly owing to the absence of correct chrono-stratigraphic constraints. The Matterhorn was again at the centre of great geological interest in the early 1900s, and gained its world-wide reputation through the genius of Emile Argand, when the Dent Blanche recumbent fold-nappe, the highest tectonic unit of the Penninic zone in the Western Alps, was revealed, carefully mapped (1908) and described (1909, 1911, 1916).

F4-10 Invitato Praturlo, Antonio

10.1474/Epitome.04.0523.Geoitalia2011

THE "SIXTIES": AN IMPORTANT STAGE OF ITALIAN GEOLOGY

CASTELLARIN Alberto¹, COLACICCHI Roberto², PRATURLO Antonio³

1 - UNIVERSITA' DI BOLOGNA - DIP. SCIENZE DELLA TERRA & GEOLOGICO AMBIENTALI

2 - UNIVERSITA' DI PERUGIA - DIP. SCIENZE DELLA TERRA

3 - UNIVERSITA' ROMA TRE - DIP. SCIENZE GEOLOGICHE

Presenter e-mail: praturlo@uniroma3.it

Key terms: GEOHISTORY; STRATIGRAPHY; TECTONICS; MAGMATISM; MEDITERRANEAN

The "sixties" are an important stage in the history of modern Italy, as an economic and demographic boom is coupled with the search of new development routes.

In 1960 the National Committee for Nuclear Energy (CNEN) is established. In 1961 the first Italian space project ("San Marco") starts. In 1963 Natta receives the Nobel award for Chemistry, for his researches on polymers, parents of the modern plastic materials. In the sixties ENI expands the network of its methane pipelines, and develops its activities even outside Italy.

In 1965 the French-Italian Mont Blanc tunnel is open. In 1968 the works for the Gran Sasso tunnel are started. In the meantime the oil drillings show the complexity of the deep structure of our country.

In the research field, Polvani in 1961 achieves the first important call-up of CNR researchers. Universities receive funds for building, laboratories and libraries. Their staff increases, institutional connections with CNR are set up through a dense network of mixed research structures ("Centri di Studio").

In the Earth Sciences field, we note an intense and lively synergy among University, CNR, Italian Geological Service, AGIP, OGS. Furthermore we assist to a meaningful reorganization of the geological thought, realized through close collaborations among the different sectors, up to now divided by a sort of specialistic drift.

The decade begins with Law. n. 15 of 3 January 1960 (known as "Legge Sullo") for the completion of the Geological Map of Italy at scale 1:100,000. The mentioned law provides for special funding and the direct involvement of Universities and other public and private institutions. The period of maximum field activity and map production is exactly the decade 1960-70s.

Within this new scientific climate, enriched by an intense international cooperation, new important CNR Institutes are established: the Istituto Internazionale per le Ricerche Geotermiche (Pisa, 1965), the Istituto Internazionale di Vulcanologia (Catania, 1967), the Istituto di Geologia Marina (Bologna, 1968), the Istituto per la Geologia Applicata alla Pianificazione Viaria e all'Uso del Sottosuolo (Padua, 1968), the Laboratorio per lo Studio della Dinamica delle Grandi Masse (Venice, 1969), the Istituto per la Geofisica della Litosfera (Milan, 1970), the IRPI of Turin, Perugia and Cosenza (1970).

The pioneer discovery of the synsedimentary extensional tectonics, documented by block faulting, listric faults with their transfer links controlling Mesozoic depositional processes, all occurred during this decade. The huge clastic deposits along the borders of the Italian Alps and inside the Apennines, were correctly interpreted as basinal deep deposits laid down by turbidity currents, as large syntectonic and diachronic bodies emplaced to the more external zones during the gradual motion of the chain toward the foreland. According to the early structural and kinematic reconstructions of the Italian orogenic system, the great structural mosaic including Alps, Apennines, Calabrian arc, Sicily and Magrebe chains was, for the first time, referred to the rotation-translation of great amplitude continental blocks fragments, generating orogenic accretion belts on the front and deep semi-oceanic basins behind.

At the same time it became evident the tectonic control of magmatism during the whole alpine and apenninic orogenesis, for instance the Peri-adriatic plutonism, surely referred to the post-thrust paleogenic intrusive activity, interesting the thrust-fold structure.

When, at the end of the decade, the new theory of Plate Tectonics reaches also Italy, it finds an immense database of information collected during field working, and a considerable number of expert scientists who try immediately to apply it to the Italian tectono-stratigraphic setting. They start from the newly accomplished synthesis of the Structural Model of Italy (scale 1:1,000,000), soon realizing that the Mediterranean geology appears more complex and difficult to understand than the one recognizable in the original oceanic areas. Therefore, starting from the essential theoretical base, an important Italian contribution is given to the development, improving and final reorganization of the new Plate Tectonics theory.

F4-11 Invitato Lettieri, Maria

10.1474/Epitome.04.0524.Geoitalia2011

150 YEARS LATER - THE GEOLOGICAL KNOWLEDGE OF THE NATION THROUGH ITS REPRESENTATION: THE NEW GEOLOGICAL MAP OF ITALY AT 1:50,000 SCALE - CARG PROJECT. □ THE RESULTS OF THE PROJECT AT THE CONCLUSION OF ITS FIRST PHASE OF IMPLEMENTATION - FUTURE PROSPECTS

LETTIERI Maria¹
1 - ISPRA

Presenter e-mail: maria.lettieri@isprambiente.it

Key terms: CARG; Geological Map; Environmental Protection

The realization of the Geological Map of Italy, an essential tool for local knowledge, hasn't had an easy life since its beginning in 1861, immediately after the Italian unification.

It has always been conditioned by the most important events related to the various historical phases of the Country, especially by the exiguity of financial support and the lack of continuity in its delivery. Today, with the planned realization of the new Geological Map of Italy at 1:50,000 scale (CARG Project) the national geological map is experiencing a new phase of renovation, thanks to the latest technical and scientific knowledge, in order to become a practical and useful tool for the environmental analysis and protection.

The CARG Project has enabled the mapping start off and the digitalization of 255 geological maps at 1:50,000 scale, 14 geothematic maps at 1:50,000 scale, 6 maps of marine geology of the Adriatic coastal areas at 1:250,000 scale, 1 morphobathymetric map of the Tyrrhenian basin. Other activities finalized to the realization of the Geological Map of Italy were also carried out.

Of the 255 geological sheets funded until now, 91 have been already printed, 33 are ready for printing, 86 are being prepared for printing, 39 have been completed with regard to the geological survey while only 6 are still under survey.

At this stage the first phase of realization of the CARG Project is almost close to the conclusion.

Today, the coverage of the 1:50,000 scale geological map is approximately 40% of the whole national territory; 374 geological sheets are still missing to complete it.

The same tenacity and conviction of the Fathers of the geological map is still necessary today to bring the mapping process to a fulfillment.

In order to adequately plan the realization of the project in the coming years, it is important to raise awareness in the political and ruling class about the need for funding. It would be also essential to review the procedures before starting a second phase of the CARG Project, thus allowing the realization of the remaining 374 sheets.

F4-12 Orale Pantaloni, Marco

10.1474/Epitome.04.0525.Geoitalia2011

THE GEOLOGICAL MAP OF ITALY 1:1,000,000 SCALE: A MILESTONE ON THE PATH OF GEOLOGICAL KNOWLEDGE

PANTALONI Marco¹
1 - Servizio Geologico d'Italia - ISPRA

Presenter e-mail: marco.pantaloni@isprambiente.it

Key terms: geological map; Italy; history of geology

The need to develop a synthetic geological map of the Italian peninsula emerged even before the unification of the country, at the 1st meeting of Italian Scientists, which was held in Pisa in 1839. The proposal was received with great enthusiasm, but with lack of determination. In fact, in 1841, during the 3rd meeting of Italian Scientists in Florence, this need was again reaffirmed because, despite all efforts, the purpose had been hitherto neglected.

Some projects were developed for personal initiative: Collegno di Provana, in 1844, presented his geological map at 1:2,000,000 scale and Balsamo Crivelli added a small geological sketch of the Peninsula to the book of Omboni "Sullo stato geologico dell'Italia" dated 1856.

Even the intervention of Cocchi, Giordano and Sella in the planning of the national geological mapping project, does not seem to change things. Too strong was the conditioning of the map realized in France by De Beaumont and Dufrenoy: the 1:1,000,000 Geological Map of France had left to local authorities the task to realize the detailed cartography, thus creating the basis for a similar behaviour in Italy.

So just after the start of the project for the Geological Map of Italy at 1:100,000 scale and the publication of some "strategic" maps by the Geological Committee, the work began on the first edition of the Geological Map of Italy 1M scale, which was finally published in 1881 during the 2nd IGC in Bologna. Because of the weaknesses in the geological survey, part of the information was taken from the regional geological maps produced so far. The presence of different criteria and methods in the representation arouse the need for more field work aimed at harmonizing them.

Following these insights, in 1889, a second edition of 1M scale map was printed, and, as stated on the title, "it was compiled based on surveys carried out by the engineers of the Royal Corps of Mines and published works of Italian and foreign geologists".

Forty-two years later, Vittorio Novarese, one of the gifted geologists of that period, engineer at the Royal Geological Survey, oversaw the realization of the 3rd edition of the 1M map: the innovations introduced resulted from the great progresses in the geological knowledge, especially on the mainland, particularly in the differentiation of the Alpine chain.

In 1961 Beneo, Director of the Geological Survey of Italy, realized the 4th edition of the 1M map. It was a review of the 1931 edition, consisting mainly in the division of the units in the legend.

On the occasion of 150 years of the Italian unification, the Geological Survey of Italy published the fifth edition of the Geological Map of Italy 1M scale.

The long period of time since the previous edition, 50 years, makes this map a representative element of the enormous scientific advances in geology. Its realization involved many researchers and was carried out through the analysis and synthesis of the scientific improvement obtained in the national geological mapping project, as well as the huge amount of scientific papers published in recent years.

The purpose of this work is to disseminate in the scientific as well as in the educational field a synthesis of the modern geological knowledge of the country, reaching a wide audience of scholars, teachers and students. The outcome is a substantially different geological map compared to previous versions at similar scale. The final product is a geological map in

which, in addition to "conventional" lithological characterization, was highlighted the geodynamic evolution; in order to provide a valuable support for the understanding of the geological and geodynamic history of the Italian peninsula.

This edition also takes a huge step forward in terms of mapping: the use of GIS and of the digital printing process allows the management of many different colours and the representation of small surfaces, allowing several possible reading keys.

F4-13 Invitato Colantoni, Paolo

10.1474/Epitome.04.0526.Geoitalia2011

THE BEGINNING AND EVOLUTION OF THE MARINE GEOLOGY IN ITALY

COLANTONI Paolo¹
1 - UNIVERSITA' DI URBINO, ITALY

Presenter e-mail: paolo.colantoni@uniurb.it

Key terms: Geophysical Survey; Submarine Morphology; Structural setting; Geology of the Italian seas

A brief look at the marine geological investigations in Italy during the recent years is presented. Proper research programs began after the World War Second when technology made it possible to use the acoustic energy to investigate the seafloor and its sub-bottom features. Thanks to A. Segre and C. Morelli we got respectively the first bathymetric maps and an extended geophysical survey. At the end of the Sixties, some CNR Marine Institutes were created. The CNR's Progetti Finalizzati (1975-80), animated by R. Selli, marked the most intense phase of research activity with the use of two oceanographic ships (Vercelli and Bannock). The collected data allowed to attempt the first interpretations of the geology of the seas surrounding Italy.

The Northern Adriatic Sea has been the subject of numerous studies concerning in particular the recent sedimentation and stratigraphy of the last glacial cycle. The Southern Adriatic Sea remains poorly known as well as the Ionian Sea. Although we got to know its complex morphology and depth, the real nature of the crust remains unknown. The Strait of Sicily's features are interpreted as due to tensional stresses in a continental crust, while the Tyrrhenian Sea shows a more complex geological shape. The intricate morphology of its Northern sector seems to be originated by compressing movements and by the origin of the roots of the Apennine chain. On the other hand, the origin of Central and Southern Tyrrhenian Sea, with its deep plain and isolated seamounts, was interpreted as due to vertical movements caused by crustal oceanization processes and later by tangential or shear forces in a back-arc basin. The activities of the ODP (Ocean Drilling Program) Legs allowed to solve some doubts and led to an international debate on the origin of the Messinian evaporites. The underwater observations of many sites using submersibles helped to acquire additional details. After a long period of crisis caused by the lack of a sea policy and the shortage of funds, the worthwhile collaboration between marine and field geologists gained new interest, thanks to the effort for mapping the marine part of the CARG project's new geological sheets. Once more, it is clear the difficulty of combining the two different surveying approaches and also the need for a new generation of scientists trained in Marine Geology and able to use the innovative supporting technologies.

F4-14 Orale D'Angelo, Silvana

10.1474/Epitome.04.0527.Geoitalia2011

THE GEOLOGICAL SURVEY OF ITALY FROM MINING TO ENVIRONMENTAL PROTECTION: THE INVISIBLE TERRITORY

D'ANGELO Silvana¹, FIORENTINO Andrea¹
1 - ISPRA - Geological Survey of Italy

Presenter e-mail: silvana.dangelo@isprambiente.it

Key terms: Geological Survey of Italy; marine geology; seafloor

The Geological Survey of Italy (at that time Mining Department of the Ministry of Industry, Trade and Craft) started to investigate sea bottoms at the end of the '60s.

Its task was to implement the geomorphological and geo-mineral knowledge of the seafloor, aimed at the realization of thematic and "special" maps to complete the geological map in the areas of mining interest. The area which served for initial practice was the Elba Island while searching for metalliferous sands.

Between 1979 and 1982 an Operational Unit of the Geological Survey participated in the CNR (National Research Council) Targeted Project "Oceanography and seafloor", sub-project "Placers". The objective was to identify metalliferous sands deposits on the mid-Tyrrhenian continental shelf, in order to determine their thickness and heavy metal content. At the end of the '80s, when the 1:100,000 scale Geological Map of Italy was completed, the new Geological Map at the 1:50,000 scale was financed (CARG Project).

The Geological Survey of Italy was transferred to the Ministry of Environment and the geological cartography started to be addressed mainly at the knowledge of the territory. Particular relevance was given to its vulnerability, which resulted from the economic and technological development. The project aimed at the realization of the geological cartography of marine areas started according to the law n. 183/89 "Soil Defense". The geological survey and cartography was extended to the continental shelf.

The change of the final objectives of the seafloor studies corresponds to a fast evolution of the remote sensing technologies and surveying methodologies, which are shared by many other disciplines concerning marine environments (bio-habitat, archaeology, civil protection, etc.). The contemporary presence within ISPRA of "historical memories" and new disciplines might be favourable to go beyond the use of common means of investigation and increase the knowledge of the relationships among different fields of research.

F4-15 Invitato Pezzotta, Federico

10.1474/Epitome.04.0528.Geoitalia2011

THE MINERAL COLLECTING IN ITALY, FROM THE ORIGIN TO THE PRESENT DAYS

PEZZOTTA Federico¹
1 - Museo di Storia Naturale, Milano

Presenter e-mail: fpezzotta@yahoo.com

Key terms: Mineralogical collections; History; Italy

Since the beginning, mineral collecting in Italy has been characterized by a significant historical, cultural and political heterogeneity, and by an extraordinary geo-diversity. This year (2011) Italians celebrate the 150th anniversary of the Unity of Italy; but of course, the roots of mineral collecting date back well before that time, to the courts and noble families belonging to very different countries and dominions that have been in conflict for centuries. In "The History of Mineral Collecting 1530-1799" Wendell Wilson (1994) described the substantial contributions given by Italians to the birth and development of mineral collecting, as we appreciate it today. In particular, in the second half of the 16th century, during the Golden Age of Renaissance, scholars and aristocrats in Italy assembled some of the first great collections of naturalia, including a remarkable number of mineralogical specimens. Throughout the 1600s and up to 1714, under the domination of Spain, the natural collecting history in Italy was influenced by the baroque attitude, as in the rest of Europe. After 1714, the onerous Spanish supremacy ended in Italy, to be replaced by the Austrian presence that fostered the formation of independent states (apart from Lombardy, which was under the direct control of Austria). In the 18th century Europe entered the Period of Enlightenment with a strong scientific impetus. Italy, because of its strong political divisions, did not develop significant industrialization which would have fostered the growth of the middle classes. Therefore, mineral collecting was confined primarily to aristocratic and academic circles. However, from the middle to the end of the 18th century, cultural exchanges with Central European countries were very active, leading to the creation of numerous collections and to the foundation of some historical museums. After the wars and political events associated with the complex Napoleonic episode, beginning in 1815, a veritable political, cultural and scientific ferment took place in Italy, which led to the unification of the country between 1859 and 1861. During this period, universities began to gain a very important role in society, and the development of mineral collecting kept pace with the development of research and scientific knowledge. Collections took on a more systematic and scientific nature. Higher-quality specimens were being collected and new occurrences of varying importance were being discovered. Mineral collecting in Italy during the second half of the 1800s was very extensive and it is interesting to note some examples that at least partially demonstrate how mineral collecting in Italy gradually evolved over the years toward more sophisticated tastes and research of greater quality. This slow but progressive evolution of mineral collecting continued during the 20th century, up to the events that led to the start of the Second World War, which marked the end of an era for mineral collecting in Italy. Mineral collecting began to flourish once again in the country in the second half of the 1960s, but it had inherited little from the pre-war collecting culture.

Through the 1980s, the 1990s and the first decade of the new century, mineral collecting in Italy has undergone a deep transformation, which led to a more demanding form of collecting, involving the refinement of taste and the appreciation of quality as it applies to various specialties. Micromounting, for example, represents a true modern multifaceted experience, strictly tied to the availability of optical and photographic instruments of high quality and ease of use, at an accessible cost.

PIEDMONT'S MINERALOGISTS DURING THE XIX CENTURY

GALLO Lorenzo Mariano¹; COSTA Emanuele²

1 - Museo Regionale di Scienze Naturali di Torino - Sezione di Mineralogia, Petrografia e Geologia

2 - Università degli Studi di Torino, Dipartimento di Scienze Mineralogiche e Petrologiche

Presenter e-mail: lorenzom.gallo@regione.piemonte.it

Key terms: mineralogy; mineralogist; Piedmont

The purpose of the presentation is to describe the contribution to the Italian mineralogy of influential mineralogists operating in Piedmont Region during the XIX century. As highlighted in the paper, the evolution of the mineralogical science in this region is strictly related to the history of the Kingdom of Sardinia (after the French annexion of the Savoy in 1801 and the restoration of 1815) and to the birth of the Italian Kingdom in 1861. From another standpoint, since preeminent mineralogists were professors or assistant professors, there is also a strong connection with the history of two of the most important institutions devoted to the teaching of science and technology: the Royal Turin University and the Technical Institute, which later became the Royal Application School for Engineers and then the Polytechnic School of Turin). Besides it should not be underestimated the influence of the industrial revolution in Piedmont on the mineralogy of the time. In particular, influential mineralogists were involved in the development of the mining sector and in the search of raw materials in Piedmont Region and in the Italian Kingdom, such as Angelo Sismonda (Professor of mineralogy and Director of the Museum of the University of Turin, and author of the first geological map of Savoy, Piedmont and Liguria), Johann Struver (called by Quintino Sella as Assistant at the School for Engineers, whose studies on Traversella mineralogy are still a masterpiece) and Guglielmo Jervis (an English geologist born in Bombay, India, Curator of the Industrial Museum of the Application School in Turin, author of a monumental work about the mineral resources of Italy).

The historical journey suggested by this work starts from one of the earliest mineralogists of the 19th century, Carlo Antonio Napione (1756-1814), artillery officer and author of the first mineralogy textbook written in Italian, and goes on showing the work of several eminent scientists until the end of the century. Along this journey in the history, the reader will meet relevant persons and founders of Museums, Institutions and Collections, such as Carlo Allione (botanic and naturalist, but also collector of mineralogical and geological samples), Etienne Borson (the first Professor of Mineralogy at the University of Turin and author of the First catalogue of the University Museum), Vincenzo Barelli (administrator of the wood and mining collection of the Sardinian Kingdom and publisher of the first catalogue of mineral resources of Piedmont and Sardinia), Angelo Sismonda (pupil of Borson and author of the geological cross section for the realization of the Frejus tunnel), Quintino Sella (expert mineralogist and Geometry Professor before becoming Economist and Minister), Giorgio Spezia (inventor of the hydrothermal method and of the relative device for the growth of synthetic quartz at the beginning of 20th century). Still, the work describes the fervent activity of many other passionate naturalists and mineralogists, who worked not only in Turin but also in the neighboring regions, and contributed to the institution of important museums, through the donation of their precious naturalistic and mineralogical collections to local authorities.

THE MINERAL COLLECTION OF THE ISTITUTO TECNICO INDUSTRIALE DI BIELLA; A WINDOW ON THE SCIENTIFIC ACTIVITY OF QUINTINO SELLA

FERRARIS Cristiano¹

1 - Muséum National d'Histoire Naturelle, Laboratoire de Minéralogie et de Cosmochimie, CP 52, 61 Rue Buffon, 75005 Paris, France

Presenter e-mail: ferraris@mnhn.fr

Key terms: Minerals Collection; Quintino Sella; Samples; Historical Collection

Quintino Sella (QS) collected an impressive number of mineralogical samples through three different paths: personal field sampling, since he started as a student at the Ecole des Mines in Paris, visiting mines in France, Germany and England; donations and trades involving some of the greatest mineralogists of the second half of the XIX century; purchases, often from famous dealers. Following the loss, for war events, of the mineral samples personally donated by scientists to the Politecnico di Torino, the collection kept at the Istituto Tecnico Industriale Quintino Sella (ITIS) of Biella, that was donated in 1909 by the son of QS, Corradino Sella (CS), is likely the only systematic evidence of the mineralogist-collector activity arriving fairly intact to our days, through more than 150 years of vicissitudes. Probably part of this collection was even previously donated by QS, according to a booklet published in 1988 to celebrate the 150th anniversary of the Institute, where the samples are divided as samples from donations of QS and samples and thin sections from donations of CS. After segregation in dusty stores lasted about three decades, as a consequence of the change of educational needs that led to the almost complete abandonment of mineralogy in the Italian high schools, thanks to the interest of the "Opera Pia Sella" of Mosso (Bi) the ITIS's collection is currently undergoing reorganization to be again exhibited in a near future. The collection consists of approximately 4500 samples and its growth during years is witnessed by the original labels that attest exchanges with privates and museums together with acquisitions. An interesting part of the collection concerns the mineralogy of Sarrabus (Sardinia) and was donated by Giovanni Battista Traverso (1881-1909), at that time director of the silver mines of this famous mining district. A manuscript, which lists about 130 samples from the district, is preserved at the "Fondazione Sella" (Bi), but unfortunately a significant number of these samples are now missing for reasons under investigations. Apparently the collection was originally housed at least in 8 cabinets with drawers containing samples arranged according to the classic chemical classification from native elements to silicates, including minerals of organic origin such as amber. Over the time, the collection was definitely altered to be used in part as teaching material. As a consequence, at least for groups of minerals were strongly affected: native elements (many samples disappeared, including diamonds, gold and silver and others such sulphur samples seriously damaged); sulphides and sulphates, now deeply deteriorated by chemical alteration; some halides now severely compromised. Overall, however, the conservation status of the collection is satisfactory. In particular, the original labels - as well as some handwritten notes by QS, CS and their colleagues and friends - are in good conditions. Regardless of their condition, some samples are of great scientific interest because they bear witness of deposits now exhausted or even disappeared, and sometimes they can be considered as rare if not unique items. About 60% of samples come from Italian outcrops. Among these, in addition to the afore-mentioned Sardinian samples, the most important are those from Baveno and Traversella, Val d'Ala, Praborna, Val di Fassa, Tuscany mines including Elba island; The volcanic complexes of Latium and Monte Somma-Vesuvius (including samples collected by Arcangelo Scacchi), Calabria mountains (garnets rarely found in other collections) and rare Sicily localities famous for sulphur, aragonite and celestine are well represented. Among the foreign localities, the collection includes a wide range of species from deposits in Scandinavia, Siberia, Binn and central Europe. Famous American locations (USA; Hidalgo, Mexico, Colombia and Chile) are well represented, while there are only few samples from Asia (Sarawak in Indonesia) and Africa.

CARLO FABRIZIO PARONA (1855-1939): HALF A CENTURY OF GEOLOGY

GROSSI Francesco¹

1 - Dipartimento di Scienze Geologiche, Università degli Studi Roma Tre

Presenter e-mail: fgrossi@uniroma3.it

Key terms: Carlo Fabrizio Parona; Italy; paleontology; applied geology; scientific popularization

Carlo Fabrizio Parona was born in Melegnano in 1855, and was one of the most influential Italian geologists and paleontologists. He received his degree in Natural Science in the Pavia University (1878), then he was taken by Torquato Taramelli as assistant in Geology in the same university, where he remained, under the guidance of his mentor, until 1890. Afterwards he became professor in geology at the University of Torino in 1889, where he held this role for over forty years. In addition to conducting his research, in this long time he was master of several generations of geologists who constituted, thanks to him, a strong school in geology and paleontology. After several years dedicated to Jurassic geology and fossils of Lombardy, the Cretacic deposits became his next specialization, particularly platform shelf facies. But his interest in Earth Science was wide, as testified by an appreciated book about geology of Italy (Parona, 1903), that had a second edition in 1924. Parona was an all accomplished geologist as they used once: those were years in which analytical specialization allowed a huge leap forward in the geological knowledge, without losing the sight of the ultimate goal, i.e. the integration of the results in order to provide the foundations of the geology of Italy, of its evolution and of possible exploitation of its resources.

In the era of colonialism in Africa, Parona was one of the most important scientists working by means of research and explorations to improve agrarian conditions of Libyan territories, as President of "Geo-agrological Commission for Tripolitania", whilst retaining his geological and paleontological point of view. He dedicated several monographs to Piedmont, his adoptive land: "Caratteri ed aspetti geologici del Piemonte" (1922) and "Il Piemonte e i suoi paesaggi" (1935) are books to be mentioned. Likewise, the link with Turin and with the "Accademia delle Scienze" was so strong: the prestigious scientific academy named him as

national member in 1899 and President in 1928. His multifaceted personality allows Parona also to investigate the applied aspects of geology: hydrogeological studies with the aim to pick up drinking water, reports on thermo-mineral sources, projects for railway communications between Turin and Switzerland, in addition to several agrarian applications: contributions that, like those of other geologists of the past, substantially contributed "to make Italy" during the first decades of '900. Besides the academic tasks, he was well aware of the importance to disclose scientific knowledge to the widest possible audience, showing his usual modesty: "Raised in the Stoppani and Taramelli's school, I wasn't strong enough to reach them, celebrated Master, but I tried to follow them, even from afar, disclosing geological knowledge ex cathedra, mean as useful and effective, although more challenging" (Parona, 1935). Carlo Fabrizio Parona died in 1939 in Busto Arsizio: these are the deeply felt words of Federico Sacco, chosen between a lot of colleagues' memories: "I totally appreciated not only the keen scientific mind of Carlo Fabrizio Parona, but also his nobility, the strong integrity of his character and his heart's kindness. But my pen is unable to write worthily of Him (...). Which the scientist, that the Man: great."

120 YEARS OF ITALIAN AND VESUVIUS HISTORY IN THE LAVA MEDALS COLLECTION OF THE OSSERVATORIO VESUVIANO

DE LUCIA Maddalena¹, RUSSO Massimo¹

1 - Istituto Nazionale di Geofisica e Vulcanologia sezione di Napoli | Osservatorio Vesuviano, Italy

Presenter e-mail: maddalena.delucia@ov.ingv.it

Key terms: Museum; Vesuvius; Historical Collection; Malladra; Lava Medals

Lava medals constitute a unique example that links Vesuvian eruptions to history, politics and science. Medals coined in the Vesuvian lava date back to the period in which the state of the volcano was characterized by an open conduit, so that warm lava was still used. This state of activity lasted from 1631 to 1944, a period of time during which effusive or effusive-explosive eruptions frequently occurred, followed by very short periods of rest. The medals were realized through metal molds or punches pinching a small amount of a still molten lava, extracted from lava flows or from the lava lake in the crater, and then dipping it into cold water. This unique industry expanded when volcanic eruptions with significant lava emissions occurred, for the increased availability of material. Furthermore, in periods of intense volcanic activity there was an increasing number of curious and visitors who bought lava medals. Especially for scientific purposes, in the early Nineteenth century collectors and scientists began to gather these unique objects, which were considered as geological specimens, as the medals coined in 1819 and 1820 by Nicola Filomarino duca della Torre, amateur volcanologist. However, he started an intense production of this objects, contributing to make them quite popular at the time.

Over time, lava medals were specifically made by craftsman and used as souvenirs; then, in the first half of the Twentieth century, they assumed a commemorative and in some cases propagandistic value. In addition to medals, vesuvian guides used to make lava objects putting a coin, a medal, a stone or a button in a piece of lava.

The Osservatorio Vesuviano has a unique collection of lava medals coined in Vesuvian lava. It consists of 78 items, dated from 1819 to 1939. Most of them belong to the period between 1920 and 1939, with a peak between 1933 and 1936.

Subjects were extremely varied: emperors, popes, kings, generals, scientists, celebrities, souvenir subjects such as Vesuvius and Italy, mythological, religious and literary characters.

During the Thirties, the purpose for which the medals were made was mostly the celebration of significant events in the history of Italy, as the birth of a king's son, the proclamation of the empire, military conquests and victories and sometimes, the exaltation of dictators like Benito Mussolini or Adolf Hitler. On the back of these medallions the names of the "artists" who had created them were sometimes engraved, such as Giovanni Preti and Salvatore Madonna.

Thirty-eight lava medals of the Osservatorio Vesuviano collection had belonged to Alessandro Malladra, who made a donation of his geological specimens to the institute where he worked for many years. In fact, he was Director at the Osservatorio Vesuviano from 1927 to 1935.

He came from Turin and was a teacher of natural sciences, well-known because he followed the construction of the Sempione tunnel as consultant geologist of the company. The encounter in Milan in 1910 with Giuseppe Mercalli was crucial for the progress of his career and changed his life. In 1911 Malladra left his homeland and followed Mercalli, becoming his assistant at the Osservatorio Vesuviano, where he studied the Vesuvius with the same passion he had for the Alps.

Meticulous and precise, Malladra systematically collected geological samples and minerals produced by Vesuvius, making them available to other scholars. He kept an extensive correspondence with scientists from all over the world and was secretary of several prestigious scientific academies.

He can be regarded as an example of that kind of scientists who have contributed greatly to the geological knowledge of the Italian territory and the dissemination of this knowledge among non-experts.

THE AUSTRALPINE-PENNINIC COLLISIONAL WEDGE IN THE INTERNAL NORTH-WESTERN ALPS: STRUCTURAL SETTING AND PALEOSTRUCTURAL RECONSTRUCTION.

DAL PIAZ Giorgio¹, MONOPOLI Bruno², SCHIAVO Alessio²

1 - Accademia delle Scienze di Torino

2 - LTS Padova

Presenter e-mail: giorgio.dalpia@unipd.it

Key terms: Western Alps; Austroalpine; Penninic; subduction complex

Most of the Cretaceous-Eocene subduction complex of the collisional wedge which is exhumed in the Aosta valley has been mapped ex novo for the CARG Project. Focusing on the upper part of the wedge, it is a tectonic multilayer of continental (Austroalpine) and oceanic (Piedmont) nappes that, as a whole, override the Penninic Monte Rosa-Gran Paradiso nappes, derived from the distal European continental margin. The Austroalpine includes the external Dent Blanche nappe (s.l.) and the internal Sesia-Lanzo zone. Argand's Dent Blanche is no more a recumbent fold-nappe but a set of independent thrust units, represented by: i) the Dent Blanche (s.s.)-Mt Mary-Pillonet thrust system (upper Austroalpine outliers); ii) a number of eclogitic slices (lower Austroalpine outliers) located north (Chatillon, Etirol-Levaz, Grun-Vollon) and south (Mt Emilius, Glacier-Rafray, Pontay, Santanel-Verres-Tilly, Tour Ponton, Acque Rosse) of the northward-dipping Aosta-Ranzola normal fault, i.e. in the hanging-wall and foot-wall of this tectonic line. Vollon and Tilly are new slices found during the geological survey, whereas the larger Verres slice, previously connected to the frontal part (Gneiss minuti) of the Sesia-Lanzo zone, belongs to the eclogitic outliers and is linked to the Santanel slice. Likewise, the Piedmont zone is structurally composite, including: i) blueschist facies (relics) ophiolitic units and minor continental cover sheets (Pantherot-Cime Bianche), both grouped within the Combin zone; ii) the underlying oceanic units of the Zermatt-Saas zone, marked by a typical eclogitic and ultra-high-P imprint. Contrasting tectono-metamorphic features allow the recognition of two couples of Austroalpine-Piedmont nappes, concerning their structural position, P-T conditions, timing of subduction metamorphism and inferred paleostructural location within Alpine Tethys, as follows: i) the upper group includes the eclogite-free Dent Blanche-Mt Mary-Pillonet thrust system and underlying Combin zone, both displaying a relatively high-P imprint (sodic amphiboles and high-Si white micas), dated as Late Cretaceous (74-73 Ma) in the Pilonet klippe; ii) the eclogitic lower group includes the lower Austroalpine outliers and the underlying or interbedded Zermatt-Saas units: the eclogitic imprint in these continental and oceanic units is dated as Early-Mid Eocene (50-44 Ma), opposite to the Late Cretaceous (80-69 Ma) in the Eclogitic micaschists of the Sesia-Lanzo zone. The underlying Monte Rosa and Gran Paradiso nappes display a syn-collisional eclogitic imprint of Eocene age (44-43 Ma). Ribbon continents, extensional allochthons and ocean-continent transition have been recently proposed instead of classic models of lithospheric microcontinents alternating with oceanic branches. The Dent Blanche-Mt Mary-Pillonet thrust system and Sesia-Lanzo zone are thought to be derived from a set of extensional allochthons probably linked to the Adriatic passive continental margin. The ophiolitic Combin units are coming from the internal edge of the Piedmont ocean and from ongoing subduction were accreted to the Dent Blanche-Mt Mary-Pillonet thrust system. On the contrary, the eclogitic lower Austroalpine outliers probably originated from one or more intra-oceanic allochthons (ocean-continent transition) that, during the Eocene, entered the subduction zone together with the Zermatt-Saas oceanic fragments, 30-25 Ma later than the upper group of nappes. The chronological gap may be filled with the ophiolitic units of the Combin zone (free of continental allochthons) and larger sectors of the Piedmont-Ligurian ocean ultimately lost into the mantle. See presentation for referencing.

EXHUMATION OF HIGH-PRESSURE ROCKS WITHOUT EROSION: INSIGHT FROM THE EOCENE WESTERN ALPS

MALUSÀ Marco Giovanni¹, FACCENNA Claudio², GARZANTI Eduardo¹, POLINO Riccardo³

1 - Università di Milano-Bicocca

2 - Università di Roma Tre

3 - CNR-IGG Torino

Presenter e-mail: marco.malusa@unimib.it

Key terms: tectonic exhumation; erosional unroofing; high-pressure metamorphism; plate divergence; sedimentary basins

Exhumation of high-pressure rocks has long remained a controversial issue in the Earth sciences. Here, we analyze the tectono-metamorphic, stratigraphic and plate-motion constraints from the Western Alps region, providing new insights on exhumation mechanisms and tectonic evolution during the earliest orogenic stages. Eocene eclogites of the Western Alps form a 20-25 km wide belt on the upper-plate side of the orogen (Eclogite belt), exposed beneath extensional shear zones at the rear of a lower-pressure accretionary wedge. Units of the Eclogite belt show the youngest peak-pressure assemblages within the subduction zone, and experienced superfast tectonic exhumation since 45-40 Ma. The role of erosion was negligible during the whole of this stage. Eocene foreland basins remained starved, and the massive arrival of axial-belt detritus began well after exhumation was completed. Tectonic reconstructions based on fixed-boundaries exhumation models (e.g. channel flow), and/or implying fast erosion at the surface (e.g. slab breakoff), are thus not consistent with geological evidence. In the lack of erosion, exhumation through the overburden requires divergence within the subduction zone. We demonstrate that this was not attained by rollback of the lower plate (Europe), but was instead attained by NNEward motion of the upper plate (Adria) away from the Western Alps trench. Such motion induced localized extension within the weak portion of the upper plate, at the rear of the accretionary wedge, and allowed tectonic emplacement of the Eclogite belt in the upper crust at rates much faster than subduction rates. Tectonic exhumation ceased in the Oligocene, when oblique-divergence along the Western Alps traverse changed into oblique-convergence. The onset of slow erosional unroofing was synchronously recorded by pressure-temperature paths in all major tectonic units of the Western Alps, and by arrival of orogenic detritus in sedimentary basins. This work demonstrates that divergence between upper plate and trench is a viable mechanism to exhume large and coherent eclogite units in continental subduction zones, which may be applied to other eclogite belts showing a similar exhumational record.

2 - IPGS-EOST, Université de Strasbourg, France

Presenter e-mail: beltrandomarco@hotmail.com

Key terms: orogeny; rifting; distal margins; subduction; exhumation

The type of lithosphere reaching subduction zones has profound implications for the evolution of orogenic belts and for mass balance calculations in subduction zones. Numerical and conceptual models of subduction generally distinguish between only two types of lithosphere: (1) oceanic and (2) continental, with the latter consisting of subcontinental mantle and a 20-30 km thick crust, overlain by pre-, syn- and post-rift sediments. However, recent studies of present day rifted margins provided compelling evidence of the existence of a third type of transitional lithosphere between typical 'oceanic' and 'continental' lithosphere. Such domains, which can be up to 200 km wide, comprise the distal continental margins and the so-called Ocean-Continent Transition Zones (OCTZ). The recognition of such transitional domains in (U)HP orogenic belts, such as the Western Alps, has profound implications for understanding the dynamics of orogens and the processes of burial and exhumation of (U)HP rocks.

Here we present two examples from the Zermatt-Saas Zone, which is part of the Eclogitic Piemonte Units, and from the Sesia Zone. The Zermatt-Saas Zone consists of abundant serpentinitized mantle, intruded by Jurassic gabbros and locally overlain by slivers of continental basement rocks and by syn- to post-rift sediments. This lithostratigraphic association has generally been ascribed to complex orogen dynamics. Our study on zircons from Permian plutonic rocks of the Etirol-Levaz continental basement slice shows that a distinctive phase of zircon growth occurred at ca. 170-160 Ma. High U/Th ratios and zoning patterns suggest that zircons grew as a result of melt infiltration related to the intrusion of mafic magmas, also dated at ca. 170-160 Ma, in the underlying serpentinites. Therefore, the continental basement slices and the oceanic basement rocks were already juxtaposed in the Jurassic and they were probably part of an Ocean-Continent Transition Zone (OCTZ). Alpine tectonics resulted only in minor reworking of the Jurassic contacts, generally preserving the original geometry.

In the External Sesia Zone, Palaeozoic continental basement is regionally overlain by a thin layer of Mn-bearing quartzite, which is interpreted as the metamorphic equivalent of early post-rift Mn-rich radiolarian cherts of Middle Jurassic age. A typical gneiss-micaschist layered sequence up to 20 meter thick, lacking any evidence of pre-Alpine metamorphism, is often found between the Palaeozoic continental basement and the Mn-bearing quartzite. A similar lithostratigraphic association, with Palaeozoic continental basement overlain by syn-rift clastic sediments and post-rift Mn-bearing cherts and calc-schists, is typically found in distal thinned margins, such as those preserved in the Err nappe in the Eastern Alps. In those circumstances, continental basement is exposed at the seafloor during rifting at the footwall of low angle detachment faults.

The partial preservation on a regional scale of the rift-related relationships between rock units that underwent subduction to (U)HP conditions indicates that (1) the association of serpentinites and continental basement does not necessarily derive from chaotic counter-flow in a subduction channel, but may also be an inherited feature from the rifting history, (2) the lack of pre-rift sediments at the interface between continental basement and syn- to post-rift sediments is not necessarily a result of orogeny-related tectonic excision and (3) the process of tectonic burial and exhumation is not chaotic but large coherent blocks behave relatively rigidly, while well-defined movement zones accommodate most of the deformation.

10.1474/Epitome.04.0536.Geoitalia2011

NORTHERN LATIUM (CENTRAL ITALY) CRUSTAL SETTING FROM RECEIVER FUNCTIONS ANALYSIS: HINTS FOR THE COMPREHENSION OF TYRRHENIAN POST-COLLISIONAL BACK-ARC EVOLUTION

BUTTINELLI Mauro¹, CHIARABBA Claudio¹, ANSELMIO Mario¹, BIANCHI Irene¹, DE RITA Donatella², QUATTROCCHI Fedora¹

¹ - INGV

² - Uniroma3-Geology dept

Presenter e-mail: mauro.buttinelli@ingv.it

Key terms: Receiver Functions (RFs); Tyrrhenian extension; back-arc; Low Velocity Layer; Tolfa Domes Complex

A Receiver Functions (RFs) study has been carried out to unravel the crustal architecture of Northern Latium area (Italy) down to the Moho, a part of eastern Tyrrhenian Sea margin which deep setting have been not univocally addressed by previous studies.

Work was based on the analysis of teleseismic data recorded by a network of temporary and permanent stations deployed in that area.

Crustal structures have been investigated via harmonic analysis performed on computed and observed RFs, yielding the imaging of the 3D Vs characteristics beneath each receiver. This allowed to reveal both dipping interfaces and anisotropic layers.

What we observe is a generally thinned Tyrrhenian crust made of an upper sedimentary cover lying on a very fast anisotropic layer related to a metamorphic complex. Thinning and shallowing of the modeled features is more pronounced in north-western sectors.

Upper crust layers are located on top of a mid-crustal low Vs strongly anisotropic layer. In our model this is a mid-crustal inherited compressional shear zone, reactivated by the Tyrrhenian extension, which caused the decoupling of upper and lower crust.

This regional feature played a major role during the evolution of this portion of Tyrrhenian margin, also promoting and driving the development of the observed shallow extensional structures as syn and post-rift asymmetric basins, low angle normal faults, and the occurrences of early Tyrrhenian magmatism, characterized by volcanic intrusions.

In particular for the Tolfa Domes Complex, located in the study area, intrusions are represented by lower crust partial anatexis materials which slightly interacted with low mantle-derived fluids. We hypothesize that the intrusive volcanism of this southernmost part of the Tuscan Magmatic Province could be linked to the observed complex crustal arrangement and to its tectonic history related to Apennine and Tyrrhenian sea evolution.

HYPER-EXTENDED RIFTED MARGIN IN THE TYRRHENIAN SEA, UPPER PLATE OF THE IONIAN SUBDUCTION ZONE

PEPE Fabrizio¹, BERTOTTI Giovanni², SULLI Attilio¹

¹ - Dipartimento di Scienze della Terra e del Mare - Università di Palermo (Italy)

² - Civil Engineering and Geosciences - Dept. Geotechnology - Delft (Netherlands)

Presenter e-mail: fapepe@unipa.it

Key terms: Southern Tyrrhenian Sea; Marsili Basin; Back-arc basin process; Continent-Ocean Transition Zone; Subduction zone processes

The Tyrrhenian Sea is a Miocene to Present back-arc basin developed in the upper plate of the Ionian subduction zone. Refraction seismic data indicate that the central sector of the Marsili Basin is a zone of thin crust ~7 km thick compatible with its oceanic origin (Steinmetz et al., 1983). Conventional models rather define a Continent-Ocean Transition (COT) with normal oceanic crust (i.e. Finetti et al., 2005). This does not seem to be the case for the whole Tyrrhenian Basin. Serpentinized peridotites, emplaced during Pliocene, have been drilled at ODP Site 651 (Sartori et al. 2004).

The W Calabria segment of the Tyrrhenian continental margin is peculiar as seismic data has excluded the presence of Miocene to Recent significant normal faults (Pepe et al., 2010). There is therefore a major question as to which structures were able to cause thinning and what does the oceanic domain look like. A possible answer is derived from the high-penetration Crop-M27 seismic line acquired along the COT of the W Calabria margin and the Marsili ocean itself.

The most surprising result is the discovery of tilted fault-blocks located within the area Marsili Basin considered as floored by oceanic crust. The blocks are generally 2-4 km wide and are composed of an acoustic basement which corresponds to the top of the Kabilian-Calabrian units and of a sedimentary cover unit that on the basis of their geometry we consider as pre-rift. The overall style of the block is comparable to dominos. The deposits filling the depressions between blocks are partly syn-rift and, more dominant, post-rift. With a very few exceptions, the infill completely smoothes out pre-existing topography and explain the very flat sea floor in the area surrounding the Marsili Basin. Its age was estimated as young as 0.45 Ma (Kastens et al., 1988).

A conceptual model for the evolution of the Marsili Basin was reconstructed along a NW-SE cross-section using seismic data and seafloor morphology (Marani & Gamberi, 2004).

Extensional tectonics during the Early Pliocene was active in the area of the future Vavilov Basin while, towards the SE, tectonics is dominated by contraction with thrust and reverse faulting.

Since ~4.2 Ma, extensional tectonics jump in the area of the future Marsili Basin. Extension tectonics affected a sector of the Kabilian-Calabrian chain and resulting in the formation of normal faults, mostly trending NNE-SSW and dipping to the NNW. The early stage of emplacement of oceanic crust was dated at ~1.8-2 Ma (Kastens et al., 1988). Extensional tectonics persisted until ~0.5 Ma resulting in the formation of ~80 km of oceanic crust and ~30 km of Continent Ocean Transition Zone with a thickness ranging from ~10 to less than ~7 km. Normal faults were active before and after crustal separation. Extensional tectonics ended ~0.5 Ma. However, this was not the end of the overall evolution of the Marsili Basin because from ~0.78 Ma to ~0.3Ma the Marsili seamount formed (i.e. Cocchi et al., 2009). The position of this volcano is not random and is probably controlled by deep transition between continental and oceanic lithosphere.

Key terms: VITRINITE REFLECTANCE; CLAY MINERALOGY; APATITE FISSION TRACKS; THERMAL MODELLING; SICILY

The reconstruction of burial and exhumation history of sedimentary successions provides important time-temperature constraints to orogen dynamics, when integrated with the structural and stratigraphic records. The maximum paleo-temperatures and the exhumation rates of sedimentary successions cropping out in Eastern Sicily, obtained by means of paleo-thermal and thermo-chronological datasets and thermal modeling, is the object of this contribution.

In detail, the results concerning four main tectonic domains of the Apenninic-Maghrebian chain in the Eastern Sicily are presented. These domains are: the Peloritani Mts. Units in the internal zone of the chain; the Sicilide Units in the accretionary prism; the tectonic units in which the Numidian Flysch is deformed and the Mt. Judica Unit in the external zone of the chain.

In the Peloritani Mts., the integration of vitrinite reflectance and mixed-layered clay minerals with apatite fission-track and (U-Th)/He ages allows to define the paleo-geothermal gradient of the Stilo-Capo d'Orlando Fm. basin in Oligocene-Miocene times, to constrain its burial evolution and discriminate between areas where it has been affected by sedimentary and/or tectonic load. In the southern area of the basin, organic and inorganic thermal parameters increase as function of depth suggesting that their evolution is only ruled by sedimentary burial. They recorded a decrease in paleo-geothermal gradient values which marked the evolution of the basin from a fore-arc to a thrust-top setting during the convergence-collision process between the Calabria-Peloritani Arc and the African plate. Differently, in the northern edge of the basin, vitrinite reflectance values (ca.0.45-0.6%) indicate that tectonic burial occurred in this area related to a late Langhian-early Serravallian out-of-sequence thrusting.

In double-verging accretionary wedge made up of part of the Sicilide Complex (Mt. Soro, Troina, far-travelled Sicilide Units) and Antisicilide Unit, the integration of thermal indicators allowed us to distinguish portions of the Sicilide-Antisicilide (SA) accretionary wedge with different evolution. We recognised a warmer core -made up of Mt. Soro and Troina Units of the Sicilide Complex- and colder units: - back-thrusted toward the hinterland (Antisicilide Unit) and gravity-mobilised toward the Hyblean Plateau (far-travelled Sicilide Units).

In detail, in the Mt. Soro and Troina Units, apatite fission-track data were partially to totally annealed during wedge accretion and the subsequent exhumation occurred mainly in Burdigalian times. Apatite fission-track data on the Antisicilide Unit confirm low paleo-temperature values. Thus far-travelled Sicilide and Antisicilide Units were probably at higher structural levels in the original accretionary prism and were re-mobilised since late Aquitanian-Burdigalian times. For the Numidian Flysch thrust stack, an increasing level of diagenesis from the uppermost to the lowermost unit has been observed, never exceeding the mature stage of hydrocarbon generation. In the Mt. Judica area, the integration of X-ray diffraction (XRD) data concerning the illite content in mixed layer illite-smectite with data derived from Fourier Transform Infrared spectroscopy (FTIR) on H-rich organic matter allowed to constrain the burial-exhumation path of the Mt. Judica sedimentary succession cropping out in tectonic window in Eastern Sicily. Thermal constraints show that the Mt. Judica succession experienced temperatures between 100-130 °C in late diagenetic conditions with a general depth-dependent thermal maturity signature. As a whole, the Mt. Judica succession experienced maximum tectonic burial (ranging between 2.4 and 3.2 km) during the Middle Miocene as a result of the emplacement of the allochthonous Units atop it. The subsequent breaching phase and erosion during Pliocene times ruled out the Mt. Judica exhumation. This last tectonic phase did not overprint thermal maturity.

DEFORMATION OF MESSINIAN EVAPORITES AND THE STRUCTURE OF "COBBLESTONE" MORPHOLOGY IN THE CENTRAL MEDITERRANEAN

Key terms: Messinian evaporites; deformation structures; cobblestone morphology; Ionian Sea; central Sicily

Evaporite formations can exert a strong control on the distribution and geometry of deformation structures in sedimentary basins (e.g. Jackson et al. 1995). In compressional tectonic settings, numerous studies interpret the role of evaporite formation, especially those formed principally of halite, as acting as regional detachment surfaces. In these settings halite (especially wet halite) is assumed to behave as a mechanically weak horizon, in accordance with its measured shear strength at geological strain rates compared to other sedimentary rocks (e.g. Jackson & Vendeville 1994). However, other evaporites show less extreme behaviour. While gypsum-anhydrite can show transient weakening (e.g. Olgaard et al. 1995), due to dehydration, in general it is stronger than poorly lithified sedimentary rocks. As many basins contain spatially-varying evaporitic assemblages natural zones of deformation might be expected to display significant variability in structural geometry and evolution. The purpose of our work is to investigate this proposition with respect to the development of basin-floor tectonic morphology imaged seismically in the Mediterranean Sea. This so-called "cobblestone" morphology is generally correlated with the top of Messinian-age evaporites (e.g. Rossi & Sartori 1981). These in turn show regional variations in composition. However, well-calibration of the seismic data is poor because of the technical challenges of research drilling through evaporite formations. Consequently we use outcrop data of broadly age-equivalent strata on Sicily to inform interpretations of seismic data acquired from the floor of the adjacent Ionian Sea.

CENOZOIC IGNEOUS ACTIVITY IN THE CENTRAL-WESTERN MEDITERRANEAN

LUSTRINO Michele¹
 1 - Università di Roma La Sapienza

Presenter e-mail: michele.lustrino@uniroma1.it

Key terms: Petrology; Geodynamics; Tectonics; Mediterranean; Geochemistry

Compared to classic collisional settings, the central-western Mediterranean area shows a range of unusual geological and magmatological features. These include: a) the rapid formation of extensional basins in an overall compressional setting related to Africa-Europe convergence; b) centrifugal wave of both compressive and extensional tectonics starting from a 'pivotal' region around the Gulf of Lyon; c) the development of concomitant Cenozoic subduction zones with different subduction and tectonic transport directions; d) subduction 'inversion' events (e.g., possibly along the present-day Maghrebian coast, in southern France and in northern Sicily, previously at the southern paleo-European margin); e) a repeated temporal pattern whereby subduction-related magmatic activity gives way to magmas of intra-plate geochemical type; f) the late-stage appearance of magmas with collision-related 'exotic' (potassic to ultrapotassic) compositions, generally absent from simple subduction settings; g) the relative scarcity of typical calcalkaline magmas along the

Italian peninsula; h) the absence of igneous activity where it might well be expected (e.g., above the hanging-wall of the Late Cretaceous-Eocene Adria-Europe subduction system in the Alps); i) voluminous production of subduction-related magmas coeval with extensional tectonic regimes (e.g., during Oligo-Miocene Sardinian Trough formation) or in the foreland of the Apennines; j) the overall geochemical and trace element similarities of "anorogenic"-type magmas, despite to the large temporal range of magma production (>70 Ma), the large area and the complex and variable tectonic evolution of the single districts. In such geologically complex areas, much care must be devoted in considering geochemistry of igneous rocks as the smoking gun for or against a given geological process.

Key terms: Petrology; Geochemistry; Geodynamics; Eastern Mediterranean

Subduction-related mantle derived melts in Mediterranean regions display large compositional variations. Focusing on mafic Tertiary plutonic and volcanic products cropping out on Eastern Mediterranean (Dinarides, Hellenides and Western Anatolia) and using major and incompatible trace elements as proxy to get insights on metasomatic events, it is shown that mafic melts ranging from calc-alkaline to shoshonitic and ultrapotassic are ubiquitous. This indicates the coeval occurrence of mantle derived melts with strongly different enrichments of incompatible elements and suggest that a heterogeneous mantle, able to generate such a rich compositional variability of melts, existed during Tertiary in the area.

The main question arises as to what processes may generate such an inhomogeneous mantle wedge. Numerical simulations of infiltration of metasomatic fluids into a lithospheric mantle wedge have been performed. We consider a fractured lithospheric mantle wedge in which metasomatic fluids, released by dehydration of the oceanic slab, infiltrate. For sake of simplicity we consider that fluids are constituted by only one "metasomatic agent" (e.g. K₂O). The fracturing of the mantle is assumed to be random. We also assume that fractures are always saturated with the metasomatic fluids and that metasomatism is developed by diffusion of such fluids from fractures to the surrounding mantle. Results show that the efficiency of the process is directly proportional to the density of fractures and this process resulted in coexisting portions of mantle that suffer metasomatism at very variable degrees, leading to a "leopard-skin" like mantle. Partial melting of such a heterogeneous mantle wedge is able to produce mafic melts with highly variable degree of enrichment of incompatible elements.

In the studied area two mantle source compositions can be considered just as two extreme end-members occurring in a mantle wedge able to generate melts spanning all intermediate potassium compositions. The first end-member can be interpreted to be derived by partial melting processes of a strongly metasomatized mantle source where K-rich phases, such as phlogopite, played a key role. The low contents of Al, Na, and Ca, and the high concentrations of compatible elements argue in favour of a restitic peridotitic source. The second mantle end-member shows higher Al, Na, and Ca contents, and lower contents of compatible elements, suggesting a derivation from a fertile metasomatized lherzolitic mantle source. On the basis of these considerations we suggest the presence, during Tertiary, of a metasomatized "leopard-skin" mantle wedge with high variable chemical compositions the partial melting of which may explain the wide compositional spectrum of mafic magmas in Eastern Mediterranean.

Mantle metasomatism and magmatism can be attributed to the complex geodynamic evolution of the area. We suggest that two subduction events metasomatized the same lithospheric mantle wedge from Early Jurassic to Tertiary in the Dinarides and Hellenides areas. In the Hellenides and South parts of the Dinarides, metasomatism was originated by fluids and oceanic sediments, whereas in the Northern part of Dinarides metasomatism was originated also by continental crust. There are systematic differences in the geodynamic evolution of Hellenides and Western Anatolia, probably associated to the presence of an asthenospheric mantle wedge, although metasomatism seems to be again linked to fluids and oceanic sediments. Partial melting of such heterogeneous mantle wedges originated mafic magmas, strongly different in geochemical characteristics, found in the studied areas.

THE WEST MEDITERRANEAN/TYRRHENIAN SINCE THE OLILOCENE: POST-COLLISION DEVELOPMENT OF CALC-ALKALINE VOLCANISM AND BASIN FORMATION

SAVELLI Carlo¹
 1 - CNR - ISMAR (MARINE GEOLOGY)

Presenter e-mail: CARLO.SAVELLI@BO.ISMAR.CNR.IT

Key terms: calc-alkaline magmas; lithosphere extension; seafloor-spreading; subduction; post-collision evolution

Exam of the spatial and temporal features of post-collision calc-alkaline (orogenic) magmatism and episodic sea-floor spreading in the West Mediterranean/Tyrrhenian (WMT) might ascertain whether NW-directed subduction was initiated in the Oligocene or afterwards. Recognizing whether and how the pre-lateMiocene tectono-magmatic situation was different from the late Miocene - Recent might suggest an alternative to the commonly accepted concept of long-lived concomitance of orogenic volcanism and slab roll-back. A deep slab beneath the Tyrrhenian Sea was associated to the spreading events of the late Miocene (ca. 8 to 6 Ma; Vavilov basin) and late Pliocene (ca. 1.9 to 1.6 Ma; Marsili basin) which were characterized by absence or scarcity of peri-basinal volcanism. Post 1.2 Ma calc-alkaline and K-rich volcanics extending from the Aeolian islands and Vesuvius to the "Roman Province" and southern Tuscany (i.e. the Tyrrhenian active margin above the deep slab) showed small across-strike extent (ca. 100 km like that of volcanic arcs). By contrast, large across-strike extent (ca. 700 km, like the continental wide-rifts)

characterized the peak of silicic and tholeiitic volcanism and the continental lithosphere extension which occurred in Burdigalian (ca. 20 to 16 Ma) time along with sea-floor spreading of the Sardinian-Provençal (Hercynian European Plate) and north Algerian basins (western portion of Mediterranean Alpine Lithosphere - MAL). Such spreading and extension caused most likely the Burdigalian start of NW subduction, the inversion from upper to lower plate setting of the "north African" plate system and shift of the shortening mode from the MAL back-thrusting to the front-thrusting of the nascent Apennines-Maghreb belt. This tectonic inversion occurred after the Oligocene to Aquitanian (ca. 33/32 to 20 Ma) magmatism of silicic character associated with continental lithosphere thinning and back-thrust shortening (MAL). Also the Alps (s.s.) saw the Oligocene stop of shortening of the front thrusts. Generation of calc-alkaline magmas and lithosphere thinning of the Oligocene Alps were supplanted by early Miocene resumption of thrust shortening and SE subduction in the absence of magmatism. In the WMT post-Burdigalian to pre-late Miocene (ca. 16 to 8 Ma) orogenic volcanism was associated to shallow NW subduction. That pre-late Miocene calc-alkaline magmas were generated presumably by "lost" volcanoes of the eastern portion of MAL (the future Tyrrhenian Sea) is suggested by the large occurrence of pre-late Miocene allochthonous volcanoclastics in the Apennines. These rocks of calc-alkaline affinity are here studied jointly with the in-situ magmatics for the first time. This is in line with some authors' suggestions that the rocks and their "lost" emission centres were originally located in the Tyrrhenian segment of MAL. The source location of these rocks lacking of the corresponding emission bodies is a much debated dilemma. However, a solution of the source problem is linked to the identification of the major event of tectonic inversion that caused presumably the down-thrusting and burial of the emission centres as the corresponding volcanoclastics (past topographic "lows") were uplifted and preserved in the Apennine thrusts. The appropriate event of tectonic inversion might be the shift from upper to lower plate setting of the "north African" plate system which occurred in the Burdigalian. The peri-basinal abundance vs absence/scarcity of calc-alkaline magmas during sea-floor spreading, and the broad vs narrow across-strike extent of such magmas reflect significant changes of subducted lithosphere development in Burdigalian and late Miocene time which modify the concept of uniform slab-pull and concomitance of calc-alkaline volcanism and subduction. Eastward flow of uprising asthenosphere was probably linked to the WMT tectono-magmatic evolution.

Presenter e-mail: ccaricchi@uniroma3.it

Key terms: NORTHERN APENNINES; TUSCAN NAPPE; VITRINITE REFLECTANCE; PALEOMAGNETISM

Paleogeothermal and paleomagnetic analyses have been performed on the sedimentary sequences of the external area of the Tuscan Nappe (Northern Apennines), in order to give new constraints on the burial and tectonic history of this portion of the chain. In particular, this study can provide pieces of information on both the structural style and the timing of the emplacement of the Tuscan Nappe (Tuscan domain) onto the internal portion of the Marnoso Arenacea foredeep basin (in the more external Umbrian domain).

The Tuscan Nappe is made of the Scaglia Toscana (Eocene) and the Macigno (Oligocene-Lower Miocene) formations. The former consists of mudstones and wackestones of continental platform ramp; the latter consists of siliciclastic turbidites, deposited into foredeep basin during the chain building.

Paleogeothermal analyses have been focused on the Macigno Formation to derive values of maximum tectonic and/or sedimentary burial and to reconstruct the geometry of the foredeep basin and its tectonic evolution. Organic matter optical analysis dispersed on sediments (vitrinite reflectance, Ro%) displays indigenous vitrinite with reflectance values between 0.6 and 0.8% in the mature stage of hydrocarbon generation. These data suggest that sedimentary succession underwent tectono-sedimentary loads in the order of a few kilometers.

Paleomagnetism has been used to investigate both the Scaglia Toscana and the Macigno Formations in order to better define the deformational pattern and to reconstruct the rotational history of this sector of the chain. The Anisotropy of Magnetic Susceptibility (AMS) shows a primary sedimentary magnetic fabric, partially overprinted by a tectonic fabric. The magnetic fabric and in particular the NW-SE oriented magnetic lineation suggests a SW-NE regional compression. Paleomagnetic data indicate a counterclockwise rotation, according to regional trend of the Northern Apennines. Tectonic rotations may reach 120° (in the Scaglia Toscana Formation), values recorded for the first time in sediments of this age. Data from this study can be used as robust constraints for the understanding of the Northern Apennines evolution in the framework of the Western Mediterranean area.

Presenter e-mail: mauro.buttinelli@ingv.it

Key terms: Tyrrhenian extensional regime; stepward migration; Northern Latium; seismic data; structural interpretation

A revision of the available seismic reflection survey in the off-shore part of the northern Latium (central Italy) has been accomplished to better

understand the shallow structural architecture of the area.

The general stratigraphy is well constrained by an off-shore deep well, a discrete amount of deep wells in the on-shore part and by a voluminous bibliography. The stratigraphic succession of the area could be divided in four main groups of units, from top to bottom: Plio-Pleistocene post-orogenic marine deposits, Cretaceous-Oligocene sub-Liguride flyschoid units, Jurassic Tuscan Nappe mainly calcareous deposits (which also comprehends Triassic evaporitic formation) and a deep basement probably belonging to metamorphic units.

Seismic reflection data analysis show that this area was affected by at least two deformational phases. After the deposition of the Tuscan Nappe sedimentary units, the area underwent: i) an initial compressional phase associated to the early Apennine chain build up, with formation of compressional features as regional thrusts, back-thrusts and fold structures (within a compressive wedge and foredeep system development). These structures are clearly visible in the deep Tuscan Nappe and sub-Liguride units setting; ii) an extensional phase related to the spreading of the Tyrrhenian Sea, probably started in the late Miocene times. This caused the formation of several small and narrow graben and asymmetric half-graben basins, with NW-SE and NE-SW direction of elongation, which bases are defined by a regional unconformity surface on top of the pre-deformed basement. The sedimentation in there is characterized by the trasgressive deposition of late Miocene and Plio-Pleistocene conglomeratic-to-clayey units, separated each other by several unconformity surfaces. This architecture is similar to that already observed in the on-shore grabens and half-grabens basins, closer to this area.

The reconstruction of the horizons related to the passage between the post-orogenic sedimentary units, focusing on the progressive activation and de-activation of normal faults which affected this layers, make us able to track the stepward migration of Tyrrhenian extensional regime from western to eastern sector. Normal faults activity can be clearly followed from late Miocene when this interested the central part of the study area, while during Plio-Pleistocene it moved stepwise toward eastern sector until late Pliocene, when the area became almost stable and the extension migrated in the present on-shore areas. This process occurred in association with the formation of Tyrrhenian ocean, characterized by a first development of syn-rift basins in a general low stretching rate regime, and followed by post-rift sequences in a general high subsidence rate regime, especially for south-western sectors.

THE DEEP STRUCTURAL SETTING OF CENTRAL SICILY BASED ON SEISMIC REFLECTION DATA. PRELIMINARY RESULTS.

ALBANESE Cinzia¹, SULLI Attilio¹

1 - Dip. Scienze della Terra e del Mare (DiSTeM), Università di Palermo.

Presenter e-mail: cinzia.albanese@unipa.it

Key terms: central Sicily; seismic reflection profiles; Sicilian fold-and-thrust belt; structural style

Deep seismic reflection profiles covering the northern sector of central Sicily have been interpreted to shed light on a segment of the Sicilian-Maghrebian fold-and-thrust belt. The study area connects the widely studied central-western Sicily, characterized by a well exposed carbonate to terrigenous meso-cenozoic collisional complex (Catalano et al., 2000) with the eastern Sicily, where the meso-cenozoic tectonic pile is buried under a thick sequence of Neogene terrigenous covers overlying a late Cretaceous-Early Miocene pelagic succession (Bello et al., 2000).

The interpreted seismic lines cross the eastern sector of the Madonie Mt., from the northern Sicily coast to the northern edge of the Caltanissetta through. This sector is well constrained by several exploration wells: more than 10 wells were used to calibrate the seismic units, while field data have been used to correlate outcropping and buried bodies. At depth, the recently acquired SiRiPro (Sismica a Riflessione Profonda) profile, located in the western adjacencies, give insight about characteristics, extent and geometries of the deepest structural layers as well as their relationships with the related crustal segment (Accaino et al., 2010).

Results arisen from this integrated analysis have revealed the occurrence of the following structural layers:

° A strongly deformed uppermost layer, identified throughout the study area as a package of medium to high frequency reflectors reaching, locally, a thickness of about 1.8 s TWT. Field and well data ascribed this body to the Numidian Flysch (Oligo-Miocene) alternated and/or replaced by Varicoloured clays (Eocene?);

° A 1.3-1.5 s TWT thick body of medium to high amplitude reflectors bounded on top by a high amplitude, almost continuous horizon. The body, correlated by well data to the Meso-Cenozoic deep-water carbonate units (Imerese-Sicanian) is frequently faulted, doubled and/or arranged in stacked thrust sheets;

° A lower layer, identified at the top by a discontinuous and high amplitude horizon, locally recognized at a depth of about 4.0/4.5 sTWT. The bottom of this body, correlated for its seismic attributes to the Meso-Cenozoic carbonate platform units (Trapanese-Saccense) outcropping and/or calibrated by well data in adjacent sectors, is not always well defined.

The structural setting of these seismic bodies, well identified on the N-S trending transects, reveals the occurrence of N-verging high angle reverse faults interesting both the uppermost and the intermediate elements, reaching, at times, the lowermost one. S-verging reverse faults have been recognized, as well, in the same tectonic layers. The interaction with the two differently verging faults generated, locally, large dome-shaped structures while, in the NW sector of the study area, N-verging thin-stacked tectonic sheets, pertaining to the uppermost and the intermediate elements, are predominant. That suggest that backthrusts are the dominant features in the analyzed sector, pointing out a common structural styles connecting central-western and eastern Sicily. The new insights arisen substantiate the hypothesis that the development of backthrusts, recognized in the adjacent sectors (Albanese, 2008), do not only have a local implication.

TECTONIC AND SEDIMENTARY RELATIONSHIPS BETWEEN TWO CRETACEOUS TURBIDITIC FORMATIONS IN THE ALPINE/APPENININE JUNCTION CONTEXT

BALBI Pietro¹

1 - Libero professionista

Presenter e-mail: balbi@geologiliguria.it

Key terms: Antola; Gottero; thrust; sedimentary

Within the complex, unclear and frequently discussed junction between the Alps and the Apennines, two cretaceous turbiditic, partially superimposed Tectonic Units outcrop: M. Antola and M. Gottero. The studied area is located in Oriental Liguria (Northern Italy) between the cities of Genova and Chiavari, where the Monte Antola Unit (Upper Campanian - Paleocene), the shallowest tectonic unit of the Ligurian stack, overlies the Internal Ligurian Units, particularly the Monte Gottero Unit (Valanginian - Paleocene). These two units are made up of Late Cretaceous Flysch, both calcareous and siliceous, and they show an intense pre-Oligocene brittle-ductile deformation followed by a mainly fragile deformation.

The recent bibliography shows an about N100° thrust that superimposes the Antola Unit on the Gottero Unit with a north-east bound movement, but an accurate and detailed field survey doesn't completely confirm this interpretation. Evidences of stratigraphic contacts between the Calcarei del M. Antola Formation and the hemipelagic rocks underneath seem to point to a slightly northward shift of the position of the thrust surface and, above all, to draw a new and deeper lithostratigraphy of the Unit that can help in reconstructing its Cretaceous paleogeography.

The above-mentioned hemipelagic rocks lie at the base of the Antola Unit and, for the time being can be informally named "Sanguinetto Member" and "Argillosisti di Maxena Formation". These rocks shows interesting lithological and temporal analogies with some basal formations of the Gottero Unit and respectively with the "Scisti Ardesiaci di M. Verzi Formation" and the "Scisti Manganiferi Formation".

Within this new scenery, the Gottero and Antola Units have an approximately coeval and partially common sedimentary history, followed by a similar succession of deformational events (mainly compressional, known as the "Ligurian Deformational Phases") during which the Antola Unit overthrusts the Gottero Unit. During these events, because of the thrust surface, the Antola Unit got folded into an antiformal shape while the Gottero Unit got its slight metamorphism (epizone) by being folded into a synform shape. It is actually possible to ascribe this deformation to the second brittle-ductile event which, in the Antola Unit, is followed by a third pre-oligocene event, as demonstrated by Corsi et al. (2001).

To a chain scale, these new data allow interpretation of the deformational history of these two Units, as it turns out to be mainly Alpine at least until the thrusting event, and it doesn't fit a complex tectonic and metamorphic path. The two mentioned Units probably formed at the same time and roughly the same area, Antola at a greater depth and Gottero closer to the continental margin, then they followed a similar geodynamical path except for the thrusting of the Antola Unit over the Gottero Unit. With the north-east bound migration of the Apennines compressional front, these Units were affected by a post-Oligocene extensional regime, that finally faded out into gravitative deformation.

THE OCTOBER-NOVEMBER 2010 SEISMIC SWARM IN THE SAMPEYRE AREA (PIEDMONT, ITALY)

BARANI Simone¹, FERRETTI Gabriele¹, PASTA Marco¹, SCAFIDI Davide¹, SPALLAROSSA Daniele¹

1 - Dip.Te.Ris. - Università degli Studi di Genova

Presenter e-mail: scafidi@diptervis.unige.it

Key terms: seismic swarm; Sampeyre; seismic network; waveform similarity analysis; strain rate

Last October, the area surrounding Sampeyre (Piedmont, Italy) was affected by an intense seismic activity, which evolved into an earthquake swarm. The word "swarm" is used here since no single earthquake in the sequence can be defined as the main shock. The whole seismic crisis lasted approximately one month, from October 13 to November 12, 2010. During this period, approximately 550 earthquakes were recorded and localized by the Regional Seismic network of Northwestern Italy - RSNI (<http://www.diptervis.unige.it/geofisica/>) in the study area. Among these events, 179 exceeded a local magnitude (M_l) of 1.0 but only two exceeded M_l 3.0 (the major event has a magnitude of 3.2). It is noteworthy that these two earthquakes occurred close to each other on two consecutive days, precisely on October 23 and 24.

The Sampeyre area is located in the inner part of the Dora Maira crystalline massif, which corresponds to the northern Tethyan margin (part of the stretched European continental crust) exhumed during the collision of the Eurasia and Africa plates. The Dora Maira massif consists of three main geological units of high-grade metamorphic rocks (gneiss, schists, eclogites): the Sanfront-Pinerolo unit, the Vanesca unit, and the Dronero-Sampeyre unit. The earthquake swarm took place in this area, more likely in continental crust (bulk crust) at a depth comprised between 5 km and 20 km. The analysis of various seismic sections, however, clearly indicates that higher magnitude events were confined between 10 km and 15 km.

The temporal evolution of the Sampeyre swarm reveals that most of the earthquakes occurred during the first 15 days since the beginning of the crisis. This period of intense activity was followed by an evident decay in the occurrence rate. A subsequent peak of activity was then recorded on November 11, when more than 40 events were generated in the area. In order to find possible correlations or similarity with previous earthquake activity, we analyzed the seismic history of the last 30 years. It reveals that the investigated area never experienced events comparable to that under study. Only in 1989, an intense aftershock sequence, but of shorter duration, took place in the Sampeyre area (approximately a tenth of events were recorded in two days). The strongest instrumental earthquakes, which occurred in January 1994 (Melle earthquake) and April 1998 (Oncino Earthquake) with magnitude 4.3 and 4.1, were neither preceded nor followed by intense activity. Also concerning the historical

seismicity, the area shows a generally infrequent activity characterized by low-magnitude events. The major shocks felt in Sampeyre were the 1905 Alta Savoia (I₀ = VIII-VIII MCS) and the 1914 Tavernetta (I₀ = VIII MCS) earthquakes but they did not produce any damage. Following a general description of the swarm evolution and the performances of the RSNI network, the study will present the results of a waveform similarity analysis, aimed to identify families of earthquakes belonging to common genetic sources. Results of a strain rate analysis will be also discussed, focusing on the release of seismic energy with time.

MAKING OUT THE INVISIBLE: THE CHALLENGE OF IDENTIFYING ACTIVE FAULTS IN THE PO PLAIN

VALENSISE Gianluca¹

1 - INGV, Roma

Presenter e-mail: gianluca.valensise@ingv.it

Key terms: Po Plain; Active tectonics; Blind faulting

When I was a young student in Earth Sciences I somehow got accustomed to the idea that the real Geology is only that seen in mountainous terrains, and that flatlands are by definition non-active portions of the Earth. It did not take very long to realize that I was completely wrong. The publication of "Hidden earthquakes" by Stein and Yeats disclosed to me a new set of scientific questions that could hardly be faced with traditional structural geology tools and approaches. When I started seeing alluvial plains simply as the result of the progressive submergence of a mountain chain by intervening sedimentary deposits, my entire perspective of active tectonics changed. The Po Plain is one of such drowned mountain chains - perhaps one of the most mysterious yet interesting ones.

The problem of understanding if and how the Po Plain may be underlain by large active and potentially seismogenic faults became a national issue in the 1970s, when the Italian government planned the construction of several nuclear power plants near the Po River or by its delta, along the Adriatic coast. The Po Plain has been the locus of significant and well known earthquakes of certain local origin, such as the 1570 Ferrara, 1624 Argenta and 1802 Soncino events, all having a magnitude close to 6.0, but its instrumental seismicity is rather limited. Extensive geophysical surveys carried out by the oil industry since the 1940s first revealed the subsurface structure of the Po Plain; still they returned little or no clues as to if and where modern tectonic activity is concentrated. Similarly, very little information on ongoing deformation could be obtained from conventional geological mapping.

The "living nature" of the Po Plain is indeed testified also by its recent evolution, and in particular by the recurrent modifications of its drainage network. This evolution is largely controlled by a combination of sedimentary and climatic processes but is then "modulated" by subtle differential elevation changes caused by the activity of some of the buried compressional structures imaged by exploration geophysics (commonly referred to as "blind faults").

Today we know that the faults and anticlines buried beneath the Po Plain hold a sizable seismogenic potential. We also know that through the ages they have controlled or triggered some of the most significant changes in the historical river patterns, such as the progressive northward migration of the Po near Correggio and Suzzara, the "Rotta di Ficarolo" of the 12th century, the abandonment of the city of Ferrara. Perhaps nowhere in Italy has tectonic activity had such a profound and lasting influence on trade, agriculture, population patterns and even languages. And the Po Plain preserves one of the most complete records of unambiguous albeit slow-paced active tectonic shortening and a unique example of converging orogens. So much for a region that traditional geologists would have considered inactive, uninteresting, and perhaps downright boring.

Key terms: slip rates; po plain; Northern Apennines thrust fronts; 3D modeling; active tectonics

The Northern Apennines (NA) are a folded mountain chain with NNE convexity and vergence including a frontal and outermost structural belt buried under the alluvial sediments of the Po Plain, and an outcropping chain. The former is deformed by blind thrusts and folds that controlled the deposition of the syntectonic sedimentary wedges, with the Plio-Quaternary sequence locally up to 7-8 km thick. The fast sedimentation hid the growing structures, and, as a consequence, today there are few direct surface evidences of the possible ongoing activity of the thrusts. The buried thrust front of the Northern Apennines shows three main folded arcs: the Monferrato arc in the western part of the Po Plain, that underwent the minor amount of shortening; the Emilia arc in the central part, partly deformed during Messinian time and with its maximum activity during Middle-Upper Pliocene; the Ferrara arc located in the eastern part of the Po Plain, active from Late Pliocene to Pleistocene times.

Present-day activity of the buried frontal thrusts of the NA is testified by historical and instrumental seismicity, the latter characterized by contractional focal mechanisms, by the influence on the drainage network and faulting and folding of recent sediments. The historical and instrumental Italian seismic catalogues show that the southern Po Plain is affected by low to moderate seismicity, with M_{max} up to 5.8. The

borehole breakouts and the focal mechanisms both show Shmax oriented perpendicularly to the trend of the buried thrust fronts.

In this study we present 3D reconstructions of different sectors of the NA thrust front, referred to the Emilia and Ferrara arcs, supporting the evaluation of the late Tertiary and Quaternary slip rates of the NA thrusts. The subsurface data we collected and analyzed come from published cross sections, seismic lines, subsurface maps and borehole data. We used them to build well constrained and geometrically consistent 3D models where all data have been analyzed as a whole.

The models were built to obtain a reliable estimate of the decompaction history applied to a 3D cylindrical volume. For our analysis we chose sections located in the central part of each thrust, in order to prevent the effects of curvature and reorientation common along the fault tips. For each section some structural culminations were analyzed in order to restore the observed deformations and to calculate the relative slip rates. To restore the displacement along the analyzed structures and to calculate the slip on the fault planes, we used different methods: for faulted horizons we used the fault parallel flow algorithm; for fault propagation folds, we used the trishear algorithm; and for the shallower and unfaulted horizons we used an elastic half-space dislocation model of surface deformation.

The horizons we analyzed include the Messinian top horizons, the Zanclean, the Piacenzian and the Gelasian tops and, where possible, the Pleistocene intervals of the Quaternary Marino Supersynthem (Costamezzana Synthem, 0.9 My) and of the Emiliano-Romagnolo Supersynthem (Emiliano-Romagnolo inferiore Synthem 0.65 My, Emiliano-Romagnolo superiore Synthem 0.45-0.35 My).

GPS studies show that convergence between the African and European plates at the Italian latitude is going on with rates ranging between 3 and 8 mm/y, while velocity field solutions across the NA fronts show a compression of about 1 mm/y, increasing from west to east and related to the rotation of the Adria indenter around a pole located in western Alps. Our results indicate an increase of the slip rates toward the easternmost sections, in agreement with the GPS convergence data.

Moreover, the reconstruction of the evolutive history of the structural culminations both in the Emilia and the Ferrara arcs, highlights that the total deformation is partitioned between different tectonic structures that are active alternatively during different time intervals.

Presenter e-mail: scafidi@dipteri.unige.it

Key terms: Temperature measurements; Deep boreholes; Geotherm; Rheology; Po plain

The present structural setting of the Po plain (Italy) is the result of a polyphase tectonic deformation history beginning in the Late Cretaceous, which involved both the Alpine and the Apennine orogenies. Here we present a thermo-rheological study of the crust of the central Po Plain (approximately 44.5-45.7° N lat, 9.4-11.2° E long), which records the convergence of the Alpine and Apennine external fronts.

The present thermal regime of the crust is based on geological and geophysical data from oil exploration (Eni Exploration & Production). A set of temperature data from 37 deep boreholes (bottom hole, drill stem, and production test temperatures) is used to estimate undisturbed formation temperatures down to 6-7 km of depth. Best quality data are used to estimate linear geotherms, which are grouped taking into considerations the following factors: i) presence/absence of relevant fluid circulation (thermal convection), ii) conductive thermal refraction, iii) recent sedimentation, and iv) other disturbing tectonothermal processes (e.g., recent tectonics). The groups are dominated by thermal conduction only (Group 1, Pede-Alpine; Group 2, Pede-Apennine), thermal conduction + recent sedimentation effects (Group 3, Apennine foredeep), and thermal convection + other disturbing effects (Group 4, Anomalous zones).

Assuming reasonable corrections for Group 3 data, and not considering Group 4 data which cannot be used to infer undisturbed deep temperatures, the other geothermal data fall within the same range and provide a homogeneous thermal signal.

Temperature measurements in the upper ~7 km are used to constrain a 1D thermal model at the crustal scale, assuming averaged 1D geometries as a first approximation. The crustal section is simplified into four layers: molasse sediments, carbonate series, upper crystalline crust, and lower crust. The best fitting modelled geotherm gives an estimated Moho temperature of 620±80 °C. Using the estimated crustal structure and composition and the best-fitting geotherm, a representative strength envelope is obtained. Frictional sliding, high-pressure failure and power-law creep are considered as deformation mechanisms. The 1D strength envelope is compared with a depth profile of the hypocentral frequency (database period 1900-2010; International Seismological Centre). For hydrostatic and supra-hydrostatic pore pressures, the calculated total crustal strength of this sector of the Adria plate (not including the upper mantle contribution) is in the 1.8-2.5 TN m⁻¹ range. Considering also the lithospheric mantle contribution for hydrostatic pore pressures, the total lithospheric strength is estimated to be between 23 (wet peridotite) and 39 (dry peridotite) TN m⁻¹.

EVOLUTION OF THE ALPINE VENETIAN FOREDEEP ALONG THE SCHIO-VICENZA FAULT SYSTEM BY SEISMIC SECTIONS ANALYSIS

RICCIATO Angelo¹, POLA Marco¹, FANTONI Roberto², ZAMPIERI Dario¹

- 1 - Università degli Studi di Padova
- 2 - Eni-divisione Exploration & Production

Presenter e-mail: angelo_85@hotmail.it

Key terms: South Alpine; Schio-Vicenza fault system; Veneto foredeep; flexure

The aim of this work is to show how and when the NW-trending Schio-Vicenza fault system (SVFS) acted during the South-Alpine

deformation in the Veneto plain. The SVFS is an inherited Mesozoic to Paleogene extensional feature currently bordering to the west the Venetian foredeep. During the Neogene development of the foredeep, the SVFS was reactivated with sinistral transtensional kinematics, which vertical component of the offset should increase moving towards the chain.

The ENI database (2D seismic sections and wells) was used to map the SVFS. About 1000 km of seismic lines were interpreted and more than 10 wells were used to calibrate the seismic interpretation. Some selected seismic sections, sub-orthogonal to the main faults, were chosen to obtain geological cross-sections through depth conversion process. This phase involved the tracking and interpretation of the most important spotlights that previously have been recognized in the sections. Moreover, more sections were used to map the hanging wall cut-off of the faults related to the Messinian unconformity.

The collected data display a complex buried fault system that extends southward with a NNW trend until the Po delta. In the cross sections the faults (most of them NE dipping) show a vertical component with down-throw in its eastern side (hanging wall block). The fault system cumulative displacement decreases from the northwest (Schio area, where the fault crops out) to the southeast (Po delta). The main displacement occurred from Early to Middle Pliocene. The results confirm that the SVFS acted as a kinematic transfer of the Neogene shortening between the South Alpine front and the innermost Giudicarie front. In this context, the SVFS tract corresponding to the western border of the Venetian foredeep accommodated the subsidence induced by the foreland flexure with a prominent throw gradient increasing moving northwards.

CRUSTAL AND UPPER-MANTLE STRUCTURES IN VENETIAN ALPS (NE-ITALY): INSIGHTS FROM LOCAL EARTHQUAKE TOMOGRAPHY (L.E.T.) AND RECEIVER FUNCTION ANALYSIS

ANSELMI Mario¹, BIANCHI Irene², DE GORI Pasquale¹, CHIARABBA Claudio¹

Presenter e-mail: mario.anselmi@ingv.it

Key terms: Venetian Alps; Tomography; Receiver Functions; Seismicity; Subduction

In the past decades several studies were carried out regarding the geometrical and kinematic characteristics of the active faults in Italy. To this end, different areas where future large earthquakes are expected were identified. These areas were monitored with local seismic networks, in order to detect background seismicity.

In this work we present the results obtained by an integrated approach using both the local and teleseismic data acquired during a passive seismic experiment located in Venetian Alps (NE-Italy).

In this study we focus on 1) the definition of the three-dimensional Vp and Vp/Vs crustal structures using the local earthquake tomography (L.E.T.); 2) the characterization of the geometrical setting of the Adriatic-Europe plates margin at lower crust and upper mantle depths through the application of the Receiver Function technique.

In the period between June 2004 and May 2005 a dataset of 310 local and almost 600 teleseismic earthquakes have been recorded.

A subset of 130 local earthquakes has been selected to calculate a well-constrained 1-D velocity model of the area. From this 1-D velocity model we have performed a 3-D local earthquake tomography, using 1960 P and 560 S- phases of high quality arrival times.

Almost 350 teleseismic earthquakes have been selected to perform the Receiver Function's analysis. The data-set is displayed as back-azimuthal sweeps of RFs binned over 20 degrees of back-azimuth angle and 40 degrees of epicentral distance, centered at 90 degrees of epicentral distance, with a 50% of overlapping area between adjacent bins. A detailed image of the seismic signal pulses on both the radial and transverse components is obtained. The RF method is very suitable to identify positive and negative velocity jumps under the seismic stations, and dipping structures and anisotropic characters could be discerned too. Venetian Alps are an interesting training zone to be investigated by this point of view since they have been shaped by the geodynamic evolution of the doubly vergent subduction/collisional system, which is still poorly investigated.

Here we show that the upper crust is characterized by abrupt Vp and Vp/Vs variations, both vertical and lateral, due to the complexity of the geological structures. In particular, high Vp bodies characterizes the shallower 15 km depth, yielding the definition of the thrust system.

Seismicity is located in correspondence with the high Vp values close to the southern thrust structures verging toward to the Po Plain. Moreover the presence of two different Mohos belonging to the Adriatic and European plates, their relative geometry and position give new details about the deep structure of this sector of the Alps.

NEOTECTONIC ACTIVITY IN THE GULF OF TRIESTE (NORTHERN ADRIATIC)

BUSETTI Martina¹, ZGUR Fabrizio¹, VOLPI Valentina¹, PETTENATI Franco¹, PETRONIO Lorenzo¹, ROMEO Roberto¹, SORMANI Lorenzo¹

- 1 - Istituto Nazionale di Oceanografia e di Geofisica Sperimentale (OGS)

Presenter e-mail: mbuseti@inogs.it

Key terms: neotectonic; Dinaric structures; northern Adriatic Sea

The setting of the Dinaric fault system and its neotectonic activity has been recently outlined in the Gulf of Trieste (Northern Adriatic), using 525 km of multichannel seismic profiles acquired in 2005 and 2009 by R/V OGS Explora.

The Gulf of Trieste area belongs to the northernmost part of the NW-SE oriented External Dinaric foreland. In particular, the gulf corresponds to the foredeep constituted by the flexured Mesozoic - Paleogene carbonate of the Friuli Platform, filled by the Eocene turbidites of the "Flysch", both outcropping onland. The Flysch has been intensively eroded from Late Miocene (Messinian) to the Pliocene, and is overlaid by Quaternary marine and continental sediment.

The presence of a Dinaric fault system in the Gulf of Trieste, which is linked to onshore structures, have been identified: it is represented by the following evidences: a) at the eastern coastal area, the Karst frontal ramp (Trieste Fault), presents a deformation zone of about 2-3 km wide and

with more than 1500 m of vertical displacement of the carbonates buried below the gulf and outcropping onland: b) across the gulf, the occurrence of Dinaric compressive/transpressive aligned features. In both structures, some fault strands affect the Messinian-Pliocene erosion surface with throws up to 30 m, and the Quaternary sediment.

The offshore occurrence of neotectonic activity provides new and unique information in the area, so far been considered tectonically quite inactive or poorly active, mainly because of the absence of evidence onland induced by the lack of data. Moreover, despite being surrounded by seismogenic zones (Dinaric faults in Slovenia and Croatia and also Alpine faults in the Friuli area), the Gulf of Trieste has long been considered to have low seismicity, as only low magnitude and shallow events have been reported by the historical and instrumental seismicity catalogues.

However, the occurrence of neotectonic deformation of the Dinaric thrusts, provides new insights into possible seismogenic activity. This is a key point in the re-evaluation of geological risks, as the area has recently been proposed as site for strategic facilities, such as nuclear power station and LNG (Liquefied Natural Gas) regasification terminal.

10.1474/Epitome.04.0554.Geitalia2011

STRATIGRAPHIC AND STRUCTURAL SETTING OF THE NORTHERN ADRIATIC SEA: A POTENTIAL LOCATION FOR CO₂ GEOLOGICAL STORAGE?

DONDA Federica¹, DE SANTIS Laura¹, VOLPI Valentina¹, CIVILE Dario¹, LORETO Maria Filomena¹

1 - Istituto Nazionale di Oceanografia e di Geofisica Sperimentale (OGS)

Presenter e-mail: fdonda@ogs.trieste.it

Key terms: Northern Adriatic Sea; Multichannel seismic profiles; CO₂ geological storage

The Northern Adriatic Sea has been deeply investigated in the framework of several studies performed by various research institutions, mainly finalized to the reconstruction of the Quaternary stratigraphic evolution of this area. A comprehensive study of the sedimentary and tectonic evolution of the Northern Adriatic sea has been also performed by Eni, based on the integrated analysis of boreholes and 2D and 3D seismic data (Ghielmi et al., 2010; Fantoni et al., 2010).

In 2009, OGS has performed a geophysical survey ("Stratigraphic and tectonic Evolution of North Adriatic in the Plio-Quaternary"-STENAP 09) in the northernmost sector of the Northern Adriatic Sea with R/V OGS Explora. About 800 km of 2D multichannel seismic and Chirp profiles have been acquired, together with Multibeam data in selected areas, aimed at the reconstruction of the Plio-Quaternary evolution of this area.

Recently, the Northern Adriatic Sea has been also investigated as one of the possible sites for CO₂ geological storage. This is one of the major OGS research activities, thanks to its involvement in several European and National projects concerning the Carbon Capture and Storage (CCS). The STENAP 09 seismic profiles, together with the data of the available boreholes drilled in the area, have been then analysed also from the possible CO₂ storage perspective, since previous, basin-scale studies already highlighted the occurrence of suitable areas offshore the Northern Adriatic sea (Donda et al., 2011). Here, several hundred meter-thick turbiditic successions, mainly represented by the so called "Porto Corsini" and "Porto Garibaldi" formations, deposited during the Pliocene and Pleistocene and commonly host natural gas fields. They also contain deep saline aquifers that would have suitable characteristics for the application of the CCS techniques.

THE ADRIATIC FOREDEEP STRUCTURES IN THE PESARO AREA

MENICHETTI Marco¹, MENCUCCI Daniela²

1 - Università di Urbino - Dipartimento di Scienze della Terra, della Vita e dell'Ambiente

2 - EcoTechSystem Srl - Ancona

Presenter e-mail: marco.menichetti@uniurb.it

Key terms: Adriatic sea; structural geology; seismotectonics; foredeep; Pesaro

The external portion of the Neogene foreland thrust belt of the umbro-marchean-romagna Apennines is buried by a thick clastic sequence pertaining to the Adriatic foredeep. The Pesaro area and related Adriatic offshore is characterized by an arcuate system of NE verging thrust sheets with at least two foredeep basins. Since Upper Oligocene, the nappes-troughs system of the Northern Apennines migrated discontinuously from West to East. During the Pliocene this system reached the Adriatic area and originated, and differentiated, several deeper major foredeep basins. These basins were progressively filled by siliciclastic sequences mainly supplied from NW, with a maximum subsidence deeper than 6000 m in the Pliocene time. The main shear zones are buried and their surface evidence is often faint because of the combination of fast sedimentation rate and low deformation rate. The geological interpretations of the structures in the Pesaro area are quite controversial with different views of geomorphological and geological structures. The deep structures described in the seismic reflection profiles mainly differ from thin-skinned to thick-skinned style of the deformation. The recent-to-current tectonic activity and the seismogenic potential of the area have been inferred from regional morphological analysis of drainage anomalies and from the altimetric evolution of the coastal terraces. Several A. consider an active compressional NE-SW stress field, computed from breakouts and focal mechanism and related to the thrust faults; others inferred an WSW-ESE oriented extensional or inactive stress field from geological data.

The geometrical and kinematic data derived from field survey are summarized in a new structural map of the Pesaro area. The stratigraphic analysis of syndepositional compressional structures related to the growing buried anticlines is combined with the geometry of the thrust sheets obtained combining seismic reflection lines with deep well logs. Several seriate cross sections permitted to discriminate the deformation rate of the thrusts sheets and the partitioning among them. The integration of all data allowed designing a new picture of the tectonic evolution of the area and recognizing the tectonically active structures. The M. S. Bartolo anticline between Pesaro and Gabcice is an arcuate complex structure with the axial direction oriented NW-SE, stretched in the southern part by N-S subvertical strike-slip faults. The anticline is asymmetric with a reverse NE limb, detaches over a sole thrust rooted in the Triassic evaporites. Several backlimb back-thrusts splay from the

Upper Miocene marls, in the SW part of the anticline forming a crestal syncline. The main thrusts and strike-slip faults are characterized by an offset of many hundreds of meters with cataclastic shear zones few decimeter thick. The kinematic analysis of these structures indicated a NNE-SSW oriented shortening direction. In the Pesaro off-shore a large syncline along the Plio-Pleistocene foredeep is affected by wrench and compressional structures related to the regional detachment. Few km towards NE, low-angle backlimb superficial thrusts seem to reach the upper part of the Upper Pliocene and the Quaternary stratigraphic sequence. The activity of this structure can be related to the evolution of the deepest part of the North Apennine front in the foredeep, where also the fluid pressure play an important role.

3D RECONSTRUCTION OF THE CENTRAL PERIADRIATIC BASIN (MARCHE-ABRUZZI ONSHORE SECTOR)

CONTI Alessia¹, BIGI Sabina¹, RUGGIERO Livio¹, CASERO Piero², LIPPARINI Lorenzo³, RECANATI Riccardo³

1 - La Sapienza

2 - Via S. Martino in Valperga, Roma. caseropiero@libero.it

3 - Medoilgas s.p.a

Presenter e-mail: alessia.conti@uniroma1.it

Key terms: fold-and-thrust-belt; anticlines; 3D modeling; seismic lines

In the Central Periadriatic Basin (CPB) the more external anticlines of the Apennine thrust belt system are buried under a syn and post orogenic, Plio-Pleistocene, siliciclastic marine sequence; this sequence records the last tectonic phases associated with the E-migration of the Apennine chain [1] and it is partially deposited on wedge top position and partially in foredeep position [2].

In this study we proposed a 3D reconstruction of the main geological structures and surfaces recognized in the CPB basin through the interpretation of 2D seismic lines, constrained with well logs and surface geology.

The structural setting pointed out is characterized by two main N-S buried tectonic trends: the Nereto-Bellante trend (NBT), located in the western portion of the basin, close to the outcropping front of the chain, constituted by the Teramo thrust [3]. A lower thrust, the Villadegna-Costiera trend (VCT), constitutes the footwall and the lower ramp of the Struttura Costiera Anticline (SCA) [4], located along the present coast line. They are characterized by deeper ramps in the carbonate sequence, long flats developed at their top, and shallower ramps and related anticlines involving the Plio-Pleistocene siliciclastic sequence.

The 3D reconstruction allowed us to correlate these main trends along strike, revealing a variation in the geometric relationships, in the displacement and in the chronology of deformation.

The NBT reaches the maximum displacement and structural elevation in the northern sector, whereas the VCT shows a regional northward axial plunging and progressively becomes the main trend moving to S, where maximum displacement is observed. The activity of thrusts results diachronic along strike: the frontal thrust of the NBT shows a main activity from the G. punctulata Zone until the G. inflata Zone, older in the southern sector. The VCT was active during the G. margaritae - G. punctulata Zones, and continued to propagate forward forming the SCA in the foreland, during the Lower-Middle Pliocene; this latter structure shows a deformation younger toward the N, where the Upper Pliocene deposits are folded at the top of the anticline, suggesting that the final activity postponed until the Late Pliocene.

A W-E cross section crossing the described structures was depth converted. Forward restoration of the SCA shows a progressive reduction from Middle Pliocene up to now of strain rate and uplift rate of this fault-related anticline. The restoration of the complete geological section led to a total shortening of about 13% corresponding to 6 km on a section of 52 Km of length.

On the same cross section hypocenters and trace of the seismogenic sources provided by DISS database [5] were projected, in order to attempt a correlation between the main trends and the seismicity distribution detected in the area. A pretty good correlation between the lower ramp of the VCT and the trace of the seismogenic source ITC5020, and between the upper ramp of the same trend and the ITC5054 seismogenic source, is observed.

Key terms: Subduction; Calabria; uplift

Calabria represents an ideal site to analyze the topography of a subduction zone as it is located on top of a narrow active Wadati-Benioff zone and shows evidence of rapid uplift. We analyzed pattern of surface deformation using elevation data with different filters and showing the existence of long wavelength (>100 km) relatively positive topographic signal at the slab edges. The elevation of MIS 5.5 stage marine terraces supports this pattern, although the record is incomplete and partly masked by the variable denudation rate. We performed structural analyses along the major active or recently reactivated normal faults showing that the extensional direction varies along the Calabrian Arc and laterally switches from arc-normal, within the active portion of the slab, to arc-oblique or even arc-parallel, along the northern and southern slab edges. This surface deformation pattern was compared with a recent high resolution P-wave tomographic model showing that the high seismic velocity anomaly is continuous only within the active Wadati-Benioff zone, whereas the northern and south-western sides are marked by low velocity anomalies, suggesting that large-scale topographic bulges, volcanism, and uplift could have been produced by mantle upwelling. We present numerical simulations to visualize the 3D mantle circulation around a narrow retreating slab ideally similar to the one presently subducting beneath Calabria. We emphasize that mantle upwelling and surface deformation are expected at the edges of the slab, where return flows may eventually drive decompression melting and the Mount Etna volcanism.

Key terms: Geoarchaeology; Tectonic evolution; Georgia

Archaeological and geomorphological data are useful in studying Holocene rivers because of the close relations between the presence of water and human settlement. In addition, the presence of active tectonics could have heavily conditioned both the geomorphological evolution and the development of human settlements.

In this study we aim to outline the late Holocene evolution of the Aradeti Orgora site, through the analysis of archaeological and morphological data. The site is located in the Transcaucasian basin, historically characterized by active tectonics.

The study area is located in the Shida Kartli Region, a hundred kilometres westwards from Tbilisi. The Kura River crossed the area following a NNW-SSE direction, while the Liakhvi River represents an important tributary, whose junction with the Kura is located near the town of Gori. The site of Aradeti Orgora-Dedopoli Gora is located at the junction of a system of rivers (Kura, Western Prone, Eastern Prone). In particular, Aradeti Orgora lies on an isolated portion of the fluvial terrace (660 m a.s.l.), about 20 meters above the recent Kura floodplain.

The site hosted an important settlement Roman/Medieval in age, which was excavated by Georgian archaeologists under the direction of prof. Julon Gagoshidze. The archaeological horizons are underlain by a long sequence of earlier levels, which date back at least to the late 4th millennium BC, and are still virtually unexplored.

The stratigraphic analysis was carried out on an exposed section on the southern sector of the terrace slope, where the archaeological levels are superimposed to an alluvial stratigraphy related to the Kura River and its tributaries. Three main archaeological horizons have been identified:

- 1) An Early Bronze Age level characterized by a sequence of layers with abundant pottery and ceramics fragments of the Kura-Araxes and Bedeni periods (late 4th-mid 3rd millennium BC) in a muddy matrix. Radiocarbon dating of a wood fragment from the base of the sequence yielded the age of the layer ($\pm 1\sigma$ 3025-2920 BC.). The level had been buried by a coarse alluvial event characterized by 1,5 m thick gravel body;
- 2) a Late Bronze Age layer characterized by muddy matrix with abundant pottery fragments;
- 3) a Roman Age and later layer at the topmost part of the site, characterized by abundant pottery and brick fragments.

The presence of coarse alluvial deposits between the two Bronze Age levels indicates a channel fluvial activity on the terrace after 4300 BP.

We suggest two possible hypothesis about the drainage evolution:

- a) The gravel layer covering the Early Bronze Age could represent the last phase of aggradation of the Liakhvi alluvial fan and its progradation toward south. Subsequently the deepening of the Kura riverbed and its northward migration triggered the small incisions of the trenches surrounding the site. The Roman Age site was probably chosen for the isolated position derived from the geomorphological evolution of the terrace. According to the present difference in elevation between the Liakhvi alluvial surface and the present Kura riverbed, the estimated total erosion is about 5 mm/year, that is the result of a joined effect between river incision and active uplift of the area.
- b) The gravel layer may be ascribed to a palaeo-Kura running waters. After about 4000 BP, the Kura was forced to migrate toward south because of an active uplift of the Transcaucasian region. In this case, most of the 20 metres in the elevation difference between palaeo and present Kura should be related to tectonic activity.

The importance of tectonic activity in the area is furthermore supported by the high seismicity of the Transcaucasian Basin and the low fluvial erosion expected in a time span in which no great climatic changes occurred. Local uplift within the basin possibly related to a contractional step-over along the Borjomi-Kazbegi fault zone or the southern propagation of the Greater Caucasus belt.

Key terms: multibeam; seismics; Apulian foreland; Calabrian Arc

The investigated area is located in the Ionian offshore of Puglia (southern Italy). Recently acquired multibeam and seismic data provide new information regarding the morphological and structural processes that involved the Apulian foreland and the Calabrian arc from Mesozoic to Present. Multibeam bathymetric data were acquired by the R/V OGS Explora in three successive campaigns, November 2003, August 2005 and the latest on October 2010 where five regional multichannel seismic profiles were also collected.

Based on the integrated analysis of the available data, we produced a geo-morphological map of the deep Ionian basin.

The tectonic domains in this area are the Calabrian accretionary wedge and the Apulian foreland. The contact between the two domains, oriented NW-SE, morphologically coincides with a NW-SE trending sea-bottom erosional channel (Taranto canyon) characterized on both sides by mass movements induced by slope instability.

The accretionary wedge/Apulian foreland boundary presents a different morphology from NW towards SE (o direttamente from NW to SE), which is controlled by the different structural setting induced by the relationships between the accretionary wedge and the foreland as interpreted on seismic profiles. Moreover, the canyon pattern appears to follow the changes of the slope morphology, with an erosional activity increasing going from NW to SE.

New processed seismic data highlighted the presence of fluid migration paths, sometimes up to the seafloor, suggesting the presence of gas. The geological-structural setting of the area, characterized by evaporites and transtensional features, is particularly favourable to the accumulation of gas. In fact, Messinian evaporites are generally considered to play a major role in controlling mud volcanism. The fluid flow occurs through the vertical conduits, represented by the distensive faults, which is highly possible in this tectonic regime characterized by thrusting and backthrusting of the Calabrian accretionary wedge.

Key terms: morphometric analysis; knickpoints; active transpression; North-eastern Calabria

The longitudinal profile of bedrock channels may yield valuable information about the landscape vertical deformation processes. In this study, inspired by previous results obtained through the mapping of the marine terraces and the reconstruction of the relative paleo-shorelines, we have performed a detailed morphometric analysis of the drainage network on the eastern side of the Pollino mountain range, Calabria, Southern Apennines frontal area. The uniform coastal lithology and climate allow us to isolate the tectonic signal from the fluvial morphometric analysis.

Along the Pollino coastal range, marine terrace paleo-shorelines show the superposition of two small-wavelength and amplitude undulations superposed to the regional uplift. These local undulations were interpreted as fault-propagation folds by performing fault numeric models of blind thrusts.

The morphometric analysis was carried out to test and improve the above mentioned deformation model. Linear regressions of the logarithms of channel gradient and drainage area data across the bedrock channel region were used to find knickpoints (kps) and to determine, the concavity

index (Θ) and the steepness index (ks).

Because of DEM (10x10 m) elevation errors, the rivers longitudinal profiles were corrected averaging the elevation through a mobile 200 m window. In order to compare channels characterized by different drainage areas, a

fixed reference concavity ($\Theta = 0.45$) was used in order to calculate a normalized steepness index (ksn). The ksn values increase regularly toward the anticlines; in other words, the rivers flowing through the areas that are affected by the higher uplift rates tend to establish a steeper longitudinal profile in order to have the energy sufficient to erode the uplifting tectonic barrier.

Several kps were detected along the longitudinal profiles of the trunk streams. Being the analyzed rivers adjusted to the sea level, it is reasonable to hypothesize that some of the kps are related to the Quaternary eustatic cycles. To test this idea, for each knickpoint (kp) the reconstruction of the interglacial profile was performed through the ks and

the Θ values calculated for the respective river. An eustatic origin was considered valid if: 1. the paleo-longitudinal profile crosses a marine terrace; 2. at least three kps are related to the same marine terrace (same eustatic regression); 3. the kps correlated to the same eustatic cycle are characterized by migration rates and positions that are in direct relationship with the landward drainage area. Besides, for some of the kps the eustatic origin is confirmed by the presence of fluvial terraces aligned with the relative paleo-longitudinal profiles. The fluvial terraces are, reasonably, the consequence of the erosive wave triggered by the eustatic regression and progressively transmitted to the entire drainage basin through the kp landward migration. Generally, the elevation of an eustatic kp is influenced by the drainage area (migration rate) and the trunk stream longitudinal gradient. As a consequence, holding constant the drainage area the kp elevation can be influenced by gradient changes determined by differential uplift rates. In the study area this theoretical prediction is perfectly confirmed: all the kps related to the same marine terrace are always characterized by an increase of the elevations toward the modelled anticlines. Finally, based on the migration rates, it was possible to determine the

drainage network response time considered to be the time necessary for a k_p to migrate through the entire drainage basin. All the analyzed rivers show a low response time (~ 10 ka) that highlights the youthfulness of the detected tectonic deformation.

The longitudinal profile analysis have permitted to confirm the results independently reached with the marine terraces and the fault modelling, evidencing that compressional regime is still active in this sector of the Southern Apennines.

COSMOGENIC EROSION RATES AND RIVER PROFILES APPLIED TO DECIPHERING QUATERNARY LANDSCAPE EVOLUTION OF THE SILA MASSIF, CALABRIAN ARC, SOUTH ITALY

Key terms: cosmogenic erosion rate; river profile; uplift; Calabrian Arc

The topography of orogenic belt results from the competition between tectonic and surface processes. This competition is mostly controlled by fluvial erosion through lowering of valley bottoms, which in turn controls hillslope processes and maximum mountain peak elevation. The sensitivity of the river system to climatic and particularly to tectonic perturbation makes the fluvial network a potential source of information about tectonic forcing on landscape.

The Sila Massif in the Calabrian Arc (southern Italy) is a key site to study the response of hydrography to rock uplift. Herean uplift of around 1 mm/yr imparted a deep imprint on the Sila landscape recorded by a high standing low-relief surface on top of the massif, deeply incised fluvial valleys along its flanks, and flights of marine terraces in the coastal belt. In this framework, we combined the longitudinal river profile analysis with the hillslope erosion rates calculated by ^{10}Be content in modern fluvial sediments to reconstruct the long-term uplift history of the massif. The analyzed river profiles exhibit a wide range of shapes diverging from the commonly accepted equilibrium concave-up form. Generally, the study river profiles show two or, more frequently, three concave-up segments bounded by knickpoints and characterized by different values of concavity and steepness indices. Cosmogenic data show a large variation in erosion rates, marking two main domains. The samples collected in the high standing low relief surface atop Sila provided low erosion rates (from 0.09 ± 0.01 to 0.13 ± 0.01 mm/yr). Conversely, high values of erosion rate (up to 0.92 ± 0.08 mm/yr) characterized the incised fluvial valleys on the massif flanks. This wide variation in cosmogenic erosion rates and the non-equilibrated river profiles suggest the Sila landscape is in a transient state of disequilibrium in response to a strong and unsteady uplift not yet counterbalanced by erosion.

Key terms: strike-slip tectonics; seismotectonics; Calabrian Arc; radon concentrations

A regional NW-SE left-lateral strike-slip with strong reverse components fault system deeply conditioned the post-Tortonian evolution of northern Calabria during the last stages of post-collisional processes which involved the Apulian block and the Calabrian Arc (Tansi et al., 2007). This system dissects and contributes to the raise an Oligocene-Early Miocene orogenic belt made of Alpine nappes overthrust over the Apennine Chain. The above mentioned system locally inverted the former geometric relationships between the units of the orogenic belt.

In this paper, superficial effects - in terms of morphology, geometry and kinematics of the structures - linked to the above mentioned regional fault system, were defined in detail through interpretations of aerial photographs and field surveys. Measurements of structural data comprise orientations of more than 500 fault planes with slickensides, gathered from 54 measure stations located along the main faults, within the cataclastic belts. Such data allowed the determination of the associated stress field (according to Angelier, 1979, method), and the in situ validation of the regional deformational model.

As atmospheric and near-surface gas concentrations are considered as background values, while concentrations conducted by faults and fractures are considered as anomalous, analyses of gas emanations is a useful way of detecting faults and of identifying possible earthquake precursors (Ciotoli et al., 1993; Klusman, 1993; King et al., 1996; Torgersen and O'Donnell, 1991). Radon gas, the isotope of which (^{222}Rn) is used in this paper, is especially useful in such work because it is inert. The movement distance of radon through the subsurface depends on diffusion rate, permeability, and the half-life of ^{222}Rn (3.824 days).

Finally, the obtained structural scheme were compared with macroseismic fields of the main earthquakes, instrumental seismicity and focal mechanism, and the soil gas radon concentrations, to infer some information about the present activity of the faults.

According to seismological, structural and morphological data, described in the present paper, an extension of the activity of the left-lateral strike-slip system up to Present seems reasonable. Moreover, when taking into consideration the regional extent and the hierarchical order of the system, together with its kinematic characteristics, it can be stated that, in NE sector area of the Calabria, sectors exposed to the highest seismic risk are those affected by the NW-SE shear zone.

Presenter e-mail: gennaro.carmelo@libero.it

Key terms: QUATERNARY TECTONICS; STRUCTURAL ANALYSES; QUANTITATIVE GEOMORPHIC ANALYSES; NORTHERN-CENTRAL SICILY

The Northern Madonie Mountains (Northern-Central Sicily), sector of the Sicilian Maghrebic chain, consist of a tectonic thrust system developed through two subsequent main contractional events: 1) a shallow-seated compressional event developed during the Middle-Upper Miocene; 2) a deep-seated transpressional event occurring since the Late Miocene. Lower Pliocene (Trubi) to Quaternary clastic deposits unconformably lie on the tectonic units and are partially involved by deformation.

In the selected area, syntectonic sedimentary basins characters are able to define the timing of deformation only until the Lower Pliocene; to resolve this gap of information application of quantitative geomorphic techniques, based on relationships between tectonics and hydrographic network development could contribute to recognize and characterize Quaternary structures in areas where clayey/marly deposits, widely outcropping, are not marked by pervasive tectonic deformations.

In order to define the geological setting of the study area and to detect Quaternary tectonic structures, geological, structural and geomorphological analyses have been carried out.

Geological and structural analyses have shown:

1) characters and style of deformation of fold structures: two main systems of folds have been recognized - the early system NW-SE-trending is refolded by a later system (trends in the E-W to NE-SW range); 2) orientation and kinematics of faults related to superimposed compressional events: an early thrust system characterized by SW-ward tectonic transport; a later transpressive system consistent with a maximum compression oriented N-S $\pm 20^\circ$, and nearly horizontal. Although the occurrence of two compressional deformation events, interplaying in the construction of the Sicilian chain, is well-known, the field data, here collected, help to better characterize the relationship between shallow-seated and deep-seated structures.

Due to rare and thin Quaternary deposits, quantitative geomorphic analysis has been performed on the hydrographic network of the study area, because the river drainage of Sicily is believed to have developed during the Quaternary age. In particular, have been carried out:

1) azimuthal distribution analysis, by cumulative length, of stream channels related to different orders, taking into account structurally and lithologically homogeneous areas to evaluate the influence of Quaternary tectonics on the geometry of drainage patterns; NNW-SSE, NNE-SSW, E-W and N-S domains have been evidenced in lower orders of channels; 2) "azimuthal transect method", performed along 16 suitable segments crossing previously inferred fault zones, able to detect possible Quaternary strike-slip kinematics. Progressive apparent rotations of stream channels have been found, documenting the occurrence along the main rivers of Quaternary faults and suggesting both right-lateral (NNW-SSE oriented) and left-lateral (NE-SW oriented) kinematic components.

The multidisciplinary approach used suggests the geological/geomorphological setting of the study area is influenced by Quaternary faults with strike-slip component, highlighting a general congruency between hydrography and tectonics.

OSL DATING OF QUATERNARY TERRACES BETWEEN MT. ETNA AND THE CATANIA PLAIN

RISTUCCIA Gloria Maria¹, GUELI Anna Maria², MONACO Carmelo¹, STELLA Giuseppe², TROJA Sebastiano Olindo²

1 - Dipartimento di Scienze Geologiche, Università degli Studi di Catania
 2 - Laboratorio PH3DRA, Dipartimento di Fisica e Astronomia, Università degli Studi di Catania & INFN

Presenter e-mail: gloria.ristuccia@ct.infn.it

Key terms: Anticline; Mt. Etna; OSL dating; Pleistocene; Terraces

In the hills of Terreforti, located between the Catania Plain and the southern slope of the Mt. Etna, the Quaternary sedimentary substratum of volcano, composed of a Lower-Middle Pleistocene foredeep succession, crops out.

The basement is folded in a E-W trending anticline, which has been interpreted as a fault propagation fold at the front of the Maghrebic thrust system.

This sequence consists of about 600 m of marly clays followed by a few tens of meters of coastal sands and fluvio-deltaic conglomerates. These last are assigned to the Mindel-Riss interglacial stage, which rest unconformably on the terraced fluvial-coastal deposits.

In this area, there are evidence of the Etnean submarine to subaerial fissural early activity, represented by products of tholeiitic-transitional affinity (pre-Etnean volcanism). This phase is coeval or next to the deposition of the Etna substratum sediments. Potassium - argon (K/Ar) method have allowed to date (320-250 ka) the lava flows outcropping at the top of the oldest terrace (T1).

This work has consented, through structural survey and aerial

photographs at a 1:33000 scale, to identify seven orders of terraces between Mt Etna and the Catania Plain. In particular, the terraced deposits of the two higher orders, were deformed with the foredeep sediments. The present results are related to the chronology of the terraces obtained by the Optically Stimulated Luminescence (OSL) technique. From the intensity of luminescence emitted by quartz and feldspar crystals content in the sediment, the OSL is used to determine the total dose absorbed since the last optical bleaching in terms of Equivalent Dose (ED). The accumulation rate of total dose is assessed measuring the natural radioelements present of the sample in order to calculate the Annual Dose (AD). The relationship between ED and AD can be traced to the bleaching event that, in the case of sedimentary layers, corresponds with the age of formation.

The outer layers of each sample have been used in the laboratory for radioactivity measurements and water content determination; while the ED values were determined using the single aliquot regeneration protocol (SAR) coupled with coarse grain sample following the PH3DRA laboratory standard methodology.

OSL ages have allowed the correlation of coastal alluvial terraces with different isotopic stages corresponding to high-stands of the eustatic curve of reference. The results agree with data reported in the literature, based on the attribution of volcanic clasts contained in the terraced deposits to different Etnean volcano-stratigraphic units. This work has permitted the reconstruction of the tectonic evolution of the area of interest during the Middle-Upper Pleistocene, constraining in time the structures which deform the deposits.

Key terms: Mt. Etna; Cosmogenic Helium; Pernicana fault; surface exposure dating; seismic hazard

Mount Etna, Sicily, is located in a complex geodynamic position. It is situated at the intersection of the outer front of the Quaternary S-verging Apennine Maghrebian thrust, and N-S oriented extensional structures formed in response to a possible reactivation of Malta Escarpment. Extension mainly affects the eastern side of the volcano where the flank is sliding eastward. The Pernicana fault system (PFS) is one of the most important active structures of the eastern side of Etna and represents the northern boundary of the unstable flank of the edifice. It is a W-E left transverse fault that is down-thrown to the south. It has been active since late Pleistocene-Holocene time, it cuts basaltic lavas over a length of about 18 km, with a maximum throw of about 30 m. The system is a complex of dextral en echelon segments with an overall direction of N°110 E. The western and central sectors of the fault are characterized mainly by stick-slip behaviour with occurrence of several recent earthquakes over magnitude 4.0 (e.g. 2/04/2010, M = 4.2). The eastern part of the system is characterized by stable-sliding motion with aseismic creep phenomena. Slip rate data are mainly based on geodetic levelling (~20 years of measurement) and anthropic displacement measurements (from ~1920 A.D. to present) on the central part of the fault with a values range between 5 and 35 mm/yr. In the western sector, slip rates between 5 and 20 mm/yr have been determined from the displacement of historical lavas (from 1614 A.D. to present). In order to accurately determine the vertical displacement rates of Pernicana fault we have initiated a program of dating lava flows that are cut by the fault using in situ cosmogenic ³He (³HeC) exposure ages. Effort has been concentrated on the western sector of Pernicana fault where the normal component of fault movement dominates. The first site chosen is in a basalt flow near Mongibello that is cut by a 13 m fault scarp. Pyroxene phenocrysts were extracted from 3 samples of uneroded lava flow tops taken from the hanging wall of fault scarp. Helium isotope ratios in the melt step are between 7.5 and 22.5 Ra indicating that ³HeC is present in all the samples. Exposure ages range from 0.9 to 1.2 kyr (n = 6), yielding an average age of 1,088 ± 96 years (that includes uncertainty in ³HeC production rate). This suggests that the western sector of the PFS has had an average vertical slip rate of 11-12 mm/year over the last 1,000 years. The measured slip rate is consistent with previous values, but more dating work is underway to calculate the slip rate in an enlarged temporal window (few thousand years) with the aim of understanding the fault behaviour in the past and improving predictions of earthquake occurrence, i.e. reducing the uncertainties on the expected mean recurrence times.

Presenter e-mail: lferrant@unina.it

Key terms: Holocene uplift; paleo-earthquakes; Capo Vaticano

Capo Vaticano promontory is located along the Tyrrhenian coast of central Calabria, and, as part of the Calabrian arc, experienced sustained Quaternary uplift, reflected by flights of coastal terraces (Bianca et al., 2011, and references therein). In addition, the area is affected by active extensional faulting and strong historical earthquakes (Cucci and Tertulliani, 2006). Although long-term uplift has been studied since long, data on Holocene coastal deformation, which could provide vital information to assess active tectonic processes, are sparse (Antonoli et al., 2009). Previous studies identified a NE tilt of the promontory as reflected by a NE-decreasing elevation of marine terraces. On the SW side of Capo Vaticano, the tilt pattern is interrupted and terraces margin are offset by an extensional faults system, made of two branches (Coccorino and Nicotera faults). On the SW and NW side of the promontory, we mapped markers of raised

Holocene shorelines (terraced deposits, wave-cut platforms, barnacle and algal rims, and locally notches). Based on the elevation of the markers and on field relations between them, we recognized two different Holocene shorelines. On the SW side of the promontory, the higher (PS2) and lower shoreline (PS1) attain elevation of ~2 and ~1.4 m a.s.l., respectively. Morphologic relations indicates that relative displacement of the two shorelines above the sea level was abrupt, possibly related to earthquake uplift. We obtained calibrated radiocarbon ages of ~5.5-5.7 and ~4-2 ka for the upper and lower shoreline, respectively. This findings constrains two episodes of co-seismic uplifts between 5.5-4 ka (~0.60 m displacement) and after 2 ka (up to ~1.4 m), respectively. These abrupt displacements are superposed on a regional uplift that in the area, is occurring at rates approaching 1 mm/yr.

On the NW side, however, two shorelines appears to attain a lower elevation of ~1 m and ~40 cm a.s.l., respectively. Radiocarbon age constrains are yet preliminary to establish whether they coincide with PS1 and PS2, or are, at least partly, of different age. A yet upper shoreline has been mapped, but age constraints are not conclusive. Nonetheless, we suspect that three shorelines are present here.

Available data from the NE side of the promontory (Anzidei et al., 2006) indicate that a post-roman shoreline (PS0) exists, but is uplifted at lower rates (0.6 mm/yr). This observation, combined with the raised shorelines on the other sides of Capo Vaticano, suggests that Holocene uplift was asymmetric, with greater magnitudes to the NW and SW, likely related to co-seismic events which are not registered in the NE. This finding places a major constrain on the location of the 1905 seismogenic source, which should be west or south of the head, but not on the north. Significantly, on the SW side of the promontory, we have comparable uplift rates at sites located across the Coccorino strand of the border fault, suggesting the fault is locked or inactive. Instead, the Nicotera strand (and its offshore extension) may be active, in agreement with seismicity data (Cucci and Tertulliani, 2006).

THE USE OF HOLOCENE GEOLOGICAL AND ARCHAEOLOGICAL MARKERS TO DETERMINE COSEISMIC DEFORMATION: NEW OBSERVATIONS FROM THE TAORMINA COASTAL AREA (NORTHEASTERN SICILY)

SPAMPINATO Cecilia Rita¹, SCICCHITANO Giovanni¹, FERRANTI Luigi¹, MONACO Carmelo¹

1 - Dipartimento di Scienze Geologiche, Università di Catania
2 - Dipartimento di Scienze della Terra, Università di Napoli - Federico II
Presenter e-mail: cmonaco@unict.it

Key terms: eastern Sicily; coseismic deformation; Holocene

Detailed mapping of geological and archaeological markers around the Capo Schiso volcanic headland, a few kilometers south of Taormina, north-eastern Sicily, has documented the occurrence of three Holocene paleoshorelines raised at different altitudes. The uppermost shoreline (PS1) is represented by a fossiliferous beach deposit which is heavily eroded and only few small sections, at elevation ranging between ~3 and ~5 m above the present sea-level, are visible. The middle shoreline (PS2) was found at a maximum altitude of ~3 m and is represented by algal rims, remnants of barnacle bands and vermetid concretions, and by a fossiliferous beach deposit. The lowermost shoreline (PS3) includes remnants of algal rims, vermetid concretions, fossil barnacle bands and a beachrock, and reaches an elevation of 1.60 - 1.80 m. New radiocarbon dating results, integrated with published data nearby, provides an average uplift rate of 1.7-1.8 mm/yr in the last 5 ka, and constrains the occurrence of three co-seismic uplift events at 4.4-3.9 ka, 2.1-1.8 ka and <1.0 ka ago. These estimates are consistent to velocities obtained by the ancient Greek slipways of Naxos: in fact, comparing elevation and age of the considered archaeological marker with the curve of the predicted sea level rise, an uplift rate of ~1.72 mm/yr for the last 2.4 Ka can be estimated.

Abrupt displacements are tentatively attributed to footwall uplift along an offshore normal fault, but further investigations are needed to better constrain the causative source of past earthquakes. Notwithstanding, based on coastal tectonic analysis, this paper provides a new assessment of age and recurrence time of Holocene earthquakes in a historically seismogenic, and densely populated area.

THE ROLE OF TECTONICS IN THE TAMMARO RIVER BASIN: A GEOMORPHOLOGICAL APPROACH

CARTOIAN Elena¹, MAGLIULO Paolo¹, MASSA Bruno¹, VALENTE Alessio¹

1 - Università degli Studi del Sannio, Benevento, Italy

Presenter e-mail: elena.cartoian@unisannio.it

Key terms: Geomorphology; Tectonics; Southern Italy

The tectonic control on the setting of the Tammaro River basin was investigated by applying several different methodologies: analysis of surface drainage network by calculating morphometric parameters; reconstruction of longitudinal profiles and hypsometric curves, in order to seek significant changes in shape indicating particular lithological conditions and/or tectonic control; and, finally, analysis and comparison of preferential directions of fault families and streams by means of statistical analysis of the azimuthal orientations.

The Tammaro River basin, located between the Molise and Campania regions and about 670 km²-wide, is characterized by a bedrock mainly consisting of sandstone and/or clay alternated with marl and limestone, belonging to the Sannio and Fortore Tectonic Units. Fault families mainly strike NE-SW, NW-SE and E-W.

As a first step of this study, a "Map of the Hydrographic Network" of the basin was created through the digitization, in GIS environment, of both the stream courses and preferential drainage pathways on 1:25,000 topographic maps produced by IGMI (Italian Geographic Military Institute). This allowed to calculate the morphometric parameters of the hydrographic network. Then, the Tammaro River basin was subdivided into the 40 partial basins of the direct tributaries of the main stream, each of which was considered as a single geomorphological unit and studied separately. Examining the values of the morphometric parameters of each partial basin, it was found that the lower values of hierarchical anomaly density (ga) and hierarchical anomaly index (Δa), generally indicating a better organization of the hydrographic network, affected those partial basins characterized by minor areal extension.

According to several Authors, the Δa trend seems to be more influenced by the type and trends of the bedrock fractures than by erosional

processes. In the studied area, the Δa values range between 0.1 and 2.3; however, most values were close to or higher than 1, which indicates an elevated disorganization of the drainage network.

The analysis of the hypsometric curves allowed to identify 3 families of curves, on the basis of the integral hypsometric values. The most frequently occurring values ranged between 0 and 0.45 and between 0.45 and 0.55. In general terms, low values are typical of well-developed streams, along which linear erosional processes are negligible, while areal erosion strongly prevails on the surrounding slopes. Conversely, intermediate values are typical of basins affected by complex dynamics, in which the areal erosion and the linear erosion intensity are the same. Using a semi-automatic methodology, the river courses were rectified and the orientations of the stretches were determined. These data were classified into classes of 10° azimuth intervals and circular histograms were plotted. The main orientation domains of the watercourses were NW-SE, NE-SW and E-W, which are coherent with the strikes of the regional tectonic features that control the evolution of the local drainage network. Furthermore, N-S, NNE-SSW, NNW-SSE and ENE-WSW orientations were identified for some partial basins; they mainly affect the first and second order streams and this was interpreted as evidence of a more recent tectonic activity.

In conclusion, the results showed a discrepancy between the data deduced from the quantitative geomorphic analysis, that indicates a disorganized pattern, and those deriving from the hypsometric analysis, which provided values typical of well-developed basins. The statistic azimuthal analysis confirmed the control by recent tectonics on the setting of the hydrographic network; these effects are not yet evident on the morphology of the river basin. Thus, the study confirmed that the tectonic effects appear more slowly on the river basins, which tend to retain longer their planimetric configuration, than on the drainage network.

LATE NEOGENE EVOLUTION OF THE FORMIA PLAIN (SOUTHERN LATIUM)

SGAMBATO Claudia¹; MASSA Bruno¹; VALENTE Alessio¹

¹ - DSBGA - Università degli Studi del Sannio

Presenter e-mail: claudia.sgambato@gmail.com

Key terms: TECTONIC EVOLUTION; GEOMORPHOLOGY; FORMIA

This work aims at the reconstruction of the Neogene geological evolution of Formia area. The study area is located in southern Latium including the westernmost portion of Aurunci Mts.; this area is bounded by Liri - Garigliano Rivers to north, the Ausente Torrent valley to east and by Ausoni Mountains to west. The Formia Plain represent the southernmost portion of this area.

The superposition of extensional and compressional tectonics is the result of the complex relationships between the central and southern Apennines that connect in this area.

A shallow water carbonate succession (Late Triassic-Cretaceous) forms the structure of the Aurunci Mts.. Chaotic dark gray mudstones, embedding blocks of different ages, locally crop out. Turbidite deposits (Tortonian) widely crop out in the eastern sector followed by clays, sandy clays and mudstones with lenses of gypsum (Messinian). A polygenic conglomerate succession (Pliocene) rests in angular unconformity on Messinian deposits and widely crops out in the area (Scauri, Incrociatura Mt., Campese Mt., Mola Mt.). Fluvial and alluvial deposits (Pleistocene-Holocene), closely related to recent tectonics, crop in the entire Formia plain. Dunes (Late Pleistocene-Holocene) can be somewhere found along the coast.

Tectonic and morphological features have been examined through the use of aerial photographs and satellite-derived DEMs. Remote studies, conducted in pair with a geological survey at scale 1:25,000, helped to clarify the spatial distribution of main tectonic structures in the Formia area and determining the relative chronology of faulting events.

We propose a new tectonic history of the area beginning with an early compressive phase determining the east-verging transport of carbonate tectonic units (Tortonian-Messinian); this phase results in the development of NW-SE trending thrust faults (e.g.: Spigno Vecchia) and N-S trending side ramps.

A Late Messinian NW-SE extensive phase is responsible for the new-formation of NE-SW trending dip-slip normal faults and reactivation of NW-SE faults with strike-slip kinematics.

Since the Late Pliocene a second extensive phase, determine the lowering of the Aurunci Mts. carbonate structure towards the Tyrrhenian Sea, through a series of E-W trending normal faults. The severe erosion of carbonate relieves, followed to this last extensional phase, led to the formation of powerful alluvial fans.

An almost Early Pleistocene E-W trending fault system affects Pliocene conglomerates at southern slope of Campese and Incrociatura Mts.. The deviation of some river courses of the Formia Plain can be a clue of late Pleistocene-Holocene tectonics in the study area.

Key terms: Pernicana Fault System; Mt. Etna; structural geology; geodesy; seismology

This contribution investigates the Pernicana Fault System (PFS), a seismogenic structure that dissects Mt. Etna (Sicily). The study was carried out through a multidisciplinary approach based on integration of structural, geodetic and seismological data, with the aim to produce a consistent model for this complex sector of the volcano edifice.

The PFS is a W-E trending fault array, organized into segments arranged en-échelon, and displays a dominantly left lateral component of strike-slip. From West to East it joins the NE-Rift (1900 m a.s.l.), crossing Piano Provenzana and Piano Pernicana, and reaches Rocca Pignatello (1050 m a.s.l.) and Rocca Campana (900 m a.s.l.) where the fault branches out SE-wards into two fault segments. The former shows a roughly N105°E orientation from Rocca Pignatello to Rocca Campana, where the fault rotates to N090°E and terminates without morphological evidence; the latter propagates downhill from Rocca Campana with a roughly N120°E orientation. During the 2002-03 Mt. Etna eruption, an intense ground-fracturing phenomenon affected the entire NE flank, allowing to identify the development of the N120°E fault segment and to trace it down to the Ionian coast.

The work has been carried out with different approaches: structural analysis, to identify the kinematics and geometry of the fault system through the study of well-recognized structural markers; seismology, based on the analysis of focal mechanisms in order to unravel the dynamics of the system, and space geodesy, in order to infer the recent ground motions due to slip along the PFS.

Three main segments are recognised within the PFS: a western, a central and an eastern segment. The western and eastern segments indicate dominantly transtensional kinematics, with both important normal and strike-slip displacements, whereas the central segment best illustrates the effects of the strike-slip component. This segment was monitored with local networks based on GPS techniques since early 1997. GPS data indicate daily displacement vectors up to 50 cm as recorded during the first days of the 2002-03 eruptive event of the Mt. Etna volcano. These data collectively indicate a sliding towards SE of the southern block identified by the PFS.

The analysis of focal mechanisms is in general agreement with data inferred from structural analysis and GPS techniques, indicating a good kinematic and dynamic consistency. The eastern segment of the PFS is characterised by a low seismic activity and by the lack of recent earthquakes, therefore outlining that this part of the PFS is dominated by aseismic creep.

ULTRAHIGH-PRESSURE MINERALS FROM BOTH DOWNWELLING AND UPWELLING ENVIRONMENTS: SNAPSHOTS OF MANTLE CONVECTION ON A GRAND SCALE

GREEN Harry W. II¹

¹ - University of California, Riverside

Presenter e-mail: harry.green@ucr.edu

Key terms: UHPM; Mantle Convection; Subduction; Ophiolite; High Pressure

The concept of Ultra-High-Pressure Metamorphism (UHPM) grew out of the discovery that blueschist minerals in metasediments required simultaneous high pressure and low temperatures that, in turn, required rapid travel to several 10s of km to grow the minerals in the first place, and similarly rapid return to the surface to avoid their reaction to greenschist facies. Both the trip down and the trip back had to occur faster than any known mechanism. The birth of plate tectonics resolved this conundrum. Subsequent discovery of coesite and diamond in shallow protoliths extended the depth of implied subduction to > 150 km but the context remained transport of surface rocks to conditions with a high ratio of P/T. Indeed, the presence of coesite or implication of its former presence became the working definition of UHPM. However, mantle rocks caught up in UHPM terranes also can carry very deep signals. Prior to that discovery, metamorphic petrology implicitly assumed that travels of rocks begin at the surface; solid-state transport of dense rock from significant depth was implicitly thought to be impossible. Peridotite is the fluid by which the mantle of Earth convects, with the unavoidable implication that large volumes of such rock have "seen" the deep upper mantle and some must have circulated deep into the lower mantle. We now understand that they can carry memories of these travels in their microstructures. A simple example of this is the ubiquitous presence of pyroxene-spinel symplectites in spinel peridotites of ophiolites and mantle xenoliths, recording the former presence of garnet. A more complex example is exsolution of pigeonite at very high angles to (001) in diopside, recording depths of ~400 km in the Alpe Arami peridotite in the Swiss Alps. UHPM terranes now have yielded "memory" in continental lithologies of almost that deep. I'll provide case studies demonstrating these facts. Even more surprising, minerals recording comparable depths are now known from an ophiolite and the presence of diamonds in another demonstrates that this deep environment is not unique. The evidence that ophiolites form at Earth's surface is overwhelming. Nevertheless, chromites within them show unambiguous evidence of a highly-reduced environment of great depth and high temperature. One of them contains coesite-after-stishovite and TiO₂ (II), as well as titanium and boron nitrides, with no evidence of down-pressure reaction. Lastly, we now know that some diamonds contain inclusions from the mantle transition zone and the lower mantle. Indeed, I will show one such an inclusion for which the simplest interpretation of its microstructures is that it comes from the core-mantle boundary, as absurd as that sounds.

What more can these rocks tell us? Beyond identification of the relevant minerals, pretty much the only evidence marshaled so far has been from microstructures. Careful use of microfabrics is now also proving useful. But these rocks should not be of interest only to mineralogists and

structural geologists. UHPM rocks from continental collision terranes are the most abundant of these rocks and their geological context clearly tells us that they went down in a subduction zone and came back up along essentially the same pathway. Thus, it would seem inescapable that these rocks must have passed through a depth interval in which fluids from dehydration reactions in the downgoing slab have passed through them on their way to fluxing arc volcanism. They must contain evidence of those fluids, potentially inclusions of the fluid itself. For example, the "white rocks" of UHPM terranes that enclose the peridotites and eclogites have clearly been exhumed along with the denser rocks (they have coesite and (rare) diamonds included in zircons) but they have otherwise completely recrystallized back to the low-pressure assemblage. They surely must have included inclusions of the hydrous fluid passing through them as they returned to the surface.

MANTLE WEDGE PERIDOTITES: DECODERS OF DEEP SUBDUCTION ZONE PROCESSES.

SCAMBELLURI Marco¹

1 - Dipartimento per lo Studio del Territorio e delle sue Risorse, Università di Genova, Corso Europa 26, 16132, Genova, Italy

Presenter e-mail: marco.scambelluri@dipteris.unige.it

Key terms: Subduction; Fluids; Mantle peridotites; Metasomatism; Relicts

The physical and chemical changes at convergent plate margins affect the subducting slabs and the overlying mantle wedges. Flux melting of supra-subduction mantle regions is caused by fluid phases released by the subducting plates. The distribution of fluids and deformation in such settings affects the extent of mineralogical and structural transformation of rocks and, hence, the survival of relict minerals and structures of previous events. So far, much research has been focussed on the slabs and still few are the observations of rocks at the slab-mantle interface. For this purpose, information can be achieved from orogenic garnet peridotites. In several occurrences these are mantle slices tectonically sampled by the subducted continental plates and disclosing the characteristics of the mantle in a 100-200 km depth range. Such tectonic 'xenoliths' can retain old events, pre-dating their engagement in the subducting crust and enabling to design the long-term dynamics of the deep mantle. These processes are yet readable as meso to micro-scale structures, the geologic significance of which is unravelled through integrated structural, petrological and geochemical studies. Two case-histories of garnet peridotites hosted in subducted continental basements are presented here. The mantle rocks record different physical pathways prior to their engagement in the crust and correspond to: (i) shallow lithospheric mantle wedge dragged to depth (Ulten Zone garnet peridotites, Eastern Alps, Italy); (ii) transition-zone mantle upwelled and accreted to cratonic roots (UHP garnet peridotites of the Western Gneiss Region, Norway). Both mantle occurrences were flushed and metasomatized by incompatible element-rich fluids sourced from the continental crust. Fluid infiltration in the two systems took place at variable depths: < 3 GPa in Ulten and about 7 GPa in Bardane, with formation of new subduction-related majoritic garnet in veins. Interaction with the subduction fluids is crucial to rock recrystallization and to the preservation of the earlier structures.

Comparable geochemical fingerprints observed in HP and UHP Ulten and Bardane mantle rocks call for concomitant subduction of the continental crust, providing the incompatible element-enriched fluids. For Bardane this implies crustal subduction to 200 km depth. The two examples show that mantle refertilization by crust-derived COH subduction fluids operates over a large depth range. The textural features of Bardane and Ulten Zone mantle rocks indicate that outside the channelways for fluid infiltration the rocks preserve pre-subduction, long-lasting stories and pristine geochemical characteristics. The available data show that crustal slabs subducted to variable depths entrain mantle wedge peridotites, the relict structures of which emphasize the stories and fate of the subcontinental mantle through time. Comparably with uprising magmas, the subducted continental crust appears to be a very efficient carrier to the surface of ultra-deep mantle tectonic 'xenoliths' that represent major observatories of diverse metamorphic and geodynamic histories recorded by the Earth's mantle at variable depths.

DEFORMATION - METAMORPHISM RELATIONSHIPS IN THE RODINGITES OF THE ZERMATT-SAAS ZONE

ZANONI Davide¹, REBAY Gisella¹, SPALLA Maria Iole²

1 - Università di Pavia

2 - Università di Milano and CNR - IDPA

Presenter e-mail: davide.zanoni@unipv.it

Key terms: Rodingite; structural and metamorphic evolution; Western Alps

The Zermatt-Saas Zone is a remnant of the Piedmont-Ligurian oceanic lithosphere, within the suture zone of the Western Alps.

The investigated rodingites are hosted in serpentinites with minor eclogitic metagabbros and chlorite-schists and record three groups of superposed syn-metamorphic ductile structures. Both D1 and D2 are associated with the development of high-pressure parageneses. Mineral and textural relics predating these stages developed during the serpentinization and rodingitization processes ascribed to oceanic metamorphism.

S1 is a relic foliation preserved only in rodingite dykes and lenses, in the millimetre thick microlithons of D2 crenulation cleavage and as internal foliation of garnet porphyroblasts; it is marked by pyroxene and amphibole or vesuvianite, chlorite and pyroxene SPO.

S2 is the dominant fabric in rodingites and metagabbros; in rodingites it is evidenced by alternating chlorite- and amphibole-layers and trails of small garnet and vesuvianite.

In metagabbros pre-D3 relics are garnet, omphacite, rutile and glaucophane + phengite and, successively, barroisitic amphibole, zoisite, Mg-chlorite, phengite and ilmenite.

D3 structures are the most pervasive in serpentinites and metagabbros; they consist of a crenulation cleavage type foliation associated with open metric folds and are correlated to post-P peak greenschist facies retrogression. S3 in rodingites is marked by Fe-chlorite, replacing zoisite. Both S2 and S3 affect the reaction rim underlying the serpentine and rodingite boundaries, which consists of chloritic schist.

HP fabrics between metagabbros and rodingites have been correlated on

the base of structural analysis, allowing the identification of the HP assemblages in S1 and S2 fabrics in eclogitized rodingites: S1 - garnetI, Mg-chloriteI, epidote-clinozoisiteI, clinopyroxeneI, vesuvianite, titanite + amphiboleI; S2 - Mg-chloriteII, vesuvianiteII, clinopyroxeneII, epidote-clinozoisiteII, garnetII (in veins), titaniteII, + amphiboleII; locally clinopyroxene forms porphyroblasts either predating S1 or S2; S3 / post-D2 - amphibole, Fe-chlorite, epidote. These results highlight that vesuvianite is coeval to chlorite, epidote, garnet, clinopyroxene HP assemblages.

NUMERICAL SIMULATION OF AN INTRAOCEANIC/INTERCONTINENTAL SUBDUCTION: THE CASE OF THE OPHIOLITIC VOLTRI MASSIF (WESTERN ALPS).

MALATESTA Cristina¹, GERYA Taras², SCAMBELLURI Marco¹, FEDERICO Laura¹, CRISPINI Laura¹, CAPPONI Giovanni¹

1 - Dip.Te.Ris, University of Genova

2 - Institute of Geophysics, ETH Zentrum

Presenter e-mail: cristina.malatesta@unige.it

Key terms: intraoceanic subduction; numerical models; serpentinite channel; Voltri Massif; exhumation

We run 2D numerical models in order to highlight the processes occurring during subduction/exhumation at intraoceanic subduction settings. We reproduced a relatively narrow oceanic basin (about 600 km-wide) surrounded by continental crust; an "heterogeneous" oceanic lithosphere, as the one produced at present slow/ultra-slow spreading ridges, floors the oceanic basin. Gabbros are discrete bodies inside the serpentinized mantle; the latter forms highs on the ocean floor that are spaced out by a discontinuous basaltic layer; a homogeneous sedimentary cover overlies them. Subduction starts at a weak zone in the mantle and the process is free to evolve. During subduction the fluids released from the slab migrate upward hydrating the overlying mantle-wedge and thus producing a serpentinite channel.

The relevance of several parameters on subduction/exhumation dynamics has been tested. In particular, serpentinite rheology, initial slab dip, structure and age of the oceanic lithosphere are the most important parameters controlling the geometry of the channel. Convergence rate and distance of the subduction zone from the continental margins have a minor role. If serpentinite is controlled by a power-law rheology, planar or wedge channels form; a Newtonian deformation style produces planar or "hourglass" channels that widen with increasing depths. Serpentinite rheology strongly controls also the mixing and exhumation mechanisms inside the channel. If we consider a Newtonian rheology of serpentinite, slab slices, sediments and mantle-wedge serpentinite are mixed together inside the channel. Slab serpentinite and mantle-wedge serpentinite can be therefore closely associated. Conversely, a continuous accretion and underthrusting of slab slices at the base of the channel occurs if serpentinite is controlled by a power-law rheology; in this case a shallow circulation inside the serpentinite wedge, enhanced by high convergence rate, prevails. Considering a serpentinite controlled by a Newtonian rheology, a stronger flux inside the serpentinite channel occurs; a mélange made of slab slices, sediment or mantle wedge serpentinite is finally exhumed even from depths exceeding 70 km. The rise of the mélange occurs after continental crust subduction and at the onset of collision. The main force driving exhumation is buoyancy, related to the presence of low density serpentinite, matched with a slight slab rollback. One of these models fits well some peculiarities that were observed in a serpentinite massif outcropping in the Ligurian Western Alps (Voltri Massif); the Voltri Massif includes ophiolitic rocks that record metamorphic peak conditions varying from the blueschist- to the eclogite-facies.

The comparison between P-T paths recorded by some metagabbro bodies of the Voltri Massif and P-T trajectories of selected gabbro lenses in the 2D simulations showed several similarities: they are clockwise, reach comparable metamorphic peak conditions and the exhumation paths are almost isothermal. Moreover, the modeled exhumed mélange and the Voltri Massif are characterized by similar exhumation velocities (mm/a) and comparable areal relationships between the forming lithologies. Finally, the analysis of the selected numerical simulation allowed us to define a hypothetical evolutionary model for the Voltri Massif. Few real outcrops were located in their paleogeographic position comparing natural and simulated P-T peaks: ophiolite outcrops recording eclogitic metamorphic conditions probably pertained either to the slab or to the upper plate, since in the model they both can reach high depths; mafic lenses recording lower metamorphic conditions (blueschist facies) can be tentatively related to portions of the oceanic lithosphere scraped from the overriding plate and dragged inside the serpentinite channel. As observed in the simulation, the final stage predicts the exhumation of the Voltri Massif rocks in relation to the presence of buoyant serpentinite.

EVIDENCE FOR ALPINE ECLOGITE-FACIES OVERPRINT IN THE MONTE ROSA MASSIF (ALPS)

GODARD Gaston¹, MARTIN Silvana²

1 - IGGP, Paris, godard@igpp.fr

2 - Dipartimento di Geoscienze, Padova

Presenter e-mail: silvana.martin@unipd.it

Key terms: Distinct metamorphic stages; Eclogite metamorphism; Monte Rosa nappe; Western Alps

On the northern side of the Aosta valley (Italy), the Alpine collisional wedge is characterized, from bottom to top, by: (i) the Monte Rosa nappe, (ii) the eclogite/blueschist-facies Zermatt-Saas and Combin meta-ophiolites, and (iii) the capping upper Austroalpine units (i.e. Sesia-Lanzo, and the Dent Blanche klippe). These 3 complexes have been classically attributed to the pre-Alpine European continental margin (Monte Rosa), Piedmont ocean (Zermatt-Saas and Combin), and Adria continental margin (Austroalpine), respectively (e.g. Dal Piaz et al., 2001). The Monte Rosa nappe may be in turn subdivided into three main units: (i) Variscan high-grade gneisses; (ii) Upper Carboniferous and/or Lower Permian granite-granodiorite plutons; (iii) remnants of Permian-Mesozoic sedimentary cover and the composite Furgg zone (Beath, 1956). The pre-granitic basement is composed of paragneiss, micaschists, and migmatite (see Dal Piaz, 2001), which have undergone high-T low-P metamorphic conditions during the Variscan orogeny (e.g. Engi et al., 2001). They were sharply intruded by Upper Carboniferous granodiorites

and Permian granites (Hunziker, 1970; Liati et al., 2001; Scherrer et al., 2001). The whole Variscan basement was deformed and metamorphosed during Alpine orogeny. On the southern side of the Monte Rosa Massif (e.g. Rifugio Città di Mantova, Pian di Verra, Brusson), the migmatitic paragneisses, as well as the orthogneisses that derived from the Variscan granodiorites and granites, show petrological evidence for two distinct metamorphic stages. An early paragenesis, typical of high-T low-P conditions and coincident with migmatitisation in the paragneiss, consists of biotite + quartz + plagioclase + garnet ± cordierite ± K-feldspar + ilmenite. During a second stage, the rocks underwent a high-P metamorphism that is indicated by several metamorphic reactions:
 Biotite + plagioclase = garnet + phengite + quartz + rutile [micro-coronas];
 Biotite + K-feldspar = phengite + quartz + rutile [micro-coronas];
 Biotite = garnet + phengite + rutile [pseudomorphs];
 Ilmenite + plagioclase = garnet + rutile + quartz [coronas around ilmenite];
 Cordierite = garnet + micas + kyanite ± quartz [pseudomorphs];
 Plagioclase = albite [possibly after jadeite] (+ minor phengite + zoisite + kyanite) [pseudomorphs];
 Monazite + plagioclase = apatite + allanite [micro-coronas].
 These reactions, which produced garnet, rutile, and phengite at the expense of biotite, ilmenite, K-feldspar and plagioclase, are typical of a high-P eclogite-facies metamorphism.
 These two stages belong to the Variscan orogeny (migmatitisation and granitic intrusions) and the Alpine orogeny (eclogite-facies coronas and pseudomorphs). Their P-T conditions have been estimated to be T = 700°C and P = 6 kbar, and T = 600-700°C and P > 20 kbar, respectively. This metamorphic history seems characteristic of the whole Monte Rosa basement, since evidence for eclogite-facies metamorphism has also been mentioned elsewhere in the Massif (Chopin & Monié, 1984; Dal Piaz & Lombardo, 1986; Le Bayon et al., 2001). Very similar rocks are also well known at Monte Mucrone (Alps, Sesia-Lanzo) and have been observed in the Variscides (see Godard, 2009).
 The Monte Rosa nappe would represent a slice of the Variscan European continental crust that underwent subduction and subsequent eclogite-facies metamorphism during Alpine convergence. In this part of the Alps, not only the meta-ophiolites and the upper Austroalpine nappes show an eclogite-facies metamorphic imprint, but the Monte Rosa basement as well, suggesting that most of the Alpine collisional wedge entered in subduction at an early stage of the Alpine orogeny.

MULTISCALE STRUCTURAL ANALYSIS IN SUBDUCTED CONTINENTAL CRUST OF WESTERN ALPS: THE MONTE MUCRONE EXAMPLE (SEZIA-LANZO ZONE).

DELLEANI Francesco¹, SPALLA Maria Iole¹, CASTELLI Daniele², GOSSO Guido¹

1 - Università degli Studi di Milano

2 - Università degli Studi di Torino

Presenter e-mail: francesco.delleani@unimi.it

Key terms: subduction-related deformation; HP metamorphism; Sesia-Lanzo Zone

The Mt. Mucrone metagranitoid is one of the extensively explored Permian intrusives belonging to the Eclogitic Micaschists Complex (EMC) of Sesia-Lanzo Zone (SLZ) within the high-pressure (HP), metamorphic belt of Western Alps (e.g. Compagnoni et al. 1977). An integrated structural and petrological study has been focused on the still poorly-analysed southern slope of Mt. Mucrone, in order to integrate the available data and to relate them with the structural and metamorphic history inferred in the Mombaron-Mt. Mars area (Zucali et al., 2002).
 EMC comprises micaschists, paragneisses, metagranitoids, eclogites and impure marbles (Compagnoni et al., 1977).
 All these lithotypes are eclogitized and typically show a foliated fabric marked by Qtz, Pg, Phe, Grt, Gln, Jd (or Omp), Rt and Zo. This HP fabric is the axial plane foliation (S1) of the oldest recognized fold system (D1). Minor volumes of eclogite, metagranitoid and paragneiss only display coronitic reaction textures. The D1 deformation is highly heterogeneous in metagranitoids where domains fully preserving the igneous texture (grey-type metagranite) are juxtaposed to foliated domains (green-type metagranite). Isoclinal folding D2 is associated to coronitic reactions producing Qtz, Phe, Pg, Omp, Aeg, Gln, Grt, Czo and Rt; a foliated S2 fabric locally develops in some metapelites. D3 meter-thick mylonitic shear bands localize a S3 foliation marked by Qtz, Phe, Pg, Rit, Brs, Win, Grt, Na-Agt, Mg-Chl, Czo and Ttn.
 The last groups of structures are associated with the growth of Ab, Qtz, Phe, Pg, Act, Ep, Chl and Bt, and consist of either open to gentle folds (D4 and D6) or centimeter-thick shear zones (D5).
 During D1, metamorphic reactions in the grey-type metagranite occurred without the development of a new planar or linear fabric: pseudomorphic replacement of the igneous Pl by fine-grained Jd, Zo and Qtz, partial replacement of Bt by Phe + Grt; development of fine-grained Phe after igneous Kfs. During D2 widespread relics of primary Bt are preserved and the whitish pseudomorphic aggregates of Jd, Zo and Qtz are only partially replaced by Aeg and/or Omp. In the green-type metagranite, the combined effect of deformation/recrystallization and fluid migration during D1 allowed the complete replacement of the igneous Bt and Pl by coarse-grained Phe and greenish Jd.
 Deformation-metamorphism relationships evolution point to the development of D1 and D2 under Qtz-eclogite facies conditions, of D3 under blueschist-facies conditions, and of D4 to D6 under greenschist-facies conditions.
 During D1, the effects of strain gradients on reaction progress influences the compositional zoning of Grt in the mylonitic metagranitoids (green-type) with respect to those observed in Grt from the poorly deformed ones (grey-type).
 As proposed for the metagranitoids of the eastern slope of Mt. Mucrone (Castelli et al., 1994), the distinction between the two types of metagranitoids, is consequent to a fabric and re-equilibration gradient during the D1, eclogite-facies transformations.

Key terms: subduction; tectonic trajectory; multiscale analysis; P-T-t-d path

Pre-Alpine continental crust of western Alps is widely affected by subduction-related high-pressure low-temperature (HP-LT) metamorphism and the Sesia-Lanzo Zone (SLZ) represents the widest crustal slice re-equilibrated under HP conditions during Late-Cretaceous (early-Alpine) times. Its Alpine tectonic evolution is compatible with an uplift during active oceanic lithosphere subduction (e.g. Spalla et al., 1996; Meda et al., 2010; Zucali & Spalla, 2011). The SLZ consists of three main lithological complexes (e.g. Compagnoni et al., 1977): i) Gneiss Minuti complex (GMC); ii) Eclogitic Micaschists complex (EMC); iii) II Dioritic-Kinzigitic Zone (IIDK). IIDK consists of kilometric lenses of pelitic and mafic granulites escaping the eclogitic re-equilibration. EMC and GMC, both pervasively eclogitized, strongly differ in the volume percentage of greenschist re-equilibration (Stuenitz, 1989; Spalla et al., 1991). In the southern SLZ the metamorphic complex of Rocca Canavese thrust sheets (RCT; Pognante, 1989 a; Pognante, 1989b) has been recognised, on the ground of its strongly contrasted Alpine metamorphic evolution, characterized by a P-climax recorded under very LT conditions. A multi-scale structural analysis has been performed to support the acquisition of new highly detailed petrologic data, useful to refine, and better constrain, the tectonic trajectory of such a peculiar crustal slice. The result of structural analysis field-work is the reconstruction of a superposed grid of metamorphic foliations allowing the regional scale correlation of structural and metamorphic stages. The micro-structural investigation identified mineral assemblages marking successive fabrics in each rock type. In this way, by means of micro-structural analysis of the successive foliations, details on relative chronology of structural imprints and metamorphic environments in which they developed have been acquired. Chemical data on mineral phases were collected discriminating the micro-structural sites, with the goal of an accurate reconstruction of a Pressure-Temperature-relative time of deformation path: a fundamental tool to infer tectonic trajectories of metamorphic units, involved in a subduction system dynamics.

Presenter e-mail: francesca.remitti@unimore.it

Key terms: Northern Apennines; subduction channel; Sestola-Vidiciatico tectonic unit; Subligurian Unit

During the Miocene, the no-longer active oceanic accretionary prism -the Ligurian Units- and its wedge-top sediments - the Epiligurian Succession- gradually overthrust the Adria plate and its sedimentary cover - the Tuscan and Umbrian Succession- as deduced from the progressive younger age of the foredeep deposits. During this overthrusting at least a second major décollement was activated, allowing the underthrusting of the different components of the Sestola-Vidiciatico tectonic unit in the southeastern part and of the Subligurian Units in the northwestern part of the Emilia Apennines to the Ligurian Units. The components of both the Sestola-Vidiciatico tectonic unit and Subligurian Units - are: a) Cretaceous to middle Eocene deep-water sediments deposited on oceanic, transitional and/or thinned continental crust (the Ligurian Units and the pre-middle Eocene Subligurian Units) originally composing the Ligurian-Subligurian accretionary prism; b) slope apron and thrust-top basin deposits (Modino succession, Porretta succession and epi-Subligurian Units) sedimented on the frontal part of the Ligurian-Subligurian prism starting from the middle Eocene. Therefore all the components sandwiched between the Ligurian prism and the Tuscan-Umbrian Units derive from the underthrusting of the toe of the overriding plate and its slope deposits which occurred during the contemporaneous underthrusting of the foredeep deposits. This evidence point to the formation of a subduction channel composed of material moving both with respect to the upper and the lower plate and bounded by two main décollements (at the top of the Tuscan and Umbrian Succession, and at the bottom of the Ligurian prism). The channel was fed mainly by a process of tectonic erosion which affected the frontal part of the upper plate. The age of the youngest block in each considered section of the subduction channel of the Emilia Apennines constrains the time of the underthrusting. The detailed reconstruction of the spatial distribution of the slope deposits of different ages shows that the time of underthrusting varies from the inner sector - at ~100 km from the Ligurian prism front- to the external sector - at ~10 km from the Ligurian prism front - and ranges from at least the early Miocene (Aquitainian) to the middle Miocene (Serravallian). During the overthrusting the upper plate remained mainly undeformed, as suggested by the subduction channel model (Shreve and Cloos, 1986).

This is testified by the Epiligurian Succession - the prism sedimentary cover- that do not show evidence of major deformation structures. From the regional thermochronological study of Thomson et al. (2010), it is known that most part of the material inside the channel underthrust from the Aquitanian (early Miocene) to the Langhian (middle Miocene), reached temperatures sufficient to reset the apatite fission-track system (>120°C) and was exhumed at a time younger than 10 Ma after the end of the incorporation of new material in the subduction channel (younger blocks are Serravallian in age) and the deactivation of the channel. New fission track data, integrated with geological data, allow to determine that part of the material was exhumed during the activity of the subduction channel (i.e., during the Aquitanian). A possible mechanism controlling this early exhumation is the deactivation of -part?- of the frontal section of the upper décollement at the bottom of the Ligurian Units and the activation of another deeper main décollement inside the subduction channel material.

Key terms: Subduction; Collision; Canadian Cordillera

In the Northern portion of the Thor-Odin dome, boudins and lenses of ultramafic rocks (JOHNSTON, 1998) occur along the Thor-Odin high strain zone (e.g. JOHNSTON et al., 2000, KRUSE & WILLIAMS 2007), at the transition between the "Selkirk allochthon" and the Monashee complex. The Selkirk allochthon has been interpreted as a sheet thrust over the Monashee complex (e.g. READ & BROWN 1981; BROWN et al. 1986), or more recently, as an upper level of an infrastructure zone (that includes both the Selkirk allochthon above, and the Monashee complex below) down-dropped by a normal shear zone, during crustal extension (KRUSE & WILLIAMS 2007). The occurrence of peridotite boudins in a regional scale shear zone makes their structural and petrologic investigation crucial to infer the tectonic context in which they were coupled with the surrounding rocks of the continental crust. The ultramafics are embodied in Bt-Sil-bearing gneisses, with minor metabasics, and are intersected by pegmatite dykes. Detailed structural mapping indicates that the peridotites are boudins aligned in the regional scale high-grade foliation and that locally they contain an internal foliation (STI) that is at a high angle to the country rock foliation. The latter, is part of a regional transposition fabric, marked by SPO of microboudinaged Sil and red brown Ti-rich Bt, wrapping garnet porphyroblasts. In the peridotites, two textural types are recognizable at the microscale: granoblastic (polygonal texture with medium grain size) or poikiloblastic (with pyroxene poikiloblasts, partially replaced by amphibole). The granoblastic type, which occurs where the ultramafics show a foliated texture (STI), contains Ol, Opx, Spl, minor Amp and Phl and opaque minerals. The poikiloblastic type is not foliated and comprises Ol, Amp, Opx, Spl, Phl, opaque and rare Cpx. Amp and Phl occur as porphyroblasts or in veins. This texture characterizes undeformed domains preserved in rocks of the granoblastic type (STI). Two kinds of Amp and Phl have been detected: (1) brown Amp, which replaces Px and is partially replaced by a thin symplectite of green Amp and Spl and (2) green Amp, which occurs where brown Amp recrystallizes, showing a foam texture. Microstructural investigations at the electron microscope scale reveal the occurrence of relics, aligned parallel to a discordant internal foliation of Ol polygonal grains defining STI. This is diagnostic for inferring the earlier metamorphic evolution of the ultramafics. Whole rock chemical composition data indicate that these rocks are metasomatized mantle peridotites. Variations in mineral chemistry associated with superposed fabrics in peridotites and country rocks allow their metamorphic and microstructural evolution to be inferred and help to unravel the emplacement history of mantle peridotites in the high-grade continental crust of the Thor-Odin dome.

RECONSTRUCTION OF PTD PATHS IN THE SHUSWAP COMPLEX, CANADIAN CORDILLERA: AN EXAMPLE FROM JOSS MOUNTAIN

ZANONI Davide¹, WILLIAMS Paul F.²

1 - Università di Pavia

2 - University of New Brunswick

Presenter e-mail: davide.zanoni@unipv.it

Key terms: Tectono-metamorphic memory; Transposition; Monashee complex

Joss Mountain is located in the south-eastern Canadian Cordillera and is

part of the Shuswap complex of the Omineca belt (SE British Columbia), which is one of the five belts of the Canadian Cordillera. This belt consists of reworked intrusive and metamorphic rocks of the Precambrian North American craton, exhumed during the accretion of terranes to the North American (Laurentia) margin during Middle-Late Jurassic and Cretaceous. The study area is in the hanging wall of a high-strain-shear zone that bounds the Thor-Odin dome of the Monashee complex, one of the deeper metamorphic core complexes of the cordilleran orogen. Rocks in the Joss Mountain area mainly comprise marbles, calcisilicates and layers of metagranitoid. Layers of metapelite and quartzite, within both calcisilicate and metagranitoid, are less common. All these rocks display a penetrative sub-horizontal transposition foliation (ST) at micro to regional scale. There are at least two generations of W- SW-trending intrafolial folds (F1 and F2) coeval with ST. The latter is overprinted by, up to km-scale SW-vergent F3 folds that lack an axial plane foliation, and an upright NW-trending regional-synform (F4). Minor F4 folds are upright, open, and plunge gently north. Felsic and younger mafic dykes crosscut all the ductile structures.

Wm-bearing metapelites and Bt-bearing schists have been analyzed at the micro-scale.

In Wm-bearing metapelites ST is defined by shape and lattice preferred orientation of WmII and BtII. Coarse-grained WmI and BtI mark intrafolial folds between ST films; also WmI forms coarse-grained porphyroclasts wrapped by ST. Coarse-grained Grt shows rare inclusion trails oblique to ST, which are straight in the core and bent at the rim of porphyroblasts, and locally are continuous with ST in the matrix, suggesting that Grt porphyroblasts grew during progressive ST development. Grt encloses BtI, Qtz, rare PII, WmI and opaques. Fine-grained Grt shows rational grain boundaries with BtII. Post-ST micro-shear zones are marked by BtIII ±Sil, and locally replaced by WmIII and Chl. Sil also rims or overgrows WmI and II.

In Bt-bearing schists ST is defined by lattice and shape preferred orientation of BtII laths and PIII and Qtz layers with very rare KfsII. Relicts of BtI, KfsI, and PII are locally deformed and wrapped by ST. Grt porphyroclasts appear pre- to syn-ST, indicated by inclusion trails at a high angle to ST, in the core and progressively asymptotic to ST in the outer part of the porphyroclasts. PIII and minor Qtz form a corona around Grt. BtIII marks shear bands at a low angle to ST. Rare Chl grew at the expense of Bt; Chl-filled fractures intersect Grt and are sub-orthogonal to the inclusion trails.

The slight variation in Ti in the different Bt generations is consistent with temperature varying between 640° and 700°C. The Ti-content in BtIII, associated with Sil, is consistent with a decompression below 0.6 GPa. Grt and Pl composition is consistent with a pressure of 0.7 - 0.6 GPa during ST development.

Pressure and temperature estimates for ST development at Joss Mountain are slightly lower than those estimated for the P-T climax during ST development in the western part of the Thor-Odin dome. This result suggests that Joss Mountain rocks were at a shallower structural level than rocks of the Thor-Odin dome during ST. This is consistent with Joss Mountain rocks being down-dropped relative to Thor-Odin rocks.

Presenter e-mail: a.grande@igg.cnr.it

Key terms: pseudotachylite; mylonite; ultramylonite; felsic granulite; deep crust

Natural examples indicate that pseudotachylites coexist in the same outcrop with mylonites and ultramylonites. Pseudotachylites intimately associated with mylonites and ultramylonites can develop in high strain zone close to the brittle-ductile transition (e.g. Passchier, 1982) or entirely within the ductile regime as result of plastic instabilities (e.g. Hobbs et al., 1986; Handy & Brun, 2004).

This study reports microstructural investigations on two pseudotachylite veins found within the felsic granulites at the base of the ~20-25 km thick Variscan crustal section outcropping in the Serre Massif (southern Calabria). Felsic granulites consist of quartz, plagioclase, K-feldspar, biotite, garnet, sillimanite and accessory minerals. Stretched minerals and S-C composite foliations are detected in zones crystal-plastic deformation. In places, felsic granulites exhibit an alternance of mylonitic and ultramylonitic bands (a few millimeters thick). Pseudotachylite fault-veins develop along planes, which have a parallel orientation to the mylonitic and/or ultramylonitic foliation. Locally, pseudotachylite fault-veins occur along the S-C composite foliations of the felsic granulite. On the other hand, the pseudotachylite injection-veins cross cut the mylonitic and/or ultramylonitic bands.

Microstructural observations indicate that the felsic granulite exhibits a strong grain-size reduction along the S-C composite foliations and near the contact with the pseudotachylite veins. Back scattered electron (BSE) images, obtained by scanning electron microscopy (SEM) and Field-Emission Gun SEM, show that in proximity of the contact with the pseudotachylite the garnet of the felsic granulite is fractured and shows rims characterized by a new crystallization of very small euhedral garnet

(3-4 μm). On the other hand, the ultramylonitic bands display a very fine-grained matrix and have a dark appearance. However, the BSE images reveal a strong penetrative foliation, which is defined by the alignment of biotite and by the shape preferred orientation of quartz, plagioclase and garnet. Moreover, the ultramylonitic bands are characterized by a new crystallization of very small crystals (a few microns in length) of sillimanite and K-feldspar, aligned along the foliation planes. Matrix of the pseudotachylites is microcrystalline and contains abundant clasts (>50%) made up of quartz, plagioclase, K-feldspar, garnet and rare biotite. Clasts in the matrix are aligned with a parallel orientation to oblique foliation of the mylonitic granulite. At the margin of the vein, garnet of the pseudotachylite may occur in two habits: 1) garnet

microlites with very small sizes (3-4 μm) and an idiomorph habit, which formed by direct crystallization from the frictional melt, and 2) garnet

clasts (a few ten micrometres in size), with rims characterized by a new crystallization of very small garnets (<2µm) and with a similar aspect to the garnet rims of the host rock. In the vein centre, the matrix is mainly composed of skeletal plagioclase and biotite (a few microns in length). Plagioclase and biotite microclots often nucleated on rounded clasts of quartz or plagioclase. Garnet microclots are absent in the vein centre. These data, combined with the indications for the formation depth of the pseudotachylytes (21-23 km) obtained by Altenberger et al. (2010), indicate that during propagation of the seismic rupture the shear deformation was highly heterogeneous and took place through the development of alternating pseudotachylyte and ultramylonite, as result of plastic instabilities.

Presenter e-mail: paola.tartarotti@unimi.it

Key terms: Southern Apennine; ophiolite; blue-schist facies; oceanic alteration; amphibole

The Southern Apennines (SA) chain is a fold-and-thrust belt derived from the collision between the African and European plates starting in Upper Oligocene. The oceanic lithosphere of the Jurassic Tethys interposed between the paleo-Africa and paleo-Europe now occurs as ophiolitic slices enclosed within the Liguride accretionary wedge, which is part of the SA chain. Ophiolites consist of dominant serpentinites and minor mafic rocks exposed in the north-eastern slope of the Pollino Ridge (Calabria-Lucania border zone). Here, serpentinitized peridotites are cut by metadolerite intrusions showing different types of structure, ranging from magmatic intersertal/intergranular through cataclastic to mylonitic. Bulk-rock chemistry suggests that the protolith of mafic rocks has a N-MORB affinity. Based on mineral assemblage and texture, three different metadolerite types were recognized: plagioclase, clinopyroxene-bearing metadolerite; plagioclase, clinopyroxene, brown amphibole-bearing metadolerite, and plagioclase, clinopyroxene, brown amphibole, blue-amphibole metadolerite. Relict primary microstructural domains were selected for deciphering the tectonic and metamorphic evolution of metadolerites and hosting serpentinites. Such domains are characterized by metamorphic mineral pseudomorphs related to oceanic alteration in the Jurassic Tethys, in turn replaced by orogenic metamorphic minerals under static recrystallization. Namely, primary clinopyroxene (augite) is first replaced by pseudomorph brown amphibole rimmed by colourless, pale green, or blue-green amphibole, although in some samples green amphibole is pseudomorphous on clinopyroxene; all these amphiboles are interpreted as being of oceanic origin. Brown amphibole shows Mg-hastingsite, edenite, pargasite, Fe-hastingsite, Mg-hornblende compositions, whereas colourless, pale green, green, and blue-green amphibole show Mg-hastingsite, hastingsite, edenite, actinolite, tschermakite and Fe-tschermakite compositions. Blue amphibole then grows at the rim of brown or green amphibole, and is interpreted as being crystallized during the early stage of orogenic metamorphism. Within some structural domains, relict clinopyroxene is replaced by pseudomorphs with a zoned distribution from rim to core, with brown amphibole being at the external rim, blue amphibole at the internal rim, and chlorite+epidote at the core. Blue amphibole has glaucophane, Mg-riebeckite, and winchite compositions. The orogenic mineral assemblage in metadolerites includes glaucophane, Mg-riebeckite, lawsonite, phengite, pumpellyite and aegerin-augite which are typical minerals of LT-blueschist facies conditions. Textural and mineralogical observations suggest that the metadolerites of the Frido Unit have been affected by early ocean-floor metamorphism in the amphibolite to greenschist facies and subsequent orogenic metamorphism under relatively HP/LT conditions. Such polyphase metamorphic evolution is well preserved in the metadolerites probably in response to deformation partitioning within the Apennine accretionary wedge.

Key terms: multi-scale; tectonometamorphic; permian; geochronology; western alps

The Dent-Blanche Unit (Austroalpine domain, Western Italian Alps) is constituted by Valpelline and Arolla units, respectively composed by high-grade pre-Alpine basement rocks and Permian intrusive with high-grade pre-Permian xenoliths. The main structural imprint of the high-grade rocks is characterized by amphibolite to granulite facies conditions, commonly associated with large melt-bearing parageneses. During this melt-producing stage the meso- and microstructural evolution is polyphase and produce decametric isoclinal locally rootless folds. The multilayer is defined by alternate garnet-clinopyroxene bearing amphibolite, marble and melt-bearing gneisses (i.e. migmatites). Locally metre-scale orthopyroxene-clinopyroxene basic granulite boudins are

enclosed in migmatites. Melt-bearing associations differs with respect to bulk chemical compositions, leading to cordierite + melt, orthopyroxene + melt and garnet + melt associations. Absolute geochronological data for the pre-Alpine history of the Valpelline unit, until now reported as pre-Permian, show that the main metamorphic and structural imprint of the Valpelline unit is Permian, corresponding to the main granulite imprint, characterized by pegmatite bodies and by the partial melting of metapelites.

These results highlight the occurrence of an important tectonometamorphic Permian event in this portion of Austroalpine basement, likely reflecting a lithospheric scale thermal perturbation in the whole African continental lithosphere (SPALLA AND MAROTTA, 2007; PERESSINI et al., 2007).

Presenter e-mail: cristina.malatesta@unige.it

Key terms: tectonic mélange; subduction channel; Voltri Massif; high-pressure rocks

A 100 m-scale tectonic mélange located in the Voltri Massif (Ligurian-Piedmontese Units of central Liguria) was considered as an example of "fossil" subduction channel (Federico et al., 2007). This exhumation mechanism considers the presence of a low-viscosity serpentinite channel between the subducting- and the overriding-plate and has been invoked to explain the exhumation of ophiolitic massifs in other sectors of the Western Alps (e.g. Monviso Massif; Guillot et al., 2004).

Could the subduction channel mechanism be applied at a larger scale in the Ligurian-Piedmontese Units and be responsible for the exhumation of the whole pluri km-scale high-pressure Voltri Massif?

We tried to answer this question studying the eastern sector of the Voltri Massif: in this area lenses of metagabbro, metabasite, slices of sub-continental mantle and sediments of continental margin origin are wrapped by severely sheared serpentinite and metasediment, that are the prevalent lithologies.

We focused on metagabbro lenses since they best preserve metamorphic peak conditions. The most evident feature in these bodies is the strong strain partitioning acting between core and rims. The cores still preserve magmatic textures statically overgrown by the high-pressure assemblages, whereas rims display tectonite and mylonite structures.

The petrographic study of metagabbro samples was coupled with garnet-omphacite geothermometry estimates and P-T pseudosections; pseudosections were used to avoid any influence of chemical composition on P-T estimates. The results gave peak conditions of 10-15 kbar and 450-500°C for the blueschist body; the eclogitic lenses reached peak metamorphic conditions in the lawsonite eclogite stability field, ranging from about 21 kbar and 450-490°C to 22-28 kbar and 460-500°C. P-T paths are clockwise with almost isothermal, slightly cooling decompression trajectory.

These results can be compared with literature data for the studied area: the metamorphic peak conditions are scattered; temperature reach values up to 650°C and the pressures range from 18 to 25 Kbars. The different metamorphic peaks show that the selected rocks reached variable depths during the subduction process.

The heterogeneous metamorphic peak conditions recorded by the Voltri Massif rocks and the pervasive strain partitioning between the highly deformed matrix (serpentinite and metasediments) and the more competent boudins of different size (e.g. metagabbro and metaperidotite) fit the characteristics of a tectonic mélange.

This study thus indicates that the eastern sector of the Voltri Massif could be considered as a serpentinitic tectonic mélange developed in a serpentinitic subduction channel where a forced-return flow acted.

EVOLUTION OF THE NEOTETHYAN OCEANIC BRANCHES IN TURKEY

GONCUOGLU M.cemal¹

- 1 - METU , Dept. Geol. Eng., Ankara-Turkey

Presenter e-mail: mcgoncu@metu.edu.tr

Key terms: Neotethys; suture belts; petrology; ages; Turkey

The alpine orogeny in Turkey is the result of the end Mesozoic- Early Tertiary closure of three main Neotethyan oceanic seaways. Remnants of their oceanic lithosphere are found as tectonic slices within the subduction-accretion complexes along the E-W trending suture belts or as olistoliths within the flysch complexes of the peripheral foreland-basins. Hence, a detailed study on the petrology of the oceanic lithologies combined with paleontological and geochronological data may help to reconstruct the paleotectonic evolution of these oceanic branches.

The previous data from the northernmost and least known branch, the IntraPontide Ocean between the Istanbul-Zonguldak and Sakarya continental microplates suggests a ridge-spreading from middle Middle Jurassic to middle Upper Cretaceous. Our new data however, indicates the

presence of late Middle Triassic oceanic sediments.

In the Izmir-Ankara-Erzincan Suture belt between the Sakarya and Tauride-Anatolide continental plates, the tectonic discrimination of volcanic rocks in the mélanges indicates four distinct groups: MORB, OIB, IAT and CAB, the first two types dominating over others. Moreover, the REE patterns very clearly demonstrate the presence of subtypes such as N-MORB and E-MORB types within the spreading ridge of IAO; calcalkaline, alkaline and tholeiitic types within the arc-related volcanics and two distinctly separate subtypes of OIB basalts that differ in the level of enrichment. Back-arc-type basaltic lavas are as old as Late Ladinian-Early Carnian. OIB-type basalts with Bajocian, Callovian-Tithonian and Valanginian-Barremian ages are typical. The youngest OIB age is Early Aptian. Oldest MORB-type basalts are Aelian in age. The MORB ages range between Carnian and Cenomanian. The supra-subduction-type basalts overall have age ranges between Aptian - Cenomanian ages. These ages are in accordance with radiometric ages from the sub-ophiolitic metamorphics. The recent data reveal that the Neotethyan Izmir-Ankara Ocean in NW Turkey opened already at early Late Triassic. The sea-floor spreading and the formation of OIB-type intra-plate seamounts within it started already in late Bathonian and persisted until early Aptian. The formation of the intra-oceanic subduction and the generation of supra-subduction-type volcanism have commenced until early Santonian and the spreading-ridge of the Izmir-Ankara oceanic plate has not been subducted until Cenomanian.

In regard to the southernmost oceanic branch of Neotethys, ophiolitic assemblages occur between the Tauride-Anatolide, the Bitlis-Pütürge-Alanya and the Arabian continental fragments respectively. Hence, the number and locations of the related suture belts are disputed. In the former case, the ophiolitic rocks are dominated by supra-subduction-type volcanic rocks and their ages are scattered around middle Late Cretaceous. The ophiolitic rocks between the Bitlis-Pütürge-Alanya terrane and the Arabian plate, on the other hand, are dominated by OIB and E-MORB type basalts of largely Triassic age with a distinct decline towards Jurassic. The oceanic branches of Neotethys well match-up with those in the east but there are critical discrepancies on the locations, ages and subduction directions towards west across the Aegean Sea.

Key terms: ophiolites; tectonics; Dinarides; Serbia; Zlatibor

Two regional cross sections across the Internal Dinarides in the Central-Western Serbia are presented. The study area is located 100-150 km south of Belgrade in a sector between the Maljen Massif, the Zlatibor Massif and Prijepolje along a ca. 40km long NE-SW transect. Three main groups of tectonic units belonging to different zones can be distinguished: Vardar Zone. Three main tectonic units have been distinguished: the Maljen Ophiolitic Unit thrust by the Brus Unit and the underlying Sub-ophiolitic Mélange Unit. The Maljen Ophiolitic Unit is mainly composed by huge slices of serpentinites and serpentinized peridotites often characterized by remnants of a metamorphic sole. The succession of the overriding Brus Unit is composed by siliciclastic Upper Cretaceous turbidites (Lijg Flysch, cfr. Brus Flysch of the Kopaonik area). Below the Maljen Ophiolitic Unit a sub-ophiolitic mélange has been recognized (Sub-ophiolitic Mélange Unit).

Dinaric Ophiolitic Belt Zone. Two main tectonic units have been distinguished: the Zlatibor Ophiolitic Unit and the underlying Sub-ophiolitic Mélange Unit.

The Zlatibor Ophiolitic Unit is characterized by an assemblage of thrust slices ranging in thickness from 200 up to 1000 m. The reconstructed stratigraphy includes, from bottom to top: the metamorphic sole (amphibolites and garnet-bearing amphibolites), serpentinized peridotites and mafic-ultramafic cumulates (cropping out in Bosnia).

The Sub-ophiolitic Mélange Unit consists of an assemblage of thrust slices derived from both continental and oceanic domains set in a shaly or serpentinitic matrix. The slices of continental origin generally consist of Triassic to Lower Jurassic? carbonate successions made up of Triassic cherty limestones and platform carbonates and Early Jurassic pelagic cherty-limestones. In addition, slices consisting of pillow-lavas and massive basalts volcanics rocks covered by cherts have also been recognized.

Adria-derived Units zone. Two main tectonic units have been recognized: the Drina-Ivanjica Unit and the Durmitor Unit. Both these units are overthrust by the Sub-ophiolitic Mélange Units or directly by the ophiolitic (Zlatibor and Maljen) Units. The Drina-Ivanjica Unit consists of a Paleozoic metamorphic succession covered by an unmetamorphic Permo(?)–Triassic sequence. The metamorphic succession is made of phyllites, micaschists, metaconglomerates and limestones with a complex structural setting, due to the superposition of different tectono-metamorphic phases, related to the Carboniferous–(?)Permian metamorphic events. The unmetamorphic succession, that lies unconformably on the top of this latter, is represented by (?)Upper Permian sandstones and continental quartzitic conglomerates followed by Middle-Upper Triassic carbonatic platform deposits. The Durmitor Unit crops out west of the Zlatibor Ophiolitic Unit in the Prijepolje area and it is represented by low-grade schists, metasediments and metaconglomerates of Carboniferous age, followed by Permo-Triassic sandstones and quartz-rich conglomerates, interlayered with acidic volcanics and subvolcanics rocks. Follow a Triassic carbonatic sequence, made up of well-stratified limestones and marly-limestones, interlayered with subordinate cherts and cherty-siltstones.

The deformed Ophiolitic units of Maljen and Zlatibor and the Sub-ophiolitic Mélange Unit are unconformably covered, starting from Early Cretaceous (?Barremian), by thick calcareous sediments known as the "Cretaceous transgressive deposits". These deposits start with continental, transitional and shallow marine coarse clastic sediments followed by marine fine clastic and carbonate sediments. Different authors describe an unconformity between the Upper Cretaceous clastic deposits and the eastern part of the Drina-Ivanjica Zone, but the real nature of this contact

is still matter of debate.

Key terms: Ophiolite Nappe; Geodynamics; Dinaric-Hellenic belt; Triassic-Jurassic; Albania

The Triassic-Jurassic ophiolites of Albania are the remnants of a thick and complex nappe originated from the obduction on the continent of a portion of oceanic lithospheric sequences.

Several main questions are still matter of debate. They concern: the original location of the parent ocean; the ages of its birth and consumption; the recognition and interpretation of its continental margins; the reconstruction of the mechanism and direction of the ophiolite thrusting.

The data collected by our team permitted us to hypothesize a model for the tectono-stratigraphic evolution of this nappe in the frame of the Dinaric-Hellenic orogenic chain.

In Albania the Ophiolite Nappe, laying on top of the Adria continent successions, includes six tectonic units. From bottom upwards they are: 1- The Rubik Complex, a tectono-sedimentary subophiolitic mélange; 2- the Porava Unit, basalts, with intercalations or covers of Middle - Late Triassic red cherts; 3- the Metamorphic soles, deriving from a protolith with OIB affinity, typical of oceanic seamounts, metamorphosed between 174.0±2.5 and 162.1±2.4 Ma, and with a top-to-the-west sense of shear; 4- the Western Ophiolite belt, massifs of Iherzolites covered by MOR magmatic sequences grading upwards to SSZ volcanic sequences and dykes, covered by Jurassic cherts; 5- the Eastern Ophiolite belt, a very thick sequence with harzburgites and only SSZ magmatic sequences, covered by Jurassic cherts coeval to those of the Western Ophiolite belt; 6- the sedimentary-type Simoni Mélange, which unconformably lies at the top of both the Western and Eastern ophiolitic sequences and grades upwards to the late Tithonian Firza Flysch.

The easternmost ophiolite massifs lie on the Pelagonian, which lies, in turn, on the Ionian units, and the metamorphic sole structure indicates, all along the Mirdita ophiolites, a clear westward movement. So, the ophiolite nappe has to come from east of Pelagonian, i.e. from the Vardar Ocean, sited between the Pelagonian (representing the eastern margin of Adria) and the the Serbo-Macedonian Massif (representing the western margin of Europe).

The early phases of the oceanization can be restored to the Middle Triassic, and the spreading was continuous up to the Late Jurassic, for about 40 my. The subduction-related sequences are Middle Jurassic, so the beginning of subduction can be considered as Early Jurassic. The coexistence of MOR and SSZ ophiolites in the Western Ophiolite belt testifies for an intra-oceanic subduction, where a trapped MOR crust was subsequently covered by SSZ magmatism.

Thus, in the Early to Late Jurassic times, the oceanic area between Adria and Eurasia continental margins was characterized by an east-dipping subduction zone.

The ocean was closed in the latest Middle Jurassic and the continental collision occurred between the uppermost Late Jurassic and the earlier Cretaceous times. Subsequently, the compression-related deformation migrated into the Adria continental margin.

Presenter e-mail: milvio.fazzuoli@unifi.it

Key terms: TRIASSIC; JURASSIC; MEGABLOCKS; ALBANIA

The Mirdita Zone in Albania is characterized by MOR- and SSZ-type ophiolites and ophiolitic tectono-sedimentary mélanges including megablocks of continental margin carbonates, up to kilometre thick and up to some tens of kilometres large. Their stratigraphic succession consists of Middle Triassic-Early Jurassic carbonate platform carbonates, Early-Middle Jurassic pelagic condensed limestones and Middle-Late Jurassic radiolarites. Several stratigraphic sections have been studied both in the Triassic and in the Jurassic units from different blocks: four examples are here presented. The "Nunziatura" Late Triassic section near Rubik consists of m-thick beds of peritidal limestones and dolomites, cyclically arranged: subtidal Megalodon-bearing beds are interlayered with intertidal stromatolitic and fenestral beds and with supratidal breccias, and rare tepee structures. All these features strongly recall the "Hauptdolomit" sequence of the Northern Calcareous Alps. The section of Shkopet, near the Mati River, consists, from bottom upwards, of Rhaetian-Hettangian subtidal beds overlain by a metres-thick condensed section, made up of Sinemurian crinoid packstones with Agerina (Vidalina) martana, an hardground, Toarcian packstone with embryonic ammonites, a second hardground, dm- to m- thick beds of pink nodular wackestone, with Protoglobigerina and abundant cm-large Mn nodules, of early Bajocian. The section of Baiwash consists of Hettangian-Sinemurian, lagoonal, massive wackestone/packstone with Lithiotis banks at the top, an hardground, about ten meter of metre-thick beds of pink nodular wackestone / packstone with crinoids and Protoglobigerina of early Bajocian, a second hardground, green and red radiolarites of Middle Jurassic age. At Leshnja (Vithkuqi), the Jurassic succession consists of Hettangian-Sinemurian, lagoonal massive wackestone/packstone, with Lithiotis banks at the top, cross-cut by pink neptunian dykes, with a coquina of thin-shelled bivalves filling, and overlain by some metres of

mudstone/wackestone with Orbitopsella of Pliensbachian age. This succession is topped by a syn-sedimentary detachment surface and overlain by slumped beds of cherty limestones, of possible Middle Jurassic age, indicating the tectonic drowning of the carbonate platform. The sequence is topped by a 20 m thick, matrix-supported debris-flow deposit, made up of a siliceous-clayey matrix and metric chunks of beds of grey cherty limestones, green cherts and Middle Jurassic red radiolarites. In general the sedimentary evolution of the studied sequences indicates a progressive foundering of a continental margin by extension until the Middle Jurassic, then followed by an important seismotectonic activity (Middle-Late Jurassic), heralding the obduction of the ophiolitic nappe, and finally the offscraping of large blocks of the continental margin and their involvement in the ophiolitic melange at the base of the obducted oceanic crust (Late Jurassic).

- 4 - Dipartimento di Scienze della Terra, Università di Ferrara

Presenter e-mail: mchiari@geo.unifi.it

Key terms: Ophiolitic mélangé; Basalt; Jurassic radiolarites; Almopias; Greece

The Vardar zone consists of an assemblage of continental and oceanic units and, in Greece has classically been subdivided into three distinct sub-zones, which are (from west to east): the Almopias, Paikon and Guevgueli sub-zones. While the Guevgueli has been intensively investigated and is interpreted as a Late Jurassic ensialic marginal basin, the Paikon and Almopias are relatively poorly known. Few works on the Paikon suggest that it represents an "Andean-type" volcanic arc developed during the Mid-Late Jurassic. The Almopias sub-zone consists of several tectonic units, mainly including ophiolitic rocks, obducted westwards onto the Pelagonian zone. They have been subdivided into three main groups: the Western (WA), Central (CA), and Eastern (EA) Almopias ophiolites. The CA and WA mainly consist of mantle harzburgites and an underlying metamorphic sole tectonically emplaced over a basal mélangé, which incorporates volcanic rocks and dykes with calc-alkaline (CAB), alkaline within-plate (WPB), normal (N-) and enriched (E-) mid-ocean ridge (MORB), island arc tholeiitic (IAT), and boninitic affinities. Few, old works on the EA report the occurrence of a number of different ophiolitic units (e.g. Ano Garefi, Mavrolakkos, Kranea, Vrissi, Nea Zoi, Liki units); though, all these units consist of ophiolitic mélangé sequences. In some of them, the scattered occurrence of MORB and WPB pillow lavas and dykes, and Late Jurassic radiolarites has been recognized.

This work is focused on the bio-chronological and petrological characterization of the EA ophiolites in order to provide new solid constraints for the tectonic evolution of the Vardar Ocean. For this reason, paired volcanic-radiolaritic sequences have been investigated in the Kranea, Vrissi and Nea Zoi units.

The Kranea Unit includes a thick sequence of CAB basalts, basaltic andesites, andesites and rhyolites. At the top of this sequence, a basaltic dolerite showing MORB affinity has been found. The radiolarian chert sampled close to the top of this basalt contains radiolarians not well preserved.

The Vrissi Unit consists of basalts with MORB affinity overlain by low-K tholeiitic (LK-T) pillow lavas and crosscut by LK-T dykes. Radiolarian cherts associated with the basalts indicated a Middle-Late Jurassic age. The Nea Zoi Unit includes basalts and rhyolites with LK-T affinity. The samples of radiolarian cherts collected near the contact with the basalts yielded radiolarians with a low preservation.

The LK-T and CAB rocks clearly pertain to the Paikon Arc, whereas MORB rocks may have formed in either a mid-ocean ridge or backarc settings.

Presenter e-mail: milvio.fazzuoli@unifi.it

Key terms: CRETACEOUS; TRANSGRESSION; OPHIOLITE; PELAGONIAN; GREECE

The ophiolitic nappes of the Dinaric-Hellenic orogenic system underwent complex deformations related to subduction, accretion and obduction onto the eastern Adria continental margin during Middle to Late Jurassic; these deformed units were later on unconformably overlain by the so-called "deposits of the Cretaceous transgression".

In western Macedonia (Northern Greece), two main tectonic units are present: the metamorphic Pelagonian Unit, consisting mostly of Triassic-Jurassic marbles, and the overlying Ophiolitic Nappe+Subophiolitic Mélangé, thrust during Late Jurassic. Moreover, in the Rhodiana area (Vourinos Massif), the ophiolites are tectonically overlain by limestones of Middle-Late Jurassic age (Zyghosti carbonate platform). At Tsimodia (Vourinos Massif), the top of the Zyghosti carbonates includes a thick Fe-Ni lateritic lens and it is overlain by limestone containing Salpingoporella urladanasi Conrad, Peybernes & Radoicic, of Barremian/Aptian age, and, on its turn, by a Cenomanian Orbitolina limestone. At Kteni (Vourinos Massif), a laterite horizon on the top of weathered serpentinite is covered by coarse- to fine-grained limestones with S. urladanasi and by a coarse-grained detrital limestone with Orbitolinidae. At Koumaria (Vermion Massif), the serpentinite is unconformably overlain by laterite pockets, by m-thick beds of

conglomerates with pebbles of marbles and ophiolites passing laterally to limestone with S. urladanasi and, upwards, by Late Cretaceous limestone with Orbitolinidae and Rudist fragments.

In southeastern Albania the Cretaceous sediments that unconformably overlie the ophiolites and the Subophiolitic Mélangé are mainly coarse clastics in the lower part, passing upwards to shallow marine limestones. At Germej, near the town of Leskovik, weathered basalts included in the Subophiolitic Mélangé are overlain by a m-thick cover of siliceous duricrust with lateritic clasts, by m-thick bodies of conglomerate with basalt pebbles scattered within reddish lateritic, sandy-clayey matrix. At Lubonja, not far from the town of Korçë, above the Subophiolitic Mélangé, a 60 m-thick succession of conglomerate crops out; the medium- to well-rounded, cm- to dm-sized pebbles are made up mostly of marble, grey to black chert, locally abundant limonitised laterite and rather rare ophiolitic rocks; the fine-grained matrix, more or less abundant, is laterite-rich. Calcarenite of Late Cretaceous age caps the succession.

All these features allow to hypothesize that during Late Jurassic/earliest Cretaceous obducted ophiolites underwent emersion, prolonged subaerial weathering and erosion, that gave origin to widespread lateritic deposits, both "autochthonous" and "allochthonous". Starting from the late Early Cretaceous, a marine transgression spread above the ophiolites (and locally on the Zyghosti Jurassic platform limestone); the flooding was heterochronous, possibly due to an uneven erosion surface. The marine flooding was connected with high-angle extensional tectonics, at turn possibly driven by low-angle extensional tectonics. The transgression, beginning from Barremian/Albian, locally developed firstly under restricted, brackish lagoonal conditions, marked by the occurrence of the dasycladacean alga S. urladanasi, and then followed by normal salinity conditions, starting from Albian. In other areas, a more severe tectonic phase gave origin to horst- and graben structures with consequent development of ophiolite-originated coarse-grained deposits in usually dark red, argillaceous-lateritic matrix. Where the exhumation involved also the Pelagonian metamorphic units underlying the ophiolitic nappes, the erosion gave origin to coarse-grained deposits with marble clasts, together with an abundant laterite derived-matrix. The frankly marine sedimentation generally started since Cenomanian.

- 1 - Dipartimento di Scienze della Terra, Università di Firenze, Via la Pira, 4, 50121 Florence, Italy

Presenter e-mail: giuseppe.nirta@gmail.com

Key terms: OPHIOLITE; OBDUCTION; GREECE

A thick nappe consisting of ophiolites derived from the Vardar Ocean along with a composite tectono-sedimentary mélangé at the base (Sub-ophiolitic Mélangé) was thrust above the eastern continental margin of Adria starting from the Middle Jurassic. After a long westward travel lasted about 140 Ma across the Adria continental units, nowadays the westernmost tips of the Ophiolitic Nappe+Subophiolitic Mélangé thrust front are emplaced onto a Paleocene-Eocene foreland turbidite sequence. In the northern Pindos Mountains the study of the stratigraphy and tectonic history of the Cretaceous to Tertiary turbidite sequences lying below the Ophiolitic Nappe allowed to add new data on the mechanisms of emplacement of the Ophiolitic Nappe on the continental crust. The studied sequences pertain to the late Paleocene-Eocene Pindos Flysch and to an assemblage of tectonic slices of Early Cretaceous continental margin sequences known as Beotian Unit, the latter overthrusting the former. The younger deposits of the Beotian Unit, considered the westward continuation of the Pelagonian platform (easternmost portion of the Adria continental margin), are characterized by the occurrence of ophiolite-bearing mass flow deposits, known as Beotian Flysch. From a regional point of view the ophiolite-bearing detritus within the Pelagonian sequences show a younging direction from the Maliac-Othrys area to the Beotia area suggesting a westward emplacement of the Ophiolitic Nappe. The Paleocene - Late Eocene Pindos Flysch is regarded as a foreland basin deposit, which was progressively overthrust westwards by the Sub-ophiolitic Mélangé + Ophiolitic Nappe. This event is recorded in the turbiditic sediments by diffuse syn-sedimentary deformations and catastrophic events of mass deposition (mega-debris flows and slide blocks) with provenance from both continental margin units and ophiolitic units.

The structural and stratigraphic analyses in the Pindos Flysch and in the Beotian Unit sequences and their integration with first order geological constraints of the Hellenic Chain allowed to discriminate between different emplacement mechanism of the Ophiolites onto the continental margin sequences: (a) obduction and (b) passive advancing through activation of main thrust in the continental crust.

Obduction mechanism started with an oceanic stage during the Middle Jurassic with development of metamorphic sole at the base of the Ophiolitic Nappe and mélangé formation. The obduction continental stage started with the overthrusting of the Pelagonian platform. During this stage the advancing Ophiolite Nappe shed with ophiolitic debris the facing continental margin basins (e.g. Beotian Flysch) and, contemporaneously, chunks from the Pelagonian platform were progressively included in the Subophiolitic Mélangé. During the Early Cretaceous, obduction ceased and was followed by emersion of the Ophiolitic Nappe and later exhumation of the underlying Pelagonian sequences followed by transgression with deposition of continental to shallow marine sediments starting from the Barremian.

During the Cretaceous-Paleocene transition the continental collision between the Serbo-Macedonian and Rhodopian Massifs (Eurasia) and the Pelagonian margin (Adria) took place. This event rejuvenated the westward thrusting of the continental units followed by crustal thickening and enucleation of a foreland basin to the west since the Paleocene (i.e. the Pindos Flysch basin). During this phase the activation of a main west-directed thrust at the base of the Pelagonian Unit carried on passively the ophiolites and mélangé to overthrust the Pindos flysch since late Eocene. The westward movement of the Ophiolites onto the Pindos Flysch ended only during the latest Eocene-early Oligocene, when a climax of compressional deformation caused eastward verging reverse faults connected with strike slip movements, that cut the Ophiolitic Nappe + Sub-ophiolitic Mélangé basal thrust.

G6-8 Orale Principi, Gianfranco
