Presenter e-mail: principi@geo.unifi.it

Key terms: Ophiolitic Nappe; Geodynamic; Hellenides; Greece

The Hellenides consist of several NW-SE-trending, parallel tectono-sedimentary belts (the 'Isopic Zones' of Aubouin). From west to east they are: the Ionian, Gavrovo, Pindos, Parnassos, Subpelagonian-Pelagonian and Vardar Zones. Macedonian Zone and Rhodope pertain to the deformed westernmost European margin. The first five zones are made of continental margin successions. An Ophiolitic Nappe with an underlying tectonic mélange overthrust the Pelagonian, Subpelagonian and, partially, Pindos Zones, and now is represented by the N-S trending Western (Pindos-Mirdita) and Eastern (Vardar Zone) Ophiolitic belts.

The Pelagonian Zone (including the Subpelagonian) consists of a Palaeozoic metamorphic basement, covered by a Permian to Jurassic succession with volcanics and sediments. According to some previous works, the Pelagonian was considered a microcontinent between a western (Pindos-Mirdita) and an eastern (Vardar-Axios) oceanic branches of the Neothethyan Ocean. The others continental zones were considered as parts of the Adriatic microplate.

Late Jurassic to Late Cretaceous calcareous successions and, in places, a Tertiary flysch overlap these mélanges and shed debris in them. Along the sub-ophiolitic mélange of the Western Ophiolitic Belt, cherts with Triassic radiolarian associations stratigraphically linked to basalts with MOR and OIB characteristics, as well as to continental rift volcanics are present. Also Middle-Late Jurassic oceanic (MOR) and supra-subduction (IAT) basalt-chert associations are widely found.

The obducted Ophiolitic Nappe (e.g., Pindos, Vourinos, Othrys) is made essentially by ultramafics, mainly hartzburgites, with minor ultramafic-mafic cumulates of IAT signature. Where present, the volcano-sedimentary covers are of Middle-Late Jurassic and the basalt have a IAT signature. At the contact between the overriding ultramafic bodies and the subophiolitic mélange, thin HT-LP metamorphic (amphibolitic) soles can be observed almost everywhere. Their ages range from 174.0±2.5 and 162.1±2.4 Ma. In the central-northern Greece, the Pelagonian suffered an Alpine metamorphic phase (green schists). Except for the metamorphic soles, the overriding ophiolites are not metamorphic. Probably, the last tectonic contact is the consequence of a low angle normal faulting, perhaps divergent, operating during the Cretaceous-Tertiary exhumation of the Pelagonian metamorphic basement.

Our data and field observations, together with many literature data, permit to establish that:

- 1- The western ophiolitic belt derive from the Vardar zone.
- 2- The Pelagonian was the easternmost part of the Adria Plate.
- 3- The ocean MORB basin originated in the Middle Triassic (latest Anisian-early Ladinian) and persisted up to the Middle-Late Jurassic.
- 4- The IAT magmatism started in the Middle Jurassic.
- 5- The westward obduction, as testified by the metamorphic, soles begun in the same age.
- 6- The Pelagonian suffered an orogenic metamorphism probably in the earliest Cretaceous or slightly older in the easternmost realm of the Pelagonian.
- 7- At the same time, the collision between the Adriatic and Rhodopian continental lithospheres took place.
- 8- Immediately after, probably during the early Cretaceous, the Pelagonian was exhumed.
- 9- From the same time, up to the Tertiary, carbonate and clastics sediments unconformably covered both ophiolitic and Pelagonian units. Finally, during the Mesozoic only one ophiolitic basin existed between Adria and Rhodope and this ocean started in the Middle Triassic (latest Anisian-early Ladinian), immediately after the beginning of the rifting stage that, starting from the Anisian, affected the Adriatic continental margin.

Key terms: ophiolites; accretionary wedge; Palaeogene; Crete; Greece

New geological, structural and petrographic data collected in central Crete on the ophiolite-bearing terranes of the Cretan mélange, result in a better understanding of the role and tectonic significance of these units in the construction of this segment of the external Hellenides. The Cretan mélange is composed of three main tectonic units that, characterized by different metamorphic facies conditions, are represented by a un-metamorphosed to weakly metamorphosed lower unit, a greenschist to HP greenschist-facies intermediate unit and a blueschist-facies upper unit. These chaotic rock-complexes include blocks of oceanic and continental deriving rocks and can be considered as a remnant of an accretionary complex. In this context the lower unit represents the toe of the wedge whereas the intermediate and upper units are referred to the innermost and deeper subducted portions of the wedge exhumed and superimposed one on each others during the early stages of continent-continent collision. The structural evolution of the accretionary wedge was controlled by two main contractional deformation events that, including distinct groups of structures developed at different crustal levels, were driven by a SSE and a SSW directions of tectonic transport, respectively. Geological and structural data strongly suggest that the ophiolite-bearing allochthonous tectonic wedge was accreted during the Paleogene subduction of a Late Jurassic-Cretaceous oceanic realm beneath the continental margin of the Pelagonian domain and was successively involved in the continental collision with the Adria (Cretan) Block. The greenschist to blueschist facies metamorphism and the subsequent

exhumation and emplacement of the intermediate and upper units above the frontal portion of the wedge may be mainly due to deep duplexing marking the onset of the continental collision. We thus suggest that the ophiolite-bearing units of Crete represent a single suture zone related to the closure of a unique oceanic domain (Pindos-Cycladic Ocean) subducted beneath the Internal Hellenides Platform continental domains thus assuming the significance of a southern oceanic seaway of the largest eastern Neothethys developed since the Triassic between the Eurasia and Africa continental masses.

Key terms: OPHIOLITES; CIMMERIAN OROGENY; INTRAPONTIDE SUTURE; SUTURE ZONE; NORTHERN TURKEY

The present-day tectonic setting of the alpine belt in Turkey consists of several amalgamated continental microplates separated by suture zones, where ophiolites occur. The study of these ophiolites is able to provide valuable insights for the reconstruction of the long-lived geodynamic history responsible of this complicate setting.

A key-area for this aim is represented by the Daday-Arac-Kursunlu geotransverse in northern Turkey where two different ophiolite-bearing suture zones can be recognized, hereafter reported as IntraPontide (IP) suture zone and Karakaya Complex.

The IP suture zone is represented by an ophiolite-bearing mélange, reported in the literature as Arkotdag Mélange, topped by a mantle slice. This suture zone is sandwiched between the Istanbul - Zonguldak Terrane at the top and the Sakarya Terrane at the bottom. The Istanbul - Zonguldak Terrane includes Late Neoproterozoic basement unconformably covered by a continuous, well-developed sedimentary succession ranging in age from Paleozoic to Cretaceous, topped by Late Cretaceous-Paleocene turbidite deposits where andesitic volcanic rocks have been found. The Arkotdag Mélange consists of huge blocks of oceanic rocks, generally bounded by shear surfaces, interlayered with ophiolite-bearing deposits. This mélange is topped by a mantle slice represented by serpentinites showing at its base a metamorphic sole. The preliminary observations on the Arkotdag Mélange suggest its formation in Late Jurassic to Late Cretaceous time span during the closure by obduction of an oceanic basin originated in Middle to Late Jurassic time span between the Eurasian plate and Sakarya microplate. The structural setting of the IP suture zone is quite complicated, as recognized along the Daday-Arac-Kursunlu geotransverse, where a new, puzzling metamorphic unit has been identified in the field. This unit, that consists of a strongly deformed succession of micaschists, para-gneisses and metabasites, is sandwiched between the ophiolite nappe at the bottom and the Istanbul - Zonguldak Terrane at the top.

The Arkotdag Mélange is thrust over the Sakarya Terrane, represented in the studied geotransverse by the Karakaya Complex and its Jurassic-Cretaceous cover. The Karakaya Complex represents remnants of Triassic accretionary wedge, where a lower sequence, consisting of E-MORB to OIB metabasic rocks folded with metacarbonates and schists, was strongly deformed under a high-pressure metamorphism ranging from blueschists to eclogite facies. Radiometric dating points out to a latest Triassic age of the metamorphism. The deformation and metamorphism recognized in the Karakaya Complex is the result of the Cimmerian Orogeny, resulting from the subduction of the PaleoTethys oceanic lithosphere below the Laurasian continental margin. The tectonic structures related to the Cimmerian Orogeny are unconformably sealed by the continental to marine Early Jurassic-Cretaceous, mainly carbonate succession, showing a transition to turbidite deposits ranging in age from Late Cretaceous to Paleocene. These deposits are characterized in their uppermost levels by carbonate and ophiolite blocks, the latter ones derived from IP suture zone.

On whole, the data collected along the studied geotransverse indicate that in the northern Turkey an old suture zone is preserved in the Karakaya Complex connected with the PaleoTethyan oceanic basin closure in the Late Triassic. The unconformably sedimentary cover indicates that deformation and metamorphism related to Cimmerian Orogeny terminated in the Early Jurassic.

A younger suture zone is represented by the ophiolites from the IP suture zone. This suture, that is still poorly known, is today marked by an ophiolitic mélange (Arkotdag Mélange) topped by a mantle slice, both emplaced southward onto the continental margin today represented by the Sakarya Terrane. The closure of this NeoTethyan basin is referred to Late Cretaceous, whereas its opening is still matter of debate.

Presenter e-mail: emilio.saccani@unife.it

Key terms: Ophiolite; Mantle Peridotite; supra-subduction zone; Zagros; Iran

The Kermanshah ophiolitic complex consists of a mélange formation, which includes dismembered ophiolitic sequences. These ophiolites are located along the Main Zagros Thrust (MZT), which marks the suture zone between the Zagros belt and the Sanandaj-Sirjan zone. They represent the Tethyan oceanic lithosphere, which originally existed between the continental margins of Arabia (to the south) and Eurasia (to the north). These ophiolites were emplaced onto platform carbonate rocks, which

represent the northeastern Arabian margin.

The Kermanshah ophiolitic complex is composed of various partial sequences, which are represented by: 1) a dynamo-metamorphic sequence of mantle lherzolite and gabbro intruded by basaltic dykes; 2) mantle tectonites consisting of depleted lherzolites and both cpx-rich and cpx-free harzburgites; 3) a troctolite-cumulate gabbro-isotropic gabbro sequence mainly showing pegmatoid texture; 4) a wehrlite-cumulate gabbro-isotropic gabbro sequence showing foliated texture; 5) pillow basalts. Mantle tectonites are volumetrically predominant and, in places, tectonically overlay the gabbroic sequences. The Foliated Gabbros are characterized by very low contents of TiO₂, P₂O₅, Zr, Y and variable amounts of Al₂O₃, CaO, MgO, which correlates with the variability of the modal composition. They display a flat N-MORB normalized incompatible element pattern and chondrite-normalized REE composition with slight LREE/HREE enrichment coupled with a slight LREE/MREE depletion. Mineral chemistry, REE composition and many incompatible element ratios (e.g. Ta/Yb, Th/Yb, Ce/Y, Zr/Nb) indicate that these gabbros are geochemically similar to gabbros generated in a mid-ocean ridge setting from a depleted MORB mantle (DMM). In terms of major elements, lherzolites and harzburgites can be distinguished on the basis of TiO₂, Al₂O₃ and CaO contents. In general, both these peridotite-types show depletion in incompatible element concentrations with respect to the DMM. Lherzolites have MREE and HREE contents higher than those of harzburgites, but show a marked LREE/MREE depletion (CeN/SmN=0.05-0.86), though one sample displays a relative enrichment in La and Ce. Cr-spinels in lherzolites show relatively low Cr# and Fe#, which are comparable to those of abyssal peridotites. REE modelling shows that they may represent a residual mantle after 15-20% removal of N-MORB melts. Both cpx-rich and cpx-free harzburgites are characterized by marked U-shaped chondrite-normalized patterns with LaN/SmN=3.69-6.02 and SmN/YbN=0.07-0.50. The (La/Sm)N ratio correlates well with the degree of depletion (Al₂O₃/SiO₂), showing that the more depleted samples have the higher relative enrichment in LREE. Cr-spinels from all harzburgitic-types show Cr# and Fe# similar to those of Cr-spinels from SSZ peridotites. REE modelling shows that they may represent a residual mantle after 25-30% removal of SSZ-type melts. The marked LREE/MREE enrichment suggest that this mantle was enriched in LREE by fluids released from the subducting slab. The rocks studied in this work record the two distinct phases of the geodynamic evolution of the Tethys in the Iran sector. The foliated gabbroic sequence and the depleted lherzolites represent the conjugate magmatic rocks-mantle residua formed in a mid-ocean ridge setting during the steady-state spreading phase, which persisted from Late Triassic to Late Jurassic. The moderate LREE/MREE enrichment observed in some depleted lherzolites suggests that the residual MORB mantle was subsequently trapped in a SSZ and enriched in LREE by subduction-derived fluids. Harzburgites represent the residual mantle formed in a SSZ setting and thus can be related to the existence of an intra-oceanic arc that is associated in turn with the convergence phase and consumption of the Tethys through a NE-dipping subduction beneath the Sanandaj-Sirjan continental margin, which started in the Late Jurassic.

Key terms: *Ophiolite; Oceanic spreading; MORB; alkaline basalt; Iran*
 Ophiolites extensively crop out along the Main Zagros Thrust (MZT) and record the geodynamic evolution of the Tethys branch between the Arabian shield and a composite puzzle of continental blocks bordering Eurasia. Many geological aspects of the Zagros have previously been examined, but the MZT ophiolites are still poorly constrained. Nonetheless, any regional reconstruction must take account of the tectono-magmatic characteristics of the ophiolitic sequences. The Kermanshah ophiolites represent a key area of the MZT, as they record the evolution of the Tethys ocean developed between Arabia and the Sanandaj-Sirjan block and are believed to represent the conjugate oceanic sector of the Oman ophiolites. These ophiolites include several distinct rock-associations that can be related to distinct phases of the oceanic evolution. In particular, these ophiolites consist of an ophiolitic mélange, which include: 1) a dynamo-metamorphic sequence of mantle lherzolite and gabbro, which is intruded by basaltic dykes (hereafter referred as metalherzolite, metagabbro and metadyke); 2) mantle peridotites affected by ocean-floor metamorphism; 3) foliated gabbroic sequences; 4) pegmatoid gabbroic sequences; 5) pillow lavas. Metalherzolites show a very little depletion in HFSE and REE concentrations with respect to the depleted MORB mantle (DMM). They show both mineral and whole rock chemistry, which is very similar to that of lherzolites from the External Ligurides of Northern Apennine. Metagabbros and metadykes have relatively high contents of TiO₂, Zr, Y and show an overall geochemistry, which resembles that of basalts generated at mid-ocean ridge. REE patterns of metagabbros and some metadykes show a marked MREE/HREE enrichment (SmN/YbN = 1.67 - 2.47), while other metadykes show no MREE/HREE enrichment. The chemistry and Sr-Nd isotopic composition of these rocks is comparable to that of gabbros and basalts from the External Ligurides and Corsica. Three chemically distinct groups of volcanic rocks can be identified. Group 1 displays a clear alkaline nature and show HFSE, REE and Sr-Nd isotopic composition, which is similar to that of alkaline within-plate basalts from oceanic island (OIB). They show LREE/HREE strongly enriched patterns and high Th/Yb, Ta/Yb and Zr/Nb ratios. Group 2 shows a sub-alkaline nature and significantly enriched incompatible and LREE patterns, as well as relatively high Th/Yb, Ta/Yb and Zr/Nb ratios. Mineral and whole rock chemistry and Sr-Nd isotopic compositions are similar to those of typical plume-type MORB (P-MORB). Group 3 have LILE/HFSE and LREE/HREE smoothly enriched patterns and Th/Yb, Ta/Yb and Zr/Nb ratios lower than those of Group 2. The overall geochemical features of these rocks resemble those of typical E-MORB. Likewise, the Pegmatoid gabbros also display E-MORB signature. REE modelling show the following results: 1) N-MORB metagabbros and metadykes with high Sm/Yb ratios are generated by 15% partial melting

of a DMM source bearing garnet-pyroxenite relics; 2) N-MORB metadykes are generated by 15% partial melting of a DMM source in the spinel-facies; 3) alkaline basalts are generated from an enriched OIB (plume-type) source by 5% partial melting that starts in the garnet-facies and continues in the spinel-facies; 4) P- and E-MORBs are generated by <7-8% partial melting of a DMM source variably enriched in LILE and LREE by a plume-type component. The rocks studied in this work record the early phases of the geodynamic evolution of the Iranian Tethys, as summarized as follows.

- 1) The Late Triassic continental break-up resulted from an asymmetric extension, which allowed the exhumation of the subcontinental mantle and the preservation of garnet-pyroxenite relics in the MORB mantle source.
- 2) The early oceanic evolution is characterized by rifting with volcanism associated with "plume" effects (i.e. OIB, E-, P-MORB), which occurred at the continent-ocean transition zone or in off-axis oceanic settings.

Key terms: *Cimmerian orogeny; Suture zone; Ophiolites; Geodynamics; accretionary complex*

The region of NE Iran is a key-area for the Cimmerian orogeny, which is related to the Late Triassic collision of Iran with Eurasia as a consequence of the closure of the Palaeotethys. In spite of recent studies carried out on the Cimmerian Orogeny in the Alborz, and in the Binalud mountains south of Mashaad, where these processes were firstly recognized 40 years ago, few information is available to the NE within the large area extending between the city of Mashaad and the Afghan border. Due to the importance of this area for the understanding of the Cimmerian event, a research project, which has been sponsored by the DARIUS PROGRAMME and MIUR, focused on the area extending east of Mashaad between Fariman and Torbat Jam. Here, the occurrence of a thick succession of Permian andesitic to basaltic submarine lava flows interfingering with carbonate platform limestones and siliciclastics poses several questions on the geodynamic significance of this peculiar rock association, previously interpreted as a Palaeotethys-related accretionary wedge. The same is true for the Permian "ophiolites" of Darreh Anjir, which were interpreted as remnants of the Palaeotethys oceanic crust. Detailed structural, stratigraphic and petrological study of this Permian succession allowed us to substantially modify previous interpretations. According to our data, the Permian units were deposited in a marine basin close to a volcanic area with complex features, where a large volume of lava flows was emplaced in submarine conditions. In addition, tectonic deformation is not compatible with an accretionary wedge as neither disruption of the stratigraphy, nor penetrative shear zones and high pressure metamorphism have been identified. Preliminary geochemical data from the Darreh Anjir and Fariman units clearly suggest an arc-related setting developed on a continental crust. We thus interpret these units as remnants of a supra-subduction arc-related complex, developed during the Permian along the active Southern Eurasian margin above a N-dipping subduction zone related to the consumption of Palaeotethys. To the north of these units, the arc-related basin of Aghdarband records the Triassic history of the collision zone. The Triassic successions show a well preserved N- to NNE-verging Cimmerian imbricate thrust fan developed in a retro-wedge position, with respect to the main N-dipping collision zone located south of Mashaad. The thrust fan interacts with an important ESE-WSW left-lateral fault zone, accommodating an important component of oblique collision of Iran through a mechanism of strain partitioning. All these structures are sealed by the Bajocian Kashaf Rud Fm., demonstrating that the main deformation, affecting also the Upper Triassic Miankuhi Fm. can be related to the Cimmerian events. This suggests that the deformation of the Aghdarband area lasted longer than in the Alborz, possibly post-dating the main collision of the Iran microplate with Eurasia.

Key terms: *intrapangean oceans; geodynamic cyclicality; Earth memory*

Considering life and location of past intrapangean oceans we note three interesting characteristics: the different duration of their lives, their cyclicality and parallelism. Regarding their lives, we can observe three main types: a) the long-lived oceans, like the present day Atlantic Ocean (in the past time the Japetus Ocean), which has a life corresponding to a Wilsonian cycle; b) The short-lived oceans, the Rheic Ocean, Paleotethys and Neotethys, which had lives corresponding to a portion of a Wilsonian cycle (infra-Wilsonian); c) the fossilized oceans, like the Gulf of Mexico or, in the past, the Western Tethys during the Early Cretaceous. Regarding the cyclicality, the long-lived intrapangean oceans (e.g., the Atlantic) reopened several times, more or less in the same places or nearby, in relation to successive Pangean break-ups and reassemblies. The formation of short-lived oceans (e.g., Paleotethys, eastern Tethys, Neotethys), the argument of this talk, seems to be linked to a continuous process, active from Paleozoic to now, which moves terrains from the passive Gondwana margin to the Eurasian active margin. The processes that took place during the Paleozoic, regarding the Rheic and Paleotethian oceans, outlived with respect to those during the Mesozoic, regarding

Vardar-Meliata, and Neotethys, but all caused a continuous cutting of Gondwana slices, which were accreted to the paleoeurasian margin. The process, active up to now in the Red Sea-East Africa rift system: This process operated and operates as if all the Gondwanian slices migrate northeastward with a not easily defined Eulerian pole located to the west. Does some type of memory exist in the interior of the Earth, responsible for these cyclic phenomena? We propose some reflections on the location and mechanisms of the supposed Earth memory.

Presenter e-mail: giuseppe.nirta@gmail.com

Key terms: CRETACEOUS; TRANSGRESSION; WESTERN SERBIA; OPHIOLITE

In the internal (eastern) part of the Dinaric-Hellenic orogenic system the ophiolitic units, accreted and obducted during the earlier tectonic phases (Middle-Late Jurassic), show evidences to have been broadly emerged during the earliest Cretaceous compressional phases, forming rather high relieves which underwent erosion and pedogenesis. In several places, the ophiolites are unconformably overlain by the so-called "deposits of the Cretaceous transgression". A detailed lithostratigraphic and sedimentological study was performed at Mokra Gora and Vardiste sections (Zlatibor ophiolitic massif, Western Serbia), in the lower part of the Cretaceous succession that unconformably overlies the ophiolites, to evidence the onset and the development of the "transgression". The lithological and sedimentological features of the succession reflect two main deepening-shallowing cycles, informally named Unit A and Unit B. The substratum consists of serpentinite and weathered serpentinite, locally covered by lateritic deposits and siliceous duricrusts. The Unit A (?Barremian) has been subdivided in four subunits. Subunit A1 consists of conglomerate and sandstones with ophiolitic clasts, deposited by braided streams. Subunit A2 consists of ophiolite-derived sandstone and siltstone, deposited by meandering streams. Above a sharp flooding surface, subunit A3 is represented by fossiliferous limestone, marl and siltstone deposited in lagoonal and marine subtidal environment. Subunit A4 consists, in the lower part, of alternating marl and limestone of marine mid/inner ramp environment passing upwards to calcareous and litharenitic sandstone of inner ramp environment. The overlying Unit B (Aptian-Cenomanian) is very thick and has been subdivided in five subunits. The sharp surface between Unit A and B represents an unconformity surface, possibly due to emersion, and marks the onset of a younger cycle of deposition. Subunit B1 consists, in the lower part, of reddish mixed carbonate-ophiolitic sandstone and siltstone of coastal plain environment passing upwards to reddish siltstone including silcrete bodies and caliche beds, owing to evidences of pedogenesis occurred in an ephemeral lagoon-coastal lake environment. Subunit B2 is made up by nodular limestone and marl with subordinate litharenitic sandstone, of partially restricted lagoon with terrigenous inflow. The surface between B2 and B3 subunits represents the flooding surface of the second cycle. The subunit B3, that constitutes the large part of the B Unit, mostly consists of fossiliferous marl and subordinate limestone with frequent bioclastic storm beds, indicating an inner- to mid-ramp environment. A dark grey marly horizon with abundant organic matter is intercalated within the subunit B3 and represents an anoxic episode and possibly the maximum flooding surface. The subunit B4 consists of alternating limestone and subordinate marl and indicates the return to the subtidal inner ramp environment. The overlying Unit C, not studied (Turonian-Senonian), is represented by massive to thick bedded bioclastic redstone to boundstone, and evidences the onsets of widespread reefal bioconstructions.

The geodynamic framework in which these deposits had developed is presumably that of a widespread tectonic collapse, involving the Ophiolitic Nappe after the Eohellenic compressional phase (?Late Jurassic - Early Cretaceous), followed by the marine flooding of the previously formed depressions, possibly in connection with eustatic rises (Aptian-Cenomanian).

Presenter e-mail: valerio.bortolotti@geo.unifi.it

Key terms: Carbonate platform; Jurassic-Cretaceous; Zyghosti; Greece

Periods of emersion and karstification with occurrences of pockets of laterites and bauxites are well known during the evolution of the "persisting" or long-lived (up to Tertiary) carbonate platform in Southern Apennines and Greece. These phenomena are very rare, if any, in the precociously drowned (during Early-Middle Jurassic) carbonate platforms of Alps, Apennines and Greece. The Zyghosti carbonate platform, present only in small tectonic chunks in the Northern Greece over the Ophiolitic Unit, presents all these features. In the Middle-Late Jurassic, mostly lagoonal facies were developed; later on, the platform suffered two emersion episodes: in the latest Middle Jurassic and in the Early Cretaceous. During the first and shorter episode, karst sinkholes developed, later on filled by Tithonian marine deposits; during the latter one, lasted about 27 m.y., a widespread karst took place and laterite levels accumulated in the depressions of the subaerial surface. Over this surface a marine transgression occurred since early Albian up to late Albian; during the early Cenomanian a large-scale tectonic collapse occurred and fine-grained pelagic sediments were interlayered by turbidites, coarse-grained mass-flow deposits and slumped beds, up to the Maastrichtian.

The long-lasting emersion cannot be explained only by eustatic

variations, but tectonic causes must also be invoked: possibly a peripheral bulge in front of the advancing ophiolitic nappes and/or the overthrusting of the carbonate body onto the obducting ophiolites during the "paleo-hellenic" tectogenetic phases. The later abrupt platform collapse was instead connected with the westward migration of the compressional tectogenesis and the consequent extensional tectonics.

THE OPHIOLITES OF THE KOZIAKAS MASSIF (GREECE): PALEONTOLOGICAL AND GEOCHEMICAL FINAL DATA

CHIARI Marco¹, BORTOLOTTI Valerio², MARCUCCI Marta³, PHOTIADES Adonis³, PRINCIPI Gianfranco¹, SACCANI Emilio⁴

1 - CNR, Istituto di Geoscienze e Georisorse
 2 - Dipartimento di Scienze della Terra, Università di Firenze
 3 - Institute of Geology and Mineral Exploration, Greece
 4 - Dipartimento di Scienze della Terra, Università di Ferrara

Presenter e-mail: mchiari@geo.unifi.it

Key terms: Ophiolites; basalts; Radiolarian cherts; Koziakas; Greece

In the Koziakas Massif (Thessaly), an Ophiolitic Nappe crops out at the top of the Western Thessaly Units, which represents the transition between the Pindos Basin and the Pelagonian Platform (i.e. the eastern margin of Adria). These units are thrust onto the Pindos Basin (i.e. the intra-continental rift located between the Gavrovo and Pelagonian platforms).

This nappe pile is unconformably covered by Oligocene-Miocene molasses pertaining to the Mesohellenic trough and consists of:

- 1- The Late Paleocene-Eocene Pindos Flysch, which includes fragments of serpentinites, basalts and cherts. Paleocurrent data indicate a provenance from NE, where the Pindos and Koziakas ophiolites were located.
- 2- The Western Thessaly Units which consist of two tectonic units (Thymaïma and Koziakas) whose latest Jurassic - Early Cretaceous sediments contain ophiolite-derived turbidites and/or olistostromes.
- 3- The Ophiolitic Nappe, which consists of four tectonic units:
 - a) The ophiolite-bearing Koziakas Mélange, consisting of small and scattered outcrops.
 - b) The Fourka Unit, consisting of thrust sheets and blocks of pillow lavas locally covered by radiolarian cherts.
 - c) A metamorphic sole consisting of scattered and thin levels of amphibolites derived from N-MORB-type protoliths and showing a clear syn-metamorphic fabric. Two K-Ar radiometric data indicate 161 and 174 Ma for the amphibolitization.
 - d) An "Ophiolite Unit", consisting of sheared serpentinites, with some dunite bodies, plagiogranite and boninite dykes.

The volcanic rocks of the "Fourka Unit" consist of basaltic rocks. Six samples display a clear alkaline affinity and are characterized by incompatible element and REE composition resembling that of typical alkaline within-oceanic plate basalts (OIB). REE modelling indicates that they are compatible with <6% of partial melting of a theoretical plume-type source and therefore, are interpreted to have generated in a seamount setting.

Two samples are characterized by incompatible element and REE patterns strongly resembling those of E-MORBs. REE modelling shows that they are compatible with 8-15% partial melting of a theoretical mixed N-MORB/OIB mantle source. These rocks are interpreted as formed from a N-MORB type mantle source enriched by an OIB-type component during the early stage of oceanic spreading or in an off-axis oceanic setting.

In the Fourka Unit, the cherts at the top of the basalts have well preserved radiolarian assemblages, which indicate Triassic ages: latest Anisian (associated with OIB) (as the trachyandesites present in the continental rifts to the west), early Carnian-middle Norian and late Carnian-early Norian (associated with OIB), early Norian (associated with E-MORB); in the Koziakas Mélange early-middle Bathonian (associated with OIB).

As regards the geodynamic evolution of the Koziakas ophiolites we can hypothesize this succession of events: a- The Vardar Ocean opening during Middle Triassic, contemporaneously with the sinking of the continental basins located to the west (e.g., Pindos Basin, etc.); b- The ocean spreading, persisted till the Late Jurassic and from the beginning of Middle Jurassic was accompanied by an intraoceanic obduction which caused a doubling of the ocean crust with formation of the metamorphic soles; c- The narrowing and closure of the ocean during Late Jurassic-Early Cretaceous times, and the overthrusting of the Ophiolitic Nappe onto the Adria continental margin (Pelagonian); d- The westward thrust of the nappe underlined by the presence of an ophiolitic detritus in the Western Thessaly Units during latest Jurassic-Early Cretaceous times, and then, more to the west, in the Paleocene-Eocene Pindos flysch.

THE KARAKAYA COMPLEX: A PALAEOETHYAN SUBDUCTION/ACCRETION COMPLEX FROM N TURKEY

GONCUOGLU M.cemal¹, SAYIT Kaan²

1 - Middle East Technical University, Dept. Geological Eng. Ankara-Turkey

2 - Dept. of Geological Sciences, San Diego State University, USA

Presenter e-mail: mcgoncu@metu.edu.tr

Key terms: Paleotethys; mélange; Anatolia; L. Triassic; accretion

The northern margin of Turkey is of particular importance as it retains the relicts of the gigantic collisional orogen that led to the consumption of the Palaeotethys. The relicts of this orogenic event, known as the Cimmerian orogeny (Sengör et al. 1984), are preserved within the Karakaya subduction/accretion complex that covers the northern part of Turkey as an E-W trending belt for over 1000 km. The Karakaya Complex lies within the pre-Liassic basement of the Sakarya Composite Terrane (Göncüoğlu et al. 1996), including a number of mélange units made up of variably deformed and metamorphosed rock assemblages. These mélange units of distinct characteristics comprise metabasic rock lithologies of oceanic origin (the Nilüfer Unit), metaclastics (the Eymir Unit), back-arc-type ophiolite assemblages (the Kure Unit), and some lithologies probably of continental rift-origin.

Of these mélange units, the Nilüfer Unit crops out widely within the central and the western portion of the Karakaya Complex, and characterized by metabasic rock assemblages primarily alternating with recrystallized limestone, mudstone and chert. The metabasic rocks have mainly experienced greenschist-facies conditions, though high-pressure varieties,

such as blueschists and eclogites, can also be found throughout the complex. The metabasic rocks are dominantly of alkaline character, and reflect OIB- and E-MORB-type geochemical signatures with no continental input. These mafic lithologies represent oceanic islands/seamounts that formed on the Palaeotethyan oceanic crust in association of a mantle plume during the Early?-Late Triassic. The latest Triassic was the time when the oceanic island/seamount system (the Nilüfer Unit) was incorporated into the accretionary prism, and chaotically mixed with the distinct rock assemblages derived from the other tectonic settings (forearc, continental-rift, intra-oceanic back-arc), forming the Karakaya Complex. The deeply subducted portions were metamorphosed in HP/LT conditions at the end of Triassic. This accretionary prism material was thrust on a Late Triassic peripheral foreland basin topping the Permian platform on the S margin of Palaeotethys. The oldest overstep sequence on top of this melange-foreland basin complex is Liassic in age.

ACTIVE TECTONICS IN THE SEAS OF SOUTHERN ITALY: EVIDENCE AND OPEN QUESTIONS

ARGNANI Andrea¹

1 - ISMAR-CNR, Bologna

Presenter e-mail: andrea.argnani@ismar.cnr.it

Key terms: active tectonics; southern Italy; seismogenic structures

The maps of macroseismic felt intensity and of instrumental seismicity show that southern Italy is a seismically active region, and also indicate that seismic sources located at sea substantially contributed to the seismic release. The sea surrounding the Gargano Promontory, the Messina Straits, the slope of south-eastern Sicily, and the southern Tyrrhenian region are the main areas where tectonic structures appear to be seismically active. In many instances, earthquakes are large enough to allow reliable focal mechanisms to be obtained, also showing that sometimes contrasting tectonic regimes coexist within short distance. Attempts to characterize the tectonic structures that may be responsible for the recorded marine seismicity have been made using different approaches. However, in most of these regions a general consensus on the nature of the deformation has not been achieved.

In the Gargano region hints of active deformation are broadly diffuse within and around the promontory. Multichannel seismic data in the peri-Gargano marine area show evidence that deformation is more intense on the NE side of the promontory. Large emphasis has been given in the literature to the offshore extent of the Mattinata fault, mostly due to the civil consequences of the San Giuliano 2002 earthquake, although both earthquakes and observed deformations are mostly marginal to the Mattinata Fault. It might be worth noting that the area to the north of Gargano is the only potential source for the 1627 tsunami, as landslides with suitable age and location are not present in the submarine slope to the SW of the promontory.

The Messina Straits is one of the most seismically active regions in Italy, and uplifted marine terraces and Quaternary faults crop out extensively onshore. Onshore faults, however, are considered inactive, and are poorly consistent with the seismic and geodetic data recorded during the large (M 7.2) 1908 earthquake, which has been located within the straits. On the other hand, evidence for the occurrence of large active faults are scarce also offshore, possibly supporting the interpretation of a seismogenic blind fault, although growth strata are not found in seismic profiles. Moreover, the tsunami associated to the 1908 earthquake can hardly be explained by a blind fault, leaving room for landslides or other faults to play a role. South-eastern Sicily has a long record of historical seismicity, including the largest event in the parametric catalogue of Italian earthquakes (M 7.1, January 1693). Often tsunamis are related to the earthquakes, indicating near-field events. The search for the 1693 seismogenic source is still ongoing, particularly onshore, where a clear fault has not been found. As onshore faults cannot explain the tsunami, a concomitant submarine landslide is required. On the other hand, offshore active faults have been well documented, together with large-scale landslides associated to footwall collapse. The offshore fault are considered too small to reproduce the estimated magnitude, although it cannot be excluded that the close time proximity of two earthquakes (9th and 11th February 1693) possibly contributed to confuse the macroseismic pattern.

The southern Tyrrhenian margin, located north of Sicily, has long been considered a classic passive margin, before it became recently evident that it is characterized by a belt of compressional earthquakes. Since then, the area has quickly been interpreted as an incipient, south-dipping subduction zone, and several papers have been devoted to explore this geodynamic issue; regrettably, very little data have been presented to back up these interpretations. Although the belt of earthquakes trends roughly east-west, the best documented seismic sequence, September 2002 offshore NW Sicily, has a marked NE-SW trend, and extensional faults that appear to be active have been reported from detailed bathymetry, further to the east.

TECTONICS, HYDROGEOLOGY AND KARSTIC MORPHOGENESIS: A NEW MULTIDISCIPLINARY APPROACH TO INVESTIGATE ACTIVE FAULTS? FROM THE EXAMPLE OF THE 1980 IRPINIA EARTHQUAKE TO THE WESTERN MARSICA CASE STUDY (SOUTHERN LATIUM REGION)

Key terms: active faulting; hydrogeology; karstic systems; Posta Fibreno fault; central Apennines

After the November 23, 1980 Irpinia earthquake (Mw 6.9), several seismically induced effects at surface have been identified. Among these, a strong variation of the Sanità spring flow rate (from 4.5 m³/sec, in the days preceding the quake, to 7.5 m³/sec, in December 1980) occurred. Such observation can be considered as an important starting point to investigate - in hydro-structural settings comparable to the Sanità spring one - possible variations of permeability thresholds of springs following episodes of activation of seismogenic tectonic structures. The present study is utilises a multidisciplinary approach aiming at the identification of sectors of the central Apennines where carbonate reliefs (carbonate hydrostructures), affected by active normal faults, are characterised by springs related to permeability thresholds and by karst systems. In particular, we investigate the southern sector of the carbonate ridge that bounds the Marsica region to the West, where the Posta Fibreno springs (10 m³/sec) are located, acting as the present base level for karstic erosion. This sector is affected by a portion of the regional tectonic structure known in the literature as "Val Roveto-Atina Line", here represented by the Posta Fibreno fault, which places in contact the cretaceous-miocenic carbonate sequences with the miocenic flysch and with quaternary continental sequences hosted by the Posta Fibreno depression. Several epigeous and hypogeous karstic landforms (dolines, abandoned valleys and karstic conduits) developed in this area along tectonic features NW-SE trending; the not well developed hydrographic network is characterised by abandoned valley which originate from the rims of the main dolines (i.e. Fossa Maiura, Pozzo la Pescara). These landforms show evidence of different stationary phases of the karstic erosion probably due to hydrological base level of the Posta Fibreno springs. From a chronological viewpoint, the onset of the karstic phenomena probably took place at the end of the Lower Pleistocene - after the deposition of the first sedimentary cycle "Conglomerato di Campoli Appennino" sequence - when the groundwater level was next to the surface. Then, during the uplift of the carbonate ridge - which was probably structurally separated by the Posta Fibreno depression by the activity of the normal fault - the karstic springs evolved in doline-springs and, subsequently, in sink dolines owing to the progressive lowering of the permeability threshold of the Fibreno springs. The above described tectonic, hydro-structural and geomorphic setting is comparable to present one, with doline-springs located both below the lake level and at the base of the relief slopes in the Posta Fibreno area. Then, within this light, the difference in elevation between the present Posta Fibreno springs and the uppermost paleo-springs (represented by the systems dolines-abandoned valleys) above described can provide useful information to estimate the amount of regional uplift and probably testifies to the activity of the Posta Fibreno normal fault to which might be associated the 1654 Sora earthquake. Lastly, the ongoing analysis of the historical data indicates that the "La Prece" doline assumed its present shape after about 1600 AD. Indeed, an high-relief attributed to this age (located in Villa Mazzenga) which depicts the Posta Fibreno village, shows a very mild depression in the "La Prece" area while a large doline is clearly visible at present.

NEW PALEOSEISMOLOGICAL DATA FROM THE FUCINO NORMAL FAULT SYSTEM (CENTRAL ITALY)

GORI Stefano¹, FALCUCCI Emanuela¹, MORO Marco¹, SAROLI Michele², BORGHESI Hermann³, CECCARONI Emanuela⁴, GALADINI Fabrizio¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

2 - Università di Cassino

3 - Cooperativa LIMES

4 - Soprintendenza per i Beni Archeologici dell'Abruzzo

Presenter e-mail: stefano.gori@ingv.it

Key terms: Paleoseismological investigations; Fucino fault system; 1915 Avezzano earthquake; Central Italy

New paleoseismological investigations have permitted to improve the knowledge about the recent kinematics behaviour of the Fucino fault system, in the central Apennines, the activation of which determined the 1915 Avezzano earthquake (Mw 7) (Galadini and Galli, 1999). The analyses of two quarry walls located at the base of the reliefs that border the eastern flank of the Fucino basin, where the surficial expression of one of the segments of the fault system - namely the S. Benedetto-Gioia branch - is located, have allowed to individuate at least three events of displacement. Two of these are referable to a chronological context comprised between 15000 BP and 3000-1500 B.C. (Saroli et al., 2008). The most recent event(s) occurred after 1466-1372 cal. B.C. (Saroli et al., 2008). Probably, the oldest and the intermediate events may represent two of three Holocene episode of activation of the Fucino fault system identified by Galadini and Galli (1999) and occurred between 5 and 10 ka BP. The most recent event(s), besides the 1915 rupture, may be associated to the event dated at 1500-1300 B.C. and/or at the Late Antiquity/early Middle Ages (Galadini and Galli 1999), likely occurred in 484/508 AD (Galadini et al., 2010).

Further paleoseismological data have been obtained from the investigations carried out in the area localised NW of the Pescara village. In particular, three excavations performed along the fault segment known as "of S. S. Marsicana" of the Fucino fault system, showed evidence of at least two displacement events subsequent to the deposition of a colluvial deposit containing fragments of pottery attributed to the beginning of the Bronze Age. Considering that the most recent event displaced the whole stratigraphic sequence, comprised the ploughed soil, we may associate it to the 1915 rupture.

On the whole, the achieved paleoseismologic data confirm that, as hypothesized by Galadini and Galli (1999), the S.S. Marsicana fault segment activated during the 1915 earthquake and allow to improve the dataset of paleo-events available for the Fucino plain.

3 - CNR-IGAG
4 - Libero professionista

Presenter e-mail: paolo.galli@protezionecivile.it

Key terms: ACTIVE TECTONICS; PALEOSEISMOLOGY; GEOELECTRICAL ANALYSES; SOUTHERN APENNINE; EARTHQUAKES

The deep seismogenetic source that generated one of the most catastrophic European earthquake in the past century (1980, Mw 6.9, ca 3000 fatalities) still shows its impressive surficial expression across the backbone of the Picentini Mountains in the Irpinia region, between the San Gregorio Magno plain at the southeastern tip, up to the northern slopes of the Mt. Cervialto, at northwest (Irpinia, southern Apennines). Here, a complex array of N270°-N350° normal faults (N315° average strike), arranged into a dozen of dextral en-echelon main strands can be followed for a total length of ca. 38 km, forming the Mount Marzano fault system. At the end of the 80s, two of these segments have been carefully investigated at two sites by Pantosti et al. (1993) and D'Addezio et al. (1991), who dug four paleoseismological trenches, founding many unknown 1980-like events during the Holocene. However, it must be stressed that the historical seismicity of this sector of the southern Apenninic chain is more complex and much more abundant than what showed today by the available Italian seismic catalogues, with several poorly known strong events clustered in a narrowed area. Most of them have a mesoseismic distribution similar to the 1980 one (as the 1466 and 1694 events; Mw 6.4 and 6.9, respectively), whereas many others known and unknown, Mw₆ earthquakes had their epicentre within the hangingwall area of the Mount Marzano fault system (e.g., 1517, 1561, 1680, 1692, 1853, 1910; see Galli et al., 2010). Nevertheless, none of these have been geologically associated to any known seismogenic structure, although the Mount Marzano fault system would seem the most reasonable candidate.

Considering the new information coming from studies concerning the seismic history of this region and in order to characterize in terms of seismogenic behaviour the entire fault system, we performed 45 high-resolution topographic profile across the 1980 surface faulting trace and/or across the surveyed fault scarp. Then we carried out several Electrical Resistivity Tomographies (ERT) across some segments of the fault system and we made further paleoseismological analyses in other trenches and pits.

Our results, besides confirming the complex pattern of surficial rupture of the Mount Marzano fault system during the 1980 event, from the Pantano Grande of San Gregorio Magno to Caposele (ca. 33 km), provide some indication concerning the post Last Glacial Maximum slip-rates and suggest robustly this structure to be responsible also for some other strong events described by the historical sources, such as the 1694 earthquake, and others previous ones.

Acknowledgements. We wish to thank all those colleagues who generously provided us with all their 1980 accounts and photos. In particular, we are in debt with F. Carraro, S. Lambiase, I. Sgroso and R. Westaway, but we are grateful also with R. Berardi, C. Bosi, L. Carmignani, A. Cinque, P. Scandone, P. Marsan and F. Ortolani. We finally thank D. Pantosti, who gave us her field maps and photos, and discussed with us some results of a new unpublished trench in Piano di Pecore.

Key terms: quaternary tectonics; sedimentation; paleomagnetism; central Italy; earthquakes

The epicentral area of the L'Aquila 2009 earthquake roughly matches with a Quaternary intermountain basin including, from NW to SE, the areas of Paganica, San Gregorio, Poggio Picenze, Barisciano and San Demetrio ne Vestini.

Morphological and stratigraphic investigations, integrated with paleomagnetic and teprostratigraphic studies and 40Ar/39Ar measurements, allowed us to recognise three main depositional cycles, here labelled as Lower (Early Pleistocene), Upper (ca. 550-350 ka) and Late (Upper Pleistocene) cycles, and to outline the basin evolution history. At its early stage (Lower Pleistocene) the whole basin, from Paganica to Civitavecchia and Campana, hosted a lake characterised by whitish carbonate silts and muds sedimentation (ca. 100 m thick; San Nicandro Fm.) indicating a very low energy sedimentation. Later in the Lower Pleistocene, the sedimentary processes changed, becoming highly energetic. At this stage the basin hosted a powerful fluvial-lacustrine system, which was characterised by pebbly braided river that, originating from the southern Gran Sasso slopes through the Paganica area (paleo-Raiale river), discharged into a vast intermountain lake. Here, it supplied a deltaic gravel-sand complex (ca. 100 m thick) which, prograding south-eastward, determined the progressive diminution of the lake size and the consequent growing of the braided river. At same time, along the north-east margin of the basin (e.g. Barisciano and S. Pio delle Camere areas), a large alluvial-fan developed (Valle Valiano Fm.), in association with slope graves (Fonte Vedice Fm.) that discharged into lake.

Before 780 ka, this fluvial-lacustrine system disappeared, and the whole area was subjected to erosional or pedogenetic processes. These processes were active up to ca. 550 ka, when in the area developed the fluvio-lacustrine system of the Upper depositional cycle, made up mainly

by volcanic-rich silty-sands, and subordinately gravels (San Mauro Fm.). This paleogeographic domain was considerably lesser than the early one being completely carved in the former and restricted to a narrow stripe around the present course of the Aterno river.

This depositional cycle ended around 350 ka when the area was again subjected to prevailing erosional/pedogenetic processes. Finally, during the Upper Pleistocene, the Raiale river and other minor torrents generated a series of alluvial fans that are geomorphologically carved in the deposits of the older depositional cycles (i.e., Paganica and Caporciano alluvial fan), being almost in equilibrium with the present hydrographic network. Some units of these three depositional cycles are associated to well-preserved, terraced, depositional top surfaces that in turn are displaced by a normal fault system composed by at least three, up to ca. 18 km-long, sub-parallel WNW-ESE trending segments (Paganica-San Demetrio fault system). The westernmost one fits with the surface breaks observed in the 2009 earthquake. This circumstance allowed us to evaluate the temporal-spatial evolution and the style of the tectonic deformation for different time windows.

On the whole, independently from the considered time windows (~1 Ma vs. 500 ka), our investigations indicate that the total slip rate across this fault system was consistently evaluable at ca. 0.6-0.5 mm/yr. Moreover, during the past 1 Myr the tectonic deformation of the paleogeographic domains was not uniform in time, space and style. Whilst the northern (Paganica) and southern (San Demetrio) sectors of the basin were preferentially downthrown by normal faulting, the central part of the basin (Poggio Picenze) experienced a gentle warping, without appreciable faulting.

As far as the timing is concerned, the easternmost fault segments started the Quaternary deposits offset early, at least ca. 1 Ma, progressively transferring the throw to the central and westernmost splay, where the most recent faulting traces, including those of 2009 earthquake, occurred.

Key terms: Val Roveto-Atina-Caserta fault; Moho step; soil gas geochemistry; radon anomalies

A multidisciplinary study based mainly on aerophotogeological interpretation and geochemical prospectings were performed in the Comino valley area which extends between Vicalvi and San Donato Val di Comino villages. The studied area covers 70 km² of a considered key-area in the geological-seismic framework of the Central Apennines. The Comino valley is located in the SW sector of the Central Apennine (Southern Latium) where the "Val Roveto-Atina-Caserta" regional fault has been studied since many years. Indeed, according with some authors, this fault can be interpreted as a crustal discontinuity probably corresponding to a deep step of the Moho. The studied area is also characterized by the presence of secondary tectonic lineaments (e.g. San Donato-Val Comino fault) having a typical Apenninic orientation (NW-SE).

The Comino valley is affected by high seismic activity: last destructive earthquake was in May 7, 1984 (ML 5.9) while during 2009 many seismic events (ML < 4) have occurred for several months suggesting a new micro-seismic activity.

The spatial soil-gas distributions have been compared with the location and orientation of brittle deformations described in the literature and/or recognized by new field surveys, as well as with morphotectonic features obtained by photogeological analysis. Soil gas results show a pervasive character of the radon, helium and methane values. Soil gas prospecting together with geological survey has provided an inedited and detailed mapping of the structural setting of the studied area and in particular new data about the Comino valley have been acquired. The identified structural lineaments by geological survey as well as the He, CH₄ and Rn anomalies in soil gas in correspondence of lineament crossing, suggest that such faults may be considered as the surface expression of a deep structure network (probably down to the Moho) playing a role of important avenue for a vertical and rapid migration of endogenous gases. In particular, the high Rn median value (51.80 Bq/L) in an area without shallow possible radon sources, suggests a deep origin for this gas and therefore a vertical migration through fractured media, i.e. faults and fractures. The elongated gas anomalies show that the area is characterized by tectonic discontinuities oriented mainly NNW-SSE in accordance with and linked to the regional Val Roveto-Atina-Caserta fault and WSW-ENE that suggest transversal fractured zones.

The investigated area is also interested by mineralized springs with a high gaseous component: CO₂ is the dominant gas (concentrations > 95 %, v/v) but also discrete amounts of CH₄ have been measured (max value: 4200 ppm). The spatial distribution of thermal springs, cold CO₂-rich springs and localized gas emissions suggests that the structural framework of the studied area, i.e. the bordering faults of buried structural highs of the carbonate basement, exerts a strong control on the uprising patterns of fluids.

Presenter e-mail: maurizio.ercoli@gmail.com

Key terms: 3D GPR; Paleoseismology; Normal fault; Mt. Vettore; Central Apennines

The faults responsible of strong earthquakes are usually studied with

quantitative geomorphologic and paleoseismological techniques investigating shallow Quaternary sediments with trenches to find geological evidences of ancient seismic events.

Recently, the improvements of applied geophysical techniques as the 3D Ground Penetrating Radar (GPR), have been successfully applied on studies in different geological environments. Some 3D-GPR application on paleoseismological studies are available in literature, showing unambiguous geophysical evidences of shallow faulting compared to 2D data.

The Mt. Vettore fault (Italy, Central Apennines) has been extensively investigated by various paleoseismological studies. This structure shows both geomorphological and trench-derived evidences of Late-Quaternary activity and a recent new seismic catalogue includes events possible related with the activity of this fault.

In our study, we employed a high-resolution 3D-GPR survey across a branch of the Mt. Vettore fault tied to trench-derived stratigraphy data in order to cross validate the two independent data. We used a 300 MHz GPR system above a small scarp rising on a Late Pleistocene-Holocene alluvial fan, recording, at first, some 2D profiles using Common Offset configuration to precisely locate the fault zone. After detecting the fault signature on 2D profiles, a 20 x 20 m high-resolution 3D-GPR grid was acquired across the fault.

The processed 3D GPR volume shows a clear imaging of the fault zone and faulted units due to the simultaneous display of profiles and time-slices. We used an open source geophysical interpretation software to interactively manage the entire 3D dataset and to detect and interpolate interesting horizons that allowed to build a detailed geometrical model of the subsurface up to 4m below the topographic surface.

Our experience demonstrates that GPR constitutes a geophysical technique particularly useful to paleoseismology, not only to optimize the possible sites for trench digging but also to obtain data along and across the strike. Moreover, the promising results make the GPR an interesting alternative to other studies in sites where topographical evidences or geological contest are poorly defined.

The study here presented provides qualitative and quantitative geological information in a completely non-invasive way, essential especially in nature reserves like the Sibillini Mountain's National Park.

NEW GEOLOGICAL-STRUCTURAL CONSTRAINTS FOR A SEISMOTECTONIC MODEL OF THE HINGE ZONE BETWEEN SOUTHERN TYRRHENIAN AND NORTHERN SICILY.

Presenter e-mail: aledilo1970@libero.it

Key terms: *Seismotectonic; Maghrebian chain; Southern Tyrrhenian; Sicily*

The Northern Sicily and its Tyrrhenian off-shore are part of the Maghrebian chain, whose the architecture is the result of a multiple-phase tectonic history from Late Oligocene-Early Miocene to Present. Since Early Pliocene, the regional tectonic activity of the area is associated with a complex structural grid related to a wider W-E trending right-lateral regional shear zone, extending for about 300 km from Ustica-Eolie alignment to the "Pantelleria rift". The main structural features, occurring from regional to outcrop scale, are represented by NW-SE to W-E striking right-lateral faults and by N-S to NE-SW striking left-lateral faults, both responsible of uplift and lowering respectively of restraining or releasing zones. The latter, filled by Plio-Pleistocene clastic sediments, are characterized by extensional faults showing listric geometry producing block accommodation and rotation along the hinge zone between the Southern Tyrrhenian margin, characterized by crustal thinning, and the emerged northern Sicilian orogen, with a moderate thickened crust. Within the hinge zone, seismicity is mainly located between 10 and 20 km of depth and clustered around high-angle dipping planes well fitting the orientation of the outcropping fault systems. The focal mechanisms showing transpressional, compressional, transtensional and extensional kinematics, are the results of the mechanical heterogeneity of the rock volumes related to the polyphasic tectonic evolution of the area.

With the aim to better define the seismotectonic model of this area, we carried out an integrated research, by means structural, geophysical and statistical analyses, in two key zones: (i) onshore, in the southern sector of the Palermo Mts. (Kumeta Mt.), where the brittle strain partitioning related to a right-lateral simple shear zone has been reconstructed, and (ii) offshore, north to Palermo, where the structural setting has been inferred from morpho-bathymetric and geological maps of the Southern Tyrrhenian basin.

Moreover, in this latter zone, a new seismological study has been carried out on a part of 2002 seismic sequence, using a database obtained by the integration of data recorded by the stations of the National Seismic Network with those recorded, in four months, from 7 three - components stations of a temporary network installed by INGV. In particular, 40 seismic events, recorded by more than 40 seismic stations, occurred between September and December 2002 have been relocated using a procedure based on the HYPODD program, and an eight layers velocity model optimized relocating some thousands events of the southern Tyrrhenian. The focal mechanisms of such events have been determined using FPFIT code.

The Coulomb stress changes related to the main events of the sequence have been also calculated in order to recognize the seismogenic volume, whose geometric characters fit well with a simple shear deformational style compatible with that one reconstructed on the study zone located onshore.

Key terms: *Anisotropy of magnetic susceptibility; Altotiberina Fault; Low-angle normal fault; extensional tectonics; northern Apennines*

Anisotropy of magnetic susceptibility (AMS) represents a valuable proxy able to detect subtle strain effects in very weakly deformed sediments. Commonly, in compressive tectonic settings the magnetic lineation is parallel to fold axes, thrust faults and local bedding strike, while in extensional regimes it is perpendicular to normal faults and, thus, parallel to bedding dip directions. The Altotiberina Fault (ATF) in the northern Apennines (Italy), is a Plio-Quaternary low-angle normal fault characterized at its hanging-wall by the presence of a 1200-m-deep basin (Tiber basin) filled with a syn-tectonic, sandy-clayey continental succession. We collected 129 oriented cores at 12 sites within this formation, and measured the AMS with a Multi-Function Kappabridge. The shape of the AMS ellipsoid (oblate to prolate), together with the anisotropy parameters, suggests that a primary sedimentary fabric has been overprinted by an incipient tectonic fabric. The magnetic lineation is well-developed at all sites with directions ranging from NE-SW (western sector of the basin) to N-S and NW-SE (central and eastern sectors). Locally, magnetic lineations sub-parallel and sub-perpendicular to relative bedding strike are observed, revealing the effect of a compressional and extensional tectonics, respectively. The presence of compressional structures at the hanging-wall of the ATF can be explained by the presence of gently, ~N-S-trending local folds (hardly visible in the field) formed either by passive accommodation above an undulated fault plane, or by simple roll-over anticline formation close to the fault planes. Accordingly, the long-lasting debate on the extensional vs. compressional Plio-Quaternary tectonics of the Apennines orogenic belt should now be revised evaluating the importance of compressional structures resulting by local effects.

Key terms: *crustal seismic anisotropy; fracturing and stress field;*

Apennine crust; automatic analysis code

During the last decades, the study of seismic anisotropy has provided useful information for the interpretation and evaluation of the stress field and active crustal deformation. Seismic anisotropy can yield valuable information on upper crustal structure, fracture field, and presence of fluid-saturated rocks crossed by shear waves. Several studies worldwide demonstrate that seismic anisotropy is related to stress-aligned, filled-fluid micro-cracks (EDA model).

An automatic analysis code, "Anisomat+", was developed, tested and improved to calculate the anisotropic parameters: fast polarization

direction (Φ) and delay time (Δt). Anisomat+ has been compared to other two automatic analysis codes (SPY and SHEBA) and tested on three zones of the Apennines (Val d'Agri, Tiber Valley and L'Aquila surroundings).

The anisotropic parameters, resulting from the automatic computation, have been interpreted to determine the fracture field geometries; for each area, we defined the dominant fast direction and the intensity of the anisotropy, interpreting these results in the light of the geological and structural setting and of two anisotropic interpretative models, proposed in the literature. In the first one, proposed by Zinke and Zoback, the local stress field and cracks are aligned by tectonics phases and are not necessarily related to the presently active stress field. Therefore the anisotropic parameters variations are only space-dependent.

In the second, EDA model, and its development in the APE model fluid-filled micro-cracks are aligned or "opened" by the active stress field and the variation of the stress field might be related to the evolution of the pore pressure in time; therefore in this case the variation of the anisotropic parameters are both space- and time- dependent.

We recognized that the average of fast directions, in the three selected areas, are oriented NW-SE, in agreement with the orientation of the active stress field, as suggested by the EDA model, but also, by the proposed by Zinke and Zoback model; in fact, NW-SE direction corresponds also to the strike of the main fault structures in the three study regions. The mean values of the magnitude of the normalized delay time range from 0.005 s/km to 0.007 s/km and to 0.009 s/km, respectively for the L'Aquila (AQU) area, the High Tiber Valley (ATF) and the Val d'Agri (VA), suggesting a 3-4% of crustal anisotropy.

In each area are also examined the spatial and temporal distribution of anisotropic parameters, which lead to some innovative observations, listed below.

1) The higher values of normalized delay times have been observed in those zones where most of the seismic events occur. This aspect was further investigated, by evaluating the average seismic rate, in a time period, between years 2005 and 2010, longer than the lapse of time, analyzed in the anisotropic studies. This comparison has highlighted that the value of the normalised delay time is larger where the seismicity rate is higher.

2) In the Alto Tiberina Fault area the higher values of normalised delay time are not only related to the presence of a high seismicity rate but also to the presence of a tectonically doubled carbonate succession. Therefore, also the lithology, plays a important role in hosting and preserving the micro-fracture network responsible for the anisotropic field.

3) The observed temporal variations of anisotropic parameters, have been observed and related to the fluctuation of pore fluid pressure at depth possibly induced by different mechanisms in the different regions, for instance, changes in the water table level in Val D'Agri, occurrence of the April 6th Mw=6.1 earthquake in L'Aquila.

Since these variations have been recognized, it is possible to affirm that the models that better fit the results, both in term of fast directions and of delay times, seems to be EDA and APE models.

Key terms: Ligurian Briançonnais; Penninic Front; transpressive tectonics; paleofaults; paleoescarpments

The External Ligurian Briançonnais (ELB) has been recently interpreted (Piana et al., 2009) as the inner part of the SW-Alps foreland fold-and-thrust belt (Provencal-Dauphinoise region). ELB is characterized by a Triassic-Eocene stratigraphic succession largely detached from its volcanoclastic Permian basement and deformed, coherently with the internal part of the Provencal-Dauphinoise Domain (PDD), by multistage flexural folds and ductile-brittle shear zones. Although a gradual decrease in the intensity of deformation from the Internal Ligurian Briançonnais to ELB is observed, the ELB boundary with the adjoining Provencal-Dauphinoise Domain (PDD) does not correspond to major changes in metamorphic grade, but to several Km-long transpressive shear zones (such as the Limone-Viozene Zone, Piana et al., 2009) that merge with the basal detachment level or displace it. Deformation developed mainly in anchi-metamorphic conditions in the sedimentary successions of both ELB and PDD (Battaglia et al., 2011), with T ranging from 150° to 280°C.

The Alpine structural evolution of ELB and PDD was strongly controlled by primary sedimentary features such as palaeofaults and palaeoescarpments and/or major thickness and facies variations that allowed partitioning of deformation into different-order sub-units showing different structural associations and different intensity of deformation.

The preservation of such km-scale continuous syn-sedimentary features (Bertok, 2007; Bertok et al., 2011) demonstrates that ELB and PDD did not suffer significant internal reorganization, neither diffused transposition phenomena. This is also confirmed, at most stratigraphic levels, by ubiquitous preservation of depositional or diagenetic features such as bedding and laminations, mineralized hard grounds, neptunian dykes and sills, bioturbations, macro- and microfossils etc..

The role of the primary features on the kinematic evolution of ELB/PDD thrust belt is here discussed. Pre-Alpine faults acted as lateral transfer during the Alpine contractional evolution, separating different-order tectonic and tectono-stratigraphic subunits, characterized in some cases only by minor detachments along the weakest stratigraphic layers, or by development of superposed fold systems, or by shear zones where closely spaced dissolution cleavages are prevalent.

The transpressive zones developed along the ELB/PDD boundary pertain to the regional transfer fault systems developed at the joining zone of the Maritime and Ligurian Alps, namely the Argentera Massif boundary transpressive faults and the "Stura fault" or "Stura couloir" system, that determined the sharp southern termination of the Western Alps arc.

Key terms: Seismic tomography; Crustal structure; Giudicarie

The Giudicarie belt (Southern Alps, Italy), that acted as a principal deformation zone since the Early Alpine age, is a crucial zone in the geodynamic context of the Alps. The Giudicarie belt has a direction (NNE-SSW) approximately perpendicular to the main Alpine chain and it is today characterized by a diffuse seismic activity of low-to-moderate

magnitude ($M_w \leq 5.0$). The most important instrumentally recorded earthquakes are the Salò event (24th Nov 2004, M_w 5.0) in the Southern Giudicarie, and the Merano event (17th July 2001, M_w 4.8) in the Northern Giudicarie.

Here we present a local seismic tomography of the Giudicarie area, in order to estimate average seismic velocities (V_p and V_s) and to characterize the principal structures of the crust.

The work is based on a set of selected earthquakes (database period 1994-2007), chosen considering event magnitude, number and quality of phases, and areal event distribution in the study area to obtain an optimal seismic ray coverage. All phases were accurately re-picked on original recordings from different networks: i) Provincia Autonoma di Trento, ii) Istituto Nazionale di Oceanografia e Geofisica Sperimentale, iii) Istituto Nazionale di Geofisica e Vulcanologia, iv) other networks available via the European Integrated Data Archive (EIDA). Phase readings, also checked through the Wadati diagram, are used to initially relocate input earthquakes. For the relocation, different 1D velocity models are computed by the code VELEST within homogeneous domains, assuming a layered crust and considering initial V_p/V_s ratios estimated from the Wadati diagrams. Geographic coordinates of the seismic stations used in the relocations were carefully checked.

The inverse problem for both V_p and V_p/V_s ratio is approached via the code SIMULPS, with the implementation of an accurate shooting ray-tracer algorithm. Taking into account the available data and their quality, the

study volume is discretized in order to have an approximate homogeneous spatial resolution of 5 km (horizontally and in depth). The reliability and accuracy of inversion results are estimated by analyzing the Resolution Diagonal Elements (RDE) of the resolution matrix and by making checkerboard resolution tests. Only areas passing a minimum quality threshold are interpreted and shown in the tomographic cross-sections. The results are discussed taking into consideration available crustal sections (Deep Seismic Soundings), the distribution of significant lithological domains (e.g., Adamello batholith, thick carbonate covers), and regional tectonic lineaments (Giudicarie and Schio-Vicenza fault systems). The main different geological domains of the area are highlighted in the resulting 3D velocity model, both for P wave velocities and for V_p/V_s ratios. In particular, the significant difference between the Giudicarie domain and the others in terms of V_p/V_s ratios is pointed out. This study also represents the necessary base both to enable better quality local seismic event (re)locations (e.g., seismic bulletin), and to perform applied hazard investigations at the local scale (e.g., seismic microzonation).

Key terms: Northern Apennines; Strike-slip; Focal mechanisms; releasing bend; restraining bend

The aim of this presentation is to propose an alternative model for the Plio-Quaternary to present evolution of the Northern-Central Apennines by combining geometrical requirements (Riedel system) with existing structural and geological geometries (fault systems and their tectonic associations).

We define three sectors characterized by different seismological, geodetic, geothermal and geological signatures: the North-Western Sector (NWS), the Western Central Sector (WCS) and the Eastern Central Sector (ECS). They result from the fragmentation of the northern-central Italian peninsula as a consequence of the NW-SE push of the African plate. According to GPS data the three blocks move independently. In particular, the NWS is bound between the Central Apennines and the Alps; this constraint leads to a stress accumulation responsible for a fragmentation into further several blocks, which move either to the NE or SW. The WCS is relatively stable; the ECS moves towards NE and is characterised by the presence of numerous releasing and restraining bends, which can be related to the action of a main NNW-SSE left-lateral shear zone. The role assumed by the strike-slip kinematics, in the Plio-Quaternary evolution of the Northern-Central Apennines, allows us to define the chain as a "transcurrent orogen".

Presenter e-mail: a.turtu@unich.it

Key terms: Olevano-Antrodoco fault zone; tectonic rotations; paleomagnetism

The Olevano-Antrodoco-Sibillini (OAS) thrust represents the outer front of the Northern Apennines. It played an important paleogeographic role during Jurassic, as it separated carbonate platform and pelagic domain. At present, its southern sector is characterized by the alternance of NE-SW and N-S oriented segments. Its kinematic evolution has been interpreted in the literature as dextral strike-slip fault, dextral transpressive fault, or frontal and oblique ramp complex linked to the reactivation of pre-existing Jurassic faults (e.g., CALAMITA et al., 2011).

This study integrates new biostratigraphical and structural data with detailed paleomagnetic analysis, in order to constrain the OAS thrust kinematics. We sampled 52 sites predominantly in pelagic limestones, collecting on average 13 samples from each site. Cores were drilled using a petrol-powered portable drill and oriented in-situ with a magnetic compass, correcting their magnetic orientation to take into account the magnetic declination.

All samples were stepwise demagnetised by thermal heating in 15 steps (up to 620°C) and measured with a 2G DC-SQUID cryogenic magnetometer at the Istituto Nazionale di Geofisica e Vulcanologia of Rome.

The samples display three magnetization components: 1. Normal-polarity low-blocking temperature removed before 180°C, lying close to the geocentric axial dipole field; 2. Intermediate-temperature component isolated between 220°C and 320°C-460°C; 3. Characteristic remanent magnetization (ChRMs) till 580°C - 620°C, well defined in 536 over the 704 demagnetized samples.

Both the in-situ and tilt-corrected paleomagnetic directions are far from the local geocentric axial dipole field direction, suggesting the absence of both pre- and post-folding magnetic overprints. Furthermore, the intermediate-temperature component, acquired during diagenesis, is antipodal to the ChRMs, suggesting a primary nature of the ChRMs. As a summary, a primary nature for the ChRMs may be reasonably inferred. The tilt-corrected directions were compared to the coeval directions expected for the Adriatic-African foreland (BESSE & COURTILLOT, 2002) in order to calculate the rotations due to the orogenesis.

Thanks to 44 retained sites, this study documents a peculiar pattern of tectonic rotations along the OAS thrust. The thrust footwall is characterized by a homogeneous domain with counterclockwise (CCW) rotations (~-31°) linked to the Latium-Abruzzi thrust system and a null

rotated domain observed in the Laga Fm. Four clockwise (CW) rotated domains have been identified in the hanging wall: 1. strongly rotated close to the NE-SW thrust orientated segment, probably related to strike-slip faulting or transpression; less CW rotated ($\sim 35^\circ$) domain at a greater distance (0.5 - 1.2 km); slightly rotated ($\sim 16^\circ$) domain close to the N-S thrust orientated segment; 4. weakly rotated ($\sim 14^\circ$) domain 8-to-15 km far from the thrust front, most probably related to the Northern Apennine oroclinal (SPERANZA et al., 1997). Rotations are stronger along NE-SW lateral ramps and close to the thrust plane, and become smaller moving away from the thrust plane. Such pattern could be interpreted as due to the development of NE-SW lateral (or strongly oblique) and N-S frontal ramps along the OAS thrust. BESSE J. & COURTILOTT V. Key terms: strain partitioning; transpressional regime; structural inheritance; oroclinal bends; kinematic constraints

In the study of curved orogenic belts deformations are often complex, with structural associations that may appear as kinematically non consistent: for instance, in these environments contractional structures, such as folds and related thrusts, are often compartmentalized by strike-slip fault systems. A wide literature ascribes this inferred thrust/strike-slip fault relationship to distinct, superposed episodes or phases of deformation; however, recent advances in the field of transpressional tectonics illustrate that coexisting thrusts and strike-slip faults may result from effective kinematic partitioning of oblique movements into components of both contractional and lateral deformation. Similarly, in the analysis of the post-orogenic evolution of mountain belts, coexisting extensional and strike-slip faults, often ascribed to distinct, superposed tectonic phases or episodes, is more reasonably explained in terms of transtensional deformation models. With this contribution we aim at investigating the association of strike-slip and boundary-normal (i.e. contractional or extensional) deformations, that are widely present in the outer and inner zones of the Alps-Appennines orogenic system. The analysis makes it possible to test the hypothesis, hitherto only proposed on the basis of merely theoretical considerations, of an oblique, i.e. transpressional and/or transtensional, origin for these complex structural associations. The arcuate shape of the Alps-Appennines orogenic system seems to provide a clue for investigating at oblique deformation processes. Indeed, the boundary-normal (i.e. contractional and extensional) structures of the central part of the system tend to be increasingly oblique with respect to the generally persistent orogenic transport direction moving towards the lateral terminations. Three key-areas, where contractional structures and extensional structures coexist with strike-slip deformations, have been investigated in detail, through compilation of original field surveys, accompanied by extensive structural data collection. It appears that pre-orogenic structures played a critical role in controlling the onset of strain-partitioning paths. The results are synthesized in a model of oblique deformation for the evolution of the Alps-Appennines system, with transpressional components in the outer zones and transtensional components in the inner zones of these paired curved orogenic belts.

RELATIONSHIPS BETWEEN THRUSTS AND NORMAL FAULTS ALONG THE OLEVANO-ANTRODOCIO-SIBILLINI TRANSVERSAL THRUST: NEW INSIGHT IN THE GROWTH OF THE NW-SE QUATERNARY NORMAL FAULTS

DI DOMENICA Alessandra¹, TURTÙ Antonio¹, SATOLLI Sara¹, CALAMITA Fernando¹

1 - Università "G. D'Annunzio" Chieti, Italy

Presenter e-mail: a.didomenica@unich.it

Key terms: Central-Northern Apennines; inversion tectonics; pre-orogenic/Quaternary normal faults; Olevano-Antrodocio-Sibillini transversal thrust

The Apennines are a curved fold-and-thrust belt that originated during the Neogene-Quaternary time and are strongly influenced by the architecture of the Mesozoic Adria paleomargin. The NNE-SSW-trending Olevano-Antrodocio-Sibillini transversal thrust (OAS) juxtaposes the Northern Apennines on the Central Apennines.

The arcuate OAS thrust is characterized by NW-SE- and NNE-SSW-trending arms to the north and south of the Mt. Vettore apical zone, respectively. Along this thrust plane, the Triassic-Miocene pelagic Umbro-Marchean carbonate succession is overriden on the Scaglia Cinerea (Oligocene), Marne con Cerrognana (Miocene) and Messinian siliciclastic Laga Fm.

The timing of thrusts and normal faults has been analyzed along the NNE-SSW-trending OAS transversal thrust that intersects the NW-SE-trending normal fault systems of Mt. Vettore-Mt. Bove, Norcia-Mt. Fema and Mt. Boragine, using their crosscutting relationships. These normal fault systems are confined in the hanging wall block of the OAS transversal thrust and, in proximity of the thrust trace, show cumulative downthrows that reach 1000-1100 m involving the carbonate succession up to the Marne con Cerrognana Fm. Normal faults with the same trend are also present in the footwall of the OAS thrust. These crosscutting relationships indicate that the NNE-SSW-trending OAS transversal thrust displaces the NW-SE-trending normal faults outcropping

in both hanging wall and footwall blocks, thereby showing a down-section trajectory corresponding to these normal faults. Consequently, the NW-SE-trending normal faults can be interpreted as pre-thrusting discontinuities that were active until the Miocene and were then passively carried in the hanging wall of the thrust during the Neogene compressional deformation stage. The restored template of geological cross sections allowed us to interpret the OAS transversal thrust as the reactivation of the NNE-SSW pre-thrusting Ancona-Anzio fault that played the role of a transfer of the NW-SE-trending pre-thrusting normal faults during the Messinian extensional deformation event.

Moreover, the NW-SE-trending normal fault systems of Mt. Vettore-Mt. Bove and Norcia-Mt. Fema show Quaternary activity starting from 2-5 km to the intersection with the OAS transversal thrust and are responsible of the development of wide Quaternary intramontane basins at a distance of 4-8 km from the OAS trace. Consequently, two inversion tectonic events can be recognized. During the Neogene positive inversion event, the NNE-SSW-trending pre-existing normal faults were reactivated as oblique thrust ramps (i.e., the pre-orogenic Ancona-Anzio fault reactivated by the OAS transversal thrust) while the NW-SE-oriented normal faults were displaced by NW-SE frontal thrusts with a shortcut trajectory. Successively, NW-SE-trending pre-thrusting normal faults were reactivated during the Quaternary negative inversion tectonic event. The distribution of the NW-SE Quaternary normal faults and the related seismicity have been controlled and compartmentalized by the NNE-SSW-trending transversal thrusts of the chain.

Key terms: Transversal lineament; Sangro-Volturno transversal thrust; inversion tectonics; Central-Southern Apennines; Adriatic Foreland

Commonly, fold-and-thrust belts are characterized by axial culminations and depressions corresponding to salient and recess shapes leading to crop out different tectono-stratigraphic units within duplex or imbricate fan tectonic styles. Within this context, the along-strike changing of the cropping out tectono-stratigraphic units usually occur throughout transversal lineaments as regards to the major trending of the chain.

In order to ensure the role of the transversal structures in the Central-Southern Apennines and in the Adriatic foreland, an integrated structural study of surface geological data and seismic line interpretation has been proposed in this work.

The Apennines are a fold-and-thrust belt compounded by two major arcs: the Northern Apennines arc and the Southern one, joined by the Central Apennines. The NW-SE trending northern and southern arcs merge toward the Central Apennines through two transversal tectonic lineaments trending approximately N-S. They are represented by the Olevano-Antrodocio-Sibillini and the Sangro-Volturno (S-V) transversal thrusts, respectively.

The NNE-SSW trending S-V transversal thrust juxtaposes the Central Apennines onto the Southern Apennines. In the Central Apennines, NW-SE trending thrusts, affecting the carbonate succession referred to the Apulian and Lazio-Abruzzi platforms with their relative slope-to-basin transitions, merge toward south in the S-V oblique thrust ramp. In the Southern Apennines, the Apulian carbonate succession is involved in NW-SE and N-S trending thrust-related folds, buried underneath the Molise-Lagonegro allochthonous units.

Along the S-V transversal thrust, seismic line interpretation revealed both hanging-wall and footwall ramp relationships with respect to the buried Mt. Maiella and Mt. Porrara thrusts, consistent with a shortening value up to 4 km. In both the hanging-wall and the footwall of the Sangro-Volturno transversal thrust, N-S and NNW-SSE trending structures (e.g., Rocchette Mts., Setteporte, Mt. Taburno, Mt. Marrone structures) show push-up or high angle thrust-related folds geometries, suggesting the reactivation of pre-existing normal faults within transpressive deformation. Otherwise, the NW-SE thrusts present short-cut relationships with respect to the NW-SE trending hinterland-dipping normal faults affecting the backlimbs of the anticlines (e.g., Mt. Arazzecca structure).

In the Central Adriatic, compressive-transpressive deformation developed a NW-SE trending tectonic lineament that transects the entire foreland (i.e., Mid-Adriatic Ridge). The Mid-Adriatic ridge is either considered a compressive foreland deformation zone or connected to the frontal thrusts of the NE-verging Apennine chain. Deep seismic profiles interpretation lead to identify high angle crustal thrusts-related folds. The E-dipping high angle thrust-related anticline (i.e., Corinna structure), interpreted on the CROP M-17C seismic line between Alessandra 1 and Corinna 1 wells, shows a growth comprised between the Paleogene-Lower Pliocene time as indicated by thinning of these intervals in the fold crest. In addition, the eastward thickening of the Early Triassic-Middle Jurassic sequence in the hanging-wall of the anticline suggests a reverse reactivation of a Mesozoic normal fault. On map view, this pre-existing normal fault represent the southern termination of a major N-S trending discontinuity within the NW-SE trending Mid-Adriatic ridge.

In conclusion, N-S and NNE-SSW trending pre-thrusting normal faults were reactivated in a transpressive deformation as push-up features (e.g., Rocchette Mts., Setteporte, Mt. Taburno structures) or high angle thrusts (e.g., Mt. Marrone, Corinna structures) in both the Central-Southern Apennines and in the Mid-Adriatic ridge. Moreover, NW-SE trending pre-thrusting normal faults were truncated according to a short-cut trajectory by the frontal thrust ramps of the Apennine chain (e.g., Mt. Arazzecca structure).

SC VS. S TECTONITES IN THE NORTHERN APENNINES (ITALY) THRUST SHEAR ZONE: IMPLICATION FOR MODE AND TIMING OF DEFORMATION

SATOLLI Sara¹, CALAMITA Fernando², TURTÙ Antonio²

1 - Dipartimento di geotecnologie per l'ambiente e il territorio, G. d'Annunzio University of Chieti-Pescara

2 - Dipartimento di Scienze, G. d'Annunzio University of Chieti-Pescara

Presenter e-mail: s.satolli@unich.it

Key terms: tectonites; shear zone; Northern Apennines

SC tectonites are fault rocks characterized by the association of two foliations related to simple shear asymmetric and rotational deformations context: S surfaces are related to the accumulation of finite strain and C surfaces are related to localized shear strain. The angle between C and S is 45° at the initial stage of deformation and decrease to 0° with progressive shear (S tectonites). Conjugate extensional shear planes (extensional crenulation cleavage) in tectonites can be the result of deformation within domains of shear zones characterized by flow that moved away from the progressive simple shear.

We analyzed the ductile-brittle shear zone associated to the Olevano-Antrdoco-Sibillini (OAS) thrust, which offers spectacular outcrops within the Tertiary marls and shales lithotypes. The Pliocene OAS thrust of the Northern Apennine has a curved shape defined by NW-SE frontal ramp and NNE-SSW oblique ramp to the north and south of Vettore Mt., respectively. In the southern sector, NNW-SSE-trending anticlines involve both the footwall and the thrust plane of the NNE-SSW arm of the Olevano-Antrdoco-Sibillini thrust, suggesting an in sequence deformation.

In the NW-SE trending sector, the shear zone is characterized by SC tectonites compatible with a simple shear deformation, where the S fabric is oriented at 45° to the shear plane C, with a top to N50-60° direction of tectonic transport. Whereas, along the NNE-SSW-trending sector of the OAS thrust, the fabric is characterized by S tectonites crenulated by conjugated extensional planes.

The compatible strains in shear zones of the S tectonites are: 1. Progressive simple shear that realizes the rotation of the S fabric until its parallelization to the wall of the shear zone; 2. Simple shear associated to negative dilatation perpendicular to the shear zone walls; 3. Sub-simple shear (combination of simple shear and pure shear). A progressive simple shear should be testified by the presence of synthetic reidel shears and rotated extension fissures that characterize strong deformed SC tectonites, eventually evolved in S tectonites. None of these features is detected in the analyzed area. In this area, S tectonites can be possibly due to sub-simple shear, whereas the extensional crenulation cleavage also involving the OAS thrust plane can be related to the pure shear strain, post-OAS thrusting. They are most probably related to the OAS thrusting contemporaneous to the footwall anticlines growing (sub-simple shear strain in the thrust shear zone) and to the definitive growth of footwall anticlines after the OAS thrusting (pure shear strain involving the thrust plane and its hanging-wall and footwall blocks, related to the fold outer arc extensional deformation).

As consequence, S tectonites cannot be related univocally to the amount of shear strain deformation (proportional to the amount of thrust shortening) that is due to the same amount of shortening along the OAS thrust sectors analyzed in this work. S tectonites are strongly affected by the sub-simple shear related to the contemporaneous development of the NNE-SSW-trending OAS oblique thrust plane and of the NNW-SSE-trending anticlines involving its footwall block and of pure shear strains during the definitive footwall anticline growth. This hypothesis is in agreement with the in-sequence development of the thrust and related folding toward the Adriatic foreland.

The analysis and comparison of SC and S tectonites along an oblique regional-scale thrust ramp allowed us to reconstruct the in-sequence deformation mechanism of the Central-Northern Apennines, which is in agreement with an inversion tectonic context characterized by the reactivation of NNE-SSW pre-thrusting normal faults as transversal thrusts. We propose the detailed analysis of thrust shear zones as a useful tool not only to define the kinematic and deformation mechanism, but also to constrain the mode and timing of thrusts and related folds development

Key terms: anatexis; migmatite; thermodynamic modelling; thermobarometry; nanogranite

We have studied fine-grained stromatic metatexites occurring c. 400 m below the contact with the Ronda peridotite (Ojén unit, Betic Cordillera, SE Spain). These rocks contain Qtz + Pl + Kfs + Bt + Fib + Grt + Ms + Ap + Gr ± Ilm and have a main foliation defined by alternating layers of biotite and fibrolite and thin (~ 0.5 cm) leucosomes. Garnet occurs in very low modal amount (<1%). Muscovite is an armored inclusion or texturally retrograde.

Microstructural evidence of melting in the migmatites includes pseudomorphs after melt films, euhedral feldspars, and nanogranite inclusions in garnet. Remelted nanogranites show granitic compositions. The latter microstructure demonstrates that garnet crystallized in the presence of melt.

We have constructed two pseudosections: one for the bulk rock in the MnNCKFMASH system, and the other for the composition of the remelted nanogranite inclusions in the NCKFMASH system. Calculated isopleths for chemical parameters of garnet (X_{Mg} , X_{Ca}), biotite (X_{Mg} , X_{Fe}) and plagioclase (An content) in the Qtz-Pl-Kfs-Bt-Grt-Sil-melt field match the actual values in the rock. The P-T conditions of equilibration were estimated at 4.5-4.8 kbar, 680-700 °C. These P-T conditions overlap with the low-T tip of the melt field in the pseudosection for the nanogranite composition. They are also consistent with the complete experimental remelting of nanogranites at 700°C.

These results indicate that nanogranites represent the anatectic melt generated at, or soon after, muscovite melting, and that garnet is able to trap melt inclusions also at temperatures lower than those of biotite breakdown melting.

Key terms: anatexis; migmatite; garnet; melt inclusions; nanogranite

Recently, Cesare et al. (2009 and 2011) showed that peritectic minerals in migmatites and granulites can trap droplets of anatectic melt that were formed by incongruent melting reactions during high-temperature metamorphism and granite formation. Detailed geochemical studies on these melt inclusions (MI) have shown that they can represent a window of information into the prograde history of partially melted rocks (Acosta-Vigil et al. 2010). However, the recovery of these information is not straightforward as remelting and homogenization of MI at ambient pressure with the routine technique in igneous petrology produced inclusion decrepitation, interaction with host mineral and volatile loss (Cesare et al. 2011).

To avoid these problems, we performed the experimental remelting of MI using a piston cylinder apparatus. MI are located within peritectic garnets, hosted in the metasedimentary migmatites from Ronda (Betic Cordillera, SE Spain). These garnets contain primary 2-10 µm MI that range from totally glassy to fully crystallized (nanogranite, Cesare et al. 2009). Partially crystallized MI are very common and generally contain quartz, biotite, muscovite and, more rarely, plagioclase, along with variable proportions of glass. Raman spectroscopy has documented the presence of liquid H₂O-filled micropores in nanogranites, in agreement with the presence of a micro- to nano-porosity observed by SEM investigation. Piston cylinder remelting experiments led to the complete rehomogenization of crystalline MI at conditions (700 °C, 500 MPa) close to those inferred for anatexis. Remelted MI have a peraluminous, granitic composition with high (up to 7.5 wt%) H₂O content; they overlap the composition of glassy MI, but differ from the composition of leucosomes in the host rock. Some CO₂ bubbles are present after remelting experiments, suggesting fluid present, a_{H₂O} < 1 conditions, in agreement with graphite being present in the protolith.

Our study shows that partially crystallized and nanogranite inclusions in peritectic minerals from migmatites can be successfully remelted and analyzed, and that this experimental approach may become an ordinary procedure for future studies on MI in anatectic rocks worldwide. We have identified the natural anatectic melt composition and fluid regime at the onset of crustal melting for this case study otherwise unknown. Hence, MI in migmatites represent a unique tool for the *in situ* characterization of anatexis in its early stages, and provide the only means of determining the volatile fluid content of anatectic melts.

NATURE OF GRANITE SOURCE(S) IN THE TUSCAN MAGMATIC PROVINCE: NEW INSIGHTS FROM SR-ND ISOTOPE DATA OF PALAEOZOIC BASEMENT

DINI Andrea¹; FARINA Federico²

- 1 - Istituto di Geoscienze e Georisorse - CNR, Pisa, Italy
- 2 - Department of Geology, Stellenbosch University, South Africa

Presenter e-mail: a.dini@igg.cnr.it

Key terms: Granite; Crustal melting; Sr-Nd isotopes; Palaeozoic basement; Tuscany

Despite granite magmatism represents the major mechanism for past and ongoing large-scale crustal differentiation and it is, therefore, central to understand the evolution of the continental crust, the processes that produce the chemical and isotopic variations displayed by granites remain poorly constrained. Miocene to Pleistocene granites from Tuscan Magmatic Province have been studied since XIX century but it is during the last two decades that a large number of geological, geochemical and isotopic data have been published (see Dini et al., 2009 and references therein). Theories about the origin of these granites changed through time, from the early highly speculative idea of a pure crustal anatexis (e.g. Marinelli, 1967) to the much more constrained hypothesis of mingling-mixing between crustal- and mantle-derived magmas (e.g. Poli, 1992). The involvement of mantle-derived magma (thermal source for overstepping of breakdown reactions in lower crust as well as a geochemical end-member in mingling-mixing processes) has been largely accepted for many Tuscan granites although in some cases (e.g. granites cored in the Palaeozoic basement of the Larderello geothermal field; Dini et al., 2005) its role has been considered relevant only in providing extra heat for the partial melting of the crust. In previous works (van Bergen et al., 1983; Poli et al., 2002), the micaschists from the Larderello basement, due to their fertile mineralogy, have been assumed to be a potential source of the Tuscan granites. However, available Sr-Nd isotope data for these Palaeozoic rocks do not fit the isotope composition of granites and different crustal sources (not exposed and/or unsampled) have been invoked. It is worth noting that the lack of appropriate sources in terms of isotopic composition is a common feature in Hercynian plutonic complexes (Pyrenees, Central Spain, Armorican Massif, Bohemian Massif, etc., Villaseca et al., 1998). A detailed geochemical and isotopic study of metagneous and metasedimentary rocks from the Palaeozoic Tuscan basement (exposed: Apuan Alps, Elba Island; buried: Larderello geothermal field) was performed in order to characterize the potential crustal sources of Larderello granites. Metagneous rocks are represented by metabasites and metarhyolites (porphyroids), while studied metasedimentary rocks are mainly micaschists. In some studied outcrops and cores (Larderello, Elba Island), amphibole-rich metabasites are interlayered with biotite-rich micaschists. Sr and Nd isotope data indicate the existence of three distinct isotopic crustal reservoirs: metasediments (87Sr/86Sr = 0.730; 143Nd/144Nd = 0.5119); metarhyolites (87Sr/86Sr

$^{87}\text{Sr}/^{86}\text{Sr}$ 0.750; $^{143}\text{Nd}/^{144}\text{Nd}$ 0.5122); and metabasites ($^{87}\text{Sr}/^{86}\text{Sr}$ 0.716; $^{143}\text{Nd}/^{144}\text{Nd}$ 0.5126). These reservoirs do not fit the isotope composition of Lardereño granites but partial melting of a metabasite-metasediment layered source can explain both the observed geochemical and isotopic variation in granites. The existence of Palaeozoic interlayered domains at depth could explain the apparent lack of appropriate anatectic sources, providing alternative mechanisms for the origin of Tuscan granites.

3 - IGG - CNR, Via Valperga Caluso 35, I-10125, Torino, Italy

Presenter e-mail: franco.rolfo@unito.it

Key terms: low-pressure anatexis; cordierite; Himalaya; microstructures; P-T pseudosections

In the eastern Himalaya, partial melting is widely documented in the Higher Himalayan Crystallines (HHC), a high-grade, several km thick lithotectonic unit located at the higher structural levels of the Himalayan belt (e.g. Goscombe et al., 2006; Searle et al., 2008). In the lower structural levels of the HHC, anatexis occurred at medium to high-P (8-12 kbar) and is recorded in Ky-bearing granulites (Barun Gneiss and Jannu-Kangchenjunga Gneiss). Toward structurally upper levels of the HHC, peak-P significantly decreases down to 4-5 kbar, as revealed by the widespread occurrence of Crd-bearing and Ky-free gneisses (e.g. Imayama et al., 2010; Streule et al., 2010; Mosca et al., 2010), locally named Namche Migmatites and Black Gneisses (e.g. Bordet, 1961; Lombardo et al., 1993).

This contribution focuses on the cordierite-bearing lithologies occurring at the higher structural levels of the HHC, by describing in detail three Crd-bearing gneisses (samples 09-29, 07-26 and 05-17) from different geological transects in Eastern Nepal from Everest to Kangchenjunga. The studied samples differ in terms of bulk composition, likely reflecting different sedimentary protoliths (from pelite to psammite), though they all consist of quartz, K-feldspar, plagioclase, biotite, cordierite and sillimanite in different modal percentages. Garnet occurs in two samples, as a relict phase in very low modal amounts. In all the studied samples cordierite is spectacularly well preserved.

Most of the observed microstructures may be interpreted in terms of melt-producing or melt-consuming reactions, such as for example: (i) Crd porphyroblasts including Sil and Bt never in mutual contact, suggesting that Crd is a peritectic phase grown at the expenses of both Sil and Bt; (ii) coarse-grained Kfs poikiloblasts containing abundant inclusions of Bt, rounded Pl and Qtz, and minor Sil, suggesting that Kfs is a peritectic phase grown at the expenses of Pl, Bt, Sil and Qtz; (iii) thin films of Qtz, Kfs or Pl with cusped shape locally occurring between adjacent grains of Qtz, Bt or Kfs possibly interpreted as pseudomorphs of liquid-filled pores (e.g. Holness & Sawyer, 2008), thus suggesting that some melt crystallized in the interstices between grains.

The lack of retrograde rehydration suggests that either the studied samples experienced a significant melt loss so that the interactions between melt and solid phases during cooling were limited, or the amount of melt produced was scanty. The results of P-T pseudosection modeling suggest that the first hypothesis is the most likely for the metapelitic samples 09-29 and 07-26, whereas the second hypothesis applies well to the metapsammite sample 05-17.

The P-T evolution of the studied samples, reconstructed combining microstructural observations, mineral chemical data and pseudosection modeling, is discussed in the framework of the "channel flow" model, which is one of the most popular paradigms to explain the tectonometamorphic evolution of the HHC and, more generally, the first-order geologic features of the Himalayan-Tibetan orogen.

Key terms: medium-pressure anatexis; decompression; Himalaya; microstructures; P-T pseudosections

Partial melting of deep continental crust may occur during either prograde heating or decompression. Although the effect of temperature on crustal melting has been widely investigated, only few experimental studies address the question of the influence of pressure on crustal anatexis, and the effectiveness of decompression melting in the production of large amounts of melt in the deep crust is still far from being universally demonstrated.

In the eastern Himalayan chain, partial melting is widely documented in the Higher Himalayan Crystallines (HHC), a high-grade, 5-6 km thick lithotectonic unit located at the higher structural levels of the Himalayan belt. Crustal anatexis in the HHC has been generally ascribed to decompression melting (e.g. Harris & Inger, 1992; Harris & Massey, 1994; Patiño Douce & Harris, 1998; Harris et al., 2004; Streule et al., 2010; Searle et al., 2010), and gave rise to significant amounts of granitic bodies and dykes crosscutting widespread migmatites and granulites. The HHC thus represent an ideal natural laboratory in which to investigate the actual influence of decreasing P on partial melting processes.

In this study we have investigated in detail the P-T evolution of two garnet-K-feldspar-kyanite-sillimanite anatectic gneisses from different structural levels of the same Unit (Barun Gneiss) in the lower portion of the HHC (Arun-Barun valley, eastern Nepal). Although the mineral assemblage is identical (Qtz + Pl + Kfs + Bt + Grt + Ky/Sil + Rt), several microstructural and microchemical features, combined with the results of P-T pseudosection modeling, suggest that the two samples experienced a different P-T evolution, dominated by decompression (sample 07-16) and heating (sample 07-35) respectively.

P-T pseudosection modeling shows that the melt productivity, related to the muscovite- and biotite dehydration melting reactions, depends on: (i) the slope of melt isomodes in the P-T space (which in turn is an expression of the slope of the reaction curve), and (ii) how the P-T trajectory crosses the melt isomodes. For the two studied samples, given the constrained P-T paths and their relations with the main melt-producing reactions in the P-T space, it can be concluded that melt production was mainly triggered by heating, with or without the combined effect of decompression. Decompression alone is not able to explain the production of large amounts of melt, in contrast to what is often suggested for the HHC.

In addition, metamorphic and petrologic data derived for the Barun Gneiss match well with the predictions of the "channel flow" model, one of the most popular paradigms to explain the tectonometamorphic evolution of the Himalayan-Tibetan orogen.

PERITECTIC PHASES ENTRAINMENT AND MAGMA MIXING: THE ORIGIN OF THE CHEMICAL VARIABILITY OF THE LATE MIOCENE GRANITIC COMPLEX FROM ELBA ISLAND (ITALY)

FARINA Federico¹, STEVENS Gary¹, DINI Andrea², ROCCHI Sergio³

1 - Department of Geology, Stellenbosch University, South Africa

2 - Istituto di Geoscienze e Georisorse-CNR, Pisa, Italy

3 - Dipartimento di Scienze della Terra, Università di Pisa, Italy

Presenter e-mail: a.dini@igg.cnr.it

Key terms: granite; peritectic phase; entrainment; mixing; Elba Island

The comparison between the chemical variability exhibited by the granitic rocks of the Elba Island granitic complex (Italy) and the composition of fluid-absent experimental melts indicates that these rocks have Fe+Mg, Ti and Ca contents that are too high to represent pure crustal melts.

Therefore, their origin demands the addition of a ferromagnesian, Ti- and Ca-rich component to an anatectic melt. Various authors, on the basis of textural and chemical data, have interpreted the chemical variability exhibited by the Elba Island granitic rocks as reflecting the progressive hybridization of an original crustal melt with mantle-derived magma(s). However, a simple mantle-crustal magma mixing hypothesis is challenged by the observation that some elements (e.g. Ti and Ca) are highly correlated with Fe+Mg, while others (e.g. Sr, K, Na) are not, as well as by the scattered major and trace element composition of the mafic microgranular enclaves. This contribution focuses on reconsidering the role of mantle-derived magmas in the petrogenesis of the Elba Island intrusive system from the perspective of the constraints imposed by crustal melt compositions. On the basis of the major- and trace element geochemical data, as well as petrographic data such as amphibole clots replacing former pyroxene and garnets in some of the Elba granitic rocks (possibly representing evidences for the occurrence of entrained peritectic phases), we propose that at least part of the compositional variations displayed by the Elba Island intrusive complex is primary, i.e. reflect the magma composition that ascended directly from the source. Following this hypothesis, the final composition of magmas may be controlled by two main factors: (i) the stoichiometry of the melting reaction(s) and the composition of reactant phases in the source, that control the composition of the anatectic melt; (ii) the degree of entrainment of peritectic mineral phases, whose nature will be dependent by (i), as well as by the P, T conditions of melting. The magma mixing relevant to the bulk of the Elba igneous products then occurred between successive (different ?) magma

batches generated by anatexis of heterogeneous source rock volumes. Mantle-derived magmas are only involved in the genesis of the most mafic magma batches.

Key terms: *crustal xenoliths; Betic Cordillera; P-T conditions; crust-mantle boundary; partial melting*

The geology of the Betic area has been characterized by several tectono-magmatic episodes related to multiple orogenic cycles and extensional phases (Puga et al., 2011; Bianchini et al., 2011 and references therein) ultimately leading to widespread subduction-related and anorogenic volcanism. The last magmatic phase (Pliocene) is represented by Na-alkaline basalts at Tallante that entrained and exhumed abundant deep-seated xenoliths of both mantle and crustal provenance. These xenoliths attracted an intense petrological interest testified by an impressive number of scientific papers. Unfortunately, most of these studies focused on the ultramafic xenoliths ignoring the crustal lithologies that were investigated only by the paper of Vielzeuf (1983). In this contribution we present new data on felsic (i.e. crustal) xenoliths from Tallante that integrate the petrological information provided by the ultramafic parageneses, highlighting the deep lithosphere stratigraphy of the area as well as constraints for the interpretation of geophysical data and models.

The felsic xenolith is characterized by a metamorphic peak assemblage composed of quartz + spinel + sillimanite. The occurrence of cordierite rims between spinel and quartz is related to post-peak metamorphism. To obtain P-T information from this texture, we calculated a P-T pseudosection for the specific mineral reaction texture spinel + quartz = cordierite. The microbulk composition was modeled in the SiO₂-Al₂O₃-FeO-Fe₂O₃-MgO system. Water has not been taken into account in order to simulate the likely anhydrous conditions occurring during the peak metamorphic stage.

The observed paragenesis Spinel-Quartz-Sillimanite indicates temperature around 1000 °C for pressure of 7 kbar, increasing to 1125 °C at 9 kbar. The formation of cordierite rims between quartz and spinel requires, in the chosen system, decompression down to < 6 kbar (T < 950 °C). This evolution was accompanied by partial melting testified by glasses films and blebs.

Therefore, felsic xenoliths from Tallante attained P-T condition overlapping those recorded by the ultramafic xenoliths of mantle provenance that are represented by spinel-plagioclase peridotite. This suggests that an intimate association of crust and mantle lithologies with pervasive interlayering and interfingering at metric to hectometric scale characterizes the Moho discontinuity in this area.

Melting preferentially occurred in the crustal domains (characterized by lower solidus conditions) generating silica-rich magmas that veined the surrounding peridotite domains, also inducing orthopyroxene-rich metasomatic aureole.

The proposed petrological scenario is discussed taking also into account the investigations on the neighboring massifs of Ronda and Beni Bousera where the fossil crust-mantle boundary is exposed, providing fresh insights for the configuration and evolution of the Moho discontinuity in collisioned plate boundaries, that are widespread throughout the peri-Mediterranean realm. The hypothesized tectonic crust-mantle boundary would represent a suitable source region for exotic magma types such as lamproites that are common within the Mediterranean area (Tommasini et al. 2011).

GEOLOGICAL EVOLUTION OF THE SOUTH EUROPEAN VARISCAN FRAGMENTS FROM CALABRIA INFERRED FROM P-T COMPUTATIONS AND U-PB ZIRCON AGES.

FORNELLI Annamaria¹, LANGONE Antonio², MICHELETTI Francesca¹,

PASCAZIO Annarita¹, PICCARRETA Giuseppe¹

Presenter e-mail: f.micheletti@geomin.uniba.it

Key terms: *P-T-t path; South European Variscan chain; U-Pb zircon ages; Calabria*

In Calabria (southern Italy) fragments of south European Variscan chain consisting of ortho- and para-derivates affected by low- medium- high-grade metamorphism crop out.

Ortho-derivates involved by green schist to granulite facies metamorphism characterize middle and deep continental crust units.

Metagabbros and metabasites affected by granulite facies metamorphism are associated with felsic granulites and migmatitic metapelites of the lower continental crust unit of the Serre.

U-Pb spot analyses on zircon separates (performed by SIMS and LA-ICP-MS) have provided constraints on the ages of protoliths and on chronology of Variscan metamorphism.

The age of magmatic protoliths of the orthogneisses and of the metabasic rocks was fixed at ~540 and ~580 Ma, respectively, representing a

bimodal magmatic contribution to Pan-African crust in Early Cambrian-Neoproterozoic times. Mafic and felsic magmas were emplaced in the Pan-African/Cadomian basement preserving memory of older terrains belonging to West African Craton. These peri-Gondwana terrains were reworked by Variscan orogenesis and look like the blocks occurring in the east European chain from the Alps to Turkey. The effects of Variscan metamorphism depend on P-T conditions and rock chemical compositions. A time memory, step by step, of the Variscan evolution was preserved in rock-types where the re-growth or re-crystallization of zircon happened. So the U-Pb zircon ages together with the petrological data in granulite-amphibolite facies metamorphic rocks of the Serre allow to depict the Variscan evolution.

Ages around 450 Ma were recorded in the metagneous rocks which coincide with the age derived from Rb-Sr isochron relative to metasedimentary rocks; this age can be related to an Ordovician tectonothermal activity or to Eo-Hercynian events.

Cluster ages of 347-340 Ma, 323-318 Ma, 300-294 Ma and 279 Ma were measured in metagabbros and metabasites from the lower portions of the section. Age peaks around 323, 300 and 270 Ma are recorded in overlying migmatitic metapelites. Undated thin luminescent rims of zircon are the only evidence of post-Ordovician events in orthogneisses interleaved with migmatitic metapelites.

Conventional thermobarometer, Thermocal calculations and pseudosections indicate clockwise trajectories Ky-Sil-And-Ky and Ky-Sil-Ky for the migmatitic metapelites and metabasites, respectively, from the deep continental crust unit of the Serre. The P-T conditions in the

metabasic portion indicate a possible P peak (P₂~1.08 GPa and T<850°C)

predating the T-peak (T=850-900°C and P~1.08 GPa) at 347-340 Ma,

probably followed by quite isothermal decompression (P=0.8 GPa) at

323-318 Ma and successive decrease of T (~750°C); a new

decompression at P about 0.65 GPa around 300 and 280 Ma ago, occurs.

During the decompression stages pervasive partial melting episodes, producing leucogranitic and trondhjemitic melts, interested these rocks in

which luminescent overgrowths mantle primary zircon cores.

The re-constructed P-T path shows even for the upper migmatitic

metapelites, P-peak at 0.9 GPa and T=650° pre-dating T-peak (750°C)

under quite isobaric conditions 323 Ma ago and a multistage

decompression at 300, 280 Ma up to 270 Ma with incremental partial

melting episodes.

An integrate approach involving U-Pb analyses on zircon and REE

distribution in garnet orthopyroxene and zircon on thin section, relatively

to the mafic granulites better constrain the Variscan evolution.

Key terms: *Sediment provenance; U-Pb zircon geochronology; Latest Proterozoic; Peloritani Mountains*

In situ SHRIMP U-Pb ages have been obtained, for the first time, for detrital zircons from metasedimentary and metagneous rocks from the Peloritani Mountains (NE Sicily), allowing some firm constraints to be put on the formation age and origins of this still poorly known

peri-Mediterranean chain. The greywacke protoliths of the paragneiss

forming the most common rock-type in the Peloritani Mountains were

deposited at c. 550 Ma, the age of the youngest detrital zircon population,

just before the intrusion of granitoid plutons at c. 545 Ma. Large portions

of flysch-type sequences including deeper equivalents of the c. 550 Ma

greywackes underwent partial melting, producing large volumes of

granitoid rocks now exposed as augen-gneisses in north-eastern Sicily, as

well as in southern and northern Calabria. Age spectra of detrital and

inherited zircons from paragneiss and augen gneiss, respectively, indicate

sediment derivation from the erosion of Neoproterozoic to Late Archaean

sources. The main components are c. 540-850, 900-1100 and 2400-2700

Ma and minor ones c. 1.60, 1.80 and 3.20 Ga. These age groups reflect a

peri-Gondwanan affinity and are consistent with deposition in a marginal

basin located at the northern Gondwana margin, between an old cratonic

area and the Avalonian-Cadomian magmatic arc (Nance et al., 2010; and

reference therein). The high abundance of Grenvillian zircon, together with

the occurrence of c.1.56-1.80 Ga grains, makes it quite unlikely that the

amphibolite facies basement of NE Sicily was derived from the West

African Craton, contrary to what is suggested for similar coeval rocks from

Calabria. Although Grenvillian zircons are known from various sectors of

northern Gondwana, such as the Saharan craton and the Arabian-Nubian

Shield, a stronger affinity with Amazonian-derived terranes, such as NE

Bohemia, NW Turkey and the autochthons of NW Iberia, is more

suggestive of an Amazonian linkage for that part of NE Sicily at the

Precambrian-Cambrian transition. Later, the Peloritani Mountains were

involved in break-up processes linked to opening of the Rheic Ocean and,

finally, in a short-lived Mid-Ordovician orogenic cycle. Magmatic activity

related to this Early Paleozoic evolution is documented, respectively, by

Cambro-Ordovician alkali metabasites and Caradocian meta-andesites and

felsic porphyroids from the volcano-sedimentary sequences of the

southern Peloritani Mountains (Trombetta et al., 2004; Cirrincione et al.,

2005). The depicted nearly continuous geodynamic evolution suggests a

basement-cover relationship between the Latest Neoproterozoic basement

rocks of NE Peloritani and the Paleozoic volcano-sedimentary sequences of

SE Peloritani. Inherited Mesoproterozoic zircon from the Mid-Ordovician

porphyroids (Trombetta et al., 2004) supports both the Amazonian

provenance and the basement-cover relationship of the northern and the

southern Peloritani Mountains. The results of the present study are in

substantial agreement with former models proposed by Acquafredda et al.

(1994) and Ferla (2000) and additionally provide the first reliable

geochronological information on the real age and early history of the

medium-high grade Peloritani basement.

Key terms: *Calabrian crust; extension; microstructures; pseudosection; geothermobarometry*

Quartz-monzodioritic dykes have intruded the Hercynian continental lower crust of Calabria 323±5 Ma ago, according to zircon spot age data. We have constrained the emplacement depth of these dykes by the construction of pseudosections and the calculation of multiple reactions using the internally-consistent dataset of THERMOCALC. Our calculations show that the quartz-monzodioritic dykes have intruded the metapelitic-migmatitic country-rocks at a depth of about 32 km. After the intrusion the dykes together with country-rocks were deformed under granulite facies conditions. This is supported by microstructural evidence and by the application of geothermometry. The analysis of fabric elements contained within the deformed dykes and the country-rocks suggests that deformation has occurred in an extensional regime. The onset of deformation can be placed to before 306 Ma, because the deformed quartz-monzodioritic bodies are locally cut by undeformed leucocratic dykes connected to the granulite masses that intruded the Calabrian crust between 306 and 300 Ma. Intrusion of these granulites has occurred during extension at mid-crustal levels. Decompression during extension of the Calabrian crust under granulite facies conditions has been pinpointed so far to the intrusion of these granulite masses. We can show that in the lower crust the extension started earlier, suggesting that it was asynchronous within the Calabrian crust, and has propagated with time from deeper to mid- and upper crustal levels. Alternatively, the whole Hercynian crust underwent thinning almost synchronously at different crustal levels.

Key terms: *post-collisional dyke magmatism; southern Calabria; andesite/boninite association; dacite-rhyodacite*

Diffuse dyke swarms with intermediate to felsic composition and calcalkaline affinity crop out in the Serre Massif (Calabria, Southern Italy). These are part of the widespread late- to post-collisional magmatism affecting most southern European basements during the waning stages of the Hercynian orogeny. The dykes are andesitic and dacitic-rhyodacitic in composition, with medium- to high-K₂O content, and show typical features of subduction-related magmas, such as LILE and LREE enrichment and HFSE depletion. Chondrite-normalized REE patterns are weakly to strongly fractionated (LaN/YbN = 8.5 to 14.0 for andesites and 2.3 to 16.3 for dacites-rhyodacites) with slightly negative to positive Eu anomaly for the andesites and markedly negative Eu anomaly for the dacites-rhyodacites.

The petrogenesis of the late- to post-Hercynian calcalkaline rocks is usually linked to an extensional post-collisional setting involving thinning of the continental lithosphere and progressive upwelling of the asthenospheric mantle. In such a context, both pure mantle, crustal and hybrid melts are likely to be generated. The andesitic dykes show mineral and whole-rock major and trace element composition resembling boninitic rock associations (anomalously high MgO, Mg#, Cr and Ni, coupled with high SiO₂, relatively low TiO₂, high Mg# in clinopyroxene, high Al₂O₃/TiO₂, high Zr/Hf, moderate LREE enrichment, low HREE and negative Nb-Ta troughs in primitive mantle-normalized diagrams). Petrological investigations suggest that they were probably produced by partial melting of an enriched mantle source metasomatized by crustal fluids/melts during former subduction of oceanic lithosphere and then suffered minor, if any, assimilation of lower crustal metapelites. Most dacite-rhyodacites were instead likely derived by hybridization in various proportions of crustal and mantle melts, whereas pure crustal metasedimentary sources, and more or less efficient restite unmixing processes, were involved in the generation of the most silica-rich rhyodacites.

Presenter e-mail: pfianna@unicit.it

Key terms: *Augen gneiss; Ediacaran; peri-Gondwanan terranes; post-collisional magmatism; Peloritani Mountains*

Augen gneisses covering an area of about 80 km² in the Peloritani Mountains (NE Sicily) have been found to be 570-540 Ma granulites after SHRIMP zircon U-Pb dating of a representative sample from each of three different areas. Similar coeval rocks are also exposed in Calabria,

indicating the presence of a large Ediacaran granulite province in the Calabria-Peloritani Terrane, currently extending from NE Sicily to northern Calabria. Two of the studied augen gneisses, from the eastern Peloritani, have many zircon grains composed of a thick ~ 545 Ma melt-precipitated rim surrounding a core ranging in age from Late Archean to latest Proterozoic. These cores are interpreted as detrital grains from sediments that were part of the source of the granulite magmas, and suggest that that source was largely composed of rocks akin to the protoliths of northern Peloritani paragneisses, which have similar patterns of detrital zircon ages. The third augen gneiss, from the western Peloritani, has a protolith emplacement age of ~ 565 Ma and contains inheritance-free zircon, implying that the magma was strongly zircon undersaturated and/or high-temperature, or derived from a zircon-poor source. The Late Ediacaran emplacement ages of the granulite protoliths of the inheritance-rich augen gneisses, together with typical high-K calcalkaline post-collisional geochemical features and strong evidence for dominantly crustal sources from zircon inheritance and isotopic features, are consistent with the widespread crustal melting and post-tectonic granulite emplacement at c. 550-540 Ma reported by many authors (e.g., Murphy et al., 2001; Linnemann et al., 2008; Nance et al., 2010) as marking the transition from subduction to strike-slip tectonics at the northern margin of Gondwana at the end of the Neoproterozoic. It has been proposed that some of the peri-Gondwanan terranes were formed in back-arc environments located between cratonic (south-American or north-African) and arc-related (Avalonian or Cadomian) domains. After a late stage of arc magmatism at c. 580-560 Ma, possibly represented in the Peloritani Mountains by the 565 Ma protolith of the western Peloritani augen gneiss, inversion of back-arc basins related to collision of the magmatic arcs with mainland areas led to the deposition of turbidite sequences at 545-540 Ma. In some cases (e.g. Lausitz Group in Saxo-Thuringia; Linnemann et al., 2007) these sequences were rapidly deformed before the intrusion, at ~ 540 Ma, of large volumes of granulites, probably derived from melting of the same turbiditic graywackes, as suggested by comparable zircon age patterns and geochemical and isotopic compositions. Many of the ~ 545 Ma igneous rims on zircon from the two studied eastern Peloritani augen gneisses overgrow virtually coeval Ediacaran inherited cores, indicating deposition of the sediments only very shortly before magmatism. This interpretation is reinforced by the c. 545 Ma deposition age obtained for the metagreywacke protolith of an eastern Peloritani paragneiss. These results may be framed in a model involving rapid erosion, burial, sediment deformation and metamorphism up to partial melting conditions in less than about 10 million years. A similar model has been envisaged by Nance et al. (2010) for the Saxo-Thuringian zone. They proposed that these latest Proterozoic examples of extremely rapid geological evolution were caused by a short-lived regime of high heat-flow linked to slab break-off resulting from ridge-trench collision. In this context, evidence for a mantle contribution to the petrogenesis of the c. 545 Ma granulites may be found in their geochemical and isotopic features, and the documented presence of coeval gabbroic rocks in the same region.

1 - Department of Geological Science - Catania University

Presenter e-mail: deborahlopo@hotmail.it

Key terms: *PT pseudosections; Hercynian Orogeny; Peloritani Mountain Belt*

The Peloritani Mountain belt is a segment of the European Alpine orogen that preserves pre-Alpine basement relics. Very low to high grade metamorphic rocks are exposed in the present-day tectonic stack of the chain. Up to now very few PT paths are available for the basement tectonic slices of the Peloritani Mountains, due to the common absence of suitable parageneses in the low and very low grade metamorphic rocks, as well as to the pervasive late Hercynian thermal re-equilibration in the medium-high grade metamorphic rocks. In this view, to estimate the relic peak PT conditions of the Hercynian evolution of this southern Alpine chain sector, phase diagram calculation method was applied, modelling the upper greenschist facies garnet-muscovite-chlorite schists outcropping in the uppermost levels of the Mandanici Unit. The investigated fine-grained metapelite are characterized by a dominant lepidoblastic texture, with ilmenite and poikilitic garnet porphyroblasts surrounded by alternating muscovite+paragonite+chlorite and minor quartz+plagioclase layers, with apatite, monazite and zircon as accessory phases. Three schistosity surfaces were recognized: S1 consists in a partially obliterated isoclinal folding schistosity developed during the first identifiable deformational event (D1); S2 is related to a penetrative microfolding (D2) producing pervasive crenulation schistosity; S3 is consequent to an extensional-shearing event (D3). Porphyroblast-matrix relationships, investigated via optical and electronic microscopy allowed the blasto-deformation sequence to be reconstructed. The attention was focused especially on garnet zoning pattern analysis. Garnet porphyroblasts have cores characterized by quartz and rare ilmenite inclusion trails with folding pattern linked presumably to the D2 event. Idioblastic rims grow over the crenulated garnet, thus representing a late to post-D2 growth stage. Fe-Mn-Mg-Ca X-ray maps and compositional profiles outlined a weak compositional growth zoning, consisting in a bell-shaped profile, with increasing almandine and decreasing spessartine contents toward the rims. P-T pseudosection was calculated in the TiMnNCKFMASH system, using the XRF bulk-rock composition of metapelite samples mainly exhibiting assemblages consistent with peak or near-peak conditions. Retrograde evolution is locally represented by garnet breakdown to chlorite. Garnet inner core isopleths intersections indicate T of 510°C at P of 0.483 GPa, just nearby the garnet-in curve, in agreement with pyrophanite isopleths composition of porphyroblastic ilmenite. Garnet outer core isopleths intersections define similar P-T conditions of T = 525°C and P = 0.485 GPa. These P-T estimates are linked to the first identifiable metamorphic stage in which isoclinal folding event (D1) and garnet core developed. Garnet rim isopleths intersections gave values of the peak metamorphism at T of 535°C with slightly lower P of 0.430 GPa, attained during the crenulation deformational event which obliterated most of the previous foliation. All the obtained intersections belong to the same pseudosection PT field characterized by chl+ms+pl+ilm+grt+pg assemblage, in agreement with the observed mineralogical assemblage. Subsequent retrograde evolution is depicted in the pseudosection PT space by garnet breakdown reaction into chlorite

with T of 500±20°C at P of 0.32±0.03 GPa, consistent with the observed partial to complete pseudomorph replacements. PT estimates obtained via garnet isopleths thermobarometry can be interpreted as the peak PT climax of the Mandanici Unit reached during the Hercynian crustal thickening at upper-middle crust conditions, while the following retrograde evolution depicts a typical retrograde clockwise PT trajectory consistent with the initial exhumation stage of the Hercynian orogen.

EVIDENCE OF HERCYNIAN HIGH TEMPERATURE RELICS REPLACED BY ALPINE MYLONITIC OVERPRINT: NEW IMPLICATIONS FOR THE TECTONO-METAMORPHIC EVOLUTION OF THE CASTAGNA UNIT (CALABRIAN PELORITANI OROGEN, SILA PICCOLA MASSIF)

SACCO Valentina¹, CIRRINCIONE Rosolino¹, DE VUONO Eloisa², ORTOLANO Gaetano¹, PEZZINO Antonino¹

1 - DIPARTIMENTO DI SCIENZE GEOLOGICHE-UNIVERSITA' DEGLI STUDI CATANIA

2 - DIPARTIMENTO DI SCIENZE DELLA TERRA-UNIVERSITA' DELLA CALABRIA

Presenter e-mail: vale_sacco@yahoo.it

Key terms: Polyorogenic evolution; Shear Zone; Sila Massif

Petrological and microstructural investigations have been integrated to unravel the tectono-metamorphic evolution of the Castagna Unit. This unit represents a pervasively mylonitised horizon located in the lower-intermediate portion of the northern Calabride continental crust section, sandwiched at the bottom by the low grade metapelite of the Bagni Unit and at the top, by the granulite facies rocks of the Sila Unit. Evidence of Hercynian high temperature relics have been observed for the first time, preserved as low strain domains within the pervasive mylonitic foliation of the metapelite horizons.

In this view, petrological, structural and microstructural analysis on mylonitic paragneiss and leucogneiss, allowed to yield reliable P-T constraints aimed to depict the tectono-metamorphic history for this little-known and discussed portion of crystalline basement in the northern Calabrian Peloritani Orogen.

Locally, low strain domains composed of garnet-sillimanite paragneiss, with intermediate to low Ti-biotite and oligoclase-andesine plagioclase, are preserved in the metapelite horizons. The quasi-absent garnet crystal zoning, suggesting the presence of pervasive re-homogenising effects of garnet interiors, represents a petrological evidence of long residence time at high T conditions in the lower crust. The narrow high Mn rim content in garnet depicts an anti bell-shaped profile suggesting a clear evidence of retrograde metamorphism.

Thermodynamic modelling, by means of pressure-temperature (P-T) pseudosection computations, in the MnNaCaKFMASH system, not allowed to yield any reliable P-T constraints about the prograde metamorphic event coeval with the former garnet growth stages. The narrow retrograde rims of this re-homogenised garnet, allowed reliable P-T constraints to be detected, with P ranging from 5.7 to 6.8 Kbar at T of 595 °C, consistent with the former stages of the retrograde metamorphic trajectory at upper amphibolite facies conditions.

The subsequent pervasive mylonitic retrograde evolution is mainly recorded in the leucogneiss horizons, characterised by ribbon-like quartz levels wrapping feldspar porphyroclasts and low phengite mica fish. Syn-mylonitic white mica shows a bimodal distribution of phengite content: a) an high phengite white mica (e.g. 3.23-3.4 a.p.f.u) can be interpreted as the result of an high pressure mylonitic stage ranging from 4 to 8 Kbar; b) a low phengite one, could represent the relic of a previous mylonitic stage developed at lower pressure conditions.

Quartz c-axis orientation pattern analysis allowed to constrain shearing temperature consistent with lower greenschist facies conditions (i.e. 400-450 °C) with subordinate evidence of prism c-slip system activation consistent with higher shearing temperature, both characterised by the same sense of shear.

New implications on the evolution of the Castagna Unit suggest as the pre-mylonitic relics preserved as low strain domain in metapelite, can be interpreted as the result of an Hercynian granulite facies mineralogical association, as supported by the re-homogenising effect on garnet interiors, affected by the former stage of retrograde evolution in upper amphibolite facies conditions, constrained by means of garnet rim isopleth thermobarometry. In this view, the Castagna Unit can represent the basal mylonitised and retrogressed portion of the originally granulitic Sila Unit, during a former late Hercynian lower pressure stage. Undeformed aplitic-pegmatitic dikes, linked to the Sila Batholith emplacement, crosscutting the mylonitic foliation, support this interpretation. The subsequent well-developed HP-LT mylonitic overprint, can be interpreted as a pervasive Alpine re-activation.

In this scenario, the "Castagna Unit's shear zone" can be interpreted as a post-Hercynian "detachment zone", postulated in order to justify the exhumation of the deepest parts of the continental crust, reworked during the building of the Alpine Orogen.

ORIGIN OF GABBROIC SEQUENCES FROM ALPINE JURASSIC OPHIOLITES: IMPLICATIONS FOR LOWER CRUST GENERATION AT SLOW SPREADING SETTINGS

TRIBUZIO Riccardo¹, SANFILIPPO Alessio¹, RENNA Maria Rosaria¹

1 - Dipartimento di Scienze della Terra e dell'Ambiente, Università di Pavia

Presenter e-mail: tribuzio@crystal.unipv.it

Key terms: ophiolite; oceanic lithosphere; gabbro

The Alpine Jurassic ophiolites are lithospheric remnants of an embryonic slow spreading basin that developed in conjunction with the opening of the Central Atlantic Ocean. These ophiolites are locally characterized by up to km-scale gabbroic bodies intruded into mantle peridotites. In particular,

large-scale gabbroic sequences occur in the Chenaillet ophiolite from the western Alps (Manatschal et al. 2011), the Internal Ligurian ophiolites from the northern Apennines (Cortesogno et al. 1987; Sanfilippo and Tribuzio 2011) and the Balagne ophiolites from Corsica (Saccani et al. 2000). These gabbroic sequences mostly consist of troctolites, olivine-gabbros and clinopyroxene-rich gabbros and include sparse olivine-rich troctolites, olivine-gabbronorites and oxide-gabbros. The large-scale gabbroic bodies from the Alpine ophiolites locally also enclose up to 100 m thick mantle bodies and bear striking structural and compositional resemblances to the gabbroic sequences from modern slow spreading ridges.

Field observations and petrological and geochemical data are used to constrain a conceptual model for the formation of the gabbroic sequences from the Alpine ophiolites. The proposed model begins with a "hot" mantle evolution under plagioclase facies conditions, in which melt transport occurred mostly in the form of grain scale porous flow. In particular, reactive channeling of primitive olivine-saturated melts formed replacive dunitic conduits, whereas residual orthopyroxene-saturated melts led to melt impregnation of the mantle section. The "hot" lithospheric evolution is followed by an evolution characterized by melt transport through fractures, which started with crystallization of melt into troctolite to olivine gabbro dykes. This dyking event is presumably correlated with the formation of the olivine-rich troctolites within the gabbroic sequences, by infiltration of MORB-type melts within dunitic conduits (Renna and Tribuzio 2011).

As the mantle section cooled significantly, the dip of the melt migration structures evolved from sub-vertical to sub-horizontal. This is shown by the occurrence of sill-shaped gabbroic intrusions that locally crosscut the gabbroic dykes. The growth of the gabbroic sequences is attributed to accretion of gabbroic sills. In particular, petrological variations and cooling rate estimates as a function of the stratigraphic height document that the large scale architecture of the gabbroic sequences is produced by the association of variably evolved sills that were derived from different primitive melt injections. After their solidification, the gabbroic sequences underwent high temperature ductile shearing, from near solidus to amphibolite facies conditions. The amphibolite facies shear zones occurred close to the ductile-brittle transition and record the penetration of seawater-derived fluids within the gabbroic sequences.

SUBDUCTED HYDROTHERMALLY ALTERED OCEANIC CRUST: WHAT HAPPENS IN SUBDUCTION ZONES? A MODELLING PERSPECTIVE FROM THE WESTERN ALPS OPHIOLITES

REBAY Gisella¹, POWELL Roger²

1 - Università di Pavia

2 - The University of Melbourne

Presenter e-mail: gisella.rebay@unipv.it

Key terms: hydrothermally altered; ophiolite; subduction; thermodynamic modelling

Eclogitised oceanic crust preserved in sutures of collisional zones has very often undergone pervasive high-pressure metamorphism, but nonetheless preserves evidence of parts of its previous history, such as hydrothermal alteration that took place in oceanic environment. The existence of this alteration is well documented in present-day and past oceanic crust. Altered oceanic rocks that enter the subduction zone are amongst the principal carriers of fluids into the mantle, and may have a profound impact on the water budget. It is thus interesting to understand in detail what happens to such hydrated rocks when they undergo high pressure metamorphism, and we have investigated this through forward modelling of mineral assemblages in the NCKFMASHTO system, using the THERMOCALC software. A bibliographic survey has been performed in order to have an idea of the composition of altered oceanic rocks, considering both present day and fossil examples. Moreover some eclogitised hydrothermal systems have been considered as well. Once a compositional line expressing the complex chemical variations in oceanic rocks was defined, modelling has been undertaken producing 4 PT pseudosections representing the progression of composition during alteration. They have then been linked with TX pseudosections in order to represent a line through compositional space, to evaluate the effect of bulk composition on the high pressure mineral parageneses. Calculated modal composition of rocks has then been determined in order to compare results with what observed in the rocks. Predicted mineral assemblages cover all the observed high-pressure rocks described in altered oceanic crust, ranging from "true" eclogites, through glaucophanite, talc-schists to chlorite schists. The modelling shows the importance of bulk composition on metamorphic mineral assemblages, even though the effects of fluid availability and of oxidation state may be also playing a crucial role. This work shows that when considering bulk composition, it is important to take into account all oxides, even those that are present in the rock in small quantities.

EXPERIMENTALLY-DERIVED CA-NA PARTITIONING BETWEEN PLAGIOCLASE AND CLINOPYROXENE: A NEW GEOBAROMETER FOR MANTLE ROCKS

FUMAGALLI Patrizia¹, BORGHINI Giulio², RAMPONE Elisabetta²

1 - Università degli Studi di Milano

2 - Università di Genova

Presenter e-mail: patrizia.fumagalli@unimi.it

Key terms: plagioclase peridotite; mantle exhumation; experimental

petrology; Na/Ca partitioning; geobarometry

The crystallization of plagioclase-bearing equilibrium assemblages in mantle peridotites is commonly considered witness of lithospheric mantle exhumation at shallow depth (e.g. Rampone et al., 1993; Ozawa & Takahashi, 1995; Newmann et al., 1999). Experimental works have pointed out that at subsolidus conditions plagioclase lherzolite assemblages are stable up to 1 GPa. Subsolidus experimental data in the complex chemical system $\text{TiO}_2\text{-Cr}_2\text{O}_3\text{-Na}_2\text{O-FeO-CaO-MgO-Al}_2\text{O}_3\text{-SiO}_2$ on depleted and fertile lherzolite compositions (Borghini et al., 2010) have documented systematic compositional variations in coexisting minerals at decreasing pressure within the plagioclase stability field, similar to what observed in equilibrated plagioclase peridotites. In these experiments, Ca-Na partitioning between plagioclase and clinopyroxene is strictly dependent on pressure, with plagioclase composition varying significantly ($An=59\text{-}83$) in a narrow range of pressure. In a recent paper, Borghini et al. (2011) have defined the anorthite isopleths in plagioclase as a function of P and T in a specific fertile lherzolite composition, and they have demonstrated that plagioclase-facies equilibrium pressures can be estimated by comparing experimental data on a fertile lherzolite and microstructural-chemical observations in natural samples with the same bulk composition. This latter method represents a first-order empirical tool to trace the decompressional evolution of the lithospheric mantle up to very low-pressure and it is potentially applicable to natural plagioclase peridotites of different origin. Nevertheless, the composition of plagioclase at variable bulk Na₂O/CaO ratios has been not fully discerned yet, making this approach directly applicable to a limited bulk composition range. Here, we present the results of new experiments on a Na-enriched lherzolite (bulk Na₂O/CaO ratio = 0.13), representative of many refertilized lithospheric peridotites at extensional settings, thus enlarging significantly our investigated compositional spectrum (Na₂O/CaO = 0.08 - 0.13). The goal of this work is to provide a formulation for a geobarometer analysis based on Ca-Na plagioclase-clinopyroxene partitioning on a larger experimental data set which takes into account the effect of bulk Na₂O/CaO ratio, and is consequently applicable to a wider compositional range of mantle rocks.

THE EFFECTS OF THE OVERRIDING PLATE THERMAL STATE ON THE SLAB DIP IN AN OCEAN-CONTINENT SUBDUCTION SYSTEMRODA Manuel¹, MAROTTA Anna Maria², SPALLA Maria Iole²¹ - Università degli Studi di Milano, Dipartimento di Scienze della Terra, Sezione di Geofisica² - Università degli Studi di Milano, Dipartimento di Scienze della Terra, Sezione di Geologia

Presenter e-mail: manuel.roda@unimi.it

Key terms: *Lithosphere thermal state; Numerical models; Slab dip; Subduction zones*

To evaluate the effects of variations in the thermal state of the overriding plate on the slab dip in an ocean-continent subduction system, a 2-D finite element thermomechanical model was implemented. The lithosphere base was located at the depth of the 1600 K isotherm. Numerical simulations were performed while taking into account four different initial thicknesses for the oceanic lithosphere (60, 80, 95 and 110 km) and five different thicknesses of the overriding plate, as compared in terms of the continental-oceanic plate thickness ratio (100, 120, 140, 160 and 200% of the oceanic lithosphere thickness). The results of numerical modeling indicate that a high variability of the subducting plate geometry occurs for an oceanic lithosphere thickness ranging from 60 to 80 km, while the variability decreases where the oceanic plates are thicker (95 and 110 km). Furthermore, the slab dip strongly depends on the thermal state of the overriding plate, and, in particular, the slab dip decreases with the increase in the upper plate thickness. The model predictions also confirm that a direct correlation between the slab dip and the age of the oceanic lithosphere does not exist, at least for subduction plates thinner than 110 km. These conclusions are supported by the good agreement between the model results and the natural data referring to worldwide ocean-continent subduction zones.

NECKING, PERCOLATION AND IMPREGNATION: THE LOVE STORY OF THE LIGURIAN LITHOSPHERE-ASTHENOSPHERE SYSTEM DURING TRIASSIC - JURASSIC EVOLUTION.PICCARDO Giovanni Battista¹, RANALLI Giorgio²¹ - DIPTERIS, University of Genova, Italy² - Earth Sciences, Carleton University, Ottawa, Canada

Presenter e-mail: piccardo@dipteris.unige.it

Key terms: *Continental extension; Asthenosphere partial melting; Melt percolation through the extending mantle lithosphere; Melt impregnation of the shallow mantle lithosphere*

Mantle peridotites record the deep mantle processes that follow the structural evolution of the asthenosphere-lithosphere during continental rifting.

Continental lithosphere extension by far field tectonic forces lead to thinning of the lithospheric mantle and its progressive exhumation. In fact, the original sub-continental lithospheric mantle, which is still preserved in ophiolites deriving from the passive margins of the basin (e.g., External Ligurides, Erro-Tobbio, North Lanzo, Upper Platta) maintain structural-paragenetic features indicating progressive exhumation. Their provenance from the deep lithosphere ($P > 2.5$ GPa) is marked by the presence of rounded mm-cm wide clusters of orthopyroxene+spinel(+clinopyroxene) formed by destabilization of precursor mantle garnet when passing to spinel-peridotite facies conditions ($P < 2.5$ GPa) and by the sporadic presence of garnet in pyroxenites ($P > 1.5$ GPa).

Most of the spinel peridotites (P between 2.5 and 1.0 GPa) show km-scale extensional shear zones with tectonite-mylonite fabrics that have been dated to 220 Ma (Lu-Hf age) and 225 Ma (40Ar/39Ar amphibole age).

These data indicate that a significant lithosphere extension and mantle exhumation was already active during Upper Triassic, having already exhumed the lower mantle lithosphere from garnet- through spinel- to plagioclase-facies conditions by a network of extensional shear zones. In fact, field and petrographic-structural investigations indicate that shear zones were formed during the whole evolution of the mantle lithosphere. After significant continental extension and lithosphere reduction, the upwelling asthenosphere underwent incipient decompressional melting during almost adiabatic upwelling. This relatively early magmatism is well consistent with the reduction of about 50% of the lithosphere width and the near-adiabatic upwelling and partial melting under spinel-facies conditions of the DM asthenosphere. Isotopic dating of the early gabbroic bodies in the mantle lithosphere suggest that this early melting occurred during (upper Triassic?) - lower Jurassic.

Spinel-facies shear zones were injected and percolated by MORB-type single melt increments and, subsequently, peridotites were percolated and impregnated by melts under plagioclase-facies conditions. Peridotites were widely impregnated and refertilised by melts percolation via porous flow as conductive heat loss prevailed on percolation heating and melt stagnated in the upper lithospheric mantle.

Shear zones formed at plagioclase-facies conditions were frequently infiltrated by aggregated MORB melts and transformed by focused and reactive porous flow to dunite channels, sometimes 10-100-meters wide. These high porosity channels are generally considered the fastest way in plastic regimes to deliver oceanic MORB to shallow levels. These melts form the gabbroic intrusions and the basaltic extrusions of the lower Jurassic oceanic crustal rocks.

Peridotites were intruded by gabbroic bodies starting from Lower Jurassic [180+/-14 Ma - Erro-Tobbio; 179+/-9 Ma - External Ligurides] and stopped presumably during Upper Jurassic (155-150 Ma - Monte Maggiore - Corsica).

In conclusion, the concomitant effects of dry extension along shear zones, inception of mantle asthenosphere, and asthenospheric melt migration through the extending lithosphere (e.g., focused melt percolation in dunite channels and porous flow migration through the mantle lithosphere) caused the intimate evolution of upwelling asthenosphere and extending (thinning) mantle lithosphere, preceding oceanization of the Ligure-Piemontese basin.

Structural and petrological-geochemical studies on the ophiolitic peridotites furnish, accordingly, significant contributions from a mantle perspective to the understanding of the geodynamic evolution of the Ligure-Piemontese system during continental extension leading to oceanic opening.

OPHIOLITIC SEQUENCES FROM THE CENTRAL SECTOR OF THE CATENA COSTIERA, (CALABRIA)FILLICE Francesco¹, LIBERI Francesca¹, CIRILLO Daniele², PANDOLFI Luca³, MARRONI Michele³, PILUSO Eugenio¹¹ - Dipartimento di Scienze della Terra, Università della Calabria² - Dipartimento di Scienze, Università di Chieti³ - Dipartimento di Scienze della Terra, Università di Pisa

Presenter e-mail: d.cirillo@unich.it

Key terms: *Accretionary wedge; ophiolite sequences; HP-LT metamorphism; Bagni Unit; Calabrian Arc*

Mesozoic ophiolites crop out in the Catena Costiera (Northern Calabrian Arc). The Northern Calabrian Arc is characterized by the superposition of three structural elements: the uppermost Hercynian continental section intruded by late-Variscan granitoids (Calabrian Nappe), the intermediate ophiolitic Nappe and the lowermost Mesozoic passive margin carbonate sequences (Apenninic Units).

The studied area is located in the central Catena Costiera where the ophiolitic sequences are characterized by both aphyric and porphyritic metabasalts with a T-MORB affinity. They represent the basement of a pelitic-arenaceous metasedimentary sequence, previously interpreted as a pre-Mesozoic continental basement (Bagni Unit of Amodio-Morelli et al., 1976). In the metasedimentary cover, a remarkable increase in the carbonatic supply is noticed moving from south to north of the study area. Two stratigraphic sequences have been defined: the northernmost San Martino di Finita ophiolitic sequence, characterized by metabasites, volcanoclastic metasediments and calcschists, and the southernmost Cozzo Cervello ophiolitic sequence, characterized by: metabasites, thin levels of volcanoclastic metasediments, rare metacarbonates, metapelites and metarenites.

The studied rocks underwent a polyphase deformation history with three main (D1-D3) deformation phases recognized:

D1, characterized by a S1 foliation, preserved as microlithons inside the S2 main foliation;

D2, a N-S trending isoclinal folding event (F2) is responsible for the formation of the S2 foliation, that represent the main surface recognizable in the field;

D3, characterized by asymmetric folds (F3) developed at different scales and showing a WNW-ESE trending axes. An incipient foliation (S3) is locally developed in the phyllosilicate-rich levels.

The petrographic analysis allows to define the mineralogical assemblage of the different lithotypes.

The metabasites are characterized by the mineralogical assemblage: Epidote + Na-amphibole ± Lawsonite + Phengite + Chlorite + Albite ± Calcite ± Quartz + Magnetite. Metapelites and metarenites are characterized by: Epidote + Phengite + Magnetite + Stilpnomelane + Pumpellyite + Chlorite + Albite + Quartz + Magnetite. The calcschist are constituted by: Calcite + Phengite + Chlorite + Albite + Calcite + Quartz + Magnetite. The described mineralogical assemblages suggest that the studied rocks underwent P-T conditions typical of the blueschist facies as suggested by the blastesis of Na-amphiboles, lawsonite, stilpnomelane and phengite along the S2 foliation.

The following metamorphic retrogression developed in the prehnite-pumpellyite facies and is characterized by a static recrystallization.

The field study and the tectonometamorphic evolution reconstructed for the ophiolitic sequences cropping out in the central sector of the Catena Costiera of Calabria show that a subduction and exhumation history inside an accretionary wedge can be proposed.

In particular, the characterization and the definition of the complex relationships existing within the ophiolitic metasedimentary cover allow us to propose:

- the source area was composite, with both carbonatic and siliciclastic contributions;
- the presence of terrigenous deposit, even in the lowermost part of the

sedimentary sequence, seem to indicate that this part of oceanic crust was located close to the continental margin;
 iii) the San Martino di Finita type sedimentary cover can be correlated with that of the Malvito ophiolitic unit (sensu Amodio-Morelli et al., 1976), cropping out in the northernmost sector of the Catena Costiera;
 iv) the subdivision between the Bagni and Gimigliano-Monte Reventino Units, as proposed by Dietrich and Scandone (1972) and Amodio-Morelli et al. (1976) for the study area, is not supported by the data collected in this work.

 3 - Università di Udine

Presenter e-mail: paola.tartarotti@unimi.it

Key terms: Alpine ophiolite; trondhjemite; Fe-gabbro; Grivola-Urtier

In the Grivola-Urtier Unit (Urtier Valley, southern Aosta Valley, Italy), the Piemonte ophiolite nappe mainly consists of serpentinized peridotites including pods and boudinaged layers of Fe-metagabbro and trondhjemite transposed in the main foliation together with calcschists and micaschists. Chloritescist and rodingite locally mark the contact between serpentinites and Fe-metagabbro/trondhjemite. In the Vallone delle Acque Rosse, the studied rocks retain a high pressure metamorphic imprint of Eocene age (44.3±0.3 Argon plateau age; 45.6±1.4 Ar isocron; Rb/Sr = 42±0.4 Phengite). High pressure parageneses are omphacite/chloromelanite-garnet-rutile-glaucophane-phengite, in the Fe-metagabbro, and plagioclase-quartz-phengite-garnet, in the metatrondhjemite, respectively. Bulk-rock major and trace elements in addition to O isotope analyses were performed in the two rock types. Fe-metagabbros are characterized by MgO wt% ranging between 6.11 and 9.63%, $\Sigma\text{REE} = 20 \div 101$ ppm, (La/Yb)_N = 0.22±0.91; trondhjemites have SiO₂ 43%, Al₂O₃ ranging between 21 and 24%, CaO ranging between 17 and 20%, $\Sigma\text{REE} = 172 \div 272$ ppm, (La/Yb)_N ranging between 1.78

and 13.70. $\delta^{18}\text{O}$ is 5.9 ‰ in a Fe-metagabbro sample and 7.4 ‰ in a trondhjemite sample, suggesting that the studied rocks have been affected by a weak oceanic (low T°C?) alteration. The Alpine HP imprint thus did not delete the primary isotopic signature.

Key terms: Basalt; Layer 2B/2C boundary; ODP-IODP Hole 1256D; Superfast spreading crust; East Pacific Rise

The boundary between seismic layer 2B (basalt extrusives) and layer 2C (sheeted dike complex) in the oceanic crust created at fast and superfast-spreading ridges is commonly characterized by intense rock fracturing and occurrence of breccias hosting metal sulfides. In ODP-IODP Hole 1256D (East Pacific Rise, Cocos Plate) the layer 2B/2C boundary corresponds to the Transition Zone (TZ) located between the overlying Sheet and Massive Flows and the underlying Sheeted Dike Complex. The TZ is about 60m thick and consists of basaltic sheet and massive flows, a cataclastic unit, and hyaloclastic breccias cemented by sulfides, quartz, anhydrite, calcite, and minor amphibole. It separates two contrasting metamorphic zones, the shallowest basalts being altered at low temperature conditions, and the deeper basalts being affected by greenschists-facies alteration. The upper and lower boundaries of the TZ have been defined at 1004mbsf and 1061mbsf, respectively. However, due to low recovery rates in Hole 1256D, especially from brecciated intervals and fracture fillings, these two boundary depths do not perfectly fit with those suggested by wireline geophysical logs and by structural data on cores. Namely, steep fractures and cataclases, likely related to the stress field induced by intrusion of dikes at depth, are concentrated up to ca. 800 mbsf, in accord with FMS and UBI images. The seismic structure of the crust is affected by fracture shape, namely, low aspect ratio (thin fractures) have much more effect on compressional wave velocity than wide open pores, with varying porosity. By integrating structural/microstructural data with physical properties investigations and geophysical logs, the actual thickness of the TZ can be revised and defined more precisely. We used structural data from cores, thin section observation, and X-ray tomography on fractured samples for characterizing the crack porosity and shape, in order to calibrate the geophysical signals along the TZ. The thickness and position of the TZ are crucial for controlling the pattern of crustal permeability and hydrothermal fluid circulation.

MANTLE MELTING AND THE ORIGIN OF THE BIMODAL MAGMATISM OF PANTELLERIA VOLCANO, SICILY CHANNEL: CONSTRAINTS FROM COMBINED U-SERIES AND SR-ND-PB ISOTOPES

AVANZINELLI Riccardo¹

1 - Università degli Studi di Firenze

Presenter e-mail: riccardo.avanzinelli@unifi.it

Key terms: U-Th-Pa disequilibria; mantle melting; withinplate magmarism; peralkaline rocks; Pantelleria

In the southernmost sector of Italy continental within-plate volcanism (e.g. Sicily Channel, Etna, Ustica) occurs in close geographical and geodynamic association with both subduction-related magmatism (e.g. Aeolian Islands) and ocean spreading (Tyrrhenian seafloor). Magmatism in the Sicily Channel (Pantelleria and Linosa) is due to the passive up-welling of asthenospheric mantle in response to the development of pull-apart basins related to south-eastward roll-back of the subduction of the Ionian plate with respect to the rest of the subducting African plate. Within the Sicily Channel, Pantelleria, the type locality of pantellerite, is a Late-Pleistocene magmatic system characterised by a bimodal association of alkali basalts and peralkaline rocks (trachytes to pantellerites), separated by a large compositional gap in SiO₂ (50-67 wt.%). The relationships between basaltic and differentiated magmas at Pantelleria, and in bimodal magmatic suite in general, have been the focus of debate in the last three decades. In particular the evolved per-alkaline products are interpreted either as derived from basaltic parental magmas by fractional crystallisation or by re-melting of a gabbroic cumulate. This study presents new 238U-230Th isotope data along with Sr, Nd and Pb isotope ratios and trace element contents of both the mafic and the felsic peralkaline products of Pantelleria volcano. 235U-231Pa disequilibria have also been measured on two samples with basaltic and hawaiitic composition. The aim of this contribution is to investigate i) the melting regimes responsible for the generation of the least differentiated alkali basaltic products, and ii) the relationships existing between mafic and differentiated peralkaline magmas.

Pantelleria mafic products have ubiquitous 230Th excesses ranging from 7% to 21%. This range is due to a rather wide variation of (238U/232Th) at an almost constant (230Th/232Th). A notable exception is constituted by two hawaiitic samples that presents comparable 230Th-238U disequilibria with alkali basalts, but at significantly lower (230Th/232Th) and (238U/232Th). Hawaiites also display similar (231Pa/235U), but different Sr, Nd and Pb isotopes with respect to alkali basalts suggesting these two types of magma derive from two distinct mantle sources, but similar melting regimes.

Trachytes and pantellerites also have (238U/232Th) similar to those of alkali basalts, but slightly lower (230Th/232Th). This feature argues against the possibility of generating the peralkaline products by re-melting of a gabbroic cumulate, favouring an origin through fractional crystallisation in timescales comparable to the half-life of 230Th

Swarms of diabase dykes and a few sills of the Central Atlantic magmatic province (CAMP) intruded the Piedmont area of the Appalachians and the coastal plains of eastern North America (ENA) between 201 and 199 Ma. Three different trends were aeromagnetically recognized, radiating from NW (mostly in the south), to N-S (in North and South Carolina) and turning NE to the north. Based on crosscutting relations, an age progression can be defined from NW- to N- and NE-oriented dykes. 70 dykes and a sill were sampled from Georgia to Virginia. ENA diabases grade in texture from ophitic to intergranular or intersertal, with few porphyritic samples, and grain size varies from sub-pegmatitic to nearly aphanitic. A typical basaltic mineralogy is observed, with ubiquitous plagioclase (An₄₇₋₅₄), pyroxenes (augite En₇₃₋₅₆Fs₉₋₃₀Wo₁₇₋₄₂, pigeonite, and rare orthopyroxene) and Fe-Ti oxides, flanked by either olivine (Fo₄₈₋₅₉) or micropegmatite, in olivine- and quartz-normative samples, respectively. SiO₂ (46.2-54.3 wt%) and alkali (1.28-4.38 wt%) contents classify these rocks as basalts and andesitic basalts with tholeiitic affinity, showing a characteristic Fe-enrichment trend with fractionation. A wide range in MgO (4.74-16.99 wt%), Al₂O₃ (12.94-18.68 wt%) and TiO₂ (0.36-1.35 wt%) suggests different degrees of low pressure fractional crystallization for this magmatic suite, controlled mostly by plagioclase, pyroxenes and olivine. Mg-, Cr-, and Ni-enrichments reflect also accumulation of mafic minerals in some samples. Incompatible trace element contents are fairly homogeneous and generally low, e.g. La/Yb_N (0.54-2.39), a characteristic typical of melts derived from a quite depleted shallow mantle-source. All the 40 samples analysed for trace elements by ICP-MS show negative Ti, Ta and Nb anomalies, suggesting either a source inheritance or the effect of crustal contamination (though discarded by other observations). Incompatible trace element contents are not correlated with isotopic compositions of ENA dykes, which display a considerable spread in initial isotopic signatures, unlike other CAMP suites, e.g. ⁸⁷Sr/⁸⁶Sr_{200Ma} (0.7043-0.7088), $\epsilon\text{Nd}_{200\text{Ma}}$ (-6.8-+2.1) and ²⁰⁶Pb/²⁰⁸Pb_{200Ma} (17.41-18.61). Pb isotopic compositions plot above the NHRL, at positive $\Delta 7/4$ (10-17) and $\Delta 8/4$ (19-73). Low ¹⁸O/¹⁶O_{200Ma} compositions (0.127-0.144), obtained for 12 selected rocks, argue for negligible amounts of crustal contamination, and coupled with the large range of Sr-Nd-Pb isotopic compositions, they

suggest generation from a strongly heterogeneous mantle source for these magmas, probably a metasomatized lithospheric mantle. Moreover, geochemical variations are not systematically linked to dyke trends, basement composition or geographic position of these intrusives, again suggesting small scale heterogeneities in the mantle source. The alternative hypothesis of a deep enriched and heterogeneous mantle-plume source, is not supported by the crystallization temperatures calculated for high-Fo (up to Fo₉₅) olivines (ca. 1350 °C), that do not argue for a very hot (i.e. mantle-plume) origin. Geochemical correlations between ENA intrusives and CAMP flows from North America (i.e. flat REE patterns, Ti negative anomaly) suggest that these dykes and sills may have fed extrusives chemically similar to Preakness and Hook Mt. flows (i.e. the youngest flows from the Newark basin and other Triassic rift basins in North America) whereas none of the analyzed dykes yields geochemical compositions similar to the slightly older Orange Mt. basaltic flows.

THE GARROTXA VOLCANIC FIELD (NE SPAIN): NEW GEOCHEMICAL CONSTRAINTS

GISBERT Guillem¹, GASPERINI Daniela¹, BOSCH Delphine², GIMENO Domingo³, AULINAS Meritxell¹, MACERA Patrizia³, FERNANDEZ-TURIEL Jose Luis⁴

2 - Université Montpellier 2

3 - Università di Pisa

4 - Institut de Ciències de la Terra Jaume Almera, CSIC, Barcelona

Presenter e-mail: macera@dst.unipi.it

Key terms: Quaternary volcanism; Geochemistry; Isotopes; EAR; Europe

The Quaternary volcanism of the Garrotxa area (NE Spain) developed during the rift-type extensional tectonics affecting the eastern margin of Iberia since the late Oligocene and related to the opening of the Valencia trough. Location of the eruptive centres is controlled by the main NW-SE faults that limit the different elevated or depressed blocks configuring the tectonic structure of the area. The Garrotxa volcanic activity is characterised by small strombolian cones and lava flows formed by very short monogenic eruptions, occasionally preatomagmatic. As result of this activity, more than 40 volcanic cones and about 30 main lava flows can be recognised in this region.

The volcanic rocks consist of basanites, alkali basalts, and trachybasalts that are aphanitic, vesicular, hipohialine and porphyritic in texture, in which olivine and clinopyroxene (\pm plagioclase and oxides) are the main mineral phases.

They show relatively homogeneous geochemical features, with FeOT/MgO and Na₂O/K₂O weight ratios \geq 1. For most of the samples, major and trace element correlations exclude significant stagnation and magmatic evolution in crustal reservoirs. Primitive mantle-normalized multi-element diagrams are characterized by a typical bell-shaped, OIB-like trend, with progressive enrichment of the most incompatible elements, except for Th, Pb, K and Rb, and significant peaks at Ta and Nb, sharing their geochemical patterns with the whole Cenozoic anorogenic magmatism of the European-Mediterranean area.

Significant variability of ¹⁴³Nd/¹⁴⁴Nd and ²⁰⁶Pb/²⁰⁴Pb ratios in the Garrotxa volcanics testify for a common heterogeneous mantle source, and are likely related to mixing processes occurred between the local lithospheric mantle and a sublithospheric, geochemically enriched component. Sr-, Nd-, and Pb-isotope compositions of the Garrotxa magmas confirm their similarity to the EAR (Enriched Asthenospheric Reservoir)-derived basalts of the Mediterranean region, showing a HIMU

(High μ = high ²³⁸U/²⁰⁴Pb)- DMM (Depleted MORB Mantle) signature. Noticeable, the Garrotxa basalts display geochemical features that are very close to those of Cape Verde, a key "end-member" in the petrogenesis of the European magmatism since the Cretaceous (Piomallo et al., 2008). In our model, the rift-related extensional tectonics favors upwelling of sub-lithospheric, plume-like mantle into the local lithosphere, originating EAR-type basalts via adiabatic decompression melting. In conclusion, the Garrotxa volcanic activity must be included within the members of the within-plate Tertiary-Quaternary magmatism of the European-Mediterranean area.

ULTRATITANIFEROUS BASALTS AND PICRITES FROM THE OLILOCENE ETHIOPIAN PLATEAU: INSIGHTS ON THE PLUME RELATED MANTLE METASOMATISM

BECCALUVA Luigi¹, BIANCHINI Gianluca¹, NATALI Claudio¹, SAVO Andrea¹, SGUALDO Paolo¹, SIENA Franca¹

1 - Dipartimento di Scienze della Terra - Università di Ferrara

Presenter e-mail: bcc@unife.it

Key terms: MANTLE PLUMES; AFAR; PICRITE BASALT; MANTLE METASOMATISM; ULTRATITANIFEROUS MAGMAS

Geochemical and petrological data indicate that the 30 Ma Northern Ethiopian continental flood basalts and picrites were generated in connection with the "Afar plume". Previous studies [1] show that: a) Basaltic lavas appear zonally arranged with Low-Ti tholeiites (LT) in the west, High-Ti tholeiites (HT1) to the east and very High-Ti transitional basalts and picrites (HT2, TiO₂: 4-6.5 wt%) closer to the Afar triple junction; b) the P-T conditions of magma generation increased from 1,3 GPa/1200 °C to 3 GPa/1500 °C from west to east; that is, from the outer zones (LT) to the core of the plume head where HT2 ultra-titaniferous picrites were generated.

Further sampling has been carried out in the inferred plume axial zone (Lalibela area) focusing on picrite rocks, as well in the Yemeni counterpart where analogous HT2 products (including picrites) are recorded in the Manakha section.

The observed parageneses dominated by olivine and clinopyroxene phenocrysts, within a groundmass containing clinopyroxene, plagioclase, Fe-Ti oxides, alkali feldspar, phlogopite and apatite are consistent with the transitional character of these lavas and their overall enrichment in the most incompatible elements and fractionated REE patterns (La_n/Yb_n up to 26).

New isotopic data carried out at the IGG-CNR Institute of Pisa integrated with those available in the literature [2] show correlations between TiO₂ (and other incompatible elements) and Sr-Nd-Pb isotopic data, thus defining the isotopic fingerprint of the plume-related metasomatic agents. These metasomatic agents can be envisaged as alkali-silicate melts that integrate various geochemical components (e.g. Titanium and related high field strength elements, low field strength elements, light rare earth elements, H₂O) scavenged and pooled along the plume axis, and derived from heterogeneous mantle materials mixed during the plume rise. Petrological modeling indicate that the resulting metasomatized mantle sources were characterized by hydrous, iron-titanium-alkali rich exotic parageneses including amphibole, phlogopite and Ti-bearing minerals such as ilmenite.

A debate is still open on the ultimate origin of the metasomatic Fe-Ti rich fluids, in turn related to depth of the plume convective cell. A direct core contribution is not plausible, and most Authors favor long-term mechanisms of Oceanic Crust (Fe-Ti basalts/gabbros and their metamorphic equivalent, i.e. eclogites) recycling deep in the mantle via ancient subductions [3]. Accordingly, the uprising plume could have remobilized domains from the mantle Transition Zone which may include relicts of older subducted slabs. Within these remobilized domains, characterized by the coexistence of peridotite and eclogite and referred to as a "piclogite" association, the eclogites melt preferentially generating Fe-Ti rich melts that infiltrates and metasomatizes the shallower lithospheric mantle.

Alternative views, suggested by studies of high-TiO₂ basalts of lunar provenance, hypothesize primordial "magma ocean" stages in which vast mantle zones were molten and subsequently differentiated with the formation of discrete Fe-Ti-rich mantle domains [4], [5], [6].

THE AXUM BASALT-TRACHYTE COMPLEX: A PARASITIC VOLCANOTECTONIC ACTIVITY AT THE PERIPHERY OF THE AFAR PLUME

NATALI Claudio¹, BECCALUVA Luigi¹, BIANCHINI Gianluca¹, SIENA Franca¹

1 - Dipartimento di Scienze della Terra - Università di Ferrara

Presenter e-mail: ntclcd@unife.it

Key terms: NORTHERN ETHIOPIA; NEPHELINE SYENITE; FRACTIONAL CRYSTALLIZATION; TRACHYTE-BASALT; PLUME PERIPHERY

The Axum-Adwa sector (Tigray, Northern Ethiopia) is characterized by a transitional basalt-trachyte magmatic complex which took place at the northern periphery of the Oligocene Northern Ethiopian Continental Flood Basalts (CFB), which are related to the Afar plume.

This complex consists of basaltic, trachyandesitic and trachytic flows and subvolcanic dome-shaped syenitic intrusions, the latter mostly occurring around Axum.

These intrusive rocks - quarried by the Axumites as the ideal material to carve their famous obelisks - bear variable amounts of nepheline/aeirine aggregates that probably developed during late- to post-magmatic stages. Major and trace element modeling by PLE and MELTS software using bulk rocks and constituent minerals, indicates that trachyandesitic and trachytic magmas could derive by shallow fractional crystallization processes from the associated transitional basalts.

Magma vents are set along an ENE-WSW lithospheric fault system that may have favored magma generation deep in the mantle, as well as their differentiation at shallower levels in the crust.

This tectonomagmatic setting, nearly perpendicular to the Red-Sea spreading axis and parallel to that of Gulf of Aden, appears to be geodynamically related to the extensional phases which radiated from the Afar triple junction after the paroxysmal eruption of the Northern Ethiopia CFB.

SMALL SCALE CONVECTION IN THE MEDITERRANEAN MOBILE BELT.

FACCENNA Claudio¹, BECKER Thorsten W.²

1 - Univ. Roma TRE

2 - Univ. Southern California

Presenter e-mail: faccenna@uniroma3.it

Key terms: Mediterranean; Subduction; Mantle Convection

Mobile belts are long-lived deformation zones composed of an ensemble of crustal fragments, distributed over hundreds of kilometers inside continental convergent margins. The Mediterranean represents a remarkable example of this tectonic setting: the region hosts a diffuse boundary between the Nubia and Eurasia plates comprised of a mosaic of microplates that move and deform independently from the overall plate convergence. Surface expressions of Mediterranean tectonics include deep, subsiding backarc basins, intraplate plateaux and uplifting orogenic belts. Although the kinematics of the area are now fairly well defined, the dynamical origins of many of these active features are controversial and usually attributed to crustal and lithospheric interactions. However, the effects of mantle convection, well established for continental interiors, are expected to be particularly relevant in a mobile belt, and modeling may constrain important parameters such as slab coherence and lithospheric strength. Here, we compute global mantle flow based on recent, high-resolution seismic tomography, to investigate the role of buoyancy-driven and plate-motion induced mantle circulation for the Mediterranean. We show that mantle flow provides an explanation for much of the observed dynamic topography and microplate motion in the region. More generally, vigorous small-scale convection in the uppermost mantle may also hold the key for understanding other complex mobile belts such as the North American Cordillera or the Himalayan-Tibetan collision zone.

SEISMIC ATTENUATION TOMOGRAPHY AND ANISOTROPY BENEATH A RETREATING SUBDUCTION SYSTEM: THE SOUTHERN TYRRHENIAN SEA CASE STUDY

BACCHESECHI Paola¹, CHIARABBA Claudio¹, DE GORI Pasquale¹, MARGHERITI Lucia¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: paola.baccheschi@ingv.it

Key terms: subduction zone processes; mantle flow; mantle wedge; anisotropy; attenuation

The Southern Tyrrhenian subduction system shows a complex interaction among asthenospheric flow, subducting slab and overriding plate. To shed light on the deformations and mechanical properties of the slab and surrounding mantle, we investigated the attenuation and the anisotropic structure through the subduction region. The 3D attenuation results show high-attenuation shallow regions corresponding to the crustal layers, while the slab is imaged as a low-attenuation body bounded by high-attenuation regions located beneath the Aeolian magmatic arc. Between 100-200 km depth, in correspondence of high concentration of earthquakes, the slab is characterized by a spot of high attenuation. Such a feature could be related to the dehydration processes associated to the slab metamorphism. A high-attenuation anomaly is present in the mantle wedge beneath the Aeolian volcanic arc and could indicate mantle melting and slab dehydration and also to the large-scale serpentinization. We also investigated the anisotropic structure of the subduction zone by analyzing shear-wave splitting of the slab earthquakes. Seismic anisotropy reveals a complex pattern of anisotropy across the subduction zone. S-rays sample mainly the slab, showing variable fast directions and delay times. Comparison of S splitting measurements to P-wave velocity anomaly at 100-200 km depth shows that where the rays primarily sample the slab the delay times are small. In contrast, where S rays sample the mantle wedge, the delay times are quite high. This across-subduction variation of delay time depicts the slab as a weakly anisotropic region relative to the mantle above and below and suggests that the main source of anisotropy in the subduction zone is the deformation of the mantle above and below the slab induced by the retrograde motion of the slab.

UPPERMOST MANTLE VELOCITY ANOMALIES AND MAGMATISM IN THE BACK ARC OF THE ADRIA-IONIAN SUBDUCTION

CHIARABBA Claudio¹, GIACOMUZZI Genny¹, CIVALLERI Marco¹, DE GORI Pasquale¹

1 - INGV

Presenter e-mail: claudio.chiarabba@ingv.it

Key terms: slab; delamination; magmatism

Recent tomographic models of the central Mediterranean region yield the definition of the Vp and Vs structure in the uppermost mantle. Broad low velocity anomalies are identified along the Tyrrhenian margin of the Apennines at about 50-100 km depth, coherently with the intense stretching and the development of Quaternary volcanism. On the contrary, low velocity anomalies seem to be absent in the southern Tyrrhenian wedge in front of the Ionian slab and underneath the Eolian volcanoes, i.e. where the magmatic signature shows the most clear subduction-related components. These latter volcanoes have localized shallow (40-50 km depth) and small low Vp volumes indicative of isolated magma chambers located at the base of the crust.

This apparent controversy is tentatively explained by a model in which low velocity anomalies in the Tyrrhenian and peri-Tyrrhenian domains represent large asthenosphere up-welling that sustained the stretching of the European lithosphere and the opening of the back-arc basins. In the Apennines, the highly heterogeneous Quaternary magmatism testifies the more recent stage of the stretching process, triggered by the delamination of the Adria continental lithosphere. Conversely, the lack of seismic evidence of asthenospheric up-welling in the mantle wedge of the Ionian slab suggests that the Eolian volcanism is fed by small magma chambers originated before the (local) onset of the stretching induced by the Ionian slab retreat.

SEISMIC ATTENUATION AND MANTLE WEDGE TEMPERATURE IN THE NORTHERN APENNINES SUBDUCTION ZONE (ITALY) FROM TELESEISMIC BODY WAVE SPECTRA

PICCININI Davide¹, LUCENTE Francesco Pio¹, DI BONA Massimo¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: davide.piccinini@ingv.it

Key terms: Seismic Attenuation; Subduction; Mantle

We analyze P and S wave spectra from moderate- to deep-focus teleseisms recorded at the Retreating-Trench, Extension, and Accretion Tectonics (RETREAT) temporary broadband seismic network to assess the variations of the Earth mantle attenuation in the northern Apennines region (Italy). For each earthquake, we compute the ratio between the spectrum at each station and the average spectrum, in order to estimate t* residuals (Δt^*) from the spectral ratio decay. The number and distribution of the teleseisms useable for the P wave t* calculation allow for a gross azimuthal analysis; although the (Δt^*) values at single station display, in most cases, azimuthal-dependent fluctuations, their overall distribution shows a partition of the study region into two main areas, whose gross features remain almost unchanged over the whole azimuthal range. This partition is confirmed by the S wave t* mean values, computed for each station over the set of useable events. We distinguish a relatively high attenuation area on the western, Tyrrhenian side and a relatively low attenuation area on the eastern, Adriatic side. By correlating our Δt^* estimates and the velocity structure derived from the existing tomographic models, we compute the ranges of possible P and S wave Q values in the mantle wedge above the Apennines slab (on the Tyrrhenian side) and in the asthenosphere below the Adriatic region. Furthermore, the determined attenuation properties are used to draw some inferences on the thermal state of the uppermost mantle and on the physical properties of the tectonic elements, which constitute the subduction system in the region.

THERMAL STATE AND GEOCHEMICAL COMPOSITION OF THE MANTLE. WHAT CAN WE INFER FROM IGNEOUS ROCKS?

LUSTRINO Michele¹

1 - Università di Roma La Sapienza

Presenter e-mail: michele.lustrino@uniroma1.it

Key terms: Petrology; Tomography; Mantle; Geochemistry

The geochemical and mineralogical compositions of mafic igneous rocks have been classically considered powerful tools to infer the composition of their magma source(s). At the same time, geochemical models (e.g., the existence of the mantle end-members DMM, HIMU, EMI, EMII, EMIII, FOZO, C-, PHeM, LONU, LOMU, HRDM, and so on) have been commonly, and dangerously, translated to physical concepts and specific seismological subdivisions of the mantle (e.g. upper mantle, lower mantle, D'). Despite the vigorous research activity and the wealth of data and hypotheses developed during the last forty years, the thermal state and the chemical composition of the upper mantle are far from being fully understood. Concepts considered well acquired, like the significance of terms like upper mantle, lithosphere and asthenosphere, the rheological behaviour of mantle rocks, the seismic wave velocity perturbations, the presence of olivine-poor lithologies, the chemical reactions and the metasomatic effects of percolating melts in the upper mantle, the origin of non-basaltic melt compositions (e.g., carbonatitic or ultra-potassic) still need profound re-thinking. Often fundamental assumptions (e.g., upper mantle with depleted compositions, presence of active upwelling of deep-rooted mantle plumes, potential temperature, geotherm(s), the definition itself of "ambient", "normal", "anomalous" and "exotic" mantle) force the conclusions towards unrealistic results.

The following remarks should be taken in mind when performing petrological models based on geochemical and geophysical arguments: 1) there is no reason to hypothesize a homogeneously depleted upper mantle; 2) the asthenosphere is not necessarily depleted nor fully convecting; 3) tomographic images based on Vs and Vp anomalies cannot be considered as thermometers; 4) positive Vs and Vp anomalies can be related with the presence of less dense material (e.g. depleted harzburgite, seismic lid) and low-velocity anomalies can be dense eclogite; 5) the presence of thermal anomalies in the form of mantle plumes is not required by any discipline; 6) the potential temperature of the mantle is not the classical 1273 °C value; 7) the concept itself of mantle potential temperature should be considered in relation to the depth of magma formation; 8) if the composition of the upper mantle is not entirely peridotitic and if olivine-poor lithologies are not volumetrically insignificant, the concept of Mg# to determine the primitiveness of a basaltic magma needs to be rethought; 9) the geochemical similarity of two magma batches cannot be considered as the proof for the derivation from the same physical mantle; 10) a given magma with a particular geochemical signature (e.g., carbonatitic, leucitic, basaltic, alkali sodic) can be generated in different tectonic settings; 11) the geochemical composition of a magma cannot be necessarily considered as a reflection of its mantle source, being very likely the possibility of strong chromatographic exchange reactions en route to the surface; 12) high magma productivity is not necessarily related with high absolute temperatures, but rather to high homologous temperatures or even ambient mantle temperature, which can be higher than MORB temperatures; 13) the geological history of the area where given igneous districts is developed can be relevant; 14) shear heating at the base of the lithosphere can contribute to the generation of magmas in intraplate settings.

With these assumptions, the source depth of the Earth's volcanism can be mostly dominated by the asthenosphere (the upper mantle boundary layer); upper 200 km of the mantle, without a significant signature of the geochemical composition of the deeper levels of the mantle, whose composition remains mostly unsolved. Some of these remarks may seem very obvious, but the scientific literature is full of oversimplifications and of models based on unconstrained and unrealistic assumptions.

Presenter e-mail: beltrandomarco@hotmail.com

Key terms: Ocean-Continent Transition zone; subduction; Western Mediterranean magmatism

The lithological composition of subducted lithosphere is likely to exert a first-order control on the generation of the fluids/melts leading to magmatic activity along convergent plate margins. In the Western Mediterranean, the Africa-Europe convergence, which started in the Cretaceous, has been accompanied by magmatism especially active since the Eocene. Plate convergence was accommodated by deformation along plate margins and by subduction of the Western Tethys lithosphere, whose lithostratigraphy can be studied directly in Alpine tectonometamorphic units that underwent subduction to high-pressure depth and were then exhumed. This study, which focuses on the Zermatt-Saas Zone and the Internal Valaisian Domain in the Western Alps, shows that a significant part of the subducted Tethyan lithosphere consisted of variably serpentinized subcontinental mantle locally overlain by slivers of continental basement and pre-rift continental shelf sediments, prior to the deposition of post rift-deposits.

The Zermatt-Saas Zone, in the Valtournenche area, consists of abundant serpentinized mantle, intruded by Jurassic gabbros and locally overlain by slivers of continental crust and pre-rift sediments, with relatively minor amounts of syn- to post-rift sediments, which underwent Alpine metamorphism at P>2.5 GPa at ca. 48-44 Ma. The association of continental basement rocks, pre-rift sediments and ophiolites has generally been ascribed to the formation of a tectonic mélange during the Alpine orogeny. However, zircons from Permian plutonic rocks of the Etirol-Levaz continental basement slice show a distinctive phase of growth at ca. 170-160 Ma. High U/Th ratios and zoning patterns suggest that zircons grew as a result of melt infiltration related to the intrusion of mafic magmas, also dated at ca. 170-160 Ma, in the underlying serpentinites.

Therefore, the continental basement slices and the oceanic basement rocks were already juxtaposed in the Jurassic and they were probably part of an Ocean-Continent Transition Zone.

The Pointe Rousse-Breuil Unit, which is part of the Internal Valaisan Domain, is located in a more external part of the Western Alps with respect to the Zermatt-Saas Zone. This unit is composed of serpentinitized subcontinental mantle in contact with slivers of continental basement and polymictic breccias, passing upward to radiolarian schists and calc-schists (Aroley - Marmontains - St. Christophe lithostratigraphic units), which underwent Alpine metamorphism at $P > 1.5$ GPa at ca. 38-36 Ma. Cataclases and gouges, developed at the expense of granitic rocks and ultramafics, are commonly found along the interface between mantle and crustal rocks, but no evidence of brittle deformation is found in the overlying meta-sedimentary sequence. These observations are interpreted as indicating that ultramafics and continental basement were juxtaposed during Mesozoic rifting by the activity of low angle detachment faults, prior to the deposition of the overlying sedimentary cover at the bottom of the Valaisan Basin.

Therefore, our results indicate that a significant portion of the Western Tethyan slab, that was consumed during the Alpine orogeny, was markedly different from a typical Oman-type ophiolite. The lithostratigraphy of the Valaisan Domain and of the Piemonte Zone is indeed comparable to the Ocean-Continent Transition Zones that have been described in 50% of present-day rifted margins and in the less deformed/metamorphosed Eastern Alps. Such domains, which can be up to 200 km wide, are characterized by a different lithostratigraphy with respect to typical 'oceanic' and 'continental' lithosphere, with windows of exhumed serpentinitized mantle between slivers of continental crust. Pre-rift sediments (typically dolostones) are present only rarely as extensional allochthons and syn- and post-rift sediments (typically thin radiolarian cherts followed by thick marbles, marls and pelites) seal the extension-related lithostratigraphy.

MELTING OF CARBONATED PHLOGOPITE LHERZOLITE AT FLUID-SATURATED CONDITIONS: EXPERIMENTAL CONSTRAINTS

TIRABOSCHI Carla¹, TUMIATI Simone¹, POLI Stefano¹, FUMAGALLI Patrizia¹
1 - Dip. Scienze della Terra, Università di Milano

Presenter e-mail: simone.tumiati@unimi.it

Key terms: COH fluids; carbonatite; trachyandesite; high pressure; experimental petrology

Mixed H₂O-CO₂ fluids, as H₂O-only fluids do, are thought to play an important role in magma genesis, triggering melting processes by lowering solidus temperature of mantle rocks (e.g., Dasgupta et al., 2007). Compared to H₂O-only and CO₂-only fluid compositions, experiments concerning high-pressure peridotite and mixed fluids are limited. In particular, experimental data on solidus relations of complex peridotite compositions are restricted to date to the two studies of Olafsson & Eggler (1983) and Wallace & Green (1988). However, these studies show many discrepancies, likely due to the different experimental strategies used.

We carried out experiments in the system KNCFMAS+COH at $P=1.8-2.8$ GPa, $T=1050-1100^\circ\text{C}$, $f\text{O}_2=\text{NNO}$, under fluid saturated conditions. A spinel lherzolite -30% olivine + 5% phlogopite (cf. Konzett & Ulmer, 1999) has been used as starting material to model a metasomatized lithospheric mantle. Seeded gels were loaded in a piston-cylinder apparatus using conventional double capsule technique. COH fluids have been generated by addition of 10 wt.% oxalic acid dihydrate and excess graphite.

The near-solidus melt at low pressure is silicatic and potassic. At 1.8 GPa, 1075°C melt pools, coexisting with orthopyroxene + augitic clinopyroxene + olivine (Fo0.91) + garnet, are characterized on average by $\text{SiO}_2=58.1$ wt.%, $\text{K}_2\text{O}=9.2$ wt.% and $\text{Na}_2\text{O}=1.0$ wt.%, being trachyandesitic (shoshonitic) in composition. Similar melts have been produced by Conceição & Green (2004) in CO₂-free, water-saturated K-bearing peridotite at similar P-T conditions (1 GPa, 1050 °C). Mass-balance calculations suggest that the amount of partial melting in our experiments at these conditions is about 5.5 wt.%.

The near-solidus melts above 2.1 GPa is magnesiocarbonatitic and display quench-related textures, showing dendritic intergrowth of about 2/3 nearly stoichiometric dolomite and 1/3 K-silicate glass. The melt composition is comparable with published data concerning experimental carbonatites (e.g., Thibault et al., 1992). Carbonatitic melt is in equilibrium with restitic orthopyroxene + garnet + olivine/magnesite. Melting takes place at the expenses of Ca-minerals, in particular amphibole, dolomite and orthopyroxene. Mass-balance calculations suggest that the amount of partial melting is about 15.1 wt.% at 2.6 GPa and 1060°C. The residual water (2.62 wt.%) should dissolve into the melt up to water-saturated conditions, which are unknown at present in this P-T range.

In conclusion, phlogopite lherzolite saturated with H₂O and CO₂ starts melting in a T range of 1050-1100°C at P between 1.8 and 2.8 GPa, with a minimum melting temperature located at about 2.3 GPa. The shape of solidus determined in this study is similar to that proposed by Green (1973) for H₂O-saturated peridotite, with a temperature shift of about +50°C due to the lower activity of water in CO₂-bearing systems. The solidus is consistent with Olafsson & Eggler (1983), especially for $P > 2.3$, while melting temperatures found by Wallace & Green (1988) are about 100°C lower.

The geotherm of lithosphere below a continental rift will intersect the determined solidus at about 2.1 GPa and 1050°C, suggesting that lithospheric mantle could start melting at approximately 60 km depth provided that COH fluids are available.

THE OXYGEN ISOTOPIC COMPOSITION OF XENOLITHS FROM TALLANTE (SOUTHERN SPAIN): EVIDENCE FOR CRUST RECYCLING INTO THE MANTLE

DALLAI Luigi¹, BIANCHINI Gianluca²

1 - CNR - Istituto di Geoscienze e Georisorse, Pisa, Italy

Key terms: oxygen isotopic composition; mantle xenoliths; Betic Cordillera; subduction; crust recycling

Mantle xenoliths from Tallante (Betic Cordillera, Spain) include samples recording a peculiar distinct style of metasomatism that induced orthopyroxene, plagioclase, phlogopite and amphibole crystallization and generated "hydrous" opx-rich mantle domains. The latter are locally crosscut by felsic veinlets containing plagioclase and orthopyroxene \pm quartz \pm phlogopite \pm amphibole. The observed parageneses and available Sr-Nd-Hf isotopic data suggest that metasomatic agents were related to recycling of crust components within the mantle, plausibly in connection with subduction processes occurred during the Cenozoic Betic orogenic cycle.

In this study we investigated representative samples of composite xenoliths consisting of peridotite crosscut by felsic veins (varying in size from centimetric to millimetric) and unveined peridotites, measuring the ¹⁸O/¹⁶O ratios of the constituent minerals by laser fluorination. Results show that the narrow O-isotope compositional "typical" of mantle rocks, and the limited oxygen isotope fractionation at mantle temperatures, make oxygen isotopes a powerful tool for identifying recycled crustal material in the

mantle. Orthopyroxene and plagioclase of the centimetric vein show $\delta^{18}\text{O}$ values of +9.8 and +10.6‰, respectively, whereas clinopyroxene of the surrounding peridotite country rock has $\delta^{18}\text{O} = +6.2$ ‰. Plagioclase of two

distinct millimetric felsic veins show $\delta^{18}\text{O}$ of 7.6 and 7.3‰. The $\delta^{18}\text{O}$ values significantly higher than typical mantle ones provide insights to the genesis of the Cenozoic subduction-related magmas of the Betic region that include silica-oversaturated calcalkaline (s.l.) and lamproite products, possibly resolving source vs. shallow level crustal contamination of the magmatic rocks. Moreover, the different O-isotope composition recorded in veinlets characterized by different thickness could provide insights into diffusion-assisted O-isotope equilibration of mantle rocks, thus constraining the time for "crust digestion" into the mantle.

Key terms: Eastern Mediterranean; Volcanism; Petrology; Isotope Geochemistry; Geodynamics

In Central Anatolia, between Konya and Kayseri, and Eastern Anatolia, in the region enclosed among Adana, Sivas and Diyarbakir, Neogene volcanic rocks largely outcrop: large ignimbrite sheets and continental sedimentary rocks are found along with lava flows, strato-volcanoes, volcanic domes and plateau lavas.

Some of these products have calc-alkaline affinity and the typical geochemical characters of subduction-related rocks; they have a compositional range from basalts to rhyolites, without any compositional gap. Some others are alkaline, mostly sodic, are strongly SiO₂-undersaturated and reveal an intraplate-type mantle source: they are basanites, tephrites, alkali basalts and trachy-basalts.

The occurrence of subduction-related and intraplate-type volcanic products in the same region is a common feature with surrounding areas in Aegean-Anatolian region. However, Central Anatolian lavas and pyroclastics have some peculiarities. Indeed, these two kind of lavas may be found in the same area, but have usually different time distribution: for instance in Western Anatolia, Central Aegean and Thrace calc-alkaline products are remarkably older than alkali basalts. In addition, mantle sources of subduction-related and intraplate-type lavas are easily distinguished by their Sr and Nd isotope ratios in Central-Eastern Mediterranean region: alkali basalts usually have ⁸⁷Sr/⁸⁶Sr around 0.7030-0.7035 and calc-alkaline and shoshonitic rocks show distinctly higher values (0.7050-0.7080).

Interestingly, in the studied rocks, there is no any clear time and/or space separation between calc-alkaline and alkaline rocks, and no sharp chemical and/or isotopic boundary may be traced. Rather there is a gentle transition, with many samples characterized by intermediate features. As an example, alkaline rocks have ⁸⁷Sr/⁸⁶Sr varying from 0.7034 to 0.7055 and Ba/Nb from 5.0 to 11, whereas the same parameters span in the ranges of 0.7039-0.7056 and 11-163, respectively, in the calc-alkaline basaltic samples. Thus, all the observed data point out for the involvement of two different mantle sources in the genesis of this magmatism, and most samples seem to be derived from interactions of these different sources. Furthermore, the distribution of calc-alkaline rocks is not strictly linked with respect to subduction dynamics. Large volumes of very young (<2 Ma) calc-alkaline rocks are found in Kapadokyan region, in Central Anatolia, even if current subduction is very slow, or stopped at all. More to the east, some calc-alkaline rocks, are found both predating and postdating the 15 Ma Arabia-Eurasia collision, either in the upper Turkish plate or the Arabian foreland. Alkali basaltic plateau lavas are sometimes remarkably older than calc-alkaline lavas and ignimbrites, as those around Sarkisla, dated at 15.7-14.0 Ma ago, and south of Sivas, which gave K-Ar ages of 5.1-4.8 Ma ago.

The Neogene Central-Eastern Anatolia calc-alkaline rocks are sourced in a subduction-modified mantle wedge. Anyway, the lacking of strict connections with the subduction dynamics and geometry indicate that the metasomatizing event of the mantle wedge may be decoupled from the event responsible for the partial melting. Intraplate-type magmas are sourced in the underlying asthenosphere, not affected by any subduction imprint. The occurrence of calc-alkaline magmas intimately connected with intraplate-type magmas and the presence of transitional samples point out for a contemporaneous involvement of two different mantle sources, located at different depths. This magmatism may be explained by the peculiar tectonic setting of the region, linked to the North Anatolian Fault and to the East Anatolian Fault. The occurrence of vertical strike-slip faults, as well as pull-apart basins, may explain contemporaneous melt extractions at different mantle depths.

Key terms: calc-alkaline; volcanoclastic succession; Early Oligocene; Apennines; subduction

During the Early Oligocene, the ~800 m thick Aveto-Petrignacola volcanoclastic Formation (APF) was deposited in a relatively short time (~32-29 Ma) in the Northern Apennines. The APF volcanic rocks are mostly basaltic andesites, andesites and dacites, with minor rhyolites and gabbroic compositions found as pebbles ~0.001-0.5 m³ in size (with average diameter ranging from ~5 to 30 cm). This volcanoclastic succession is interpreted as the product of subaerial effusive to explosive arc magmatism and is associated to turbidite sedimentation. Petrographic, mineral chemical, major and trace element content, as well as Sr-Nd-Pb isotopic ratios are all compatible with a calc-alkaline magmatism generated as consequence of the metasomatic modifications of mantle sources related to the subduction of oceanic lithosphere.

The APF volcanic rocks are a puzzle in the geodynamic evolution of the Italian area. This Formation is now part of the Apennine thrust system, developed as consequence of the West-directed subduction system that involved recycling of the oceanic lithosphere of the Mesogeane/Liguride ocean(s) beneath the southern paleo-continental margin of Europe. Such a subduction system was associated with production of abundant calc-alkaline/arc tholeiitic magmatism starting from Late Eocene/Early Oligocene in SE Spain (Malaga arc tholeiitic dykes), Sardinia (e.g., Calabona microdiorite) and SE France (Esterel microdiorite). During the Middle-Late Eocene, the Alpine Tethys subduction system had already ceased, followed by Adria-Europe continental collision. In other words, during the emplacement of the APF subduction-related volcanic rocks, the Alpine subduction system was already shut down, whereas the Apennines subduction system was fully developing. Notwithstanding this, we propose that the APF volcanic rocks are genetically connected to the Alpine subduction system rather than the Apennines.

We propose that the APF volcanic rocks are generated by a mantle source modified by components of the Alpine slab detached during Middle-Late Eocene, and still wandering beneath the Adriatic lithosphere after the closure of the Piedmontese (Liguride) Ocean. The effects of the "zombie" slab would be a metasomatic modification of the original peridotitic matrix, allowing hydration with the consequent formation of amphibole. Local effects of stress release in the Apennines foreland and in the Alps hinterland would have played an important role to trigger magmatism. Paradoxically, the subduction-related igneous activity in the APF area developed several Ma after the cessation of oceanic lithosphere subduction in an area that, few Ma later, would have been involved in a completely different orogenesis (Apennines tectonics).

In summary, the APF volcano (now completely eroded) would have been generated as consequence of Alpine tectonics, but would have been involved in the Apennines thrusts soon after its formation. According to this view, the APF and the Mortara volcanoes, the latter now buried beneath the Po Plain, would have the same origin. The formation of the Po Plain (representing the foreland of the Apennines and the retro-foreland of the Alps back-thrusts) would have prevented the Mortara volcano from being eroded, leaving it in its original position on the north-western margin of Adria.

Key terms: Southern Ethiopia; East African Rift; mantle xenoliths; Nd-Hf isotopes

New Hf and Pb isotopic data from clinopyroxenes from East African Rift (EAR) mantle xenoliths (Mega, Sidamo region, southern Ethiopia), coupled with recently published Nd isotope and trace element compositions, provide compelling evidence for multiple episodes of mantle depletion and metasomatic enrichment. Radiogenic values (ϵ_{Nd} up to +22.5 and ϵ_{Hf} up to +1076) suggest that mantle domains currently located beneath the Main Ethiopian Rift suffered extreme melting regimes, possibly in the presence of residual (majorite?) garnet, effectively fractionating Sm/Nd, Lu/Hf and Nd-Hf systematics. Positively correlated Lu/Hf and $^{177}\text{Hf}/^{177}\text{Hf}$ provide an apparent ingrowth of 1.96 Ga, close to the CHUR model age of the most radiogenic sample (1.95 Ga) and is consistent with other local records of Proterozoic melting events. Pb isotopes are clearly decoupled from the Nd-Hf systematics, displaying $^{208}\text{Pb}/^{206}\text{Pb}$ up to 20.1, $^{207}\text{Pb}/^{206}\text{Pb}$ up to 15.70, and $^{208}\text{Pb}/^{232}\text{Th}$ up to 39.8. These data suggest vigorous convection cells, possibly triggered as a far field dynamic consequence of the Afar plume impingement, preferentially occurred beneath this site, where important lithospheric discontinuities exist between the Archean/Early Proterozoic Tanzanian craton and the Late Proterozoic Pan-African mobile belt. Such deep mantle dynamics may contribute to stabilizing distinct EM1 and HIMU metasomatic components in the EAR lithospheric mantle.

Key terms: Pontine Archipelago; submarine volcanics; calc-alkaline rocks; alkaline (potassic) rocks; subduction

The spatial-temporal distribution and compositional variability of Plio-Quaternary magmatic products emplaced in the Tyrrhenian and surrounding regions is related to subduction processes and extensional phases, which acted in different ways in the northern and the southern part of the basin. In this framework, the magmatism of the Pontine Islands is very interesting as 1) emplaced at the boundary between the Tuscan and the Roman Magmatic Provinces; 2) strictly related to geodynamic processes involved in the opening of the Tyrrhenian oceanic domain.

Previous studies defined that: 1) Pleistocene volcanic episodes were represented by potassic products, with basic to intermediate rocks in the islands of Ventotene and Santo Stefano and with intermediate to highly evolved rocks (trachytes up to peralkaline rhyolites) in the south-eastern part of Ponza and Palmarola island; 2) Pliocene volcanic episodes are represented by calcalkaline products, with silica-rich volcanic units constituting the dominant products in Ponza and Zannone islands; the latter were characterized by lack of primitive rocks raising questions on the petrological processes as well as on the tectonic mechanisms that triggered magma genesis.

In this contribution we present new data including the investigation of the Pontine submarine portions carried out in four oceanographic cruises (aboard RV Urania), during which seafloor samples were dredged. An important result is that off-shore sampling also recovered less-evolved terms, i.e. basalts and andesites, of the calcalkaline series.

The new sample collection has been characterized through major/trace element data and Sr-Nd isotopic analyses, implementing the data-set already available in the literature to provide better constraints on the genesis of both calcalkaline and potassic series.

Previous studies (Conte and Dolfi; 2002; Cadoux et al., 2005) interpreted the Pontine magmatism in the framework of a transition from subduction-related to intraplate geodynamic settings. The new data suggest that such transition has not been fully accomplished, pointing to ubiquitous and persisting subduction-related signatures in the Pliocene-Pleistocene mantle sources. In particular, geochemical and isotopic characters of the mafic products indicate highly heterogeneous mantle sources, in turn related to crustal components recycled in the mantle via subduction. Further assimilation of crustal materials possibly occurred as result of shallow level processes in the plumbing system, contributing to define the observed isotopic fingerprint.

HIGH TiO: PICRITE BASALT/RHYOLITE BIMODAL ASSOCIATION AS INDICATOR OF INITIAL RIFTING AT A "PLUME AXIS": THE CASE OF NORTHERN ETHIOPIAN PLATEAU

NATALI Claudio¹, BECCALUVA Luigi¹, BIANCHINI Gianluca¹, SAVO Andrea¹, SGUALDO Paolo¹, SIENA Franca¹

1 - Dipartimento di Scienze della Terra - Università di Ferrara

Presenter e-mail: ntlcld@unife.it

Key terms: RHYOLITE; CONTINENTAL FLOOD BASALT; CONTINENTAL RIFTING; AFAR PLUME; TECTONOMAGMATIC SETTING

Voluminous felsic volcanism has been recently associated to 1) mafic Large Igneous Provinces (LIP) where rhyolites are comparable to A-type granites or 2) continental convergent margins Silicic LIP (SLIP) where rhyolites share similarities with S- and I-types granites [1]. An intriguing petrological debate has concerned the genesis of bimodal silicic-mafic volcanism in continental LIP [2]. In several Continental Flood Basalt (CFB) provinces of the Gondwana realm - such as Paraná-Etendeka, Karoo, Ferrar, Deccan, Madagascar, Seychelles and Afro-Arabian region - extensive (104-105 Km²) rhyolitic volcanics occur, generally late in the sequence and sometimes interbedded with basalts [3].

In this contribution we present petrological and field data on the high-TiO: picrite basalt/rhyolite bimodal association in the north-eastern Ethiopian plateau (Lalibela area) which is considered the axial zone of the 30 Ma CFB activity related to the Afar plume [4].

In this area the volcanic sequence consists of ca. 1700 m of mostly very high TiO₂ (4-6.5%) picrite basalts, covering an area of ca. 15000 km², topped by an average thickness of ca. 300 m thick rhyolitic ignimbrites and lavas which discontinuously extend over an area of ca. 10000 km².

Petrogenetic modelling, using rock and mineral chemical data and phase equilibria calculations (by PELE and MELTS), indicates that: 1) very high TiO₂ picrite basalts could generate rhyolitic, sometimes peralkaline, residual melts (liquid fraction 9-16%) with persistently high TiO₂ content (0.4 - 1.0%); 2) by closed system fractional crystallization processes developed at 0.1-0.3 GPa pressure range, 1400-750 C° temperature, at QFM fO₂ conditions; 3) the highest crystallization rate - involving 10-13% of Fe-Ti oxide removal - in the temperature range between 1070 and 950 C°, represents an "ephemeral" fractionation stage, resulting in the absence of erupted silica intermediate products (Daly gap). The eruption of highly differentiated products capping the basic volcanics implies a rapid change from "open" to "closed" tectono-magmatic system, which favoured trapping of parental picrite basalts and their fractionation in upward zoned magma chambers, ultimately leading to low aspect ratio fluorine-rich rhyolitic ignimbrites and lavas. This tectono-magmatic evolution resulted from the onset of continental rifting at the plume axis, with faulting and block tilting, allowed magma differentiation in shallow - N-S elongated - fissural chambers parallel to the developing Afar Escarpment. In this scenario, rhyolitic eruptions represent the transition between the plateau basalt stage to the incipient rifting progressively evolving to continental break-up and formation of the Red Sea basin.

Key terms: Triassic basalts; Sicily; tholeiitic; alkaline; continental rift

During Early Mesozoic, a diffuse magmatic activity developed in western-central Sicily in relation to the extensional tectonics associated with the opening of the Neotethys Ocean. In this work, we report and discuss geochemical and Sr-Nd isotopic data for Sicilian Triassic tholeiitic and alkaline volcanic rocks. Tholeiitic basalts from western Sicily are characterized by relative HFSE enrichment, high HFSE/LILE ratios, flat REE patterns (La/Nb = 2.27-2.48), Ti, Sr and K negative anomalies and Pb peaks in primitive mantle-normalized diagrams. The Sr ($87\text{Sr}/86\text{Sr} = 0.707\text{-}0.708$) and Nd isotopic compositions ($\epsilon\text{Nd} = \text{from } -1.7 \text{ to } -2.2$) are compatible with an origin from enriched mantle sources. Additionally, the relatively high Sr isotopic ratios and diagnostic trace elements ratios, such as La/Nb (~ 1.7), La/Nb (~ 1.20), Nb/U (~ 20) and Pb/Nd (~ 0.3), could reflect involvement of the lower crust in the magmatic evolution of the tholeiitic rocks.

Alkali basalts from central Sicily preserve a clear geochemical signature despite the intense alteration. The behaviour of immobile elements such as the low Y/Nb and Zr/Nb and high Th/Yb and Ta/Yb ratios, positive

Nb-Ta-Ti anomalies, and the radiogenic Nd isotope ratio ($\epsilon\text{Nd} = +3.4 \text{ to } +3.7$) suggests an OIB-like source. The LREE/HREE ratio (La/Nb = 7.43-8.76) is higher than in the tholeiitic samples, suggesting a possible role of residual garnet in the magma source, or a lower degree of partial melting, or both. The behaviour of mobile elements, such as the Sr isotopic composition ($87\text{Sr}/86\text{Sr} = 0.706\text{-}0.707$) and the K depletion, does not contradict this.

On the basis of trace elements and Sr-Nd isotopic composition, the Sicilian Triassic dykes could reflect the early stages of rifting in a continental setting, including initial lithospheric thinning, passive upwelling of hot asthenosphere, and related processes of partial melting involving differently enriched mantle reservoirs.

Presenter e-mail: a.paonita@pa.ingv.it

Key terms: noble gas; trace elements; radiogenic isotopes; mantle geochemistry

We carried out a geochemical investigation of the mantle beneath Hyblean area through ultramafic enclaves (peridotites and pyroxenites) found in Miocene age Hyblean volcanics. Major and trace elements, in the whole rock and in the single mineralogical phases and Sr-Nd isotopes in clinopyroxenes were analysed together with noble gases entrapped in CO₂-rich fluid inclusions hosted in olivines and pyroxenes.

The pattern of REE, the Zr/Nb and $143\text{Nd}/144\text{Nd}$ ratios highlighted clear compositional differences between the peridotite group ($\text{Zr}/\text{Nb} = 14$; $143\text{Nd}/144\text{Nd} = 0.5129$) and the pyroxenites ($\text{Zr}/\text{Nb} = 20$; $143\text{Nd}/144\text{Nd} = 0.5130$). Also, the REE analyses suggested the presence of cryptic metasomatic events which would have re-fertilized the peridotitic layer previously depleted by extraction of melts. In this context, the metasomatizing agent, namely a deep-seated magmatic liquid intruding the peridotites at different levels, would be represented by the pyroxenites, as suggested also by their finding as veins in peridotitic nodules.

The noble gas analyses confirmed the above compositional difference between the peridotites and the pyroxenites. In particular, we focused our attention on the $3\text{He}/4\text{He}$ and $4\text{He}/40\text{Ar}$ ratios because they represent important tracers of mantle processes. The $3\text{He}/4\text{He}$ and $4\text{He}/40\text{Ar}$ ranges measured in the fluid inclusions of peridotites (7.0-7.4 Ra and 0.4-8.0, respectively) were in average lower than that shown by the pyroxenites (respectively 7.2-7.6 Ra and 0.6-15). In order to explain the observed mantle heterogeneity in noble gas systematics, we hypothesized a mixing between two end-members:

- 1) a shallow peridotitic layer having R/Ra of ≈ 7 and $4\text{He}/40\text{Ar}$ ratio lower than that the typical production range ($4\text{He}/40\text{Ar} \approx 2\text{-}5$), due to melt extraction events;
- 2) a deep pyroxenitic metasomatizing melt characterized by a R/Ra of ≈ 7.6 and with a variable $4\text{He}/40\text{Ar}$ ratio due to degassing processes connected with the ascent of magma at different levels of the hosted peridotite.

The whole geochemical dataset therefore suggests the presence of two different mantle sources for the above highlighted peridotitic and pyroxenitic groups, respectively a shallower HIMU-type source for the former and a deeper DM-type source for the latter.

PETROPHYSICAL AND PETROLOGICAL FEATURES OF DEEP- SEATED

XENOLITHS FROM MIOCENE TUFF-BRECCIAS OF THE HYBLEAN PLATEAU: SUGGESTIONS FOR A LITHOSPHERIC MODEL BENEATH SOUTH-EASTERN SICILY

PUNTIURO Rosalda¹

1 - Department of Geological Sciences, University of Catania

Presenter e-mail: punturo@unicit.it

Key terms: Hyblean xenoliths; Petrophysics; Lithospheric column

As it is known, deep-seated xenoliths act like an "open window" to the inaccessible portions of lithosphere, and permit lithological models to be set out with a great detail.

In this work, attention focused on xenoliths collected within Miocene tuff-breccias from the Hyblean Plateau (south-eastern Sicily, Italy). According to main petrographic features, the studied xenoliths may be grouped into: a) ultramafic, which consist of spinel facies peridotite and pyroxenite (some garnet bearing); and b) feldspar-bearing suite, represented by mafic granulite and minor metagabbro and anorthosite. Spinel facies peridotite rocks (harzburgite and harzburgitic lherzolite) exhibit protogranular to (rare) porphyroclastic texture; they are constituted by olivine (Fo₈₉₋₉₁), orthopyroxene (En₈₈₋₉₁; mg# 90-92), clinopyroxene (Cr-diopside: En₅₁₋₅₄Fs₂₋₄Wo₄₄₋₄₈), Cr-rich spinel (Cr#23-35). Very rare phlogopite occurrence testifies that the Hyblean mantle underwent metasomatic event.

Pyroxenite specimens classify into: Cr-diopside websterite (Cr-diopside, Ca-poor pyroxene, Cr-Al spinel +/- olivine and amphibole); Al-diopside websterite (Al-diopside, Ca-poor pyroxene, Al-spinel, garnet (Py₅₄5Alm₃₂Gr₁₃5). Al-augite pyroxenite (interpreted as igneous adcumulitic products) are composed of Al-clinopyroxene, Al-spinel, garnet (Py₆₄Alm₂₅5Gr₉6). Finally, feldspar-bearing xenoliths are mostly represented by mafic granulite (plagioclase, Ca-pyroxene, Ca-poor pyroxene and Al-spinel +/- amphibole). Metagabbro and metadorite (plagioclase, Ca-pyroxene, Fe-Ti oxides, apatite) and anorthosite (plagioclase +/- Al-spinel and pyroxene) occur at a lesser extent. Pressure-temperature estimates, based on two pyroxene and garnet mineralogical assemblage within pyroxenite provided equilibration values of 0.98GPa at 740°C for spinel pyroxenite and 1.32GPa at 1040°C for garnet pyroxenite.

In addition, petrophysical investigation was carried out on three selected lithotypes (peridotite, pyroxenite and mafic granulite), whose large size of collected xenoliths allowed laboratory seismic measurements (Vp, Vs, Poisson's ratio, seismic anisotropy) at various P-T conditions (up to 600MPa at 600°C).

Since investigated xenoliths are considered to be representative of large scale lithological units, petrophysical results combined with petrological information permit available geophysical data to be constrained and interpreted at a better extent and may provide useful suggestions for a lithospheric model underneath the Hyblean Plateau.

Key terms: Finero; Chromitite; Geochronology; Zircons

The mafic-ultramafic Finero complex represents the northernmost sector of the Ivrea-Verbano Zone (IVZ), Southern Alps. It consists of a mantle body, surrounded by a mafic-ultramafic intrusive sequence [1], documenting an association of mantle and crustal rocks inferred to be placed at the bottom of the continental crust of the Adria plate before the opening of Ligurian-Piedmontese branch of the Jurassic neo-Tethys.

Nevertheless, the Finero complex shows several tectonic and petrochemical differences with respect to those of the central IVZ. For instance, published geochronological U-Pb zircon data constrain the emplacement of the Mafic Complex in the central sector of the IVZ at 280-to-295 Ma ([2] and references therein). Conversely, the intrusion age of almost part of the Mafic Complex in the Finero area (SHRIMP U-Pb zircon dating) indicate that the External Gabbro, the largest unit forming the Finero Mafic Complex, intruded the bottom of the Kinzigite Formation during Ladinian [3]. A Triassic ages have been also determined for the multiple metasomatic and intrusive events affecting the associated mantle body ([4] and references therein). This is mainly formed by harzburgite modally enriched in phlogopite and amphibole and with large LILE contents. Based on the geochemical and isotopic composition, several authors proposed that the growth of phlogopite-bearing assemblages was related to the migration of melts containing significant crust-derived components. With the aim to place constraints on the timing of melt migration through the Finero mantle body, zircons were separated from three, dm-thick chromitite bands enclosed in huge dunite bodies outcropping along the Cannobino River and on the Mt. Sasso Rosso. U-Pb ELA-ICP-MS data result in concordant ages comprised in the range of 188-186 Ma, which is believed to date the segregation of the chromitite bands during channelled porous-flow melt migration. These ages are significantly younger than that determined through conventional multigrain dating by [4], whose data define an intercept Triassic age of 208±2 Ma. Although the studied chromitite bands do not show primary phlogopite, the major and trace element mineral chemistry point to a cognate origin with the migrating melts forming the phlogopite harzburgite. The finding that the porous-flow ascent of LILE-enriched melts through the Finero mantle unit postdates the emplacement of the Finero Mafic Complex, and the absence in the latter of the record of this magmatic stage, suggest that the Finero mantle unit might have been emplaced tectonically in contact with the lower crust at some time after lower Jurassic. This hypothesis is supported by the observation that the contact between mantle unit and Mafic Complex is always tectonic. As a whole these data confirm that the northernmost part of the IVZ, represented by the Finero complex, cannot be longer considered as a part of the central IVZ, thus suggesting that the entire geological setting of the area should be revised.

Key terms: Tuffites; Zircon; Geochronology; Triassic; Magmatism

In the western sector of the Southern Alps, tuffaceous levels are occasionally found in the Triassic sedimentary sequences. The direct age characterisation of these layers is very limited: in fact, a U-Pb zircon age of 245±1 Ma is available only for the tuffites from Mt. San Giorgio area (Lugano, CH: [1]), which results slightly older than that expected according to the stratigraphic position. Besides, no geochemical information is presently available for these layers and the geodynamic setting of the related volcanism is still matter of debate. Thus, with the aim to place further constraints of the geodynamic evolution of the Southern Alps in Mesozoic times and increase the accuracy of the age record of the sedimentary sequence, we have performed a mineralogical, geochemical and geochronological study on tuffaceous deposits outcropping within the Anisian-Ladinian succession of the sedimentary cover of the Strona-Ceneri Zone in the Borgosesia area [2,3] and recovered at the same stratigraphic position in wells of the Villafortuna-Treccate oil field (western Po Plain, Piedmont region, NW Italy: [4]). CO₂ concentration was determined by Dietrich-Frühling calcimeter. XRD data indicate that such tuffaceous deposits are constituted by a variable mixture of magmatic and sedimentary components. Major and trace element compositions, assessed by means of XRF analysis, suggest a calc-alkaline affinity for the magmatic component. To provide accurate geochronological constraints, zircons have been separated with conventional methods from four tuffaceous outcrops, namely "Lembo di Sostegno", "Lembo di Crevacuore" and "Lembo di Monte Fenera" outcrops, as well as from a buried tuffaceous sample of the Villafortuna-Treccate oil field. Zircons were mounted in epoxy resin and characterised under cathodoluminescence (CL). Based on colour, morphology and internal structure, they have been divided in two populations. One group is constituted by light-pink coloured zircons with prismatic habits and tight oscillatory zoning suggesting growth under magmatic conditions. The zircons from the second group are colourless, rounded in shape and with only relics of magmatic zoning, consistent with metamorphic recrystallization. U-Pb ELA-ICP-MS data point to ages of 237±8 Ma and 229±9 Ma for the magmatic growth of the zircons from the tuffites of "Lembo di Crevacuore" and "Lembo di Sostegno", respectively, which are in agreement with their stratigraphic position. The volcanic activity producing these layers might be linked to the intrusive Triassic magmatism documented in the Finero Complex (NE Ivrea-Verbanio Zone [5,6]). Conversely, the zircons from the "Lembo di Monte Fenera" and Villafortuna-Treccate oil field produce a very large range of crystallisation-recrystallisation ages, which span from Proterozoic to Paleozoic to the Permian-Triassic boundary, thus indicating a dominant contribution of the crystalline basement to the zircon population. LATE NEOPROTEROZOIC DYKES SWARMS AND EARLY PALEOZOIC BASIC INTRUSIONS IN BOHEMIAN MASSIF (CZECH REPUBLIC): PETROLOGY AND GEODYNAMIC IMPLICATIONS IN ARMORICAN MICROPLATES.

D'ADAMO Francesco¹, NARDUZZI Francesco¹, DE MIN Angelo¹

- 1 - Dipartimento di Geoscienze, Università degli Studi di Trieste

Presenter e-mail: francefranceschin@gmail.com

Key terms: Armorica; Bohemian Massif; Dykes Swarms; Late Neoproterozoic; Geodynamic Implications

In the Bohemian Massif (Czech Republic), the Moldanubian (M) and the Tepla-Barrandian (TB) terrains were assembled during Variscan orogenesis. In ancient times, both regions were the site of quite coeval basic intrusions which identified extensional geodynamic contexts. In M such "igneous" rocks are mainly represented by amphibolites and by quite rare transitional slightly metamorphosed dykes with a supposed age of 600-550 Ma (Janoušek et al., 2008). These cut the paleoproterozoic granitoids of the Svetlik formation and suggest an original continental-cratonic setting. While amphibolites appear to be chemically spread, the dykes show a strong elemental OTB (Sun & McDonough, 1989) affinity (Dy/YbCN = 1.3 vs 1.68; La/SmCN = 2.07 vs 2.33; La/NdCN = 1.48 vs 1.86). In TB, scarcely metamorphosed basic bodies have been intruded by rare dykes swarms (524 Ma; Dörr et al., 2002) showing a fairly cumultic

texture, a quite high silica content coupled with a high mg#, a N-MORB (Sun & McDonough, 1989) like REE pattern (La/SmCN = 0.54 vs 0.55; Dy/YbCN = 1.15 vs 0.97; La/NdCN = 0.61 vs 0.66) and an evident negative Nb anomaly followed by a positive Ti one. Differences in the mantle sources involved in the TB and M dyke genesis could be also explained by the La/Ce (0.3 vs 0.4) and La/Yb (1.0 vs 1.4), the first being a direct feature of the source and the second a possible consequence of variable amount of garnet in the residual source mantle. Notably, such behavior cannot be easily modified by sub-solidus processes.

To explain the genesis of the TB dykes, an extensional event which immediately followed the evolution of an Island Arc system has been suggested by several authors (Dörr et al., 2002; Zulauf et al., 2004). Indeed, for the M Late Proterozoic magmatism, which outcrops in a region strongly tectonized where the amphibolites were mainly investigated, a clear geodynamic context is also undefined.

Notwithstanding, the supposed ages of the magmatic event and the chemical behaviors of the slightly metamorphosed dykes, could be inserted within the recent 600-500 Ma plate reconstructions proposed by Pisarevsky et al. (2008). So, such magmatic event could be interpreted as a minor occurrence of the plume related continental extension responsible of the Baltica-Amazonia-Laurentia-Avalonia break-up, which should represent the last great extensive-transpressive moment between the Rodinia Break-up and the Great-Gondwana assemblage.

Key terms: Southern Apennine chain; Frido Unit; Rodingites; Metasomatism; Garnet

The Southern Apennines chain is a fold-and-thrust belt derived from the collision between the African and European plates starting in Upper Oligocene. The ophiolitic sequences occur in the Southern Apennine Chain as remnants of the Liguride accretionary wedge. The Liguride tectonic units derived from the western Tethys ocean which separated the European plate from the African one. The studied ophiolitic rocks emplaced in the Ligurian domain of the Alpine Tethys Ocean during the middle Jurassic. These units outcrop extensively in the southern Apennines in the northeastern slope of the Pollino Ridge. Liguride Units of the Southern Apennine include sequences characterized by HP/LT metamorphic overprint in the Frido Unit. They consist of sedimentary sequences ranging from the Upper Jurassic to the upper Oligocene ages and several bodies of oceanic and continental crust. The ophiolitic rocks occurring in the Frido Unit consist of serpentinites derived from mantle lherzolite and subordinately harzburgites. Rodingites outcrop as dikes cutting through serpentinites and are a few centimeters thick, grayish-white and show a ductile deformation. Petrography and mineral chemistry of rodingites facilitated the finding of the igneous and metamorphic mineral assemblages related both to the primary magmatic protolith and to the subsequent metamorphic evolution. Rodingites show granuloblastic texture. The primary igneous assemblage consists of plagioclase and clinopyroxene; these minerals cannot be preserved in rodingites due to a more accentuated rodingitic alteration. The metamorphic mineral assemblage consists of garnet, prehnite, chlorite, pumpellyite and quartz. Accessory minerals are titanite, epidote, opaque minerals, zircon and apatite. In order to obtain mineral chemistry electron microprobe analyses were performed on the garnet. Brown-yellow garnet crystals show a sub-idiomorphic and xenomorphic habit and/or replace plagioclase. Garnet crystals have coronas and rims of titanite and epidote crystals. Garnet overgrowing on plagioclase is mostly hydrogrossularite-grossularite rich and range between 79.107 and 95.071 Mol%, in the structural formula recalculated on the basis 22 oxygens; end member are Prp, Alm, Grs and Sps (pyrope, almandine, grossularite, and spessartine). Ocean-floor metamorphism occurs with the metasomatic processes of rodingitization typical of dike-cut serpentinite. Rodingitization produces Ca-rich basic rocks during serpentinization. Rodingitization metasomatic reactions in rodingitic dikes are demonstrated by the replacement of plagioclase by hydrogrossularite.

Key terms: Variscan crust; External Crystalline Massifs; HP granulite; migmatite; geochronology

The "External Crystalline Massifs" of the Western Alps (Aiguilles Rouges, Mont Blanc, Grandes Rousses, Belledonne, Pelvoux, and Argentera) consist of a polymetamorphic Variscan basement, which was only marginally reworked during the Alpine tectonometamorphic cycle. This contribution focuses on the magmatic and Variscan metamorphic history of the Argentera Massif, the southernmost and largest of the External Crystalline Massifs exposed in Italy. Its evolution is compared to that recorded in the Mont Blanc-Aiguilles Rouges Massif, the other External Crystalline Massif extensively exposed in the Italian Alps, and to that recorded in the Maures-Tanneron Massif of Provence, France, the area of Variscan Europe nearest to Argentera. Some speculations on tectonic models for this evolution are also proposed. The main geological events recorded by these Massifs are similar. They experienced: a) pre-Carboniferous intrusions of both acid and basic magmas; b) a Carboniferous Variscan history consisting of subduction with metamorphic peak at ca. 700°C and 1.5 GPa, continental collision developing amphibolite-facies metamorphism, anatexis, and emplacement of granitoids; c) Carboniferous exhumation to shallow crustal levels. A few of the events well documented in the Mont Blanc-Aiguilles Rouges and Maures-Tanneron have not yet been characterized in the Argentera Massif. In particular, the Late Proterozoic emplacement of granitoids in a (meta-)sedimentary sequence documented in the Maures and the Late Ordovician granite plutonism documented in the Mont Blanc Massif, still await to be confirmed in the Argentera by geochronological data, though field observations generally support the occurrence of these magmatic events. On the other hand, the age of the high pressure (HP) metamorphic event documented by eclogites and HP granulites found in all the massifs is well constrained so far only in the Gesso-Stura-Vésubie (GSV) Terrane of the Argentera Massif, where Carboniferous ages at ca. 340 Ma were obtained for zircons in the Frisson HP granulites. The LP metamorphism and partial melting in the GSV Terrane are not directly dated, but a Late- to Mid-Carboniferous age for migmatization has been proposed on the basis of a zircon lower intercept age obtained from the Meris eclogite. These geochronological data link together in a single orogenic cycle the HP and the amphibolite-facies metamorphisms, and suggest that the evolution of the Variscan belt of the Western Alps and Provence may resemble that of present-day collisional settings, such as the Himalayan belt. Similarities between the Variscan and the Himalayan orogenies include the conditions of HP granulite-facies metamorphism, and the rapid (within 20 Ma) succession of HP peak metamorphism, fast exhumation and widespread late anatexis.

Presenter e-mail: ferretti@unimore.it

Key terms: Carnic Alps (Austria); Lower Paleozoic; paleobiogeography; sedimentology; chronostratigraphy

Significant advances in reconstruction of the geodynamic processes that controlled the dispersal of the North Gondwana margin between Early Ordovician and Carboniferous times are now emerging. Diverse lines of investigation within this regional and temporal context are being applied to the Paleozoic sequences of the Carnic Alps (Austria), in particular to the critical Late Ordovician-early Silurian interval.

Acquisition of paleontological and paleoenvironmental data by study of pelagic faunal exchange, microfacies and climate sensitive sediments of this pivotal middle paleolatitudinal temperate sector of the Southern Variscan Realm has highlighted critical new evidence based on this non-geochemical method of dating paleocontinent position and opening/closure of seaways. Faunas suggest plate movement from a moderately cold environment of c. 50°S latitude (Late Ordovician) to a reef belt of c. 30°S (Devonian). Eustatic changes are correlated across four paleocontinents (1).

Sedimentological evidence records the Hirnantian glaciation cold water influx as diamictites within the successions at the Nöblinggraben and Raichkofel South sections, now precisely constrained biostratigraphically, thus adding further data for timing this event along the North Gondwana Margin. This level is characterized by pyrite and phyllosilicate, (mainly chlorite) -rich arenites and rudites. The coarser detrital fraction includes subrounded mm to cm sized crystalline clasts, interpreted as dropstones. Their composition of finely banded gneisses characterized by ribbon quartz layers and quartzites, suggests erosion and reworking from a polymetamorphic area. The sulfide rich matrix suggests a cold reducing environment. Mineralogical and petrologic analyses are ongoing. Further evidence for the Hirnantian Stage is based on the recent

identification of the $\delta^{13}C$ Excursion (HICE) in the Cellon Section (2). Documentation of igneous activity within this sector of the Southern Alps provides a valuable database for unravelling the related geodynamic history, in particular for the Late Ordovician-early Silurian interval. 97 K-bentonites have been recorded from the Upper Ordovician (Hirnantian) to Lower Devonian (Lochkov) sequences, constrained biostratigraphically within the international standard biozones (3). Volcanism belongs to a tectonically active terrane dominated by calc-alkaline mafic lavas of clear volcanic arc affinities, most samples fall within the andesite and rhyodacite/dacite fields. Upper Ordovician K-bentonites are rare and have few European equivalents. Abundant Llandovery - middle Ludlow levels similar to those in the British Isles, Sweden, Canada and North America may document widespread volcanism related to the closing of the Iapetus Ocean, however, a local origin within northward drifting microplates derived from the Northern margin of Gondwana is considered more likely. Pridolian K-bentonites compare with those from Podolia with a source area in the Rheic Ocean. Characterization by petrography, isotope geochemistry and U/Pb radiometric dating on zircon of these ash levels will yield reliable geotectonic and paleogeographic inferences and

internationally important time-lines for chronostratigraphy within both a regional and global context.

THE VARISCAN SEGMENT OF SARDINIA (ITALY) AND ITS RELATIONSHIPS WITH THE EAST VARISCAN SHEAR ZONE (EVSZ) IN RELATION TO THE LATE PALEOZOIC CONSOLIDATION OF PANGAEA

ELTER Franco Marco¹, PADOVANO Matteo¹

1 - Dip.Te.Ris. - Università di Genova

Presenter e-mail: elter@dipters.unige.it

Key terms: NE Sardinia; EVSZ; Variscan belt; Pangaea

Recent studies define that the Variscan orogeny should be considered as the result of accretion of peri-Gondwanian terranes rather than a continent-continent collisional belt. The origin of the peri-Gondwanian terranes is linked to a continue evolution and fragmentation of the northern Gondwana margin which started, at least, since the Cambrian with the opening of the Rheic Ocean and the separation of Avalonia. From Devonian times, the northern Gondwana margin has been further affected by separation of continental masses, due to the opening of the Paleotethys, with the formation of a narrow terrane known as Hun superterrane or Galatian ribbon continent. The closure of the Paleotethys, due to the northward motion of Gondwana, started at ~ 330 Ma and led to the final collision and continental amalgamation between Gondwana, Gondwana derived continents (e.g., Avalonia and Armorica) and Laurussia, with the formation of Pangaea, at ~ 300 Ma. In this geodynamic context, the high-grade metamorphic rocks outcropping in the Variscan segment of NE Sardinia experienced an oblique collision under a transpressive tectonic regime during the Early Visean (c. 340 Ma)-Bashkirian (c. 320 Ma). Field evidences and finite strain analyses carried out on the HT rocks of NE Sardinia, define that the exhumation of these rocks could have been driven by telescoping processes along a regional "snake" strike-slip shear zone. Such a shear zone could have induced shear heating processes which led to crustal melting in the order of 3-5%.

The restored direction of this shear zone allow us to identify it with the East Variscan Shear Zone (EVSZ). The EVSZ is a NNW-SSE dextral transpressive regional shear zone running from Brunia to the Calabria-Peloritani arc affecting the scattered Variscan Massifs of the Alps as well as the Maures-Tanneron massif, the Corsica-Sardinia massifs and the basement of Northern Apennines.

In more recent times, the EVSZ could have represented a pre-existing intra-continental band of weakness on which the following tectonic processes will develop: the Permian-Triassic rifting, the Alpine cycle, the Apenninic cycle and the Miocene-Pliocene opening of the Tyrrhenian Sea.

Key terms: Amphibolite Complex; U-Pb LAM ICP MS; Neoproterozoic; Cambrian; Ordovician

In northern Sardinia, the inner zone of the Southern Variscan belt includes a Medium Grade Metamorphic and a High Grade Metamorphic, mainly migmatitic, Complex, originated in igneous and sedimentary protoliths. The igneous ones were recently recognized of Ordovician ages (Cortesogno et al. 2004; Palmeri et al. 2004; Giacomini et al., 2006; Oggiano et al., 2010). A kilometre-thick mylonitic mélange zone (Posada Asinara line) exhibits ductile deformation and occurs between the HGMC and the other medium to low grade Variscan Nappes (Casini et al. 2010). Also in the Asinara Island (Oggiano and Di Pisa, 1992), juxtaposed tectono-metamorphic units exhibit an intermediate to high grade granulitic crustal section. In particular, at Punta Scorno, a millimetre to decimetre layered leptino-amphibolite complex (Ca-amphibole+plagioclase+garnet) occurs characterized by cm to meters thick leucocratic (quartz+plagioclase+garnet) layers including sparse amphibole-dominated ultrabasic and metagabbroic boudins with relic coarse-grained hypidiomorphic textures. The peak metamorphic conditions for this association were estimated under granulite (740°C and P > 0.8 GPa) followed by amphibolite facies (500-600°C and P 0.3-0.4 GPa; Di Pisa et al., 1993). The metagneiss bimodal complex is associated with a K-feldspar-phyrlic orthogneiss presently re-equilibrated under HT/LP high grade metamorphic conditions evidenced by staurolite surrounded by biotite + andalusite coronitic intergrowths and sillimanite + cordierite ± K-feldspar; the tectonic contact between the two lithologies is parallel to their main schistosity.

The leucocratic layers of the basic complex and the associated orthogneiss were selected for U-Pb radiometric dating on zircons separates by ELA ICP MS at CNR - IGG Pavia.

The preliminary elaboration highlights several populations of U-Pb Concordia ages: in the orthogneiss, an early Paleoproterozoic event at 2006 ± 25 Ma and a second Neoproterozoic between 623 ± 13 and 579 ± 12 Ma. A subsequent Cambro-Ordovician age interval is recorded between 478 ± 11 and 437 ± 11 Ma, followed by a Devonian event 413 ± 11 and 403 ± 7.4 Ma.

In the "leptino-amphibolite" complex with granulite relics, each leucocratic layers yielded different ranges of Concordia ages, starting from a

Neoproterozoic time interval (stepped between 672 ± 12 and 588 ± 16 Ma) until a Cambrian system closure (514 ± 22 to 506 ± 15 Ma). An Early Ordovician group of Concordia ages spans between 491 ± 13 and 474 ± 12 Ma. Late Ordovician - Early Silurian ages fall in the 461 ± 10 to 435 ± 12 Ma time interval. Some Devonian and Carboniferous age values are also recorded mainly from homogeneous metamorphic cores. Some considerations thus derive: i) the orthogneiss contains evidence of an ancient basement, older than Neoproterozoic which was previously excluded in the north Gonwana margin (von Raumer et al. 2002), in fact the presence of ca. 2 Ga old inherited Pb component in zircon suggests this crustal residence age of the inferred metasedimentary protolith i) the U-Pb system of the orthogneiss opened diachronous with respect to the basic complex iii) within the leptino-amphibolic complex, different age population arise from different felsic layers, likely pointing out that each of them recorded a different timing of events or that they have different protolith ages. This could occur for instance by several steps of partial melting that caused multiple injections of felsic magmas within a deep crust; iv) the orthogneiss and the amphibolite shared a common evolution since the Devonian.

Key terms: Permian volcanic; Southern Alps; paleoenvironments

In the Southern Alps, at Permian times, post-Variscan extension is commonly associated with widespread plutonic and volcanic activities [1, 2]. We addressed a poorly investigated succession outcropping in the western Southern Alps between Lugano and Maggiore lakes (Valganna area). The Permian volcanic to subvolcanic (Valganna granophyre) sequence is almost tectonically undisturbed. In the area 3 volcanic series [1, 3, 7] were investigated and our field and petrographic observations suggested different environments of subaqueous lacustrine and subaerial emplacement.

Series I (basal series): this extrusive series, directly deposited upon a non-conformity surface over the Scisti dei Laghi basement [4], consists of a few metres-thick volcanoclastic mass-flow followed by lithic-crystal and crystal tuffs interbedded with thin cinerite levels. The M. Piambello rhyolite lava flow ends this series.

Series II: it starts with andesite to dacites agglomerates in turn covered by tuff and cinerite levels, the Alpe Tedesco rhyolite flow and a final ignimbrite (P. Ganna ignimbrite), whose geometrical relationships with the youngest Valganna granophyre are unclear.

Series III: it starts with the M. Piambello dacite lava flow followed by lithic-crystal and crystal tuffs and a rhyolitic ignimbrite.

The whole of volcanic products from the three series show high-K calc-alkaline affinity with similar PM- and REE-normalized patterns, which are characterized by LILE and LREE enrichment relative to HFSE and HREE, respectively. Whereas the andesite to dacite extrusive products show very similar geochemical behaviour, the most outstanding differences are among the acidic volcanic products. The rhyolite tuffs and ignimbrites, as well as the very homogeneous rhyolite lava flow of the Series II, mainly differ from those of the Series I and III in: 1) higher K₂O, Rb, Nb and Y and lower Na₂O, MgO, CaO, TiO₂, Sr and Zr contents; 2) more pronounced negative Ba, Nb, Sr, P, Zr and Ti and positive Th, K, Pb spikes in PM- normalized multielement diagram; 3) higher HREE, but similar LREE, contents that lead to a flatter REE pattern with a more pronounced Eu anomaly.

In Valganna, the petrography of the volcanic complex reflects different environments of emplacement. The basal extrusive series (1800-2000 m-thick) was probably emplaced in a shallow lacustrine environment, whereas the Series II could reflect a subaerial apron. The Series III suggest a syntectonic emplacement along an active lineament at the boundary of the paleo-lake (Series I) and its shoulders (Series II). Petrographic and geochemical data reveal an igneous evolution by fractional crystallization within each series together with density selection during the emplacement. The enrichment in LILE and LREE observed from Series I to III could originate in the different abundance of the crustal component or in different source levels in magma genesis. Moreover, the association of high-K-calc-alkaline (Series I and III) with K-rich transitional Series II is consistent with a transtensional setting, probably driven by Permian strike-slip faults at regional scale, as already reported for the Collio and Orobian basins [2, 5].

In progress SHRIMP U-Pb geochronological dating of the key-units will allow to make regional scale correlations with volcanic rocks of similar age and evolution [1, 2, 6].

THE TRANSITION FROM LOW-P TO CONTACT METAMORPHISM IN CALABRIA RELATED TO PLUTON GROWTH IN THE INTERMEDIATE CRUST

CAGGIANELLI Alfredo¹, FESTA Vincenzo¹, LANGONE Antonio², PROSSER

Giacomo³

1 - Università di Bari

2 - IGG - CNR, Pisa

Key terms: Hercynian granitoids; low-P metamorphism; numerical modelling

Granitoids represent a large proportion of the Hercynian crustal sections exposed in Calabria. In the Sila and Serre massifs the granitoid stack has a cumulative thickness of 9 to 13 km and includes tabular intrusions of tonalitic to granitic composition with minor dioritic and gabbroic bodies. Emplacement of the granitoids occurred sometime between 300 and 290 ± 10 Ma during the extensional tectonic stage, following collapse of the Hercynian chain. The heat advected by granitoids was considered responsible both for contact metamorphism in the upper crust and regional low-P metamorphism in the lower to intermediate crust. This was shown by static and dynamical numerical models. A main limitation of the models was the instantaneous emplacement assumed for the magmas. In the light of the general consensus existing on the idea that large magma chambers can be filled through dykes in a short time (< 100 kyr in Petford, et al., 2000), the instantaneous emplacement was considered a permissible simplification.

In recent years, the rapid growth of plutons has been questioned, on the basis of radiometric dating at different levels of the magmatic body (e.g., Glazner et al., 2004). Even though the melt flow entering in the magma chamber can be high, feeding may be discontinuous. Consequently, pluton accretion by repeated melt injections can be completed in some million years (Matzel et al., 2006). Another interesting point raised is the way the pluton grows (downward or upward) because this affects the intensity of thermal perturbation above and below the magmatic body (Annen, 2011). On the basis of these arguments we have formulated a new 2D thermal model, to be applied on the Calabria crustal sections, that takes into account the incremental growth of the pluton. We examined the consequences of the end-member processes of pluton accretion and of different growth rates.

In case of under-accretion, contact metamorphism in the upper crust occurs before regional low-P metamorphism in the intermediate to lower crust. Model indicates that pluton growth must be completed in a short time (< 200 kyr) to reproduce observed peak temperatures (540-590 °C) in the contact aureole. Deformation structures related to pluton growth, overprinted by peak T minerals, must be formed in an even shorter time interval. In case of over-accretion, an opposite sequence of low-P and contact metamorphism is produced and peak temperatures can be generated even when pluton construction lasts for 5 Myr.

In comparing data of the Calabria crustal sections with results of under- and over-accretion models, the second option is preferred. Model results suggest also that the smooth transition from regional low-P to contact metamorphism may reflect upward pluton growth and concurrent exhumation by extensional tectonics.

Key terms: lower crust; granulite facies; partial melting; melt segregation; shear zones

Introduction

In the Serre Massif of Calabria an about 8 km thick sequence of granulite facies rocks constitutes the lower crust of the former Variscan orogen. The base of this lower crustal section is made up of layered garnet-bearing meta-gabbros which are interspersed with lenses of metapelite and layers of metapyroxenites and meta-hornblendites (Moreti et al., 1978; Schenk, 1984). Single zircon conventional and spot U-Pb isotopic analyses place the age of the gabbroic protoliths into the Precambrian (Schenk, 1984, 1990; Micheletti et al. 2008).

The main metamorphic overprint under granulite facies conditions of the gabbros has occurred during the Variscan orogeny. Zircon dating constrained the metamorphic peak close to 300 Ma in coincidence with the emplacement of huge masses of granitoid magmas in the middle crust (Schenk, 1984; Caggianelli et al., 2000; Micheletti et al., 2008). Reaction microstructures have induced Schenk (1984) to infer that the lower crust of the Variscan orogen in Calabria was subjected to isothermal decompression immediately after the thermal maximum. He has deduced that the lower crust became decompressed from about 750 to 550 MPa at 800° C and then affected by slow isobaric cooling down to 200° C over the next 250 million years.

Acquafredda et al. (2008) have shown that decompression occurred during two different stages and involved a much thicker continental crust than previously assumed. Internally consistent thermodynamic modelling of the pre-decompression mineral assemblage results in 900° C and 1.1 GPa for the metamorphic peak conditions.

New data

We can now show that metagabbros became deformed under melt present conditions. This is evidenced by the occurrence of cm-thin shear zones wherein the partial melt was drained. Shear-zone development occurred in a general deformation regime, with shortening partitioned next to the shear zone resulting in an intense crenulation of the earlier Variscan foliation. Ti-rich pargasitic amphibole layers were involved in this crenulation deformation and recrystallized. Recrystallized amphiboles have the same chemical composition as those tracing the older layering. Application of the semi-quantitative "Ti-in-amphibole" geothermometer of Ernst and Liu (1998) to the recrystallized pargasites results in a deformation temperature of 870° C, whereas application of the amphibole-plagioclase thermometer (Holland & Blundy, 1994) results in temperatures of 818 to 857° C (in the pressure range 0.5 to 1 GPa). Minimum pressure conditions of 500 MPa can be assessed using the semi-quantitative Al-in-amphibole geobarometer of Ernst and Liu (1998). However, application of the crystal structure modelling geobarometer of Nimis & Ulmer (1998) to clinopyroxene in equilibrium with the plagioclase-rich melt of the shear zones shows that pressures during deformation have been rather close to 1 GPa. Melt present deformation of the mafic complex was followed by cooling starting from temperature conditions closely identical to that registered by the recrystallized amphiboles. Reaction seams of quartz+phlogopite around Opx suggest that a dehydration reaction of the type phlogopite (Phl) + quartz (Qtz) = orthopyroxene (Opx) + melt has been crossed backwards during cooling. Peterson & Newton (1989) place this reaction above 800° C.

Conclusion

The recognition that plagioclase/Cpx melt-bearing shear zones developed at about 1GPa pressure and 870°C temperature suggests that incipient melting of the mafic complex of the lower crust may have triggered the extensional tectonics in Calabria.

TIMING OF HIGH-GRADE SOUTH EUROPEAN VARISCAN EVOLUTION: CONSTRAINTS FROM TRACE ELEMENT PARTITIONING IN GARNET, ZIRCON AND ORTHOPYROXENE ON U-PB ZIRCON AGES.

FORNELLI Annamaria¹; LANGONE Antonio²; MICHELETTI Francesca¹; PASCAZIO Annarita¹; PICCARRETTA Giuseppe¹

2 - IGG-CNR, PISA

Presenter e-mail: f.micheletti@geomin.uniba.it

Key terms: south European Variscan evolution; trace element partitioning; in situ U-Pb zircon ages

U-Pb zircon ages and chemistries of zircon, garnet and orthopyroxene from different structural sites of a thin section of a granulitic rock from the Serre (Calabria, southern Italy) have been considered in order to reconstruct the evolution of a fragment of south European Variscides. The rock consists of Pl+Grt+Bt+Opx+Qtz+K-feld and accessories as zircon, apatite and opaques. The matrix shows layers containing different abundances of biotite and orthopyroxene. One porphyroblastic garnet (~3 cm in diameter) rimmed by a Opx+Pl+Bt+opaques+Zrn+Ap symplectitic corona occurs.

Ten zircon grains are exposed in the thin section: eight in the Bt-rich matrix, one within the corona and one in the rim of the garnet. Zircon shows generally core-rim structures. Frequently, zircon cores appear chaotic, consistently with modification induced by high-grade metamorphism and some are rimmed by unstructurless lobate rims, invading cores, commonly related to interaction with fluids and/or melts. U-Pb analyses have been performed in situ by LA-ICP-MS (IGG-CNR, Pavia). Two core domains of zircons from the matrix give the oldest concordant ages: 357±11 and 334±12Ma; five concordant data ranging from 324±12 to 320±11Ma give a mean concordia age of 323±2Ma. Two younger concordant ages (305±9 and 300±9Ma) are relative to low luminescent inner rims and similar apparent ages have been determined on luminescent zircon rims from matrix, symplectitic corona and garnet rim.

Trace element compositions were collected on specific domains of zircon, garnet and orthopyroxene in different textural sites by LA-ICP-MS. Two trace element profiles relative to porphyroblastic garnet were performed. Garnet is very rich in middle-REE and shows nearly flat profile in the core and fractionated pattern in the rim. The transition zone from core to rim (outer core) is poorer in HREE. Zircon is characterized by a steep pattern with low LREE and high HREE contents both in cores and rims in which, however, the MREE and HREE are lower than in garnet, apart from its outer core region. The orthopyroxenes show fractionated patterns of MREE and HREE.

The apparent DHREE between zircon-garnet and orthopyroxene-garnet pairs have been calculated and compared with literature data considered as suggestive of equilibrium relatively to natural samples and experimental results.

The calculated DREE_{Zrn/grt} and DREE_{Opx/grt} define linear and positive trends for zrn or opx/core and outer core combinations of grt evidencing regular, but variable partitioning and reaching even values higher than unity. So the calculated DREE values seem to be indicative of steps of approaching equilibrium.

The combination zrn rim/grt rim, instead, indicates disequilibrium suggesting that the zircon rim formed earlier than garnet rim, which subsequently broke down producing corona. The combination with the outer core of garnet gives higher D than the combination with the inner core suggesting, according to experimental results, lower temperature for the former; this is in agreement with the petrology.

The calculated DREE_{Opx/grt} approach those suggestive of equilibrium from Er to Lu in the combination opx matrix-grt core. The combination opx corona-grt rim is far from the equilibrium. Probably, orthopyroxene from corona is a residue of the matrix.

Accordingly, a well constrained contribution to PTt path relatively to fragments of south European Variscides emerges: the Variscan metamorphism of the lower part of the Serre crust section peaked much earlier than previously assumed (at least ~340Ma ago against 300Ma) and the multistage Variscan decompression after the metamorphic peak lasted tens millions of years, at least locally. The decompression probably protracted after 300Ma.

U-TH-PB DATINGS OF VARISCAN SHEAR ZONES IN SARDINIACAROSI Rodolfo¹; MONTOMOLI Chiara¹; TIEPOLO Massimo²; FRASSI Chiara

1 - University of Pisa

2 - IGG Pavia

Presenter e-mail: carosi@dst.unipi.it

Key terms: Variscan belt; shear zone; geochronology; transpression

A transpressive geodynamic setting has been recognized since a long time in the Variscan belt of Sardinia (CAROSI & OGGIANO, 2002; CAROSI & PALMERI, 2002). Crustal scale shear zones and folds, with diffuse strain partitioning, have been well documented in the inner zone of the belt (CAROSI ET AL., 2004; IACOPINI ET AL., 2008; CAROSI ET AL., 2009). Only recently a similar geodynamic setting has been proposed for some other branches of the European Variscan belt (GIACOMINI ET AL., 2008; CORSINI & ROLLAND, 2009; GUILLLOT & MENOT, 2009). The overall change of the shortening direction in a large sector of the orogenic belt with the occurrence of increasing orogen-parallel displacement, may be regarded as a general mechanism affecting the exhumation of rocks and preventing the overthickened and thermally softened collisional crust from undergoing a diffused gravitational collapse. Shear zones represent efficient ways to exhume deep-seated rocks in collisional orogens (PASSCHIER & COELHO, 2006), transpressional belts (GOSCOMBE & GRAY, 2009; FRASSI ET AL., 2009) and extensional settings.

As consequences, assessing the geometry and kinematics of mylonitic belts provide important informations to individuate the mechanisms of exhumation (XYPOLIAS & KOUKOUVELA, 2001; LAW ET AL., 2004; CAROSI ET AL., 2006, 2010; LARSON ET AL., 2009) whereas the timing of shear activity is fundamental to constraint the tectono-metamorphic evolution of the exhumed rocks.

Several systems of shear zones have been distinguished in the inner zones of the Variscan chain in Sardinia pointing out opposite sense of shear (FRASSI ET AL., 2009). Structural relations point out that dextral shear zones deform sinistral ones.

U-Th-Pb geochronology has been applied on zircons and monazites sampled from both systems of shear zones.

The new isotopic data led to constrain at ~320 Ma the activity of both systems so that a switch from the sinistral simple-shear- to the dextral pure-shear-dominated regime has to be invoked. The dextral shear belt remained active at upper structural levels before the emplacement of the larger part of the late Variscan batholith.

PETROPHYSICAL PROPERTIES OF VARISCAN MYLONITIC LEUCOGRANITE OF MONTE GRIGHINE, WEST-CENTRAL SARDINIACOLUMBU Stefano¹; CRUCIANI Gabriele¹; FANCELLO Dario¹;FRANCESCHELLI Marcello¹; SPANO Maria Elena¹

1 - Dipartimento Scienze della Terra - Università di Cagliari

Presenter e-mail: gcrucian@unica.it

Key terms: Petrophysical properties; Protomylonite; Ultramylonite; Monte Grighini; Real density, Porosity

Monte Grighini Complex consist of a pile of variscan Nappes and of a suite of granitoid rocks, mostly tonzogranite and leucogranite (Musumeci, 1992), that intrudes the tectonic unit of Monte Grighini. Rb/Sr and Ar/Ar radiometric data give, for granitoid rocks, an age of about 305-300 Ma (Carmignani et al., 1987; Laurenzi et al., 1991). A late variscan shear zone affects the SW side of the complex and produces a wide cataclastic and mylonitic zone, along which leucogranite can be mostly found. In this zone an outcrop, that shows a rapid change in the intensity of mylonitic deformation, has been investigated in detail. The outcrop is affected by a pervasive N162-170° foliation dipping 60-65° W.

Petrographic and XRD analysis show the following mineralogical assemblage: quartz, k-feldspar, plagioclase (albite), muscovite, biotite, iron oxides and ± tourmaline ± apatite ± zircon ± epidote. Almost all samples are characterized by k-feldspar porphyroclasts in a quartz-phyllonitic matrix.

On the basis of porphyroclast/matrix ratio protomylonite, mylonite and ultramylonite layers have been identified. In protomylonitic layers k-feldspar phenocrysts are fractured and sometimes perthitic. Quartz occurs in microcrystalline lens and bands following the foliation. Phyllonitic matrix consists of biotite, subordinate muscovite and chlorite. Mylonitic layers are similar to the previous ones but show a decrease in grain-size. Ultramylonitic layer consists of rare k-feldspar relics in a very fine-grained phyllonitic matrix.

The following physical properties have been determined in 12 series of samples with varying degree of deformation: the open porosity, the total porosity, the real and apparent density, the water imbibition coefficient, and the water saturation index. To calculate the closed and total porosity

the real density of ground samples were determined. The ultrasonic velocity of the studied samples has been determined in three directions: 1) perpendicular to the foliation, 2) parallel to the foliation and to the direction of mineral stretching lineation, 3) parallel to the foliation and perpendicular to the direction of mineral stretching lineation. The overall results indicate that the samples of protomylonite, mylonite and ultramylonite have different physical properties values. The average values of the real density of samples vary from a minimum of 2.66 ± 0.02 g/cm³ in the protomylonitic samples, to a maximum of 2.72 ± 0.01 g/cm³ in the ultramylonitic samples. The mylonitic samples show intermediate values with an average of 2.68 ± 0.01 g/cm³. The open porosity shows a similar trend; it ranges from $4.1 \pm 0.2\%$ in the protomylonitic samples, to $6.3 \pm 0.9\%$ in the mylonitic samples, to $9.2 \pm 0.5\%$ in the ultramylonitic samples. Therefore, there is a positive correlation between the degree of mylonitization and these physical parameters.

The ultrasonic velocity values show on one side of the greater porosity of ultramylonites than proto-mylonites and mylonites, on the other side confirm a higher anisotropy degree in the ultramylonitic samples revealed perpendicular to the foliation. Preliminary results seem to suggest a relationship between the petrographic and petrophysical characteristics of the layers.

Key terms: Metabasite; Eclogite facies; P-T pseudosection; Variscan orogeny; Sardinia

The Punta de li Tulchi metabasite crops out as a N80/60-oriented decametric lens, hosted in the migmatites of the High Grade Metamorphic Complex in NE Sardinia. The metabasite consists of brownish clinopyroxene + garnet (Cpx+Grt) layers alternated to greenish amphibole + plagioclase (Amp+Pl) layers from a few centimeters up to 50 cm in thickness (Franceschelli et al. 1998, Min. Petrol., 62, 167-193). The Cpx+Grt layers mainly consist of millimetric garnet (with inclusions of omphacite) embedded within a fine-grained clinopyroxene + plagioclase symplectite matrix. Orthopyroxene also occurs in these layers, as well as minor amphibole and quartz. Garnet in contact with symplectite is rimmed by amphibole + plagioclase coronas.

The Amp+Pl layers consist of millimetric to submillimetric-sized white pods of plagioclase + amphibole + garnet relics set in a amphibole-rich matrix. Less abundant minerals in these layers are quartz, titanite, ilmenite, rare biotite, and chlorite.

Four main metamorphic stages have been recognized basing on microstructural features: (i) a M1 pre-symplectite stage, (ii) a M2 symplectite stage, (iii) a M3 coronitic stage, and (iv) a M4 late retrograde stage.

The pre-symplectite (M1) and symplectite (M2) stages have been modeled using the P-T pseudosection approach in the NCKFMASH model system (calculated in the range 550-950°C and 1-25 kbar, at aH₂O=0.5), and using the bulk rock composition of a representative Cpx+Grt layer. Garnet core composition and Na content in omphacite allow to define a M1c stage at T=610-640°C and P up to 17 kbar corresponding to the field Cpx+Amp+Grt+Bt+Qtz+Rt. Garnet compositional zoning indicates a progressive increase in both temperature and pressure during garnet growth from the M1c stage up to a M1r stage (T=620-660°C; P=19-22kbar), allowing to reconstruct a prograde segment of the P-T path. The peak pressure was reached in the M1r stage under amphibole-eclogite-facies P-T conditions. As revealed by the composition of the symplectitic minerals, the M1r stage was followed by heating and decompression, resulting in the formation of clinopyroxene + plagioclase symplectite (M2 stage) at T=750-800°C and P=9-12 kbar (granulite-facies conditions).

The coronitic stage (M3) has been modelled in the NCFMASH model system at aH₂O=1.0 by using the bulk composition of the effectively reacting microdomain, calculated from mineral compositions and stoichiometric coefficients of the corona-forming reaction. By comparing the measured composition of coronitic minerals with the modeled compositional isopleths, amphibolite-facies P-T conditions (T = 580-640°C, P = 5-7 kbar) have been obtained for this stage.

The P-T conditions of the M4 stage can be estimated at about 300-400°C and <2-3kbar.

The P-T path reconstructed for the Punta de li Tulchi metabasite has significant analogies with that described by Giacomini et al. (2005, Lithos, 82, 221-248) for the retrogressed eclogite of Golfo Aranci, NE Sardinia, and with that of the Punta Orvili metabasite from the Metamorphic Complex with Mainly Amphibolite Facies Assemblages described by Cruciani et al. (2011, Lithos 121, 135-150).

Key terms: HT-metamorphism; Corsica-Sardinia Batholith; Thermal modeling; Matlab

This note focuses on the thermal evolution of the Sardinian Variscan crust

during the post-collisional stage. One-dimensional thermal modeling has been performed by a Matlab-derived code (geothermMOD1.2), which allows us to simulate the past crustal geotherms for a given model crust with variable distribution of heat-producing elements such as ²³⁸U, ²³⁵U and ⁴⁰K. Heat flow is assumed to be controlled only by conduction, hence geotherms have been calculated by solving the second-order partial differential equation $d^2T/dz^2 = -A/z$ (1), where the term A represents the heat-production rate [W/m³], z is depth [m] and T is temperature. The term A is calculated from the content, within each layer, of ²³⁸U, ²³⁵U and ⁴⁰K at the relevant model times. The past vertical distribution of these elements is inferred from a data sets including about 400 samples acquired directly in the field with a portable NaI(Tl) gamma-ray spectrometer, and about 100 samples measured in laboratory with a HPGe spectrometer. In a first step, the heat-production rate of each layer is calculated at the model age by back-correcting for the radioactive decay. The corrected A values and two boundary conditions T₀ = surface temperature [°C], and Q_b = basal heat flow [W/m²], were finally used to solve numerically the eq. (1).

The evolution of the Variscan crust of north Sardinia has been modeled by two sets of numerical experiments covering the time span 350-280 Ma. In the first group of experiments, which address a fully crustal evolution, Q_b is assumed to be constant throughout time within each experiment. The value of Q_b increases linearly with time in the second set of experiments, to simulate an increasing heat flow contribution from the mantle. In all experiments, crustal sections are designed at 320, 310, 300 and 285 Ma with specified thickness, whereas the geometry is based on present-day seismic profile, and Al-in hornblende barometry of dated granitic plutons. The validity of the two models, i.e. the 'fully crustal' and the 'mantle contribution' ones, is checked out by comparing the experimental geotherms with the available petrological data sets.

ANALOGUE MODELS VS GEOLOGICAL STRUCTURES: THE STUDY CASE OF NE SARDINIA (ITALY)

PADOVANO Matteo¹

1 - Dip.Te.Ris., Università di Genova

Presenter e-mail: matteo.padovano@unige.it

Key terms: Analogue models; NE Sardinia; Variscan

Recent studies defined that the emplacement of the Variscan HT metamorphic rocks outcropping in NE Sardinia occurred in a transpressional tectonic regime, induced by the oblique collision of Gondwana derived terranes with Laurussia during the Middle-Upper Carboniferous. The possibility to exhumate deep crustal rocks by compressional/transpressional kinematics has been tested through an experimental approach based on the production of several analogue models. They consist of three layers, put one on the top of each other: the bottom and the middle layers are made of plasticines with a power-law rheology simulating the behaviour of lower and middle crust; the uppermost layer consists of sand, in order to simulate the brittle behaviour typical of the upper crust. The models have been thus deformed by a thermomechanical apparatus, located at the "Institut für Geowissenschaften Johann Wolfgang Goethe-Universität, Frankfurt am Main", that induced compression coeval to orthogonal extension, following different finite strain percentages. The temperature and the strain rate conditions have been set in order to generate a viscosity contrast between bottom and middle layers of 2/3 orders of magnitude, reproducing thus the real viscosity contrast deduced for the lower and middle continental crust.

The experiments performed at 20% and 30% of finite strain show processes of cylindrical folding, while at higher finite strain conditions (40% and 50%) the processes of uplift of the lower crust become dominant. In fact, from the observation of cross sections perpendicular to the direction of extension, it is possible to notice that the uplift of the lower crust starts at 40% of finite strain and becomes even more evident at higher strain conditions (50%). The uplift is facilitated by the development of brittle/ductile shear zones which attract the deepest material to shallower levels, (i.e. processes of telescoping), leading in some cases to the formation of laccolith-like structures. The observation of sections parallel to the direction of extension, at the same finite strain conditions, highlights a dome-type geometry, where the long axis of the dome is parallel to the main direction of extension of the system. The top view of the models shows that the fractures responsible for the telescoping processes described above, are characterized by lateral displacements and reproduce en-echelon structures.

Being aware that the analogue models represent an oversimplified representation of natural cases, it is nevertheless possible to outline some correlations between experimental structures and geological observations:

- 1) The dome-type geometry obtained with the experimental approach has been already proposed in literature, on the basis of geological-structural data, for the High Grade Metamorphic Complex (HGMC) of Sardinia; 2) The Variscan granitic bodies of southern Corsica and NE Sardinia are bounded by sets of shear zones which often show lateral displacements and resemble en-echelon structures; 3) Several geological cross sections of the HGMC show that the contacts between high-grade and middle/low-grade Variscan units are often overturned. The same geometries are observable in numerous cross sections of the analogue models, where the lower crust overrides the middle one during its uplift driven by the development of shear zones; 4) The laccolithic bodies observed in the models are directly observable in the HGMC of Sardinia (i.e. Capo Ferro area), where Variscan syn-tectonic granitoids are emplaced within regional shear zones.

The results obtained by the analogue models, compared with the natural geological structures, confirm and strengthen the hypothesis that the HT Variscan rocks of NE Sardinia could have been exhumed by the action of regional shear zones, which developed under a main transpressional tectonic regime.

Key terms: Metavolcano-sedimentary; Paleozoic; Geochemistry; Variscan Chain; Sardinia

An interesting metre-sized metavolcano-sedimentary sequence was discovered a few km south of the Lula village during a geo-petrographical survey within the Variscan Chain in NE Sardinia. A detailed petrographical and geochemical study of the collected samples allowed eight different layers from bottom (Layer A) to top (Layer H) in that sequence to be distinguished.

Layer A, a few decimetres thick, is rich in 4-5 mm-long albite crystals, showing submillimetric muscovite inclusions and ubiquitous epidote overgrowths, locally concentrated in the crystal cores. A submillimetric matrix made up of quartz, albite to oligoclase grains, chlorite, muscovite, epidote and minor chloritized biotite surrounds the albite phenocrysts. The main foliation is defined by muscovite, chlorite and minor Fe-oxides. Epidote occurs as anhedral 0.2-0.3 mm-sized zoned crystals when scattered in the matrix, and as patches with patchy zoning when replacing albite. Rounded apatite grains also occur.

Layer B, 5-8 cm-thick, albite-rich, light-coloured, consists of an aggregate of several micrometric (<50 microns in size) albite grains enveloping 2-3 mm-sized albite crystals. The foliation is defined in the matrix by biotite-chlorite-Fe-oxide trails. Quartz occurs as submillimetric-thick veins or as clusters of anhedral grains. Apatite and monazite also occur.

Layer C, 10 cm-thick, similar to layer A as regards microstructural features, differs from it for higher phyllosilicate content, widespread occurrence of late-crosscutting muscovite, more pronounced foliation, more evident microfolds and quartz-filled veins.

Layer D, 20 cm-thick, light-coloured and poorly foliated, shows up to 1.5-2.0 mm-sized albite crystals surrounded by a quartz-albite matrix, with a grain-size <70-100 microns and albite/quartz ratio ~1, including poorly oriented scattered muscovites, clusters of chloritized biotites, apatite and Fe-oxides.

Layer E: thin, cm-thick dark metapelite bed.

Layer F, 40 cm-thick, shows almost the same microstructural features exhibited by Layer A.

Layer G, 15 cm-thick, medium/coarse grained, contains 5x2 mm-sized albite crystals embedded in a quartz-albite-chlorite-biotite foliated matrix. Unlike layer A, muscovite is rare; neither epidote growth, nor inclusions in albite were observed.

Layer H, 40-45 cm-thick, is characterized by up to 0.7-0.8 cm-sized albite porphyroblasts with several inclusions of titanite, epidote, chlorite and apatite. The quartz-albite matrix is striated by elongated muscovite-chlorite-chloritized biotite S2-oriented trails. A relict foliation is revealed by preserved microfoliations.

The Lula layers, compared with the Lower Paleozoic paragneisses and Ordovician metapelites from Sardinia reveal: 1) a strong enrichment in Na₂O and depletion in CaO, K₂O, Rb, Ba, that could suggest an albitization process of the whole sequence and in particular of the Layer B, whose composition is almost pure albite; 2) major and trace element contents similar to those of the Sardinian metavolcanites, the nearest ones, and significant differences with the farther Sarrabus-Gerrei metavolcanites; 3) some low SiO₂, high Al₂O₃ and V contents suggesting a possible contribution of a clay component to a probable altered volcanic or volcanoclastic protolith; 4) high contents of FeOtot, MgO, Cr, Co, Ni indicating a significant mafic component in the protolith; 5) a significant depletion in P₂O₅, LREE, HREE, Th, U that could be explained in two ways: a) they are original features of the igneous protolith; b) they are the product of alteration or sedimentary reworking processes of an igneous protolith. Further research is needed to clarify which is the correct hypothesis.

PERMIAN STRATIGRAPHY FROM SELECTED CONTINENTAL REGIONS OF SOUTHERN EUROPE: PALAEOGEOGRAPHIC AND GEODYNAMIC IMPLICATIONS

CASSINIS Giuseppe¹, PEROTTI Cesare¹, RONCHI Ausonio¹
1 - Earth Science Department, Pavia University, Via Ferrata 1-27100 Pavia, Italy

Presenter e-mail: cperotti@unipv.it

Key terms: Southern Alps; Late Palaeozoic; Interregional correlation; Geodynamics

The Late Palaeozoic South-Alpine successions can be subdivided into two main and well differentiated tectono-sedimentary Cycles, which are separated by a regional unconformity sealing a gap of as-yet imprecise duration (10 to 20 Ma).

In the Southern Alps, which represent the main reference sector of this review and, more generally, in the selected south European or western Mediterranean areas, these cycles mirror two very different "worlds" in terms of tectonics and sedimentation.

The Lower Cycle, up to a maximum thickness of more than 2000 m, consists of calc-alkaline, acidic-to-intermediate igneous products and alluvial-to-lacustrine sediments, both infilling fault-bounded intracontinental basins, generally interpreted as strike-slip or pull-apart basins affected by a transcurrent regime. Based on palaeontological evidence (macro-microfloras and tetrapod footprints) and isotopic ages, this Cycle ranges from the Carboniferous (Moscovian) to Early Permian (Kungurian).

The Upper Cycle, which is devoid of volcanics, is wider but less thick than the Lower Cycle and dominated by an extensional regime linked to the Variscan crustal thinning. It mainly includes the Mid?-Late Permian Verrucano Lombardo/Val Gardena Sandstone fluvial red clastics (up to about 800 m thick), in part laterally and upwardly replaced, east of Val d'Adige, by gypsum-bearing sabkha sequences and the shallow-marine carbonate of the Bellerophon Formation. According to many authors, this Cycle is regarded as the beginning of the "Alpine Cycle".

The comparison with some continental successions in southern Europe allows to reconstruct their evolution and set up correlations. A marked stratigraphic gap shows everywhere between the aforementioned Cycles.

As in the Southern Alps, it began during the Middle Permian, near the Illawarra Reversal geomagnetic event (~265 Ma). In western Europe, however, as in Provence and Sardinia, this gap persists upwardly to Late Permian and Early Triassic or slightly younger times, even though in northeastern Spain (Iberian Ranges, Balearic Islands) it is generally interrupted by late Guadalupian to Lopingian deposits.

The major regional angular unconformity between the two Permian cycles was probably caused at least in part by a deformation pulse, which

induced faulting, gentle folding, uplift and erosion or non-deposition. This tectonic event, connected to the transformation from a strike-slip to an extensional tectonic regime, and to a change of the relative plate directions, can be related to the so-called "Mid-Permian Episode". Therefore, in this geological context, the above Cycles reflect two main geodynamic events, which are respectively characterised by the Late Carboniferous-Early Permian transformation of the Gondwana-Eurasia collisional margin into a diffuse dextral transform margin and the Middle-Late Permian opening of Neotethys, with the onset of a generalised extensional tectonic regime and a progressive westward marine incursion.

In our reconstruction this dextral megashear between Gondwana and Laurasia should be due to the onset of the subduction of the Palaeotethys active oceanic ridge. The dextral shear would be induced and supplied by the nature of the triple junction itself, and is compatible also with the classical Pangaea A configuration.

STUDY OF THE GEOTHERMAL POTENTIAL OF TETITLAN AREA (NAYARIT, MEXICO) USING FLUX AND SOIL-GAS GEOCHEMISTRY

VOLTATTORNI Nunzia¹

1 - INGV

Presenter e-mail: nunzia.voltattorni@ingv.it

Key terms: soil-gas geochemistry; geothermal system; degassing estimation

The soil-gas method has been widely used to infer the nature of subsurface geology/geochemistry since gases released from active geothermal systems, can freely rise through overlying cover to be detected in the near-surface. The high mobility of some gases makes them the best pathfinders for concealed natural resources. Indeed, the gases produced and/or accumulated in geothermal reservoirs can escape towards the surface by diffusion, through transportation by rising hot fluids and by migration along fractures and faults.

The Tetitlan area (Nayarit, Mexico) has been investigated by CFE (Comisión Federal de Electricidad) since nineties by means of exploratory wells for geothermal purposes and gravimetric prospectings. On the basis of obtained results, a potential deep geothermic reservoir has been inferred in spite of the scarcity of evident surface manifestations (e.g., hot springs, vents).

A total of 154 soil-gas samples and 346 CO₂ and CH₄ flux measurements were collected in an area of 72 square kilometres. The performed soil-gas and flux geochemical surveys highlighted a general rising patterns linked to local fault system. Experimental variograms confirmed the presence of anisotropies highlighting different spatial domains. The contour maps elaborated on the basis of the calculated experimental variograms, demonstrated that gas emission at the surface is not spatially heterogeneous within studied area with the important implication that the highest fluxes, as well as concentrations, could be used in undeveloped geothermal systems to identify main upflow regions and areas of increased and deep permeability.

Further, the total natural gas emission has been calculated in order to estimate the exploitation potential of the inferred system. The overall calculated levels of CO₂ and CH₄ emissions (2.35 10⁴ t/day and 6.6 10³ t/day, respectively) from the Tetitlan system is found to remain within the range of normalized emissions measured for geothermal, volcanic, non-volcanic and hydrothermal systems worldwide.

2 - Dipartimento di Scienze Geologiche, Università Roma Tre

Presenter e-mail: marialuisa.carapezza@ingv.it

Key terms: geothermal exploration; diffuse CO2 soil flux; evaluation of reservoir permeability

In geothermal exploration it happens rather frequently that deep wells find high temperatures but are not productive because they don't cross any permeable fractured reservoir. Because of the high cost of deep drillings, this aspect represents one of the main economic risk of geothermal exploration. The aim of this paper is to show that a detailed survey of diffuse CO₂ soil flux allows to identify from the surface the permeable portions of a deep-seated actively degassing geothermal reservoir, drastically reducing that risk. The first application of the method has been made in the Quaternary Latera caldera, North of Rome. We will show that productive wells were all located on high CO₂ flux zones, whereas the not-productive wells were sited on low flux areas. In addition the survey allows to identify some as yet unexplored portions of the geothermal reservoir where future wells should be conveniently located. The same technique has been applied in the geothermal exploration of Platanares and Azacualpa, Honduras and of Las Pailas, Costa Rica. Obviously, CO₂ flux cannot provide any estimate of temperature at depth, which has to be assessed with other geochemical or geophysical exploration techniques.

Key terms: Turrialba volcano; fluid geochemistry; diffuse degassing; hazard assessment

Turrialba volcano (3340 m a.s.l.) is a stratovolcano located in the Easternmost sector of the Cordillera Central (Cartago Province, Costa Rica). Its volcanic products belong to the calcalkaline serie, ranging from basaltic andesites to dacites. The eruptive activity of the past 10 ky is mainly characterized by Strombolian to sub-Plinian eruptions. Turrialba volcano last erupted in 1864-66. Since 1996, after 150 years of quiescence, it progressively underwent deep modifications like the appearance of new fumaroles and fractures, the increasing in the fumaroles temperature and gas discharge as well as of deep magmatic components and seismicity. On the 4th of January 2010 volcanic activity reached its peak with a series of phreatic explosions occurred at the South-West crater. Turrialba volcano is presently considered to be in a phase of eruptive unrest showing signs of potential reactivation.

The final goal of our surveys in a such a delicate phase was the evaluation of the present volcanic activity at Turrialba volcano through extensive geochemical surveys, considering that fluid geochemistry of high-temperature fumaroles, gas plume, and diffuse soil gas are precious tools in evaluating the state of the volcano.

Two field works were carried out by the Authors in the past three years. The first one, on March 2008, was a preliminary study mainly addressed to understand if the damages to the vegetation along the volcano Western flank were caused by diffuse gas emission from the soil rather than from windborne plume gases. Soil gas samplings and an extended CO₂ soil diffuse degassing coupled with soil T measurements in the crater area were carried out. In addition 5 profiles across Ariete fault, a major volcano-tectonic feature located on Turrialba's Southern flank, were performed. The March 2011 investigation was a comprehensive and more detailed geochemical study and it consisted on the repetition of the 2008 survey with the purpose of comparing the two datasets and to define the new degassing path system in the summit area. Chemical and isotopic analyses from sampled soil, fumaroles and plume gases were performed in order to provide a geochemical model of the volcanic degassing system. A total of 973 CO₂ soil flux and soil T measurements on a surface of 0.81 km² (840 measurements and 0.78 km² on 2008) were carried out in the crater area on a nearly regular grid of 30 m spacing permitting to realize detailed CO₂ soil flux and T maps. The total CO₂ diffuse degassing output obtained for the 2011 survey is 277.4 tons/day (308.6 tons/day on 2008, before the opening of the phreatic vent acting as a preferential gas discharge pathway as inferred from the T map). In 2011, 5 CO₂ soil flux and T profiles were carried out on the volcano Southern flank across the Ariete fault and in its proximity showing CO₂ and T anomalies on 4 profiles whereas on 2008 only the 3 uppermost profiles were characterized by anomalous values displaying the down slope expansion of hydrothermal activity. Soil gas was sampled on 229 sites and then analyzed by means of a portable gas analyzer. Furthermore 10 fumaroles (Tmax 470°C) were sampled in order to define their chemical composition and the isotope ratios of He, C, Ar, dD and d18O while the plume was sampled to characterize its F, Cl, Stot, and metals content.

In order to define the expected eruption, of primary importance for the hazard assessment, the identification of the magma likely present in the feeding system of Turrialba volcano by volcanological studies and their petrological and geochemical characterization are needed. In addition its reology and fluid content have to be investigated by experimental petrology studies.

APPROACHING 10 YEARS OF RADON MEASUREMENTS AT STROMBOLI VOLCANO

CIGOLINI Corrado¹, LAIOLO Marco¹, COPPOLA Diego¹, PISCOPO Davide¹
1 - UNIVERSITY OF TURIN

Presenter e-mail: diego.coppola@unito.it

Key terms: radon gas; RADON network of stations; STROMBOLI; threshold, anomaly; Multiple Linear Regression statistic

Radon emissions at Stromboli volcano, were collected by means of different, passive, measurements since May 2002. A network of 21 sampling sites has been deployed onto the NE sector of the island. Periodic measurements with track-etch detectors and EPERM electrets allowed us to record variations in radon emissions during 2002-2007. The large dataset acquired by using EPERM electrets gave us the opportunity to perform a statistical analysis to detect background and threshold values, as well as anomalies for each measurement site. However, considering the entire network and data set, radon activity values were ranging (in space and in time) from 0.3 to 30 kBq/m³. Results confirm a close relationship between volcanic activity and 222Rn concentrations and shows that structural alignments (such as faults and fracture systems) represent a preferential pathways for radon migration toward the surface, particularly those that rim the crater area. These fractures may be affected by periodic self-sealing likely due to variable degassing regimes.

Since May 2007 we installed two real-time, fully-automated stations measuring radon concentrations, soil temperature and atmospheric pressure at selected sites. Data were acquired every 15 minutes. The two automatic stations were deployed within the summit area (named PZZ at 890 m a.s.l.), and nearby an historical eruptive fissure (LSC at 500 m a.s.l.). Average radon values are 12 kBq/m³ and 1.7 kBq/m³, respectively.

Negative correlations are observed between radon emissions, soil temperature and, to a lesser extent, atmospheric pressure. In contrast, an increase in radon concentrations have been observed during periods of higher rainfall conditions. Therefore, trends in radon concentrations may be decoupled from those of other geochemical parameters (CO₂ fluxes and CO₂/SO₂ plume ratios) during periods of heavy to moderate rainfalls. Multiple Linear Regression statistics (including the effects of tidal forces) led us to compute the residuals given by the difference of measured and calculated 222Rn concentrations. The cross-check between the daily measured radon activities and the absolute variations in radon residuals, for the data collected at the summit station, give us the opportunity to suggest a methodological approach that can be used in the attempt of predicting some major changes in volcanic activity.

Key terms: CO₂ degassing; thermal water; conceptual model; physical model

The area of Bagni San Filippo is located in the NW periphery of the Mt. Amiata volcano, in the eastern side of the Siena-Radicofani graben, is part of the Mt. Amiata geothermal region and is located within a regional CO₂ flux anomaly interesting the whole Perityrrhenian sector of central Italy. The geological framework of BSF is characterized by outcrops carbonate-evaporite triassic-giurassic formations in the western side and by ligurides flysch overlying the carbonate-evaporite sequence on the eastern side. BSF is affected by a strong and widespread CO₂ emission that emerges as vents, diffuse soil emissions, large travertine deposits and as CO₂ rich thermal water outflows of HCO₃⁻-SO₄²⁻-Ca-Mg composition and temperatures from 23 to 48°C. The strong CO₂ emission represents a natural hazard in the area as indicated by the lethal accidents occurred to humans also in recent times. A multi-parametric geochemical study of the BSF area was performed in order to quantify the CO₂ degassing, to define the conceptual model of the degassing process and to constrain a physical-numerical modeling of the system. A general soil CO₂ flux survey showed the presence several degassing structures that were investigated by specific surveys. The mapping of CO₂ flux, by geostatistical method, highlighted that the larger CO₂ degassing structures are associated to faults involving the carbonate formations and to areas of actual or "fossils" water outflow (i.e., where travertine outcrops). A total CO₂ release of about 200 t/d was estimated. A geochemical reaction path model of water-rock-gas interaction was then applied to the thermal waters in order to model the dissolved carbon content and the composition of dissolved gas. The comparison of experimental data with the model supports that the thermal waters are the result of the mixing between shallow groundwater and a hot, CO₂ rich, vapour phase reasonably derived by an underlying geothermal system. Coupling together the results of the CO₂ flux survey with geochemical, hydrogeological and geological data the following conceptual model was derived for upper part of BSF system: the groundwater recharge, from local carbonate outcrop, infiltrates and circulates in the buried carbonate aquifers where it is heated (up to 60°C) and enriched in CO₂ (up to 10 bar of P_{CO₂}) by the input of geothermal vapor. This anomalous and relatively shallow aquifer feeds both CO₂-soil degassing and the thermal water outflow. The physical feasibility of such conceptual model was successfully tested by a physical-numerical simulation using the TOUGH2 code.

ELEMENTAL FLUXES AND ADVECTIVE HEAT FLOW ASSOCIATED TO THE REGIONAL GROUNDWATER FLOW IN THE NARNI-AMELIA AQUIFER SYSTEM (CENTRAL ITALY).

FRONDIANI Francesco¹, CARDELLINI Carlo¹, CALIRO Stefano², CHIODINI Giovanni², MORGANTINI Nicola³

Presenter e-mail: frondini@unipg.it

Key terms: aquifer; heat flow; carbon dioxide

The elemental fluxes and the heat flow associated to large aquifer systems can be significant both at local and global scale. In fact, the large amounts of heat transported by regional groundwater flow can cause changes in the subsurface thermal regime, and the amount of matter discharged toward the surface by large spring systems can be significant if compared to the elemental fluxes of surface waters. The Narni-Amelia regional aquifer system (Central Italy) discharges toward the surface more than 13 m³/s of groundwater characterized by a slight thermal anomaly, high salinity and high PCO₂. During circulation in the regional aquifer, groundwater react with the host rocks (dolostones, limestones and evaporites) and mix with deep CO₂ rich fluids related to the mantle degassing process that characterize Tyrrhenian Central Italy. This processes cause the transfer towards the surface of large amounts of dissolved substances, in particular carbon dioxide, and a considerable amount of heat. Considering that practically all the water circulating in the Narni-Amelia system is discharged by few large springs (Stifone-Montoro), the enthalpy of these springs can give a good estimation of the total heat transported by advection from the entire system towards the surface. By means of a detailed mass and energy balance of the aquifer, and considering the soil CO₂ fluxes measured from the main gas emission of the area, we computed for the whole Narni-Amelia system a total CO₂ discharge of about 900 t/d and an average heat flow of 554 ± 120 mW/m². The CO₂ discharge is relevant both at local and global scale and it is comparable to the gas discharged by several active volcanoes. The advective heat flow is much higher than the conductive regional heat flow and is of the same order of magnitude of the heat flow measured in geothermal areas of Tyrrhenian Central Italy.

Key terms: Gas dispersion; Carbon Dioxide; Solfatara (Campi Flegrei);

Disgas; Greenhouse gas

A model to describe the cloud dispersion of gas denser than air is presented here. The dispersion of heavy gas is basically governed by the gravity but, when the density contrast (gas vs air) is not important the dispersion is controlled by the wind and atmospheric turbulence (so-called "passive dispersion"). DisGas is a model for dense gases which are dispersed under passive conditions, based on the full solution of the advection-diffusion equations for the gas concentration (Sankaranarayanan et al., 1998). The wind field can be assumed with a horizontally uniform profile calculated in accord to the Monin-Obukhov similarity theory or it can be estimated by the so-called DIAGNO, a Diagnostic Wind Model (DWM) developed by the US Environmental Protection Agency, the latter option requiring topographic data, average wind and atmospheric stability information within the computational domain. The model is able to forecast gas dispersion over large and complex terrain. Following the study of Costa et al., (2005), we present here an application of DisGas on the gas dispersion from the crater of Solfatara (Campi Flegrei) which releases a large quantity of CO₂ into the surrounding densely-inhabited areas. For the simulated cases, the soil CO₂ flow rate was assumed to be about 800 ton/day, such as the average of twelve different surveys carried out in the period 1998 to 2008 (Chiodini et al., 2010). Local atmospheric dynamics (3-components of the wind, friction velocity, Monin-Obukhov length) were derived by a two-year period of observations with micrometeorological technique inside the Solfatara crater. Our main finding showed that the urban area of Naples is affected by the CO₂ buildup above the normal air CO₂ content for this "natural" contribution, particularly in the no windy nocturnal situation. Estimated values show the absence of any risk to the population safety at the present emission rate but suggest that volcanic CO₂ contributes towards deteriorating and warming the urban air of Naples. DisGas model is able to simulate the dispersion of a heavy warm gas accounting for obstacles, topographic effects, variation of atmospheric conditions and wind direction. So, a possible application is the cloud dispersion of pollutant and/or greenhouse gases emitted by industrial chimney over urban or suburban environmental.

FLUXES OF VOLATILES DISCHARGED FROM OPEN AND CLOSED VOLCANOES SYSTEMS: A CASE OF STROMBOLI AND VULCANO ISLANDS (AEOLIAN ARCHIPELAGO, ITALY)INGUAGGIATO Salvatore¹
1 - Istituto Nazionale di Geofisica e Vulcanologia, Italia

Presenter e-mail: s.inguaggiato@pa.ingv.it

Key terms: Geochemical Monitoring; CO₂ fluxes; Stromboli volcano; Vulcano Island; SO₂ fluxes

Stromboli is an open conduct volcano characterized by "Strombolian" activity. This activity is the result of a "delicate" dynamic equilibrium between continuous refilling of deep volatiles exsolved from the magma batch and superficial degassing. In particular, the main peripheral manifestations are represented by dissolved volatiles in the basal hydrothermal aquifer, as well as structurally controlled soil degassing at the lower parts of the volcanic edifice. Summit degassing is manifested by active and passive degassing. During "normal" Strombolian activity this dynamic equilibrium allows the discharge of the volatiles in the atmosphere arriving from the depth. During overpressure of the plumbing system, paroxysmal activity is necessary to maintain the dynamic pressure equilibrium, so allowing the dynamic equilibrium between deep and superficial volatiles. In fact, through the opening of new fractures and consecutive lava flow or by major explosions and paroxysms the system decreases the total pressure of volatiles and restores the dynamic equilibrium of the Stromboli plumbing system. On the basis of the experiences acquired during the last two eruptions (2002-2003 and 2007) we improved our geochemical monitoring network by installing new equipments for remote continuous monitoring. In particular, we installed an automatic equipment for measuring dissolved CO₂ in the thermal well located in the N-E side of Stromboli (Stromboli village) and two UV-scanning DOAS to measure SO₂ plume fluxes.

Vulcano is characterized by a solphataric activity state since the last eruption occurred in the 1888-90. Total CO₂ output discharged from fumaroles, soil gases, bubbling and water dissolved gases was estimated. The preliminary results indicate an overall output of about 500 t/day of CO₂ from the island. The main contribution to the total output is from the summit area of the active cone (453 t/day) being 362 t/day and 91 t/day from crater fumaroles and crater soil degassing, respectively. These preliminary data allow the estimation of the background mass release and related thermal energy from the volcanic system and represent the first complete data set, collected during moderate volcanic activity. On the basis of the acquired information, through this geochemical survey, an automated CO₂ soil monitoring station has been installed on the summit area of Vulcano island in September 2007. Here we report the first three years of CO₂ flux measured hourly. The first preliminary data of continuous CO₂ flux (2007-2010) highlight a good correlation with the recorded variations of gas/steam ratio and temperatures of fumaroles. Moreover a clear increase of solfataric activity was recorded in the period September-December 2009 and corroborated from the plume SO₂ fluxes data acquired in continuous with UV-scanning DOAS.

10.1474/Epitome.04.0691.Geoitalia2011

HALOCARBONS IN FUMAROLAS AND AIR FROM THE ETNA VOLCANO SUMMITCAPECCHIACCI Francesco¹, TASSI Franco², VASELLI Orlando¹, CAPACCIONI Bruno²1 - Department of Earth Sciences, University of Florence, Italy
2 - Department of Earth and Geological-Environmental Sciences, University of Bologna, Italy

Presenter e-mail: francesco.capecchiacci@unifi.it

Key terms: ETNA VOLCANO; VOC'S; FUMAROLAS; AIR QUALITY

Non-methane volatile organic compounds (VOCs) are commonly found in fumarolic fluids discharged from geothermal and volcanic systems (e.g. Isidorov et al., 1990; Tassi et al., 2010). In the present study, VOC composition in fumarolic fluids from Etna volcano (Sicily, Italy) with outlet temperatures between 94 and 337 °C is presented and discussed to investigate their origin. A particular attention was devoted to the

qualitative and quantitative determination of CFCs, HCFCs, furans and dioxins. VOCs in air samples collected from several sampling stations located at the Etna summit were also analyzed to evaluate the local impact of the fumarolic activity and the behavior of these compounds once released into the atmosphere. VOC analyses were performed by GC/MS on samples collected using solid traps (ST) consisting of stainless-steel three phase adsorbent tubes. VOC composition in fumarolic gases is largely dominated by alkanes, alkenes, aromatics, thiophenes and furans. CFCs and HCFCs were also recognized at concentrations ranging between 0.05 and 0.79 ppbv. These compounds have a strong environmental impact, since they participate to the chemical reactions occurring in the stratosphere and are responsible for the destruction of the ozone layer (Anderson et al., 1986). The measured concentrations of CFC11, CFC12, CFC13, CFC113 and CCl₄ in the fumarolic gases are consistent with those expected considering the air fraction contaminating these fluids, suggesting that the origin of these compounds is totally atmospheric. On the contrary, HCFC and others halocarbons concentrations (e.g. CHClF₂, CH₃Cl, CH₂Cl₂, C₂H₂Cl₂, C₂HCl₃) concentrations are too high to be ascribed to the air fraction in the gas samples, suggesting the occurrence of a significant endogenous production of these compounds. Compounds pertaining to the group of furans, although at relatively low concentrations (from 0.2 to 6.8 ppbv), were also detected. This feature is not surprising, since these compounds are typically enriched in high-temperature gases (Tassi et al., 2010). Conversely, dioxins, whose formation can occur through furan condensation and combination with Cl, i.e. processes theoretically possible in the Cl-rich magmatic-related fluids released from the Etna fumaroles, were not recognized. These results, although preliminary, may have important implications for evaluating the environmental impact of naturally discharged fluids. Moreover, systematic investigations of these compounds may shed light on their geochemical cycles that are presently almost unknown. Consequently, further studies of these classes of VOC in fumaroles from different volcanic and geothermal systems are currently in progress.

MANTLE-DERIVED FLUIDS RELEASED FROM THE EXTINCT VULTE VULCANO: A RE-EVALUATION OF THEIR FLUX AND ASSESSMENT OF THE RELATED VOLCANIC HAZARD.CARACAUSI Antonio¹, NUCCIO Pasquale Mario¹
1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: a.caracausi@pa.ingv.it

Key terms: Geochemistry; mantle-derived fluids; crater lakes; volcanic hazard

In 1984 and 1986 two disastrous events, when huge amounts of CO₂ were released from Monoun and Nyos crater lakes (Cameroon), located on volcanoes which are no longer active. These dramatic events, causing loss of human life, draw attention of the scientific community towards those crater lakes able to accumulate massive amount of CO₂, which could be catastrophically released. Hence, investigations on other crater lakes have been carried out with the purpose of evaluating the gas hazard related to an instantaneous release of dissolved gas. Obviously, crater lakes, where the probabilities of dissolved CO₂ accumulation are higher, have been the preferred selected targets, even though volcanic activity was definitely ceased.

With this in mind, we studied two small crater lakes, formed about 140 ka ago and located along a NW-SE system faults, cutting the Mt. Vulture volcano, the easternmost occurrence of the Quaternary Italian volcanism. According to historical reports, both lakes have been repeatedly affected by sudden degassing. In fact, a 6-m-high water column formed in LGM on 1 June 1810 and a new event was observed two months later on 31 July. Ten years later, a similar event occurred in LPM, when a waterspout reached a height of 5 m, and a lot of dead fishes were found on the land, indicating the explosive nature of the event. During the 10 years leading up to 1820, every so often LPM reached similarly explosive conditions. Our previous investigations have shown that a hypothetical instantaneous release of dissolved CO₂ and CH₄, would produce a volume of gas of 2.3 x 10⁵ m³ for LGM and of 5.8 x 10⁵ m³ for LPM.

Our additional investigations have confirmed that LPM displays a heat flow of 75 mW m⁻² in excess at least of 20 mW m⁻² if compared to the expected values. Also, they have shown that major dissolved volatiles are biogenic methane and inorganic CO₂, having an isotopic signature in the range of mantle-derived CO₂. Indeed, dissolved He displays a seasonal variation of its isotope ratio between 6.1 and 5.3 Ra, within the range of values measured in the olivine fluid inclusions both of mantle xenoliths and ejecta.

We also measured the isotopic composition of He dissolved in aquifers of Mt. Vulture and its isotopic signature fits with He of the lakes water, supporting a diffuse degassing of mantle-derived He on regional scale all around the volcano. Our new dataset of spring and well waters suggest that the CO₂ flux is up to an order of magnitude higher than values reported in literature and comparable to that of Flegrea Fields. In this framework we realized that an active degassing of mantle-derived He occurs more than 20 km away from Mt. Vulture margin along the prolongation of the NW-SE tectonic lineament crossing the LPM.

Taking into account that:

- ° the Mt. Vulture volcanic activity was characterized by long lasting inter-eruptive periods (up to 350 ka);
 - ° the mantle isotope signature of both He and CO₂;
 - ° degassing of mantle-derived fluids (i.e. He, CO₂) from the entire edifice of the volcano and controlled by the main regional tectonic discontinuities;
 - ° the C/3He ratio of 8.3 x 10⁹, in the range of sub-continental mantle;
 - ° the estimated 3He/heat ratio of 2.13 x 10⁸ atoms/J;
 - ° the historical reports of gas bursts occurred in both lakes;
- although the last Mt. Vulture volcanic activity occurred 140 ka ago, we evaluated the possibility that a degassing magma is present at depth and the related hazards for dangerous gas bursts, triggered either by crustal accumulation of mantle-derived CO₂, and/or by a resuming of explosive volcanic activity. For these reasons, in our opinion, further investigations are strongly recommended.

Finally, we hope that our study will draw attention towards all those crater lakes located in volcanic areas apparently no longer active with a special attention to those situated in areas of tourist interest, where gas risk is probably underestimated or even ignored.

SAMPLING AND ANALYTICAL METHOD FOR GEOCHEMICAL SURVEY OF DISSOLVED GASES IN BRACKISH THERMAL WATERS

LIOTTA Marcello¹, MARTELLI Mauro¹

1 - Istituto Nazionale di Geofisica e Vulcanologia; Sezione di Palermo

Presenter e-mail: m.liotta@pa.ingv.it

Key terms: Dissolved gases; Brackish thermal waters; Gas solubility

Dissolved gases are often utilized in geochemical studies for investigating hydrothermal and/or magmatic contributions to shallow aquifers. Between the several methods applied for analyzing dissolved gases in water, the head space equilibration technique is probably the most used because it does not require any strain before or during the water sampling in the field and can be adapted to various aims in the laboratory, with multispecies analysis by common gas chromatography. This type of technique has been developed and applied. We propose a revised method of gas-liquid partitioning at equilibrium that allows a host gas aliquot to be introduced directly into the gas chromatograph (GC) and accurate analysis of dissolved O₂, N₂, He, CO₂, CH₄, CO, H₂, and Ar in water samples with salinities ranging from 0 to 40 PSU. Provided that the analyzed gases represent close to 100% of the originally dissolved gases, a mass balance relative to the host gas can be used to obtain an independent estimate of the overall quality of the major species determination. The method allows the rapid characterization of several sites and represents a useful tool for geochemical surveys. A comparison between replicate samples analyzed using different procedures demonstrates the efficiency of the method and indicates that the abundances of the main dissolved gases can be obtained, which is helpful for determining the underlying geochemical processes. A rigorous numerical approach allows the molar fraction in the headspace to be estimated when the natural abundances of dissolved gases are known within a given range, thus allowing the optimal choice of the volume ratio between the headspace and solution to conform to the detection range of the used GC.

Key terms: Mud volcanoes; VOCs; thermogenic; biogenic; Azerbaijan

Mud volcanoes are usually cone-shaped edifices of variable dimensions, or craters and bubbling pools discharging a three-phases (gas, water and sediment) mixture. The origin and distribution of this natural phenomenon are widely discussed in the literature (e.g., Dimitrov, 2002; Etiope & Milkov, 2004, and references therein). More than 900 mud volcanoes are recognized on land (Etiope & Milkov, 2004), whereas more than 1000 mud volcanoes supposedly occur in the oceans (Milkov, 2000). Methane is the main gas species discharged from mud volcanoes. The origin of methane is generally assessed on the basis of the stable carbon and hydrogen isotopes and chemical composition of light alkanes (Schoell, 1983; Bernard et al., 1978). However, misleading information from these geochemical parameters can be caused by secondary processes, such as oxidation and molecular separation during migration of the CH₄-rich fluid. According to the classification proposed by Etiope et al. (2009), more than 76 % of the terrestrial mud volcanoes from 12 different countries discharge thermogenic methane.

In this work we present data of hydrocarbon composition in gas emissions from mud volcanoes located in different areas of Italy (Northern Apennines, and Sicily) and eastern Azerbaijan. Chemical analysis of hydrocarbons, focused on the determination of C₄-C₁₀ alkanes, cyclics and aromatics, were carried out by GC-MS. The main gas species were analyzed by GC-FID. Methane is the most abundant component of all the investigated gases, with the exception of those from Sicily (Salinelle mud volcanoes) that are rich in carbon dioxide. Non-methane hydrocarbon composition is dominated by alkanes, mainly composed of ethane (up to 99.7 %). Aromatics, consisting of benzene, toluene, ethylbenzene and xylenes, are a significant fraction of all the collected samples, and are particularly enriched (up to 36 %) in the two CO₂-rich Sicilian gases. The most relevant feature of hydrocarbon composition is represented by the presence of more than 20 different cyclics in most of the methane-rich gases. Noteworthy, these hydrocarbons are almost absent in the two CO₂-rich samples, as well as in the mud volcanoes and gas seeps located in the southeastern sector of the Northern Apennines (i.e., the Romagna Apennines; Dragone, Bergullo, Portico, Bagno di Romagna). The four Romagna gases can be also distinguished on the basis of the isotopic signature of methane, which is significantly more negative (¹³C/¹²C < -60 permil V-PBD and ¹H/²H < -190 permil V-SMOW) than that characterizing the other Italian gases, as well as those from Azerbaijan (¹³C/¹²C > -50 permil V-PBD and ¹H/²H > -180 permil V-SMOW). This would indicate that the presence of cyclics is related to a thermogenic deep source, suggesting that the formation of these compounds occurs at high pressure conditions, likely thought the "closure" of the C-C chains of linear and branched alkanes. This is consistent with the structural setting of the Northern Apennines. "High pressure" gases are in fact expelled from mud volcanoes lying where the Ligurian Units (uppermost in the Apennine nappe pile) provide a thick, impermeable cover that may exceed 2-3 km in thickness; in contrast, comparatively lower pressure conditions result from the Romagna gases where this cover is much thinner or absent. These results imply that the cyclic compounds may play an important role

as tracers for evaluating the origin of fluids from mud volcanoes, as well as from other type of hydrocarbon-rich natural fluid emissions.

MIXING BETWEEN DEEP AND SHALLOW MAGMATIC FLUIDS BELOW MOUNT ETNA AND ITS KEY ROLE DURING THE 2006 AND 2008 ERUPTIONS

PAONITA Antonio¹, CARACAUSI Antonio¹, MARTELLI Mauro¹, RIZZO Andrea

1 - Istituto Nazionale di Geofisica e Vulcanologia - Sezione di Palermo

Presenter e-mail: a.paonita@pa.ingv.it

Key terms: noble gas; fumaroles; geochemistry; magmatic processes; modeling

Here we display the results of five-years long geochemical survey of some fumaroles at Voragine crater rim of Mt Etna, coupled to the synchronous monitoring of some well-known peripheral emissions, with the aim to reveal the genetic relations of the discharged gases. Our geochemical study has joined together the isotopic compositions of Ar, He and CO₂ besides to chemical compositions.

Once the effects of post-magmatic shallow processes have been recognized, quantified and removed, the geochemistry of gas emissions at Mt. Etna volcano has provided key information about the magma dynamics in the feeding system. Our study has in fact displayed that the summit crater fumaroles are aligned along the identical degassing path of the peripheral sites in terms of He/Ar versus Ar/CO₂ ratios. Interestingly, the carbon isotope composition of the fumaroles, coupled to noble gases, put into evidence that a part of the exsolved magmatic gases at high depth interacts with gases from magma batches stored at shallow levels and modifies the compositional ratios of the main geochemical indicators of magmatic degassing. The crater fumaroles therefore result from a two-endmember mixture of magmatic gases, composed by a deep member coming from variable pressures of 400 to 200 MPa depending on time, and a shallower one exsolved at about 130 MPa. The same as the crater fumaroles, the He isotopic compositions of the peripheral sites, coupled to the He/Ar* ratios, highlight similar processes of mixing between a deep gaseous endmember and a shallow one whose exsolution pressure seems to be very variable in time. More importantly, coupled peripheral and crater emissions show that the He isotopic marker of magmas stored at shallow levels and/or in the most external portions of the plumbing system is sensibly lower, in terms of R/Ra, than that of the parental magmas from the deep source. Resident magmas can also be modified as a consequence of massive recharges of the primitive, high-R/Ra melts. This probably occurs when, besides the fluids, batches of the recharging magmas reach the shallow reservoirs. Our investigation thus reveals a complex magma dynamics and even more complex evolution of the fluid phase, in agreement with recent geochemical and petrological studies on Mt. Etna. The time variation of He isotopic compositions, as well as their spatial distribution, are coherent with the idea of a multipart plumbing system made of dykes, sills and reservoirs barely interconnected, in agreement with the most recent views of Mt. Etna structure arising from geophysical studies.

The geochemical resolution of the deep and shallow gaseous endmembers allows to distinguish the periods during which the deep magmatic fluids become more important and/or new magmas coming from depth invade the shallow levels of the Etnean plumbing system. This result provides key information on volcanic activity in the middle and long term. The recognized episodes of magma recharge below Mt Etna have in fact accompanied periods of rising volcanic activity, such as those preceding the 2006 and 2008 eruptions. The final months of the 2010 have been once more marked by the increase of such replenishment from depth, suggesting that the volcano is again experiencing a phase of high eruptive potential.

Key terms: Poàs; Geochemical monitoring; Volcanic fluids

Geochemical monitoring of fluid discharges from active volcanoes can be used to mitigate the volcanic hazard. Many authors (e.g., Tedesco and Sabroux, 1987; Martini, 1989; Gigenbach, 1996) have stressed the importance of periodical monitoring of the chemical and isotopic composition of volcanic gases in order to predict changes in the volcanic activity. The physical and chemical characteristics of the fluids circulating in a volcanic environment reflect the different contributions from magmatic, hydrothermal and meteoric sources. Unfortunately, long-term geochemical observations are available only for a few volcanic systems, including White Island and Phlegrean Fields in Italy, Showna-Shinzan in Japan, Wulke Island in New Zealand and Mount Ebeko in Russia. In this work we describe the evolution of gas chemistry of the crater fumaroles from Poàs volcano (Costa Rica) recorded in the last 12 years, in order to investigate the mechanisms regulating the compositional modifications affecting these fluids in this span of time during which migration of fumarolic vents and phreatic eruptions have been occurred. The basaltic-to-dacitic volcano of Poàs (2708 m a.s.l.) is one of the most active in Costa Rica and is characterized by three N-S oriented craters: Von Frantius, Botos and the Active crater. The latter two host a volcanic lake: Botos is cold with the latest eruption dating back to ca. 7,500 years ago; Laguna Caliente is one of the most acidic lakes of the world (pH=0) and is the site where phreatic, phreato-magmatic and strombolian events have occurred since 1828. In 1988-1991 the acidic lake dried out revealing sulfur vents and fumaroles with temperatures up to 900 °C.

Since 1998 a discontinuous geochemical sampling and analysis has started at the fumarolic vents of Poas volcano. The first sampling was only concerning a relatively vigorous fumarole (no longer existing) discharging in the southern sector of the inner crater. Significant modifications of the fumarolic field location were recorded since then as the fluid discharges moved to the east. Then, new vents opened in the NE flank. Since 2006 several phreatic events (the first after that occurred in 1994) have shaken Poas volcano also during the Chinchona earthquake (8th of January, 2009). Presently, the fumarolic activity is centered at the interface between the Dome and the acidic lake and has increased in the last five years likely also due to the diminished lake water level in the last decade (15 m). Despite the phreatic activity no significant variations of the fumarolic outlet temperatures close to the Dome (always ranging between 90 to 120 °C) are reported until July 2008, when a jet-fumarolic discharge has shown a temperature of 650 °C. In June 2010 despite of the increasing difficulties to reach the sampling site the highest temperature (800 °C) was achieved since the 1988-1991 crisis. As far as the chemical variations are concerned, the Dome fumaroles evidence an overall increment in time of the concentrations of magmatic-derived gases (e.g. SO₂, HCl, HF) as well as those of the temperature-dependent species, such as H₂, CO and H₂S.

The complex interplay between the magmatic and hydrothermal components is likely regulated by permeability variations. Overpressuring and hydrofracturation may be responsible for the increasing release of deep fluids originating the observed phreatic events that so far have only produced relatively large vapor blasts and ballistic products. The proximity of a spine of magma close to the surface (about 500 m), the increasing values of the outlet temperatures and of the magmatic species in the fumarolic discharges cannot rule out the possibility of more explosive events.

The western sector of the Sabatini Volcanic District (SVD) and the Tolfa Mountains (TM) are characterized at depth by the presence of a horst-graben system bordered by extensional faults, along which recent volcanic activity occurred. Two different geological domains are recognized: i) a sedimentary domain, exposed in the TM, constituted by silico-clastic turbidite deposits and Plio-Pleistocene clays and ii) a volcanic domain formed by acid products of the Tuscan Magmatic Province and Quaternary undersaturated alkali-potassic volcanic rocks of the Roman Magmatic Province. The volcanic products overlie a sedimentary sequence which ends with a thick Mesozoic carbonate formation containing a pressurized geothermal reservoir from which fluids escape to the surface producing thermal waters and CO₂ dominated gas emissions. A total of 197 fluid discharges (cold waters, thermal waters and bubbling pools) and 15 gas emissions have been sampled to define the processes governing their chemical and isotopic composition. Two main reservoirs are recognized at different depth. The deepest one is hosted in the Mesozoic limestones and shows a Ca-SO₄(HCO₃) composition, likely produced by fluid-rock interaction at high temperature involving Triassic anhydrite layers at the base of the carbonates. The shallower one is hosted both in the volcanic and in the sedimentary domains and displays a Ca(Na, K, Mg)-HCO₃ composition. Significant contribution of CO₂-rich gases rising from depth into the shallow aquifers produce acidic cold waters, while low-pH (<4) acid-sulphate waters are produced from the near surface oxidation of H₂S, accompanying CO₂ in the uprising gas phase, to H₂SO₄. deltaD and delta18O data indicate that water recharging deep and shallow aquifers has a meteoric origin, while isotopic exchange between water and CO₂ or evaporation processes prevail for CO₂-rich water and bubbling pools.

Carbon dioxide, largely dominating the free gas phase, has a twofold origin, being related to mantle degassing and thermo-metamorphic reactions occurring in the carbonate reservoir. Helium shows a crustal isotopic signature, but the R/Ra values (from 0.37 to 0.62) indicate low but significant presence of mantle He. Methane and H₂S seem to be mainly produced by thermogenic reduction of CO₂ and of the Triassic anhydrites, respectively. Upraising of thermal waters and deep gases occurs along the extensional faults bordering the structural highs. Their distribution seems to be mainly controlled by NNE-oriented tectonic lineaments, in correspondence with the boundary between the volcanic domain of the SDV and the sedimentary domain of the TM, that represents an important hydrogeological barrier.

Exploration surveys investigated this area during 70's-90's for geothermal purpose, but the area still results unexploited. The presence of thermal waters and of anomalous heat flow, together with demographical growing of the last years, make this site a suitable location for the exploitation of the geothermal resource.

Key terms: Mt. Amiata; geochemistry of water; regional tectonics; geothermal system; discharging fluids

The Mt. Amiata geothermal area (southern Tuscany, central Italy) is located in an extended continental crust, where extensional structures developed from the Middle Miocene to the Quaternary, whilst collisional structures occurred from the Cretaceous to the Early Miocene. The recent extensional stages are divided in: a) Middle-Late Miocene, when widespread extensional segmentation, mainly affected the Tuscan Nappe via normal faults with staircase geometry, produced space accommodation of the sediments filling the neighboring Neogene basins; b) Pliocene-Quaternary, when marine sediments filled the relic Miocene structural depressions, which were affected by intense faulting activity. In the Pliocene a magmatic body was emplaced in the thinned continental crust. The observed high heat flow is due to this magmatic body which is located about 6-7 km below sea-level and not completely cooled down. The body is responsible for a negative Bouguer anomaly and localized uplift of around 3,000 m centered on the Mt. Amiata volcano. At the top of the convex structural culmination, a crustal fissure striking N50° produced the eruption of the Mt. Amiata volcano during the Late Pleistocene.

Hydrothermal circulation typifying the Bagni di S. Filippo and Bagnore areas is mainly concentrated at the intersection between this crustal fissure and two normal faults striking N160° and 180°. Mt. Amiata is the most recent (3-200 ka) and the largest volcanic apparatus of the Tuscan magmatic Province. The Amiata geothermal system is characterized by the presence of two reservoirs: the shallower one, having a temperature of 200-230 °C, is at depth of 500-1000 m in the carbonate-evaporite formations, whereas the deeper one (depth > 3000 m) is within the metamorphic basal complex where temperature are up to 350 °C. Both reservoirs are bi-phase systems and used for the production of the electrical energy by ENEL.

In this work, a relatively large data-set of chemical and isotopic compositions of discharging fluids was acquired in order to investigate if the deep-seated fluids may interact with the shallower volcanic aquifer. Thermal and cold springs associated to a CO₂-rich gas phase are mainly located in the north-eastern and south-western sectors of the Mt. Amiata volcanic edifice. These types of fluid emergences are practically missing in other sectors of the volcano. The studied waters are chemically characterized by i) a Ca-SO₄ composition, ii) relatively high TDS (total dissolved solids) values, iii) an associated CO₂-rich gas phase and iv) anomalously high concentrations of B, Li, Cs, HS and NH₄⁺. A Ca-HCO₃ shallow aquifer, having low TDS being directly recharged by meteoric water, is hosted within the fractured volcanic sequences, above the low permeable Ligurian Units that prevent a hydraulic connection with the deep hydrothermal aquifers. This aquifer fed cold springs that can abundantly be recognized all around the volcano. Accordingly, the spatial distribution of the CO₂-rich Ca-SO₄ thermo-mineral waters confirms that they are controlled by regional faults and tectonic structures in the area.

Key terms: alkaline Na-HCO₃ waters; geothermal area; Tierra del Fuego

The small geothermal area of Rio Valdez is located in the central portion of the Isla Grande de Tierra del Fuego (South Argentina), ten kilometres south of the south-eastern sector of Fagnano Lake. It is characterized by a series of thermal springs distributed in an area of less than 1 km², with low discharge rates and temperatures in the range of 20-33°C. Thermal waters can be defined as partially equilibrated, alkaline, Na-HCO₃ waters with low salinity but relatively high fluorine contents. Thermal waters are characterized by slow circulation at depth, possibly driven by deep tectonic discontinuities connected with the Magallanes-Fagnano Fault (MFF) system. According to geothermometric calculations, thermal waters reach temperatures in the range of 100-150°C and an almost complete chemical equilibration with the alkali-feldspars of the rocks they interacted with. The relatively high fluorine contents can be explained by the slow ascent and cooling of deep groundwaters, followed by a progressive re-equilibration with F-bearing, hydrated Mg-silicates, such as chlorite, which has been recognized as an abundant mineral in the meta-volcanics of the Lemaire Formation. As a matter of fact, deep rock-water interactions with the alkaline intrusives belonging to the Fuegian Potassic Magmatism may also have contributed to the high fluorine contents of the thermal waters. Finally, the isotopic composition of the investigated samples is consistent with the infiltration of meteoric water from local snowmelt at altitudes in the range of 610-770 m asl.

Key terms: geothermal system; mantle fluids; tectonics

Twenty kilometers away from the Mt. Vulture volcanic edifice (Central-Southern Italy) is located the Maschito Mefita, known since historical times as lake Fetente. Actually no evidences of the lake subsist. A surface of 300 m² is lacking of flora and rests of died animals are frequently found all around the area, which is characterized by smelly

exhalations. It is located along a regional tectonic discontinuity, close to the boundary between the foredeep and Apulian foreland.

The gas is CO₂ dominated (98%), followed by H₂S (<1%), CH₄, N₂ and other hydrocarbons. He, Ne and Ar are in trace amounts. CO₂ isotopic composition falls in the range of the main active Italian volcanic gases. The helium isotopic ratio (4.7 Ra) fits with values measured in Mt. Vulturno volcano and particularly in olivine fluid inclusions of ejecta of the last volcanic activity (140,000 years). 40Ar/36Ar isotopic ratio of 392 suggests a non atmospheric contribution and, following the Schoell classification,

both $\delta^{13}C$ and δD values of methane indicate its thermogenic origin. Multiple equilibrium temperature of gases at depth have been carried out:

1) Assuming that a boiling biphasic system (liquid/vapour) is present at depth, we estimated the equilibrium temperature among H₂O, CO₂, CH₄ and CO, according to the following reactions:

The computed temperature is 195°C. The calculated fH₂O value falls into the typical field of the geothermal systems.

2) The equilibrium reaction which involves light alkanes, 2C₂H₆ = C₃H₈ + CH₄ gives temperature of 180°C.

3) carbon isotope geothermometer based on CO₂-CH₄ equilibrium gives a temperature of 174°C.

4) H₂/Ar geothermometer give a temperature of 140°C.

These results support the existence in the area of a biphasic (liquid/vapour) thermal system with a temperature in the range of 140°C-195°C.

The estimated CO₂ fluxes from the area are around 3200 Tons/year, which are comparable with those of several emissions from geothermal fields in Italy. The calculated mantle-derived helium flux is 2x10¹⁰ atoms m⁻²s⁻¹, three orders of magnitude higher than typical stable continental crust and characteristic of the region where addition of mantle-derived fluids in the crust occurs. Moreover the C/3He ratio (2.9x10⁹) is in the typical range of magma released fluids. These results strongly support an active degassing of mantle-derived fluids feeding the recognized geothermal system. Therefore, considering that Maschito gas emissions falls along the same faults system where the Monticchio maars formed during of the last activity of Mt. Vulturno are located, our results strongly support the possibility that such fault system is connected to a magma body at depth.

It is worth of note that recent aeromagnetic studies have identified an anomaly located at a few kilometres towards North of Maschito area, interpreted as a sill intrusion, also confirming the main role of tectonics in controlling magma transport through the crust.

Key terms: Biomonitoring; Moss-bags; Trace elements; Volcanic emissions

Biomonitoring may be defined as the use of organisms and biomaterials (biomonitors) to obtain informations on certain characteristics of a particular medium (atmosphere, hydrosphere etc.). In particular, mosses accumulate large amounts of trace metals, making them good bioaccumulators to estimate atmospheric pollution. The moss-bags technique, introduced in the early 1970', has become very popular. Such active biomonitoring technique is particularly useful in highly polluted areas and has been extensively used in industrial and/or urban areas to examine deposition patterns and to recognize point sources of pollution. The main objective of this study, which represents the first application of the moss-bags technique in an active volcanic area, was to test its efficacy in such environment. Complementary objectives were: to determine the different behavior and the geographic dispersion of volcanogenic elements emitted from Mt. Etna; to check the usefulness of a simpler analytical techniques (leaching instead of mineralization of the moss samples).

A mixture of Sphagnum species was picked in a clean area, treated in laboratory (washed, dried and packed) and exposed in field for 1 month. Sites were chosen considering the prevailing wind at Mt. Etna's summit. Milled samples were analysed for major and trace elements concentrations, after microwave digestion (HNO₃ + H₂O₂), by ICP-MS and ICP-OES techniques. The same elements were also analyzed after simple leaching with deionized water (1/50 weight ratio for 4 hours). Leaching solutions were also analyzed by IC for F, Cl and SO₄.

Analyses clearly showed the efficacy of the moss-bags technique also in this peculiar environment. Several elements were strongly enriched in the mosses exposed to the volcanic emissions. The highest enrichment was measured on the rim of the summit craters, but evidences of metals bioaccumulation were also found in down wind sites, at several km from the volcanic source. The accumulation factor (exposed/unexposed moss) allowed us to distinguish a group of elements (Tl, Bi, Se, Cu, As, Cd, S), which are highly mobile in the high temperature volcanic environment. Also alkali metals showed a significant increase in their concentrations, probably because of their affinity for the halide species carried by the volcanic plume.

Also the simple and cheap leaching technique gave important indications on the plume dispersion pattern, especially for highly volatile elements (F, Cl, S, Tl).

Key terms: CO₂ Fluxes; Geochemical monitoring; Vulcano Island; SO₂

fluxes

Vulcano Island, located in the Aeolian Archipelago, is an active volcano that has been in state of solphataric activity since last eruption (1888-1890). Today, the main exhalative activity is located in the northern part of the island and is characterized by the presence of a) a wide fumarolic field, on the active part of the edifice of "La Fossa" crater, (100°C < T < 450°C); b) low temperature fumaroles (T < 100°C) and seawater bubbling gases in the Baia Levante area; c) strong soil degassing occurring in the Vulcano Porto area and around the volcanic edifice, where the active tectonic discontinuities drive CO₂ to the surface. The estimation of CO₂ degassing budget from volcanic systems has a relevance both for geochemical and monitoring activities.

The total CO₂ output of 571 t d⁻¹ was estimated for the whole Vulcano Island area considering discharged fluids from fumaroles, bubbling and dissolved gas and soil degassing (Inguaggiato et al. 2009).

The main contribution, at these degassing processes, is the fluids discharged from the summit area of the active crater (532 t d⁻¹), with 362 and 91 t d⁻¹ from crater fumaroles and crater soil degassing areas respectively.

On the basis of the acquired information, through this geochemical survey, an automated CO₂ soil monitoring station has been installed on the summit area of Vulcano island in September 2007.

Considering that the summit area represents the main contribution to the degassing fluids from the whole Vulcano Island, we decided to make several campaigns for measuring CO₂ fluxes on the crater soil degassing areas.

In particular, 7 surveys of CO₂ flux budget have been carried out from 2007 to 2011 for monitoring the solphataric degassing process from the summit area and for comparing it with the continuous CO₂ flux measured with the automatic station located on the North-East side of the crater. Two anomalous degassing processes were recorded in 2009 (September to December) and in 2011 (February-May). The results show a good correlation between the discontinuous surveys and the continuous flux measurements on time, suggesting that the continuous CO₂ flux measured on the summit area (VCS) is representative of the whole degassing process of the crater area.

Finally, the SO₂ flux from the "plume", acquired in continuous with UV-scanning DOAS, and the gas/water ratio of the fumaroles were also measured to better constrain the observed geochemical variation.

Key terms: Mt. Etna; melt inclusions; trace elements; mantle sources; ghost-plagioclase signatures

Mount Etna, the largest volcano in Europe, displays the peculiar condition of lying on continental crust and close to the subduction-related Aeolian volcanic arc, while its products shows typical affinities with Ocean-Island Basalts (OIB). The finding of subduction-related geochemical tracers in the volcanic products of the last thousand years, along with an increased explosivity of eruptions, led to develop a model for Etnean magmas that states that the mantle source is progressively undergoing metasomatic influx by slab-derived fluids released from the Ionian slab (Tonarini et al., 2001).

We present the results of a geochemical study of olivine-hosted melt inclusions (MIs) from 2001-2006 Mt. Etna basaltic lavas. Two different suites of MIs were observed. They represent different magma batches that variously evolved inside the feeding system before their entrapment in host olivines. Type-1 MIs share their trace element signatures with bulk-lavas and closely approach OIB-like magmas whereas type-2 reveal "ghost plagioclase signatures", namely lower concentrations in strongly incompatible elements and positive Sr, Ba and Eu anomalies. Noticeably, both melt types occur in 2006 MIs, which, more importantly, include composite inclusions consisting of plagioclase surrounded by type-1 melt. Trace-element critical ratios, namely Ce/Nb, Ba/La and K/La, which are not or poorly affected by process of global differentiation, provide evidence that sources of type-1 MIs are highly heterogeneous in composition, with signatures that are intermediate between those of HIMU/FOZO-like and EM-like sources. Differently from type-1, type-2 MIs testify for en-route processes that are peculiar for eccentric eruptions. These latter are strongly controlled by tectonics or flank instability, which occasionally promote the upraise of undegassed and more primitive magma that may interact with variable volumes of crystal mush and plagioclase-rich cumulates before reaching the surface. Previously formed plagioclase crystals are thus trapped in olivine, possibly along with minor reacted melt, and then forced to react and melt due to the high magma temperature, as suggested by Danyushevsky et al. (2003, 2004) to explain the "ghost plagioclase signatures" in MORB olivine-hosted MIs. It is also emphasized that the occurrence of melt inclusions with distinct geochemical signatures, rather than different melt types and sources, may reflect important en-route processes that are occasionally recorded only on a micro-scale and cannot be identified from chemical investigations of bulk-lavas.

Key terms: Stromboli; source metasomatism; melt inclusions; isotopes; trace elements

Several studies provide evidence that magma sources beneath the Aeolian arc volcanoes were contaminated by variable amounts of metasomatic agents released from the subducting slab. It has been proposed that the composition of the mantle wedge beneath Stromboli is strongly influenced by the addition of a recycled sedimentary component, and that two distinct enrichment events triggered by slab-released aqueous fluids and supercritical liquids were responsible for its source metasomatism (Tommasini et al., 2007).

We carried out an elemental and isotopic (Pb, B and Li) characterization of olivine-hosted melt inclusions (MIs) to explore the sources of Stromboli magmas and to assess nature and relative contributions of slab components and metasomatic agents involved in the source metasomatism. The studied MIs have primitive calc-alkaline to high-K calc-alkaline basaltic compositions; they are trapped within early-formed highly forsteritic (Fo_{83-91}) olivine phenocrysts, which were collected from lava (San Bartolo lava) and pumices erupted in historical times. The studied melts cover a compositional range far wider than that exhibited by the whole-rocks and differ in key trace element ratios. San Bartolo melts are characterized by lower incompatible trace element abundances, higher LILE/HFSE, LILE/REE, U/Nb, Ba/Th, U/Th and Pb/Ce, and lower La/Yb ratios relative to the pumice-hosted MIs and pumiceous melts erupted during paroxysmal events. The MIs Pb isotope composition is highly heterogeneous and extends from EM2 (Enriched Mantle)-like compositions (San Bartolo sample) to lower $^{207}Pb/^{206}Pb$ and $^{208}Pb/^{206}Pb$ values that are similar to those observed in lavas from the central and western Aeolian volcanoes and point to a FOZO-like fingerprint. The MIs B isotope compositions for San Bartolo and pumice samples are slightly

heavier ($\delta^{11}B \sim -2.0\%$) and significantly lighter ($-8.6 \div -13.7\%$) than whole-rock compositions, respectively. Their Li isotope signature of olivine-hosted MIs from pumices is more heterogeneous and significantly lighter than bulk-rock samples.

These features testify small-scale heterogeneities in the source regions of magmas feeding the present-day and >2 ka Stromboli activity. Isotopic melt compositions are consistent with a two-stage mantle enrichment process during which supercritical liquids and aqueous fluids partially overlapped on the same mantle domain. Variable amounts of Th-rich supercritical fluids mainly released from the altered basaltic oceanic crust are required to explain the composition of both olivine-hosted MIs from pumices and the high $^{208}Pb/^{206}Pb$ ratios of San Bartolo melts. However, the distinct geochemical and isotopic fingerprint of San Bartolo melts can be modeled only assuming a later metasomatic event driven by U-, B-, Ba- and Pb-rich aqueous fluids. These latter were probably expelled at relatively shallow depths from both sediments and basaltic crust (~30 and 70%, respectively) and promoted higher degrees of melting. In contrast, a later flux of aqueous fluids is not necessary to model the geochemical signatures of olivine-hosted MIs from pumices. Rather, their light Li and B isotope compositions indicate that they formed from mantle sources modified by supercritical liquids escaped from dehydrated metabasalts and metasediments constituting the deep portion of the slab. An overall important contribution from laterally heterogeneous subducted sediments characterized by high Th and U contents and variable Th/U ratios was most likely responsible for the large variations observed in Pb isotope ratios.

Key terms: Bidkhan; A.F.C; crustal contamination; F.C; magma mixing

Mt. Bidkhan's volcanic rocks (South-east Iran) cover a compositional spectrum from andesite to dacite. A plot of K_2O+Na_2O Vs SiO_2 suggests a medium to high calcalkaline for volcanic products. The geochemical trends of the Bidkhan volcanics are depicted through the use of the harker diagrams. Many of compositional arrays of Bidkhan samples are linear (e.g. Fe, Ca, Y) which support amagmatic differentiation in parental magmas. Some element arrays, however, are scattered (e.g. Ba, Sr, P) or curvilinear (e.g. Al, Na). These suggest that processes such as crystallization, and assimilation also probably operate in the magma chamber. In addition, some features such as high amounts of Th/Nb and Zr/Nb ratios in Bidkhan samples, suggest crustal contamination has been played an important role in the evolution of Bidkhan parental magmas. Field observations and whole rock chemistry for Bidkhan rocks suggest that the last melts that have differentiated and erupted from shallow magma chambers had been intermediate (probably andesitic) melts and have been repeatedly invaded by newly intermediate batches of magmas during differentiation. Then we have to search the traces of magma mixing in mineral chemistry, especially plagioclase crystals in the Bidkhan rocks. Bidkhan's plagioclases can be divided in 4 category: 1) Normal zoned plagioclases, in this type, An mol% varies from 53 in core to 10 in the rim; 2) Reversely zoned plagioclase crystals that make up a significant percentage of the Bidkhan plagioclases and occur in all of the rock types, with a compositional range from 30 An mol% in core to 55 in rim; 3) Normal oscillatory zoned plagioclases that also occur in all of the rock types; their An mol% fluctuates from core to rim, The ΔAn in oscillations are relatively small (~5 An mol%), that suggest newly melts were nearly similar in composition; 4) Reverse oscillatory zoned plagioclases, in this group of plagioclase crystals, An mol % content fluctuates and increases from their core to rim overally. Investigation of chemistry data in Bidkhan reveals that there are some plagioclase crystals with calcic cores (An 75 mol %) in andesites. These features must be established due to magma mixing. This situation that has stated by Toothil (2007) means a combination of

fractionation and magma mixing, where crystals growth in a relatively shallow magma chamber has periodically been interrupted by injection of other melts, with nearly similar composition of some many plagioclase phenocrysts. All these data suggest that, in Bidkhan, before and during eruption, some phenomena like fractional crystallization (F.C), assimilation and crystal fractionation (A.F.C), crustal contamination and magma mixing processes have a greater role to construction of Bidkhan's volcanic products.

LARGE-VOLUME EFFUSIVE ERUPTIONS AND CALDERA COLLAPSES AS THE RESULT OF UNCOMMON MAGMA STORAGE CONDITIONS AT MT. ETNA VOLCANO (SOUTHERN ITALY)

NICOTRA Eugenio¹, VICCARO Marco¹

1 - Università di Catania

Presenter e-mail: eugenio.nicotra@unict.it

Key terms: Etna; plagioclase; cicirara; magma chamber; ascent dynamics

The emission of plagioclase megacryst-bearing lavas, locally known as "cicirara", is rare throughout the volcanic record of Mt. Etna and generally related to unusual volcanological dynamics. Highly porphyritic lavas were emitted either during the final phases of the Ellittico volcano (14-16 ka) in association with a caldera collapse or during long-lasting and large-volume, effusive events of the XVII century. This eruptive period culminated with the catastrophic 1669 AD eruption, which was followed by the formation of a caldera at Piano del Lago (ca. 2500 m a.s.l.), as reported by detailed historic chronicles.

We tried to decipher the magma chamber processes and the structural features of the plumbing system that led to the formation of large plagioclase crystals (up to 1.5 cm). Selected plagioclase megacrysts, belonging to the final phase of the Ellittico and to the XVII century, were investigated through high-resolution BSE images and core-to-rim compositional profiles for An% and FeO wt%. A similar approach recently provided key information on the feeding system and ascent dynamics at Mt. Etna for mildly porphyritic lavas of the historic and recent eruptive record (Viccaro et al., 2010). Larger crystals (>7 mm) showed patchy zoning at the core followed by oscillatory-zoned envelopes. Crystals with size 1-7 mm display coarse sieve-textures at the core followed by oscillatory-zoning towards the rim. The most frequent texture is oscillatory-zoning, which is recorded by crystals of the dimensional class <7 mm. Three types of oscillations, characterized by different wavelength and frequency of An content, were observed. Oscillatory zoning can be interrupted towards the rim by other textures such as stripes of melt or fluid inclusions or strongly sieve-textured envelopes. Patchy zoning provides important indications on the styles of magma ascent between the plagioclase nucleation threshold and the volatile saturation depth (~6 km beneath the summit craters), suggesting limited ascent in the deep levels of the plumbing system. At shallower, water-undersaturated levels ascent might be faster, as testified by crystals smaller in size affected by coarse sieve-textures. Conversely, oscillatory zoning and the other textures give information on the magma evolutionary processes during storage at shallow, water-saturated levels (above 6 km of depth). Stripes of melt or fluid inclusions and strongly sieve-textures towards the rim are an indication that other physical and chemical perturbations occur at shallow levels. Stripes of melt inclusions can be associated with steps of magma ascent coupled with volatile loss, whereas layers of fluid inclusions may be related to episodes of volatile influx into the residing system. Finally, strongly sieve-textured envelopes with an increase and constant FeO (found exclusively in lavas of the XVII century) may be related to mixing with magmas similar in composition but more volatile-rich. The manifestation of "cicirara" lavas in some specific periods of the volcanic record is evidence that the plumbing system structure underwent a progressive coalescence of the complex network of dykes and sills as a response to increasing magma supply rate from depth, which finally led to a large reservoir at shallower depth. Huge amounts of magma withdrawal during long-lasting, purely effusive eruptions from this reservoir may be linked to episodes of summit instability that caused major caldera collapses at Mt. Etna in the past.

MICROANALYSIS AS A TOOL FOR DEFINING THE MAGMATIC SYSTEM: THE EXAMPLE OF LIPARI- VULCANO HISTORICAL ACTIVITY

BARCA Donatella¹, DAVI Marcella¹, DE ROSA Rosanna¹, DONATO Paola¹

1 - Dip. Scienze della Terra- UNICAL

Presenter e-mail: donatop@unical.it

Key terms: LA-ICP-MS analyses; Aeolian Islands magmatism; Lipari-Vulcano magmatic system

Trace elements distribution in volcanic minerals is influenced by a number of factors including, beside the composition of the magma, also its temperature, pressure, oxygen fugacity and volatile contents. Comparing the trace elements content in crystals of products of different eruptions can allow to understand whether they formed in the same conditions and if they are, therefore, related to the same magmatic system. We applied this principle to the products of historical eruptions occurring almost simultaneously along a N-S tectonic alignment on the island of Lipari, Vulcano and on the Vulcanello peninsula, with the aim to demonstrate that during the last 1000 years, in this sector of the Aeolian arc, eruptions were fed by a common deep magmatic reservoir. The historical magmas of Lipari and Vulcano range in composition from shoshonites (Vulcanello, 1100-1600 A.D.) to rhyolites (Rocche Rosse; Lipari, 1230±40 A.D.; Commenda and Palizzi; Vulcano, 1200 A.D.; products of 1888-90 eruption on La Fossa). Mafic enclaves of latitic composition are present in the obsidian rhyolitic lava flows of Rocche Rosse and Commenda, or are emitted as lavas (Palizzi) and/or pyroclastics (Vulcanello). In order to compare minerals in equilibrium with the same melt composition we focused our study on these intermediate products. Many similarities exist between the different latites in terms of petrography and whole rock chemistry. Clinopyroxene ($Wo_{43-46}En_{39-44}Fs_{13-15}$, $Mg\# = 0.72-0.76$) is always

the most abundant phase, followed by plagioclase (An₂₅₋₄₀Or₁₂₋₈), sanidine (An₁₅₋₃₅Or₅₀₋₇₀) and olivine (Fo₅₀₋₇₀). A detailed LA-ICP-MS microanalytical study on all the mineral phases showed that the pyroxenes of the different latites have very similar trace elements and REE patterns, with an Eu negative anomaly of about 0.65. Also plagioclase and K-feldspar show almost superimposed trace elements and REE patterns. Due to their small size it was possible to analyze olivine crystals only in Vulcano and Rocche Rosse latites; their FME contents are also very similar. The strong geochemical similarities of the latites suggest a common origin, i.e. the same volcanic system or the same magma. On the basis of geochemical models drawn using major, trace and isotopic data, a possible common parental magma has been recognized in the shoshonitic basalt found in the olivine melt inclusion within La Fossa cone 1888-1890 products [2]. The present work supports the hypothesis of Davi et al. 2009 and 2010 [3,4] suggesting a common deep feeding system for both islands in historical time. Mafic melts of the deep system can directly reach the surface (e.g. at Vulcano) and/or periodically refilling shallower magma batches with latitic to rhyolitic composition, enabling the rhyolitic eruption. Hazard evaluation in the southern sector of the Aeolian islands should consider Lipari and Vulcano as a unique magmatic system.

Key terms: Helium; Isotopes; Stromboli

Noble gas compositions (He, Ne, Ar) and isotopic ratios (He, Ar) in olivine- and clinopyroxene-hosted fluid inclusions were measured for the (i) present-activity basalts, i.e. Low Porphyritic (hereafter LP) pumices and High Porphyritic (hereafter HP) scoriae, and (ii) ultramafic nodules within the ~2 ka old San Bartolo basaltic andesite lavas. The ultramafic nodules (mostly wehrlites) are igneous cumulates consisting of clinopyroxene and olivine crystals with abundant fluid and melt inclusions. Textures and mineral chemistry of the wehrlites suggest that they are the products of early crystallization of primary basaltic magmas at mantle conditions. In addition, ultramafic cumulate and LP pumice crystals show similar major oxide composition (olivine and clinopyroxene) and trace element patterns (clinopyroxene). The gas content in mafic crystals decreases from ultramafic nodules to LP pumice and finally to HP scoria. This is probably due to the decreasing pressure (and depth) of fluid entrapment. In agreement with previous knowledge, the HP crystals are severely degassed and, as a result, the measurement of their 3He/4He ratio was unsuccessful. The 3He/4He of LP pumices and San Bartolo ultramafic nodules converge to a range of 4.2-4.7 Ra that we interpret as the magmatic value of the least degassed actual feeding system of Stromboli. This also allows the helium isotopes of the thermal waters of the Stromboli basal aquifer to be considered a mix between mantle-derived and atmospheric fluids. Therefore, the 3He/4He values measured in the Stromboli rocks represent the upper limit that should be expected in thermal fluids during long-term monitoring in case of events such as lava effusions and/or paroxysms.

OXYGEN FUGACITY VARIATION RECORDED BY SULFUR SPECIATION IN ETNEAN OLIVINE-HOSTED MELT INCLUSIONS

ROSCIGLIONE Alberto¹, NUCCIO Pasquale Mario¹, PAONITA Antonio², CAVALLO Andrea³

- 1 - Dipartimento di Scienze della Terra e del Mare (DiSTeM), Università degli studi di Palermo

Presenter e-mail: a.rosiciglione@unipa.it

Key terms: Mount Etna; sulfur speciation; melt inclusions; oxygen fugacity

Although sulfur is a minor element in magmas it plays key roles in processes of magma evolution, volcanic degassing and eruption. As a dissolved species in magmas, sulfur mainly exists as sulfide (S²⁻) under reducing conditions, and sulfate (S⁶⁺) under oxidizing conditions. Probing sulfur in magma is challenging because more than 90% of the sulfur initially dissolved is released at the time of eruption. Silicate melt inclusions trapped within early crystallized olivines provide a means of preserving melt compositions prior to significant modification of the magma such as assimilation, crystallization and degassing. Melt inclusions can provide reliable estimates of melt oxidation state at the time of inclusion entrapment.

Oxidation state in melt inclusions has been assessed by electron microprobe (EMP) measurements of sulfur speciation, determining the relative proportions of S²⁻ and S⁶⁺, on the basis of the sulfur K α X-ray peak shift method. This technique provides relatively rapid analysis of

small samples (~30 μ m) and is therefore ideal for application to melt inclusions.

A selection (30 to 40) of olivine-hosted melt inclusions and relative matrix glasses from 2001-2006 Mt. Etna eruptions, embedded in epoxy resin, were considered for this investigation. The selected samples have been previously characterised as for texture, major, minor and volatiles (including S). All the studied inclusions are hosted by forsteritic olivine (Fo78-82) and sulfur concentrations widely range from approximately 400 to 8000 ppm. Pyrite, Troilite, Sphalerite, Cinabro, Barite and Celestine

mineral grains were used as reference materials to define the peak position for SK α for a wide range of different S⁶⁺/S^{total} ratios and defining the peak position for pure sulfide and sulfate. With the aim of better constraining the oxygen fugacity in our MIs we also measured, by EMP,

iron speciation (Fe²⁺/Fe³⁺) by using the iron L α /L β intensity ratios. Aim of this study is to characterise the variations of sulfur speciation in melt inclusions as a result of natural magmatic processes. Based on sulfur X-ray wavelength measurements, calculated oxygen fugacities for etnean basaltic melt range from -0.4 to +2.5 log units (Δ NNO), with the highest calculated oxygen fugacity from the 2006 eruptive products. S⁶⁺/S^{total} ratio in melt inclusions generally well correlate with that of relative matrix glasses, although we observed a wider range in the former. Large ranges in measured sulfur speciation in naturally quenched melt inclusions may be related to degassing of the melt synchronous with entrapment in the olivine host crystals during closed-system ascent of etnean basaltic magma.

We normally observed that dissolved water and sulfur contents in melt inclusions simultaneously decrease during melt degassing, and according to that melt inclusions with higher S⁶⁺/S^{total} (more oxidized) appear to correspond to high water concentrations.

A notable exception was observed in some melt inclusions of 2002 eruption showing a very different behaviour, mainly characterised by large differences in S content at almost constant K₂O, and displaying an inverse relation between H₂O and S. The former condition is compatible with a rapid decompression accompanied by a limited crystallization processes, that causes rapid degassing with irrelevant chemical evolution of the melt. An attempt to explain the opposite variation of H₂O and S occurring in some primary etnean melt inclusions was made taking into account the involvement of an immiscible sulphide melt phase which has been observed and documented in some etnean melt inclusions.

PLAGIOCLASE TEXTURES AND COMPOSITIONS TO UNRAVEL THE FEEDING SYSTEM DYNAMICS AT AVACHINSKY VOLCANO (KAMCHATKA, RUSSIA)

VICCARO Marco¹, GIUFFRIDA Marisa¹, NICOTRA Eugenio¹, OZEROV Alexei²

- 1 - Università di Catania
- 2 - Institute of Volcanology and Seismology (Petropavlovsk, Russia)

Presenter e-mail: m.viccaro@unicat.it

Key terms: Subduction zone; Volcanism; Sieve texture; Patchy zoning; Oscillatory zoning

Aim of the work is the identification of the feeding system processes and styles of magma ascent before the 1991 eruption at Avachinsky through whole rock and textural/compositional data of plagioclase crystals obtained by high-resolution BSE images and core-to-rim profiles. The 1991 volcanics at Avachinsky are porphyritic basaltic andesites and andesites with low-K (tholeiitic) affinity. Major oxides are within the compositional range of other Kamchatka products of similar evolutionary degree. Trace elements define two trends: some samples show a progressive evolution from basaltic andesite to andesite that can be ascribed to crystal fractionation, whereas other products are not in accordance with a differentiation process driven by crystals removal. A two-steps fractionation modeling for both major and trace elements was performed to justify the basaltic andesite and the andesite compositions. Results of the first step show that basaltic andesites are consistent with fractionation from a poorly-evolved basaltic andesite of 27 wt% ~An80 plagioclase, 12 wt% aegitic clinopyroxene, 4 wt% orthopyroxene and 6% opaque oxide (P = 150 MPa; T between 1150°C and 1000°C; initial H₂O = 2.0 wt.%; fO₂ at the QFM+1 buffer). The second fractionation modeling justifies the andesite starting from the less evolved basaltic andesite of the 1991 eruption dataset. Results show that the andesite can derive from the basaltic andesite by fractionation of 24 wt% An75 plagioclase, 7 wt% aegitic clinopyroxene, 4 wt% orthopyroxene and 3 wt% opaque oxides (P = 50 MPa; T between 1150°C and 1000°C; initial H₂O = 2.6 wt.%; fO₂ at the QFM+1 buffer). Trace element geochemistry suggests the occurrence of other differentiation processes beyond the two-steps fractionation. The coupled increase of Zr - Ba/Sr - Rb/Sr for some samples indicates that some assimilation may have occurred during the evolution from basaltic andesite to andesite. Other basaltic andesites keep Ba/Sr and Rb/Sr rather constant at increasing Zr, ruling out the contribution of a crustal component. Thus, a hypothesis of new magma recharge was verified through the integrated textural and compositional study of plagioclase crystals. Several texture types were found: 1) small and large-scale oscillation patterns; 2) disequilibrium textures at the crystal core (patchy zoning, coarse sieve-textures, dissolved cores); 3) disequilibrium textures at the crystal rim (strongly sieve-textures); 4) growth textures consisting of melt inclusion alignments at the rim. Disequilibrium textures found at the cores testify episodes of destabilization at variable decompression rates under water-undersaturated conditions, which suggests different pathways of magma ascent at depth. At shallower, water saturated conditions, plagioclase textures and compositional profiles suggest that crystallization continues in reservoirs not affected by important chemical and physical perturbations (oscillatory zoning develops). Strongly sieve-textured rims are evidence for the occurrence of a mixing process prior the 1991 eruption: the behaviour of An and FeO suggests that the recharging magma was geochemically-distinct at rather comparable evolutionary degree and with higher temperature and volatile contents than the residing one. Assuming a certain degree of undercooling, the timescales derived to develop this envelope indicate less than 4 months. The occurrence of only two types of textures that cut the oscillatory zoning (strongly developed sieve-textures or thin alignments of melt inclusions) evidences that crystals underwent common histories at shallow levels, favouring the hypothesis of the existence of a large magma reservoir at ~5 km of depth, more than several separated batches. The presence in a hand-size sample of these two types of textures also implies that crystals mix mechanically at very shallow levels, supporting the existence of a small magma reservoir at ~1.5 km of depth.

Presenter e-mail: sinigois@units.it

Key terms: magmatic system; underplating; caldera; Ivrea; Sesia magmatic System

The Sesia magmatic system allows direct study of the links between silicic plutonism and volcanism in the upper crust and the coeval interaction of mafic intrusions with the deep crust. In this talk we focus on the chemical stratigraphy of the pre-intrusion crust, which can be inferred from the compositions of crustal-contaminated mafic plutonic rocks, restitic crustal material incorporated by the complex, and granitic rocks crystallized from anatectic melts. These data sources independently indicate that the crust was compositionally stratified prior to the intrusion of the Mafic Complex, with mica and K-feldspar abundance decreasing with depth and increasing metamorphic grade of the restites. Reconsideration of published zircon age data suggest that the igneous evolution initiated with sporadic pulses at around 295 Ma, when mafic sills intruded deep granulites which provided a minor amount of depleted crustal contaminant. At increasing rates of the intrusion, between 292 and 286 My, mafic magmas invaded a significantly more fertile crustal level, consisting of amphibolite-facies paragneisses, so generating hybrid rocks with distinct chemistry. At this point, advanced anatexis produced a large amount of silicic hybrid melts that fed the incremental growth of upper-crustal plutons and volcanic activity, while the disaggregated restite was largely assimilated once ingested by the growing Mafic Complex. This "igneous climax" was coincident with an increasing rate of intrusion, when the upper Mafic Complex began growing according to the "gabbro glacier" model and, at about the same time, volcanic activity initiated. In conclusion, the fertility of "under/intra-plated" crust plays a crucial role in governing the generation of large volumes of continental silicic magmas.

MONOGENETIC VENTS DISTRIBUTION AND CRUST MECHANICAL LAYERING IN THE MAIN ETHIOPIAN RIFT

MAZZARINI Francesco¹, ISOLA Ilaria¹

1 - Istituto Nazionale di Geofisica e Vulcanologia, sezione di Pisa

Presenter e-mail: mazzarini@pi.ingv.it

Key terms: monogenetic vent; basaltic volcanic field; continental rift; Main Ethiopian Rift; East Africa

Basaltic volcanic fields, formed by several volcanic constructs, are common features in the main Ethiopian Rift. Their age spans from 3 Ma to Holocene and are distributed along belts in the rift floor and clustered along magmatic belts close to the western rift margin. The strict relation between vent and dike allows analysing the vent spatial distribution in relation with tectonic features and crust layering. Observed vent distribution suggest a strong control in vent location by crust layering and by tectonic features. Moreover, vent distribution is defined by power-laws (fractal distribution). These distributions are defined by upper and lower cut-off lengths, where the upper one shows scaling relationship with the thickness of the crust beneath the volcanic field. This point suggest that vent distribution could be used as a proxy in defining the distance between the reservoirs and the sink, that in the case of basaltic magmas often represent the crust thickness.

Key terms: volcanic ashes; geochemistry; isotope data; microanalytical analyses; Eyjafjallajökull volcano

During the 39 days of summit activity at the Eyjafjallajökull volcano (14 April-22 May 2010) a nearly continuous injection of tephra in the atmosphere with a large production of ash caused disruption to the aviation over Europe. The activity consisted of an initial intraglaciale phase (14-19 April) of Vulcanian-type explosions, followed by intermediate phase (19 April-3 May) of weak magmatic explosions and lava emission; a final renewed phase of pulsatory explosions occurred between 3 May-22 May. The eruption emplaced about 0.1 cubic km (DRE) of benmoreite tephra with 10-20% of fine ash (< 10 micrometers) (Thordarson et al., 2011, G.R.A., 13, EGU2011-12046). The summit activity was preceded (20 March-12 April) by a mildly Na-alkaline basaltic fissure eruption on the East flank (Fimmvörðuháls) of the Eyjafjallajökull volcano, where up to 150-m-high lava fountains, emplaced 0.025 cubic km of lava (Thordarson et al., 2011, G.R.A., 13, EGU2011-12147).

We sampled a pristine fallout sequence packed in the snow 5 km East from the vent, representing the opening, the 14-15 April and the 17 April activity, respectively. A sample of falling particles was also collected 5.5 km from the vent on 6 May. Lapilli and lava of the Fimmvörðuháls basaltic

fountains were also collected. Samples were processed for grain size analyses; juvenile clasts were hand-picked in the range 0.710-1 mm and selected clasts were analyzed and characterized with SEM imaging. Matrix glasses of the chosen tephra clasts have silica ranging between 58-64 wt%, FeO between 7-10 wt% and K2O between 2-3 wt%. Compositions are extremely homogeneous within single clasts but slight variations can also occur between different clasts of the same sample. Major and trace elements and isotope data on whole-rock samples were also performed. Tephra samples show small compositional variations (SiO2: 58-64 wt%, MgO: 1.5-3.0 wt%, FeO: 8-10 wt% and K2O: 1.6-2 wt%). Although a good correlation between trace elements and silica exists, the trends of incompatible elements cannot be simply explained with fractional crystallization of the present mineral phases (olivine, clinopyroxene, plagioclase, magnetite and apatite). Matrix glasses of variably-vesiculated clasts, showing different composition and crystallinity, were also micro-milled and analysed for Sr isotope ratios by TIMS at the University of Florence. We found a range in 87Sr/86Sr values that nearly encompass that of Iceland magmas at the Eyjafjallajökull latitude (Sigmarsson et al., 2008, Jökull, 58), with the exception of some higher values which seem to be correlated with the phase of eruption and/or with magma evolution. No correlation has been found between 87Sr/86Sr and vesicularity or microlite content of the groundmass.

Magma mixing and/or mingling between a new basaltic melt and a residing evolved magma is proposed to be occurred before the explosive eruption, with end-members that changed in composition with time (Sigmarsson, 2011, G.R.A., 13, EGU2011-12589). Our data help to shed light on this hypothesis and on the eruption dynamics, although they also highlight a more complex plumbing system.

A NEW INTERPRETATION OF PHLEGRAEAN FIELDS CALDERA USING ANALOGUE MODELS

D'ALBORE Filomena¹, LUONGO Giuseppe¹

1 - Università degli studi di Napoli "Federico II"

Presenter e-mail: menadalbore@libero.it

Key terms: analogue models; caldera; Phlegraean Fields

Recently, to better understand structures and deformations of volcanoes new data became available by the use of analogue models that reproduced natural events in laboratory, simplifying them reducing the number of variables, and allowing to characterize the main phases of the processes by a well defined scale ratio between the events and their reproductions in laboratory. We used an analogue model by gelatine as a material analogue to the crust, in order to identify a new mechanism explaining the origin of the Phlegraean Fields Caldera, a volcanic structure that extends over the city of Naples and its western surroundings and formed during a distensive tectonic phase associated with the opening of the Tyrrhenian Basin and eastward migration of Apennine Chain.

The volcanic field is constituted of two calderas and of several monogenic cones. The oldest caldera is related to the Campanian Ignimbrite eruption that occurred about 39 ka B.P., and the youngest caldera formed 15 ka B.P. with the Neapolitan Yellow Tuff eruption.

An accurate analysis of the volcanic history of the Phlegraean Fields area and of the data available from the literature brought out doubts on two issues: 1) source of Phlegraean volcanism; 2) actual location of the limits of the Campanian Ignimbrite (CI) Caldera.

Our research began with previous interpretations that at the origin of the Neapolitan volcanism there is a mantle upwelling occurring about 2 Ma B.P., associated with tensile tectonics generated by the opening of Tyrrhenian Basin. In order to simulate a rising plume in the Neapolitan area we built two analogue models, set by volcanological, geophysical and geochemical constraints. The models were built using a layer of gelatine in order to obtain a spatial distribution of fractures in the material, source pressure values, scaled elastic parameters, a 3D model constrained by geological data. The difference between the models was the type of source: in the first model, a silicon balloon was placed at the bottom of the gelatine layer and was slowly inflated to simulate a rising plume; in the second model, animal fat was injected in the gelatine through a conduit in order to constrain it during the upward migration.

The effect of the experiment by the silicon balloon was the tumescence of the surface of gelatine layer with the formation of fractures just like a triple junction, followed by detumescence when the source pressure decreases.

For the second model, experiments were realized by varying the overburden thickness, hence the source depth. The effects were different: by greater source depth, a fat sill expanded in the analogue crust triggering the formation of a horizontal fracture, from sill to the surface, and it was followed by a triple junction. In the second case, by a shallower source, the fat sill only triggered the formation of a triple junction. The analogue models allowed to obtain the pressure of the magmatic source necessary for the overburden uplift and the formation of triple junction, in the Phlegraean Fields, and were used to determine the plume diameter. Therefore, the evolution time of deformation phenomenon in the analogue model allowed to scale the time of pre - Campanian Ignimbrite Caldera volcanism: the formation of CI Caldera was preceded from a fracture along which volcanic activity would develop initially and then migrate to the Gulf of Pozzuoli favoring a director E-W corresponding to the fault scarps of half graben basement of Campanian Plain; during this process of activity migration, a triple junction grows slowly giving rise to the Campanian Ignimbrite eruption and the subsequent collapse; the time between the first activity along fracture and the formation of the CI Caldera is about 25 ka scaled by the analogue model; a further triple junction was generated as a result of a new rising magma inside the CI caldera giving rise to the formation of Neapolitan Yellow Tuff caldera about 15 ka BP.

Presenter e-mail: lucia.civetta@ov.ingv.it

Key terms: Campanian Ignimbrite; magmatic degassing; residence time; caldera collapse

The late Pleistocene trachytic Campanian Ignimbrite (CI; 300 km³ DRE) covers the Campanian Plain near Naples, and is found behind ridges more than 1,000 m high at 80 km from source, the Campi Flegrei caldera (CFC). Distal ignimbrite deposits reveal downhill and/or downvalley flow directions prior to deposition, whereas in the absence of significant topography, deposition came from a flow moving in a roughly radial direction. These features point to very dilute currents, that together with the huge amount of discharged magmatic material, suggest a magma reservoir highly enriched in volatiles, rather than fluid entrainment from hydrothermal bodies or seawater. Petrologic and geochemical modelling of erupted products and their chemical and textural zoning, together with MI-based studies of gas-melt saturation, corroborate this view and show that the CI huge volume differentiated and mixed at shallow depth (6-3 km). With respect to compositionally similar but also smaller CFC eruptions (e.g. Agnano-Monte Spina, A-MS), the large amount of volatiles discharged by IC was likely due to fractional crystallization and longer residence times of volatiles sourced by the subducting Apenninic slab. This yielded high-water contents (up to 6-7 wt%), as well as high void fractions (~70-80% for IC, ~45% for A-MS) and also produced an overpressurized CO₂-dominated gas cap (about 150 km³), uniformly distributed at the top of the magma chamber. The onset of the eruption tapped this cap, with consequent depressurization and fast volume decrease that facilitated or even drove the caldera collapse, and allowed the water-rich magma to be discharged during the pyroclastic current phase. The gas saturation-based estimates of the tapped foamy magma are compatible with the extent of magma chamber roof collapse, strong expansion revealed by textural data and transport and deposition mechanisms, reflecting depressurization and magma inflation within the collapsed and laterally confined caldera.

Key terms: Lava flows; Calcite; Colli Albani

The Colli Albani (hereafter CA) ultrapotassic volcanic district (near the city of Rome, Central Italy) belongs to the Roman Province whose magmatism is thought to result from the combined effects of crystal fractionation and crustal assimilation on a parental magma derived from a metasomatized mantle source. The CA district represents one of the most peculiar volcanic districts on the Earth because of its liquid line of descent

characterized by differentiated, low silica ($\leq 45\text{wt}\%$), K-foiditic magmas. Field, geochemical, and experimental studies have demonstrated that such a differentiation trend, starting from trachybasaltic parental magma, is mainly due to magma-carbonate interaction (Gaeta et al. 2009 and references therein). Despite many studies have investigated petrological and geochemical features of the Colli Albani magmas, several questions remain unanswered. One of these concerns the occurrence of calcite crystals in the groundmass of some lava flows. In general all CA lava flows are made up of leucite and clinopyroxene phenocrysts; some deposits (corresponding to less evolved products) also contain forsteritic olivine. The groundmass, is generally made up of leucite, clinopyroxene, and Ti-magnetite; more evolved products may also contain amphibole or, and these are the object of our study, calcite, usually associated with nepheline.

The textural study of calcite-bearing lava flows, by means of Field Emission SEM, revealed that calcite usually occurs as interstitial phase, intergrows with nepheline and, in some cases, contains inclusions of oxide (e.g. hematite) or fluorite. Calcite is also present: i) as spherical "ocelli" with tangentially arranged crystals of clinopyroxene; ii) interstitial at clinopyroxene rim and leucite; and iii) rarely, around coronitic texture of leucite produced at the expense of K-feldspar xenocrysts. All these textural features indicate that calcite occurring in the lava flows groundmass crystallize above the solidus temperature.

The high activity of calcium in the lava flow groundmass is also supported by the mineral chemistry of silicate phases. For example, olivine crystals in groundmass are enriched in FeO and CaO (up to 4 wt.%) and a positive correlation between CaO in olivine and melt differentiation (i.e. Mg#) is observed. Carbon and oxygen isotope values, as well as trace elements abundance, have been determined on calcite and phenocrysts occurring in the CA lava flows. Oxygen isotope values (25-26 ‰ SMOW) result higher than that of phenocrysts (6-8 ‰ SMOW) and, interestingly, coupled with very low carbon isotope values (-14.4 - -15.7 ‰ PDB). Trace elements abundance in calcite is lower than abundances measured in both clinopyroxene phenocrysts and bulk rocks (LREE ≤ 100 chondrite).

Textural and mineral chemistry data indicate, unambiguously, that calcite in the CA lava flows has crystallized from a carbonate-bearing melt in a magmatic environment (Freda et al., 2011). Although carbon isotope values could suggest a mantle origin for the carbonate-bearing melt, oxygen isotopic composition and trace element abundance suggest a different origin. We propose that calcites in CA lava flows form as result of a mingling process between Ca-rich melts, originating in skarn environment and/or during sin-eruptive carbonate assimilation, and potassic magmas.

LONG-TERM VS. SHORT-TERM GEOCHEMICAL CHANGES OF MT. ETNA LAVAS: THE PUZZLING EFFECT OF A VARIATED MANTLE

VICCARO Marco¹, NICOTRA Eugenio¹, CONTICELLI Sandro², CRISTOFOLINI Renato³, FERLITO Carmelo³, MILLAR Ian L³

Key terms: Southern Italy; Volcanism; Mantle heterogeneity; Metasomatism; FOZO

Mt. Etna volcano fascinated the scientific community during the last decades due to its unusual geodynamic location and geochemical signature of the erupted lavas. Although the edifice is placed above the front of a compressive regional tectonic setting, volcanic products have a marked intraplate signature. The volcano has shown a complex geochemical variability during the half-million years of life, with sub-alkaline products erupted during the early stage of volcanism up to ~220 ka ago, then followed by a Na-alkaline stage. The alkaline stage also exhibit short-term changes in some periods. For example, an increase in some LILEs and volatiles together with marked changes of the Sr-Nd-Pb-Hf isotope ratios are observed since the 1971 (Viccaro and Cristofolini, 2008; Viccaro et al., 2011). Mt. Etna can surely be considered as one among the most studied volcanoes on Earth, although the features of the source are still matter of discussion. The absence of mantle material (xenoliths), which is efficiently fractionated in the deep levels of the feeding system, makes more intricate the picture. Thus, indirect information can be only attained from magma compositions. The behavior of incompatible trace elements for mantle-equilibrated magma compositions of the Ellittico (60-15 ka) and Recent Mongibello (15 ka-present), and of their enrichment ratio show that the Etnean magmas are produced by a variable, low degrees of partial melting. The enrichment ratio also reveals that magmas can be generated from a classic garnet peridotite variably enriched by metasomatic mineral phases (amphibole-phlogopite). The Zr/Nb vs. Ce/Y and Ba/Th vs. Lu/Hf diagrams highlight the enriched signature of the Etnean mantle. The Zr/Nb vs. Ce/Y diagram evidences the progressive contribution of metasomatic phases with time. The Ba/Th vs. Lu/Hf diagram shows the short-term coupled increase of the contribution by metasomatic agents and partial melting degree during the last 400 years of volcanic activity. In terms of mantle components, the integration of Sr-Nd-Pb-Hf isotopic ratios suggested that FOZO is the dominant component in the Etnean source (Viccaro et al., 2011). However, the FOZO component is not able to fully account for the isotopic changes from the Ellittico to Recent Mongibello magmas. Indeed, the isotopic compositions of the Ellittico and Recent Mongibello volcanic products can be explained by addition of an EM1-type component (up to 10%) to a dominant FOZO. The integrated analysis of Sm/Hf and Th/Hf ratios, together with Hf isotope ratios, gives evidence that the enriched component may be metasomatizing silicate melts. Long-term vs. short-term compositional changes at Mt. Etna are here related to partial melting of a recycled, altered oceanic lithosphere, infiltrated by metasomatizing silicate melts. Variable amounts of the enriched component participating to partial melting are able to affect its degree and the geochemical signature of the produced magmas.

RELATIONSHIP BETWEEN MAGMATIC PROCESSES IN THE PLUMBING SYSTEM OF MT. ETNA AND THE DYNAMICS OF THE EASTERN FLANK: INFERENCES FROM THE PETROLOGIC STUDY OF THE PRODUCTS ERUPTED FROM 1995 TO 2005

CORSARO Rosa Anna¹, CIVETTA Lucia², DI RENZO Valeria³, DISTEFANO Salvatore¹, MIRAGLIA Lucia¹

Key terms: Mt. Etna; Magmatic processes; Flank instability; Recent eruptive activity

Mt. Etna is located in a quite complex tectonic context and large sectors of the eastern and south-eastern flanks of the edifice move downward at very different rates. During last years, the flank slip has been somehow related to the magmatic intrusions refilling the shallow and deep portion of the volcano plumbing system, suggesting a feed-back between flank dislocation and magma emplacement within the volcano. The petrologic studies performed during last decades at Mt. Etna, evidenced that the plumbing system of the volcano has a quite complex geometry, variable in space and time and consisting of storage zones at different depth, where magma ascending to the surface experiences complex processes such as mainly fractional crystallization and mixing.

In this framework it's quite interesting to further investigate if a possible cause-effect relationship exists between the displacement of the volcano East flank and the pre-eruptive magmatic processes in the plumbing system. We went into this matter with a petrologic study of the products erupted in the decade 1995-2005. In particular we analyzed the petrography, mineral chemistry, geochemistry, Sr and Nd isotopes emitted by the four summit craters of Mt. Etna (South-East, North-East, Bocca Nuova and Voragine) from 1995 to 2001 and integrated them with petrologic data already available in literature for the investigated decade. This approach allowed us to better constrain the temporal evolution of the main magmatic processes occurring in the plumbing system of Mt. Etna (mainly mixing between compositionally distinct magmas and fractional

crystallization) and to make inferences on the geometry (shape and depth) of the shallow (>5 km b.s.l.) storage zone. In the studied decade, the comparison between petrologic data and deformational patterns evidences that, from 1995 to July 2001, the aforementioned pre-eruptive magmatic processes did not significantly influence the displacement of the flank, which maintained slow and quite-regular downward movement throughout these years. Differently, the onset of the 2001 flank eruption leads to an accelerated displacement of the movement, up to 2005. Well-known petrologic published data evidence that during the 2001 activity (and 2002-03 too) a primitive, volatile-rich, sub-aphyric basalt upraised directly from a deeper (8-10 km b.s.l.) reservoir to the surface. In conclusion, at least for the investigated period, the pre-eruptive magmatic processes in the shallow portion (<5 km b.s.l.) of Mt. Etna plumbing system, do not seem to directly affect the movement of the volcano eastern flank. Conversely, a magma intrusion which forcefully opens a new path from a deeper zone (8-10 km b.s.l.) of the plumbing system, causes a dramatic increase of deformational pattern, which strongly accelerates the slide of the volcano eastern flank, as it occurred during both 2001 and 2002-03 eruptions.

PLAGIOCLASE AS A TOOL FOR UNDERSTANDING MAGMA DYNAMICS - THE 2001-2006 ERUPTIVE PERIOD AT MOUNT ETNA

GIACOMONI Pier Paolo¹, COLTORTI Massimo¹, FERLITO Carmelo²
1 - Università degli Studi di Ferrara
2 - Università degli Studi di Catania

Presenter e-mail: pierpaolo.giacomoni@unife.it

Key terms: Mount Etna; Plagioclase textures; Magma chamber processes; Crystallization conditions

Mount Etna activity is characterized by different eruptive styles, from effusive to highly explosive, involving both central and lateral feeding systems, not accompanied by significant variation in lava compositions. The most important parameter in determining the eruptive styles is therefore the dynamic of magma within the feeding systems. Plagioclase is the most common phenocrysts in all terms of the etnean magmatic suite (~50% in volume). Its stability field is dependent on chemico-physical variations of the melt and it can be used as a tool to highlight the dynamics of magma uprising. Textural and compositional study of plagioclases has thus performed on the products emitted during the 2001-2006 eruptive period, and compared with theoretical models that constrained its stability field and with the eruptive mechanisms put forward by various authors. During 2001-2006 eruptions plagioclase with an average length of about

1mm present i) clear crystals (about 800µm in size), rich in An (An90-85) with oscillatory zonation pattern or ii) phenocrysts with clear or dusty cores lower in An content (An85-75) with complex dissolution textures

(4-500µm): when simple dissolution occurs cores are rounded and clear, while if partial dissolution occurs cores are dusty due to numerous glassy inclusions (coarsely sieved cores) (Tsuchiyama, 1985). In the latter case both cores are followed by a lower An overgrowth ranging in size from 100

to 400 microns. Finally two types of rims (max 100µm) can be also recognized: i) partially dissolved dusty rims, with An-rich composition and ii) a more albitic rims characterized by alignments of melt inclusions along crystallographic planes.

MELTS calculations have been performed to constrain the crystallization conditions, starting from the most primitive magma (2004/2005 eruption) under different pressure (2500-0 bars) and water contents (3.5-0 wt%). Based on whole-rock composition the program estimates the liquidus temperature, which were decreased by step of 20°C down to 1030°C. Volatile saturation depths were estimated using VolatileCalc and water content in Etnean lavas by the plagioclase-liquid hygrometer/thermometer of Lange et al. (2009). Independent determinations of oxygen fugacity (fO₂) of the system have been calculated using the method of France et al. (2010), indicating a range of values varying from ΔQFM=0.3 to ΔQFM=2.8, with an average of ΔQFM=1.8.

These simulation indicate that An-poor (An75-85) plagioclases crystallized at about P=2500 bars and 1 wt% H₂O, while An-rich (An85) plagioclases is stable only at P=800 bars and 2.5 wt% H₂O. Thus clear An-rich (>An85) crystals can be obtained only at very shallow pressure (<1000 bars) with water content of about 2.5-3.3 wt%.

Clean or dusty dissolved cores An85-75 in composition cannot be in equilibrium with high water content at depth greater than 3km. Dissolution processes suggest disequilibrium conditions within the deep magma reservoir which can be related to an input of new undegassed magma or decompression during magma ascent which rise the water pressure. The more albitic overgrowth probably develops at shallower level where the magma can rest, followed by water oversaturation and degassing. The outermost narrow rims can be explained by i) input of new basic magma or ii) rapid growth due to degassing just prior to the eruption.

Textural and compositional study reveals a dependence of plagioclase liquidus on water content dissolved in the melt. Furthermore, the textures at the crystal rims suggest different trigger mechanism of the eruption: an active one, induced by magma mixing and a passive one, promoted by decompression due to fracture opening, probably associated to regional tectonics.

Key terms: Mount Etna; 2002-2003 eruption; Petrography; Fractionation model; Magma dynamics

The 2002-2003 eruptive event of Mount Etna lasted from 26th October 2002 to 28th January 2003 and was characterized by the contemporaneous activity at the NERS (North East Rift System) and SRS (South Rift system).

A detailed and stratigraphically controlled sampling was developed along the SRS between 2,900 and 1,700 meters a.s.l. Whole rock major and trace elements analyses were carried out and results compared with those obtained from the NERS (Ferlito et al., 2009). Eight main eruptive stages were distinguished on the basis of Catania-INGV daily Reports. The first stage, T1, correspond to the beginning of volcanic activity at SRS on 26 October 2002, although samples referable to this period are no longer accessible. From T2 to T5 the activity was concentrated along the NERS with the opening of three main fracture segments and the contemporaneous emission of several lava flows that reached the touristic centre of Piano Provenzana. The last three stages, from T5 to T8, developed on the southern flank.

On the base of petrographic (P.I.) and geochemical features (mainly K₂O, Rb, Nb), three different magmas have been recognised: (1) High-K Porphyritic (HKP) group with high-potassium contents (K₂O>2 wt%) and P.I. ranging between 20 and 32%; (2) High-K oligophyric (HKO) group with high-potassium content (K₂O>2 wt%) and P.I. ranging between 10 and 18%; (3) Low-K oligophyric (LKO) group with low potassium content (K₂O<2 wt%) and P.I. between 10 and 17%. Low-K lavas are only present at the NERS. HKP lavas emitted at T5 on the southern flank of the volcano are similar to those found on the lowest segment of the NERS, although the former are less differentiated. Quarzarenitic xenoliths are present in lavas from both sides of the volcano.

Major and trace elements mass balance and Rayleigh fractionation models were developed on representative NERS and SRS samples. The modeling indicates that NERS T5 lavas can be fractionated from those outpoured at SRS, suggesting a common fractionation trend. Textural and petrological studies of plagioclases enclosed in these lavas also suggest that chemical-physical conditions at depth were similar, while at shallow levels lavas evolve independently.

These new geochemical and mineralogical data, together with published seismotectonic data, support the idea that the main magma feeding the eruption was common on both sides of the volcano even though magma ascent probably occurred through the South Rift fractures and was intercepted from the NE Rift system only at relatively shallow depth. New magma inputs were recognized at SRS where eruption lasted until the end of January. On the other hand at NERS eruption, which was most probably passively triggered by tectonic activity, lasted only for few days.

A NEW RECONSTRUCTION OF THE VAL CALANNA VOLCANIC SUCCESSION (MT. ETNA, ITALY): INFERENCES ON A NEWLY DISCOVERED, SMALL-SIZE ERUPTIVE CENTER

NICOTRA Eugenio¹, FERLITO Carmelo¹, VICCARO Marco¹, CRISTOFOLINI Renato¹

1 - Università di Catania

Presenter e-mail: eugenio.nicotra@unict.it

Key terms: Valle del Bove; geological survey; magma differentiation; crystal fractionation; shallow feeding system

Since the beginning of its activity about 500 ka ago, Mt. Etna has been characterized by the growth and destruction of several eruptive centers. Our knowledge on the most ancient of them derives from the study of the steep and friable walls of Valle del Bove, carved on the eastern flank of the volcano edifice. The understanding of long-term variation in terms of volcanological and geochemical evolution of basaltic magmas at Mt. Etna can lead to a more global view of the volcanic system. Within this frame, a multidisciplinary study on ancient eruptive centers can also offer new insights for interpreting the current volcanic activity, providing general models of magma evolution and eruptive behavior. An integrated study embracing geology, petrography and geochemistry was undertaken on the Val Calanna area, located at the south-eastern end of the Valle del Bove. The volcanic succession of Val Calanna is of interest for the study of the Mt. Etna evolution, as the remains of several eruptive centers attributed to the first stages of the alkaline activity outcrop on its flanks. The new geological survey of the Val Calanna area, along with petrographic and geochemical data, highlighted some differences in the volcanic succession with respect to that previously reported in literature.

Our study confirms that the most ancient volcano-stratigraphic Unit of the VdB crops out at Mt. Calanna, recently interpreted as a dyke swarm. The Mt. Calanna Unit is overlain by the 80-m-thick lava succession of the Salto della Giumentata Unit, one of the Ancient Alkaline Centers, which at its top is mantled by pyroclastic flow and epiclastic deposits. Above this, volcanics of the Mt. Zoccolaro Unit constitute the frame of the present-day homonymous ridge with a 200-m-thick succession of benmoreitic lava flows characterized by amphibole megacrysts and showing features similar to those of the Trifoglietto phase (80-60 ka). The eastern portion of the Mt. Zoccolaro edifice is overlain by the volcanic succession of a newly recognized, small-sized, eruptive center: the Fior di Cosimo (FdC).

The FdC Unit is constituted of a sequence of alternating lavas and pyroclastic deposits which dip radially away from an inferred vent hypothetically located in the middle of Val Calanna. The relationship between major oxides of FdC lavas and their stratigraphic position shows an increasing degree of differentiation through time, from basalts to benmoreites. Simulations of crystal fractionation through MELTS revealed that the most evolved FdC lavas can be derived by subtraction of 54% of solid phases (An66-82 plagioclase, augitic clinopyroxene, Fo68-72 olivine, Ti-magnetite and traces of apatite) from a basaltic composition. The proposed model for the FdC magmatic evolution is therefore the intrusion of a slightly differentiated magma at shallow crustal levels. Magma supply should have then ceased forming a reservoir that allowed differentiation by crystal fractionation, gradually leading to an increase of the volatile pressure of the system. This favored amphibole crystallization, as observed in the last-emitted products. The available data suggest that FdC can be attributed to a pre-Ellittico eruptive phase.

VOLCANO-SEISMIC EVENTS ALONG THE ANDEAN MARGIN

SCALERA Giancarlo¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: giancarlo.scalera@ingv.it

Key terms: Earthquakes-eruptions correlation; Global geodynamics; Natural disaster forecasting; Cause of PM and TPW; Expanding Earth

Scalera (2007, 2008) using the data available in 2006 in the Smithsonian Institution Catalogue of volcanic eruptions revealed evidence that South-American Wadati-Benioff zone earthquakes with $M > 8.4$ are associated to enhanced rates of volcanic eruptions.

The occurrence of the Chilean Maule earthquake of 27 February 2010 ($M=8.8$) has been the occasion to rework all the data adopting a non-compressional framework of mountain building. This framework suppose a common secular process involving the complete South American Pacific margin linked to TPW. Indeed, in the expanding Earth schema both PM and TPW are explained by assuming an emplacement of mass in the Southern Hemisphere on the Nazca region. The TPW path through geological time is then naturally linked to the slow displacement of the region of maximum planetary expansion.

Passing from the older Andean volcano-seismic correlation events to the 2010 one, it is clear the trend - as soon as the data have become more precisely located on the time axis - of an enhanced rate of eruptions before the main seismic event.

The 1868 event - In this case data were collected only by visual witness, listening inhabiting of localities nearest the volcanic apparatuses or people passing for a direct inspection. The date of the eruptions may be confused with the observation date, displacing the event many months ahead and possibly one or more years ahead. The peak of eruptions after the quake, can be then an artifact.

The 1906 event - This event is a pair of great earthquakes (Ecuador, January 31; $M=8.8$; Chile, August 16; $M=8.4$) that occurred in the same year separated by very long distance. Only the southern district appears to have a peak of eruptions correlated to the earthquakes. The maximum is one year after the seismic event but the growing of the eruptions' amount starts in the same year of the quake. Then the real distribution on the time axis must be different and considering the reasons explained above in the preceding 1868 case, some of the real onsets could be occurred many months before and also one year before.

The 1960 event - The earthquake occurred (1960, Chile, $M=9.5$) in the times of more modern scientific instrumentations and surveying facilities (quick transportations, airplanes, helicopters). This time the maximum eruption rate is in the same year and the growing of the rate starts before the quake occurrence.

The 2010 event - This time all the onset date of the eruptive events are known thanks to modern surveillance methods. The rate of eruptions occurred in the northern and southern volcanic district increased from one-two erup/year to five in 2009 and we expect that an enhanced rate will be revealed until the end of 2010. The northern volcanic district was active in 2007-2009, while the central district did not contribute to the constitution of the volcano-seismic correlation event. There is then a precursory behavior of the northern and southern volcanic activity in this case.

Moreover, a possible synchronicity should be considered. If on the same plot both the secular polar motion (from 1846 to 2009) and the time of occurrence of the volcano-seismic events of correlations are represented, it is possible to see: i) Only three volcano-seismic events, 1906, 1960 and 2010, can be correlated to the series of PM data 1846-2009. ii) The PM data preceding 1900 are not homogeneous with the 1900-2009 ones. iii) The events of 1960 and 2010 occur about 12 years after a five-years window of 'stasis' of the secular PM (a very low velocity, witnessed by the extreme proximity of the annual averaged points in the plot). Albeit the data are not against the same mutual pattern between the event of 1906 and the PM data of the last decade of the XIX century, the non-homogeneity of data do not allow a positive conclusion. iv) To ascertain the reality of this synchronism with the Markowitz oscillation of PM, a greater amount of volcano-seismic events is needed.

STRUCTURAL AND PETROLOGIC FRAMEWORK OF STROMBOLI PLUMBING SYSTEM

CIGOLINI Corrado¹, LAIOLO Marco¹

1 - Università degli Studi di Torino

Presenter e-mail: corrado.cigolini@unito.it

Key terms: mineral-melt equilibria; thermobarometry; magma reservoir; strain rates

Structural, geophysical and petrological data are used to refine current models on the inner plumbing system of Stromboli volcano. Active vents are located on a NE trending fracture zone affected by pure extensional regimes that controls the geometry of the plumbing system. Fine thermobarometry, based on a grid of selected reactions, have been used to define the stability field of mineral-melt equilibria and constrain the P-T regimes of the magma reservoir. Current primitive Stromboli basalts equilibrate at $\sim 0.27-0.12$ GPa for temperatures approaching 1170-1150 °C, and progressively crystallize, cool and degas before being erupted. Pure extensional regimes and recent geophysical data suggest the existence of a prolate ellipsoidal magma chamber below Stromboli. Stress regimes are likely proportional to the geometry of the reservoir and constrain its volume at approximately 1 km³. It is suggested that the cyclic onset of effusive phases is modulated by variable strain rates associated with spreading along the NE summit fracture zone. Current average strain rates are of the order of $10 \exp(-13)$ sec⁻¹, typical of regimes generated within thermoelastic shells surrounding active magma chambers.

GEOLOGY AND PETROLOGICAL FEATURES OF THE

POST-COLLISIONAL OLIGOCENE MIAGLIANO STOCK (WESTERN ITALIAN ALPS)

SOGNO FORTUNA Lorenzo¹, CIGOLINI Corrado¹

1 - Università degli Studi di Torino

Presenter e-mail: corrado.cigolini@unito.it

Key terms: Miagliano stock; Ivrea Verbano Zone; calcalkaline; comagmatism

The Oligocene small Miagliano stock together with the Adamello batholith are the only Periadriatic plutons that outcrop to the southwest (or south) of the PFS (Periadriatic Fault System). The Oligocene Miagliano stock is represented by two intrusive bodies, volumetrically defined in a main and a minor one with different petrographic features, located in the Ivrea Verbano Zone, in proximity of the Canavese Line. These masses are close to the main Valle Cervo pluton (part of an Oligocene volcano-plutonic complex), which is located about 3,5 km NW of Biella (Western Italian Alps). The main intrusive body is cross-cut by the Cervo Valley and ranges in composition from Hornblende-Biotite Gabbro (peripheral and intermediate sector) to Hornblende-Biotite Diorite/Tonalite. The inner part consists of Hornblende-Biotite Leucotonalite with plurimillimetric (up to 7-8 mm long) pectilic hornblende crystals. An enrichment in alkali-feldspar characterizes the NW sector of the main mass where Granodioritic rocks locally outcrop (being in contact with gabbros and monzonites deriving from the plutonic rocks). The minor mass is located NE of the main body and shows a "peripheral" of Biotite-Muscovite Granodiorite and a "core" of fine-grained Biotite-Muscovite Tonalite. The Miagliano Tonalites belong to a calcalkaline calcalkaline H-K series with high contents in LILE and HFSE. The rocks of the main body are more enriched in TiO₂, P₂O₅, Sr, Y e Zr and depleted in Rb, Ba and La with respect to the minor mass. The latter shows highly fractionated REE patterns [(Ce/Yb)_N around 13] with respect to the main mass [(Ce/Yb)_N around 6]. All samples analyzed show a weak to moderate Eu anomaly. REE patterns, spider-diagrams and Pearce element ratios suggest comagmatism with the rocks of the nearby volcano-plutonic complexes (Valle Cervo pluton, Valsessera satellite intrusives, and the calc-alkaline-shoshonitic volcanics of the cover series of the Sesia Zone). It is concluded that the above plutonic rocks likely represent the remnants of the magma chambers that were active during Oligocene times.

Key terms: Vulcanian eruptions; Island of Vulcano; Tephra fall deposits; Pyroclastic density currents; Aeolian Islands

Historical chronicles reported several eruptions at the Island of Vulcano during the ADXV-XIX centuries from the Fossa cone, the most currently active center of the island.

In this work the internal stratigraphy of all eruption of la Fossa cone (i.e. the chronology of the eruptive events), including the last eruption Vulcanian eruptions (AD1888-90, Mercalli and Silvestri 1891), was studied in detail together with the main emplacement mechanisms of both primary and reworked materials. In addition, the morphological evolution of the summit crater area of the Fossa cone resulting from these eruptions has been characterized.

Based on the analysis of the historical chronicles, the Fossa cone renewed its activity in the AD1444 with an high-energetic steam-blast eruption (Forgia 1), that occurred eccentrically with respect to the summit crater area of the Fossa cone, in its northern flank and affecting an area currently occupied by the Vulcano Porto town. This eruption "opened" a new stage of the activity of the Fossa cone, characterized by the ascent of viscous plugs of magma that powered at least 8 discrete eruptions lasted from days to years. These eruptions were mainly of Vulcanian style, including the first historically described Vulcanian eruption (AD1888-1890), but frequent steam-blast explosions occurred, generally before the onset of the main magmatic phase. One effusive phase (Pietre Cotte lava flow) characterized the long-lasting, complex eruption that occurred on AD1731-39. The erupted volume ranged between 0.001 and 0.01 km³, affecting a wide area that comprised at least the northern Sicilian coast and probably reached the Mt. Etna (De Fiore et al 1922), about 70 km far from the island.

Comparing the pre- and post-AD1888-90 topography of the summit crater area, a minimum value (0.0165 km³) of deposited material was produced. This volume approximately corresponds to 88% of the tephra volume (0.0185 km³) calculated by the methods of Bonadonna and Houghton (2005), confirming the evidence of high-deposited volume in the summit crater area during these stage of eruptions. During this eruptive crisis, the summit crater area of the volcano grew at an average rate of 0.34 m³/s in a period of ~ 20 months.

The data on emitted tephra volumes during the AD1444-1890 eruptions suggested that the Fossa cone experienced eruptions ranging between 1 and 3 in the VEI classification (Volcanic Explosivity Index, Newhall and Self 1982), without a clear evidence of waning. These data are useful for future "short-term" hazard evaluations for the Island of Vulcano, that should consider an eruption of VEI 3 as the most likely scenario. Widespread and long-lasting fallout events and lahars represent a frequent phenomenon associated to Vulcanian eruptions in Vulcano and, therefore, should be considered in a comprehensive hazard assessment of the island.

Data on the AD1444-1890 eruptions provide an opportunity to improve the hazard assessment at the Island of Vulcano and neighboring islands. In particular, the abundance of ash-rich fallout deposits associated with Vulcanian eruptions, previously interpreted as mainly associated with dilute PDCs, pose an high hazard level not only on the Island of Vulcano, linked to proximal to medial tephra accumulation, but also in the

neighboring Island of Lipari, due to the toxicity of breathable ash and potential damage to lifelines, transport networks and agriculture. Recent or on-going eruptions (e.g., Eyjafjallajökull 2010, Iceland) also have shown how moderate explosive eruptions can cause widespread damage to aviation and regional economy if combined with unfortunate wind conditions.

Key terms: Ash eruption; Eyjafjallajökull volcano; tephra studies; eruption dynamics

The 2010 eruption at Eyjafjallajökull volcano (Iceland) clearly demonstrated that mid-intensity explosive eruptions can have a large societal and environmental impact. In addition, the direct observation of the eruption confirmed the importance of studying the eruptive processes driving this type of events, often characterized by a complex sequence of eruptive phenomena which can pose problems to hazard assessment and crisis management.

Following an initial effusion of alkali basalt on the northeast flank of the Eyjafjallajökull volcano which continued from 20 March to 12 April, activity resumed from the summit caldera on 14 April, characterised by complex, sustained, explosive to mixed activity, and more evolved (trachyandesitic) magma. The first phase of the summit eruption (14 to 17 April) was initially characterised by interaction between glacial melt water from the icecap and erupting magma, and by two main pulses during which dark ash plumes were dispersed to the SE and S, reaching heights of 8-10 km. In the following phase (from 19 April to 4 May) a decrease in the intensity of the explosive activity was associated to the emission of a lava flow. Activity renewed in intensity on 5 May, when an ash-laden plume, up to 10 km in height, was continuously dispersed until 18 May. After this phase, activity progressively declined and eruption closed on 9 June.

In the frame of the PRIN 2008 AshErupt project, a collaborative work with researchers of several institutions was initiated immediately after the eruption onset, and volcanological, geophysical, geochemical and experimental data were collected by direct observations of eruption dynamics and tephra dispersal and on selected samples of the different eruption phases.

Tephra samples were collected in the field from the deposits of April 14 and 17 (the two main eruptive pulses of the first phase of the eruption), from the deposits of the mixed, explosive-effusive phase, and directly during fallout from the plume in the period 5-8 May. Ash samples were characterised by their grainsize, componentry, ash morphology and textural features of juvenile material, and time-related compositional and isotopic variations of the juvenile material were also investigated on glass and groundmass minerals. Indirect data on the volatile phase occurring in the plume were obtained from ash leaching experiments. The substantial variations observed in the analyzed parameters can be related to the eruption dynamics, from the initial phreatomagmatic activity to the prevalent magmatic-driven, final stage of the eruption. Due to the low intensity of the eruption, an important role of clast recycling was expected. In order to characterize this process, experiments on high temperature transformations on juvenile clasts were performed, highlighting the importance of this phenomenon.

Finally, information on sedimentation dynamics was derived from direct measurements of sedimentation rate and from samples collected during the 5-8 May activity, confirming the importance of ash aggregation in driving both proximal and distal sedimentation. Aggregation processes were inferred by using SEM images and leachate data on undisturbed samples. An estimate of the total grainsize distribution of the material erupted during the 5-8 May activity was also obtained by using grain size data integrated with radar satellite data.

Key terms: particle aggregation; settling velocity; tephra deposit; weak plume

The 14 April - 21 May 2010 eruption of Eyjafjallajökull volcano (Iceland) was characterized by a nearly continuous injection of tephra in the atmosphere up to 9 km above sea level with a large production of ash that was mainly dispersed towards the east and south-east reaching as far as the southern parts of Europe and causing significant damage to vegetation and various economic sectors in Iceland and a global-wide interruption of air traffic. During 4-8 May 2010 various experiments and sampling were carried out in order to investigate particle sedimentation and characteristics.

Tephra accumulation and tephra accumulation rate varied between

0.02-0.68 kg m⁻² and 0.06-7 x 10⁻⁴ kg m⁻² s⁻¹ respectively at different locations between 1.5 - 55 km from the vent and over collection periods between 600 and 8220 seconds. Associated tephra deposits show one or two populations with M_{dphi} and sorting varying between -0.9 - 4.5 phi and 0.8 - 1.2 respectively. Accumulation rate show two exponential segments with break-in-slope at about 18 km from the vent, whereas M_{dphi} shows a linear increase until about 18 km from vent reaching a plateau between 18-55 km of about 4.5 phi. Volcanic particles fell as ash clusters, coated particles, structureless pellets and liquid pellets. Nonetheless dedicated collections showed that aggregate typologies changed spatially and that a same location can be characterized by different types of aggregates. Particle and aggregate settling was investigated with the Doppler-radar PLUDIX (i.e., X-band Doppler radar designed for the detection of hydrometeors). For the first time, the PLUDIX was calibrated to transform frequency shift and power spectrum in size distribution and intensity of ash fall applying adapted inversion methods of Gouhier and Donnadieu (2008), which showed very promising agreement with observations. For three selected samples we have i) analyzed the Doppler spectrum, ii) derived the associated settling velocity spectrum by inversion, iii) calculated the grainsize distribution and iv) compared the PLUDIX-derived grainsize distribution with the grainsize distribution observed in the field. Quantitative ash cloud characteristics have also been retrieved using MSG-SEVIRI satellite measurements during May 6, 2010, which has been recorded as the most powerful episode of the April-May, 2010 Eyjafjallajökull eruption. Satellite data well complement ground-based techniques as they provide insights on the dynamics of ash cloud far from the vent (>100 km). Minimum sedimentation and sedimentation rate is ~ 24 t/s and 0.2 to 0.4x10⁻⁶ kg/m²/s respectively which is in good agreement with ground observations for that day. Typical ash concentrations calculated during this event range between 0.5 to 4 mg/m³, with 3 distinct ash radius modes of 1.2, 2.8, and 4 µm.

RADIATIVE HEAT FLUX AT STROMBOLI VOLCANO DURING 2000-2010: A DECADE OF MODIS OBSERVATIONS

COPPOLA Diego¹, PISCOPO Davide¹, LAIOLO Marco¹, CIGOLINI Corrado¹, RIPEPE Maurizio², DELLE DONNE Dario²

 2 - UNIVERSITY OF FLORENCE

Presenter e-mail: diego.coppola@unito.it

Key terms: RADIATIVE HEAT FLUX; STROMBOLI; MODIS; STROMBOLIAN ACTIVITY; EFFUSIVE ACTIVITY

A decade of night-time MODIS (Moderate Resolution Imaging Spectroradiometer) observations, has been analysed to detect and quantify the radiative heat flux of Stromboli volcano (from March 2000 to December 2010). Using an accurate background subtraction of the MODIS

signal at 4µm, we were able to discriminate two main regimes of radiative power, related to different levels of volcanic activity. Effusive eruptions (occurred on December 28, 2002 and February 27, 2007) radiated at a time averaged rate of 170 and 470 MW, respectively, which is about 1 order of magnitude higher than the mean radiative energy detected during the typical strombolian activity (~12 MW). Although during an effusive eruption the radiative heat flux is basically controlled by the lava discharge rate, we found that during the strombolian activity the energy radiated is essentially correlated with the explosive rate (number of daily explosions) detected in the crater area. In particular, during the weeks that preceded the two effusive eruptions, as well as during periods of very high explosive activity an heat flux higher than 50 MW has been measured. This was associated to sustained spattering from active vents, which eventually accompanied small lava outflow. We suggest that a MODIS-derived radiative flux of 150 MW separate the two thermal regimes (effusive and strombolian) and may be considered a threshold value that may lead to minor lava outflow or the onset of an effusive cycle. We suggest that this methodological approach may be applied in monitoring other open-system volcanoes and may contribute to improve volcano surveillance.

RECONSTRUCTING THE PALEO-TOPOGRAPHY AND PALEO-ENVIRONMENTAL FEATURES OF THE SARNO RIVER PLAIN (ITALY) BEFORE THE AD 79 ERUPTION OF SOMMA-VEUVIUS VOLCANIC COMPLEX

MAERKER Michael¹, VOGEL Sebastian²
 1 - University of Florence DiPSA

Presenter e-mail: mmaerker@unifi.it

Key terms: Sarno River Basin; Roman paleo-topography; Paleo-environment; Stratigraphical core drillings; Classification regression trees

The Plinian eruption of Somma-Vesuvius AD 79 that destroyed the ancient city of Pompeii, resulted in a nearly complete burial of the Sarno River plain. Hence, the pre-AD 79 paleo-surface and paleo-stratum of that entire landscape were conserved. To reconstruct the pre-AD 79 paleo-topography and paleo-environmental conditions of the Sarno River plain we collected, localized and digitized a total of 1,840 core drillings to gain a representative network of stratigraphical information covering the entire plain. Besides other stratigraphical data including the characteristics of the pre-AD 79 stratum, the depth to the pre-AD 79 paleo-surface was identified from the available drilling documentation. Instead of applying a simple interpolation of the drilling data, we reconstructed the pre-AD 79 paleo-surface with a sophisticated geostatistical methodology using a machine based learning approach based on classification and regression trees.

We hypothesize that past and present-day geomorphic processes are related to terrain characteristics that can be described by topographic indices (elevation, slope, curvature etc.). Hence, deposition, erosion and transport processes during the eruption of Somma-Vesuvius AD 79 were controlled by the pre-AD 79 topography. Consequently, the present-day topography reflects the ancient topography and gives valuable clues for reconstructing the ancient conditions. Therefore, a high resolution, present-day digital elevation model (DEM) was generated and a detailed terrain analysis was carried out to deduce

15 different primary and secondary topographic indices. Then, a classification and regression model was generated combining the present-day topographic indices to predict the depth of the pre-AD 79 surface. This model was calibrated with the measured depth of the pre-AD 79 surface from the drilling data. To gain a pre-AD 79 digital elevation model (DEM) the modeled depth of the pre-AD 79 surface was subtracted from the present-day DEM.

To reconstruct some paleo-environmental and paleo-geomorphological features the modeled pre-AD 79 DEM was compared with the classified characteristic of the pre-AD 79 stratum, identified from the drilling data. Hence, the paleo-coastline, the paleo-Sarno River and its floodplain, alluvial fans near the Tyrrhenian coast as well as abrasion terraces of historical and protohistorical coastlines were delineated. It is the first time that the paleo-topography and paleo-environmental features of the Sarno River basin were systematically reconstructed using a detailed database of input variables and sophisticated data mining technologies.

THE DIAPYRIC STRUCTURES OF THE "SERRA DI PARINGIANU" WELDED IGNIIMBRITE (SW SARDINIA, ITALY): A MODEL OF EMPLACEMENT.

MUNDULA Filippo¹, CIONI Raffaello², MULAS Maurizio¹

1 - Dipartimento di Scienze della Terra, Università degli Studi di Cagliari, 2 - Dipartimento di Scienze della Terra, Università degli Studi di Cagliari, - INGV, sezione di Pisa, Italy

Key terms: diapir; blister; welded ignimbrites; Serra di Paringianu; San Pietro Island

Welded ignimbrites commonly show a wide variety of rheomorphic structures. The time scale of cooling below the glass transition temperature represents the upper limit for the duration of the process of plastic deformation. The field characterization of deformational structures, coupled with the results of numerical models able to reproduce the cooling-compaction history of welded ignimbrites, allows to constrain the time scale for the development of specific rheomorphic structures and to derive the main physical properties of the ignimbrite.

The Serra di Paringianu rhyolitic ignimbrite (SEP) is the youngest major ignimbrite of the Cenozoic volcanism of SW Sardinia. It widely crops out on San Pietro and Sant'Antioco islands, while scattered outcrops are present in the Sulcis mainland. At "La Punta", north of San Pietro Island, SEP is constituted by a single cooling unit, subdivided into four eruptive units: 1) a lower unit (U1), comprising basal, dm thick, argillified fall and surge deposits, overlain by a 1.4 m thick, black ignimbrite (vitrophyre)

and by a 10-12 m thick, densely welded ($\rho = 2200 \text{ kg m}^{-3}$), red ignimbrite with parataxitic texture; 2) an intermediate lower unit (U2), comprising a 10 m thick, lithic rich, white to pink to red, partially welded

ignimbrite ($\rho = 1600 \text{ kg m}^{-3}$); 3) an intermediate upper unit (U3),

represented by a 5-6 m thick, red to pink, densely welded ignimbrite ($\rho = 2200 \text{ kg m}^{-3}$) with eutaxitic texture 4) an uppermost 4 m thick, grey-violet, partially welded ignimbrite unit (U4).

At the same locality, tens meters-sized mushroom-shaped diapiric structures (DS) and metric to decametric lens-shaped voids, (blisters) have been observed within SEP. DS are constituted by the partially welded intermediate unit (U2) intruding the upper densely welded cover (U3). DS are generally connected with their source region and their roots, characterized by vertical re-orientation of flattened purple scoriae, are placed about 8-10 m below the roof, within the U2. In plane-view, stem region is generally elongated and characterized by sub-vertical dip of the foliation planes. Cup region presents horizontal cross-sectional shape, varying from circular to elliptical to lobate. Within the cup, foliation shows an approximately concentric distribution, with dip increasing from the margins to the center. Eutaxitic structures as well as flow banding, foliations and contact-transit between the different eruptive units are mainly sub-horizontal at "La Punta". These structures deviate from their planar-horizontal character close to the contact with blister and inside and outside DS.

Blisters have horizontal, circular to elliptical, cross-sectional shape and vertical, lens to cupola cross-sectional shape. Horizontal vs. vertical dimensions ratio ranges between 3 and 4. Foliation seems to envelope completely the blisters, reproducing their shape close to the contact with them.

We present a plume-like model in which the formation of diapiric structures is triggered by the density-driven buoyant rise of partially welded lithofacies into the densely welded cover in a time scale of few months. The model of emplacement of the diapiric structures takes into account: - the rheology of the host and intruding rocks; - the textural and physical modification experienced by the partially welded lithofacies during rise; - the textural and physical modification induced in the host rock. After the vertical rise of the lighter material ceased, it started to expand laterally and degas. Diapiric structures are in fact closely associated in space to meter sized, lens-shaped voids (blisters), occurring in the upper densely welded lithofacies, interpreted as degassing structures where upward escape of gas was prevented by the impermeable nature of densely welded ignimbrite. In this case, blisters could represent gas filled voids partially fed by the degassing head of the diapires.

Key terms: fluxing; Neapolitan volcanoes; caldera resurgence; redox state

Ischia, a volcano island located 18 miles NW offshore Naples (Southern Italy), is a densely populated active caldera (last eruption 1302 A.D.). Melt inclusions (MIs) in phenocrysts of the Vateliero and Cava Nuclele shoshonite-latitude eruptive products (VI-IV century B.C.) constrain structure and nature of the Ischia deep magmatic feeding system. The volcanic rocks of Ischia bear clear evidence for CO₂ dominated gas fluxing, under very oxidized conditions, and consequent dehydration of magma portions stagnating at major crustal discontinuities. The geochemical features of the studied products make Ischia a natural borehole probing the deep physico-chemical conditions of magmas generated in a mantle contaminated by slab derived fluids largely dominated by CO₂. Volatile concentrations in MIs require gas-melt equilibria between 3 and 18 km depth. MI-based evidence for CO₂ fluxing is further supported by selective enrichment of K and related trace elements during magma differentiation. Accordingly, the budgets of magma degassing show that at Ischia there is much less magma than that needed to directly supply the amount of released magmatic fluids, thus constraining the role of CO₂ rich deep fluids in originating the volcanism and generating caldera resurgence. The acquired data, together with those from the other Neapolitan volcanoes (Procida, Campi Flegrei -CF-, and Somma-Vesuvius -SV-) show that, despite the compositional and eruptive style differences within the poorly extended Neapolitan Volcanic area, the different kinds of volcanism are mostly linked by supercritical CO₂ fluids produced by devolatilization of subducted terrigenous-carbonatic metasediment, that infiltrate the mantle wedge, generate magmas and control their ascent up to eruption. Geochemical features of Ischia and the other volcanoes reveal that the extent of fluid contamination of the pre-subduction asthenospheric-mantle was similar at Ischia, Procida, CF and SV. However, the different isotopic composition (more enriched in radiogenic Sr at Ischia, CF, SV with respect to Procida) and water amount in the source (almost double at Ischia, CF and SV than at Procida), reflect the different flow-rate of deep slab-derived fluids through the mantle wedge that, in turns, controls the amount of magma generation. The high bulk permeability below Ischia, CF and SV, determined by the intersection of regional NW-SE normal and NE-SW transfer fault systems, favours fluid upraise and accumulation at crustal levels, with consequent magma production and storage larger than at Procida, that is located along the NE-SW system.

Presenter e-mail: orsi@ov.ingv.it

Key terms: Pantelleria; Caldera resurgence; Peralkaline magmatism; Peralkaline volcanism

Pantelleria, the type locality for pantelleritic rocks, is an active volcanic field in the Sicily Channel Rift Zone, dominated by a nested, resurgent caldera. Regional tectonism and volcano-tectonism have exerted a striking control on both evolution of the magmatic system and distribution of the vents of eruptions fed by magmas of variable composition. The island is divided into two sectors by a NE-SW fault system, which likely represents a crustal discontinuity along the axial ridge of the rift. The north-western sector, affected only by NW-SE crustal structures, includes most of the exposed basaltic rocks. The south-eastern sector includes silicic peralkaline rocks. Eruption of differentiated magmas and occurrence of the nested caldera, suggest that crustal magma chambers were established in this sector, probably at the intersection of the main tectonic lineaments. The youngest caldera has been affected by resurgence through a simple-shearing mechanism. The results of geological, geochronological, volcanological and petrological studies have allowed us to re-evaluate the recent volcanic and deformation history of this caldera, including its magmatic feeding system. In particular timing of the younger-than-15ka volcanic activity, through ¹⁴C dating, chemical and isotopic composition of the erupted magmas, and location of the eruption vents have been assessed. Volcanism was concentrated in two periods of activity. It produced only pantelleritic eruptions, mostly explosive and subordinately effusive. The explosive eruptions generated prevalently pyroclastic sequences of fallout deposits, mostly in proximal facies, and only very scarce pyroclastic density current deposits. Effusive eruptions produced lava domes, many of which collapsed in the later stages of their growth and generated variably extended lava flows. The eruption vents active during each of the two identified periods of activity, were located in a specific structural position, characterised by different structures, although all related to resurgence. The erupted magmas range in composition from comenditic trachyte to pantellerite, matching the typical range of evolved peralkaline composition of Pantelleria. Both macroscopic and microscopic textural, as well as mineralogical and geochemical features that bear evidence for mingling/mixing among less and more evolved peralkaline magmas, are very common.

The results of a combined interpretation of all the data contribute to stress the intimate interplay among magmatic processes, volcanism and deformation. Such relationships have to be taken into account in any attempt to perform a volcanic hazards assessment and eruption scenarios forecasting, in case of renewal of volcanism in short-mid terms at Pantelleria.

INSTABILITY PROCESSES IN THE NEAPOLITAN VOLCANOES: EXPLOSIVE CALDERA, COLLAPSE CALDERA, RESURGENCE CALDERA, AVALANCHE CALDERA

LUONGO Giuseppe¹, CUBELLIS Elena², D'ALBORE Filomena¹

1 - Università di Napoli "Federico II"

2 - Istituto Nazionale di Geofisica e Vulcanologia - Sezione di Napoli, Osservatorio Vesuviano

Presenter e-mail: giuseppe.luongo@unina.it

Key terms: Neapolitan volcanoes; Caldera; Regional tectonics; Mechanical model; Convection process

The onset of volcanism in the Neapolitan area and the tensile tectonics of the Tyrrhenian margin of the Apennine chain have been related to the opening of the Tyrrhenian Basin, which may have resulted in horizontal asthenosphere flow giving rise, in turn, to crustal distension, local mantle upwellings and ensuing volcanism.

The last in this area could be associated with doming of the Mantle which started in the Quaternary. We hypothesize that this doming process generated radial fractures in the continental crust along three branches, equally separated by 120° angle: one branch developed in the Campi Flegrei and at Vesuvius; another along the Campi Flegrei - Island of Ischia; the third branch could be related to extinct or aborted volcanism in the Campanian Plain. The structural continuity of the volcanic activity from the Island of Ischia to the Campi Flegrei through the island of Procida and from the Campi Flegrei to Vesuvius through the eruptive centres of the city of Naples, supports our hypothesis that volcanism is confined to fractures radiating from the Campi Flegrei area. Such fracture mechanism was analyzed with analogical, analytical and numerical models in physical terms on the assumption of an elasto-plastic behaviour of the crust and with reference to "limit analysis theorems".

The focus of volcanic activity in the last 10,000 years to some nodal points as Vesuvius, Campi Flegrei caldera, Island of Ischia, permits to hypothesize that in these areas the magma volumes are much higher than in other zones along the radial fractures. The concentration of higher quantities of hot magma at these spots would facilitate the rise of additional magma from the depth, acting as a heat insulator. Thermal conditions would have stabilised the activity at the three main eruptive centres, while in intermediate zones of the radial fractures thermal conditions were less stable due to the presence of limited volumes of magma.

The obtained models provide information about the size and depth of the source, the size and shape of the caldera associated with the process hypothesized, the size of the surrounding area involved and the acting stress field together with associated deformations.

Somma Vesuvius consists of an older, repeatedly collapsed strato-volcano, currently forming the semicircular Mt. Somma caldera rim, and a more recent cone, Vesuvius, built inside the caldera. Its load onto the weak sedimentary substratum and the tensile regional tectonics induce gravitational spreading which generates volcano summit extension and basal compression. This process appears to influence the style of eruptions and the chemistry of the erupted products.

Campi Flegrei caldera is a resurgent nested caldera resulting from two main collapses related to the Campanian Ignimbrite (CI - 39 ka BP) and Neapolitan Yellow Tuff (NYT - 15 ka BP) eruptions, respectively. The quasi-time cyclicity of volcanic activity and up-down ground motion at Campi Flegrei are generally assumed to be related to successive magmatic injections from the mantle. The interpretation of the dynamics of this system does not necessarily require a new input of magma from outside. In fact these phenomena might be explained in terms of a non-linear evolution of convective cells operating at decreasing time and spatial scales to interpret the volcanic activity starting from the CI phases, through the NYT, up to Mt. Nuovo and the recent bradyseismic crisis, well schematized by the so-called Lorenz equations.

A model of caldera resurgence was applied to the Island of Ischia to explain uplift of Mt. Epomeo and avalanche caldera collapse of southern side of island, as well as historical seismicity and slow ground movements recorded for the past 2000 years. The uplifted block of Mt. Epomeo has been undergoing to dismantlement processes during the resurgence. These processes have produced a horseshoe-shaped morphology of Mt. Epomeo and large hummocky deposits.

Key terms: volcanic ash fallout; inversion problem; Vesuvius; HAZMAP model

A common problem in volcanology is the reconstruction of the eruption parameters starting from sparse measurements in the volcanic deposits (eg: deposit thickness and density, grain size distribution, etc.). The objective of the inversion procedure is the definition of the total erupted mass, bulk particle size, density and shape distribution, column height and shape, and the wind field.

The approaches to this problem are different, ranging from methods based on the numerical integration of the deposit volume to methods based on the best fit of ash dispersal models with the deposit, under different input and environmental conditions. Here a method based on the best fit of an ash transport model with the sampled deposit is presented. This method is based on the repeated simulation of the deposit using a simplified numerical model (eg: HAZMAP, Macedonio et al., 2005) under different input conditions, until a best fit with the deposit is found. This procedure is very time consuming and is not immune from risks. In fact, as in other inversion problems, different input conditions (solutions) may produce comparable fits. A typical source of the ambiguity is caused by the insufficient number of deposit samples or samples distributed in a too restricted area. This is particularly true when the procedure involves the estimation of the mass of the fine particles which mostly fall outside the sampled area of the deposit.

In this work, we present a new procedure for solving the inverse problem related to the reconstruction of tephra fallout deposits of an eruption for which only few sampling data are available.

Moreover, we present an application of the procedure to the reconstruction of the sub-Plinian 472 AD eruption of Vesuvius.

CALDERA TYPES: HOW END-MEMBERS RELATE TO EVOLUTIONARY STAGES OF COLLAPSE

ACOCELLA Valerio¹

1 - Roma Tre

Presenter e-mail: acocella@uniroma3.it

Key terms: caldera; structure; evolution

Currently proposed caldera types (downsag, piston, funnel, piecemeal, trapdoor) are mainly based on field evidence and are each viewed as end-members. An overview of recent experiments on caldera formation, under different conditions, shows remarkably consistent results and suggests four experimental stages characterized by progressive subsidence. Distinctive structural features of each stage are found in many calderas, highlighting an overall consistency. The evolutionary stages adequately explain the architecture and development of the established caldera end-members along a continuum, where one or more end-member may correspond to a specific stage. While such a continuum is controlled by progressive subsidence, specific collapse geometries result from secondary factors, such as roof aspect ratio, collapse symmetry and pre-existing faults.

Presenter e-mail: kiara_29@libero.it

Key terms: Pele's hair; basaltic activity; volcanic glass micro-textures

Pele's hair are long, thin strands of volcanic glass formed when small drops of magma are thrown into the air and spun out by the wind into long hair-like strands. In literature the origin of these thin strands of glass has been linked to lava fountains from Hawaiian basaltic eruptions. Beside the high fountaining, Pele's hair are actually found in other volcanic environments and not only as products of basaltic volcanoes. We investigated in detail Pele's hair from three different environments of formation at Hawaiian volcanoes: high fountaining, weak explosive activity and lava ocean entry (magma-water interaction) together with a 40 cm thick Pele's hair deposit recently found in the Stromboli products outcropping on the Vulcanello peninsula. Samples have been characterized in terms of micro-textural and morphological features. Pele's hair of different provenance all consist of long strands of gold sideromelane, showing variable length, from an half to tens of mm, sometimes including Pele's tears inside or at the end. Their surfaces are mostly rough, with 'ploughs' of different sizes and large cavities. Vesicles are visible in the cross sections of Pele's hair. There are two mostly size population of bubbles: one elongated, central and parallel to the axis of elongation of the hair and the other one smaller and rounded, dispersed across its cross section. Beside these common features, Hawaiian samples from the three volcanic environments have different shapes, surface textures and micro-textures. Pele's hair from Halemaumau (weak explosive activity) show the most elongated shapes, typically hair-like shaped. Instead those from Kilauea Iki (lava fountain) are the smallest and the tubbiest. A strong variability can be observed, in terms of aspect ratio: samples from lava lake of Halemaumau vent are long, with thin shapes and smooth surfaces, showing an inner channel parallel to the axis of elongation linked to bubble coalescence phenomena. Pele's hair from lava fountain are smaller than Halemaumau. They are short, with stubby shapes and rough surfaces, showing a lot of small ploughs. In the inner section vesicles seem to be mostly elongated, parallel to the axis of elongation of the fragment, maybe due to bubble coalescence, and also rounded. Instead Pele's hair from Waikupanaha 2009 eruption (magma-water interaction) show textural features intermediate between the Halemaumau and Kilauea Iki products. They have thin shapes, with rough surfaces and large ploughs. As for surface texture, their length is intermediate between the two end-members and they still show an inner channel of bubbles parallel to the elongation of the fragment. Almost all contain Pele's tears inside or even at their end. Samples from Vulcano Island closely resemble the inner shape of Pele's hair from Hawaiian lava fountain. Even if they show bigger sizes and are more stubby shapes than Hawaiians, all fragments have almost two populations of bubbles: one elongated and another one smaller and rounded, with bubble coalescence phenomena. They also show micro-phenocrysts in the groundmass that form small knots in the hair, around which the glass adapt their shape. Crystals are present also in the samples from Kilauea Iki 1959 eruption, but not in Halemaumau ones. Pele's hair from magma-water interaction even show sometimes micro-phenocrysts. All these features give inferences on the mechanism of formation of Pele's hair among the different eruptive environments. Halemaumau activity showed, at the time of sampling, passive degassing and Pele's hair formed inside the vent; Kilauea Iki 1959 eruption produced a lava fountain hundred meters high, in which Pele's hair formed at the outer side of the fountain, as well as those from magma-water interaction (2009 Waikupanaha eruption). Pele's hair from Vulcano represents a fall like deposits, and their similarity to the Kilauea Iki ones could reflect a similar origin.

Presenter e-mail: ddigenova@uniroma3.it

Key terms: viscosity; magmas; volatile-bearing; adam & gibbs theory

The rheological properties of silicate melts control fluid-dynamics of transport, eruption style and rates of physico-chemical processes (degassing and crystallization) in natural magmas. The most widely used parameterization of viscosity is the empirical three parameter Tamman - Vogel - Fulcher (TVF) equation. One of the most significant limitations of this parameterization is that it does not account for the effect of dissolved mixture of volatiles and the fact that it is an empirical function with no sound theoretical basis. In fact, no single model exists that considers the effect of composition and water, and the presence of minor volatile (CO_2 , F, Cl, Br, S-species). In this study we investigated the effect of H₂O and CO_2 on the liquid viscosity on several multicomponent systems. Viscosity measurements were carried out using a micropenetration technique on four sets of samples. Pantelleritic (Khaggiar dome, Pantelleria), trachytic (Agnano Monte Spina eruption, Phlegrean Fields), latitic (Fondo Riccio eruption, Phlegrean Fields) and trachybasaltic (Etna 1992 eruption) compositions have been analyzed over a range of water contents from anhydrous up to 5.3 wt% and CO_2 content up to 4000 ppm. Viscosity ranged from 10^6 to 10^{13} Pa s with decreasing temperature from 1100 to 630 K.

The Adam-Gibbs theory represents a reliable way to incorporate the viscosity data into a model, as it is based on strong theoretical framework which allows confident extrapolation beyond the range of conditions of the viscosity measurements. We therefore decided to fit experimental data according to the Adam & Gibbs theory in which configurational entropy (S_{conf}) is the main factor controlling the viscosity of melts. Using this theory the viscosity variation with temperature is directly correlated with the thermodynamic properties of the melts. From calorimetric measurements, and assuming that the vibrational contribution to the liquid C_p remains constant above T_g , we determined the configurational contribution to $C_{p,\text{liq}}$ and thus calculated the variation of the S_{conf} as a function of T and water content in the liquid state. Combining viscosity measurements with the configurational entropies for our liquids, we parameterized the variation of viscosity as a function of temperature and volatile content within the framework of the Adam and Gibbs theory of structural relaxation.

Presenter e-mail: silvia.gentili@alice.it

Key terms: Pyroclastic rocks; Pyroxenes; Quantitative analysis; SCXRD; XRPD

The Orvieto-Bagnoregio Ignimbrite (OBI) is a pyroclastic flow cropping out over a wide area, in the eastern sector of the Vulsini volcanic district, northern Roman Magmatic Province (Peccerillo, 2005). Emplacement age varies from 0.49 to 0.32 Ma. The juvenile components consist of pumices and scoriae ranging from trachybasalt and phonolitic tephrite to trachyte and tephritic phonolite, with potassic to ultra-potassic alkaline affinities. Geochemical and mineralogical investigations have been focused on three key outcrops of the OBI, at Orvieto, Civita di Bagnoregio and Porano. Both juvenile components and matrix have been investigated. Quantitative determination of abundances of amorphous and crystalline material was performed by Rietveld method on the bulk rocks, by using X-Ray powder diffraction data and Topas software, whereas geochemical characterization for juvenile material and single phases was obtained by EMPA and LA-ICP-MS analyses. Detailed crystal-chemistry analysis of the pyroxenes selected from juvenile components was also carried out by using geometrical data from a full three dimensional refinements with SCXRD data and chemical data from EMPA and LA-ICP-MS analysis. The main phases found in samples from all outcrops are clinopyroxene, biotite, anorthite, leucite, analcime and zeolite, in particular phyllipsite and chabazite, Cl-scapolites, REE-Si rich apatites, magnetite are common accessory minerals. Quantitative mineralogy analysis indicated large relative variations among phases, and in particular between sanidine and amorphous material. Along the Orvieto sequence, the amorphous ranges from 0.6 to 22 wt%, sanidine from 9% to 61% and chabazite from 6% to 68%. Sanidine and zeolite abundances are negatively correlated, and sanidine/ratios change rhythmically along the sequence. Texture analysis by SEM indicate that zeolite likely derives from the devitrification of volcanic glass. The variation in zeolites/sanidine content across the pyroclastic sequence indicates strong variation on the relative abundances of glass and crystal across the deposit. Such a feature was likely acquired during emplacement of the pyroclastic flow by variable degrees of loss of glassy ash material from the body of the flow via elutriation processes. Rhythmical variation of sanidine/zeolite at Orvieto suggests that the pyroclastic deposit consists of various flow units. Anticorrelation between sanidine and zeolite is also observed at Civita di Bagnoregio and Porano, but no rhythmic variations are observed in these outcrops, suggesting emplacement by a single flow unit. The clinopyroxene composition ranges from salite to Fe-salite and shows same trend of major and trace elements in three outcrops. The M2 site shows high Ca, low Na and low Mg contents, in M1 both VAl and Fe³⁺ were found. The sum R_{M1}^{3+} show an increase from pumices to scoriae. Geometrical data confirm a good correlation of M₁-O₂ distance with R_{M1}^{3+} content as found in different clinopyroxenes of potassic alkaline rocks. Similar chemical compositions and structural lattice parameters of samples from OBI indicate a common mineralogical and petrogenetic affinity. The cell and M1 volume of clinopyroxenes, suggest very low pressure of crystallization in comparison with data obtained in other magmatic province (Nazzareni et al. 2001). Incompatible element contents in juvenile clasts and clinopyroxenes show very high content in all samples as expected for this magmatic province. More detailed features of REE and trace elements distribution evidence a variation along the sequence with a decrease of the REE content moving from the bottom to the top of the Orvieto sequence, a clear indication of the chemical zoning of the magmatic chamber.

THE "UNCOMPAGHGRITIC PEGMATITE" AT SAN VENANZO VOLCANO (CENTRAL ITALY): AN EXAMPLE OF LATE CRYSTALLIZATION CONTROLLED BY FLUIDS CARRIED IN THE VENANZITE LAVA FLOW

LUCCI Federico¹, COZZUPOLI Domenico¹, BRIZZI Silvia¹

1 - Università degli Studi Roma TRE

Presenter e-mail: flucci@uniroma3.it

Key terms: Ultrapotassic volcanism; volatile compounds; Venanzite; fluids; SanVenanzo

Pian di Celle tuff rings is the major vent of SanVenanzo volcanic complex: an explosive-effusive center (<2Kmq) located 30Km NNE to the Vulsini Complex, on the western edge of Tiber Valley Graben (TVG) in an area controlled by NW-SE extensional and NE-SW transensional elements. Volcanic rocks present a kamafugitic composition (Lct+Ol+Mel+Kfs+Phl+Cpx or Venanzite) associate to a minor carbonatitic compound. Pian di Celle, defined by authors as "tuff-ring", shows a complete explosive - effusive cycle: i) initial lapilli-ash tuff sequence (surge-like stratification and subordinate fall deposits at crater); ii) a massive unwelded channelized pyroclastic deposit with coarse lapilli, bread-crust bombs and sedimentary lithics; iii) tephra beds (rich of lapilli and lava-bombs) with reomorphyc flows; iv) final production of two venanzite (VNZ) lava flows for decompressional uprise of the magma. At the head of the northern and major VNZ flow, an outcrop of macrocrystalline uncomphagrite (known as leucite-olivine-melilitolite pegmatite (PEG)) is present. Authors have defined PEG as an irregular sill body intruding, with dykelets pattern, the overlying VNZ. PEG presents a well-defined fabric, but also difficulties in definition of strikes and dips, since there is no regular structural control or correlation between injections and joints of hosting VNZ. Even if at mesoscale the contact between PEG and VNZ could appear relatively sharp, at microscale it is possible to observe a progressive almost continuous rapid texture transition from porphyric microcrystalline in VNZ to equigranular macrocrystalline in PEG.

Moreover transition is characterized by evolution of mineral assemblage: 1) normal trend of Ol+Cpx from fosterite-diopside to chrysolite-hedembergite; 2) modal content growth of apatite+phlogopite; 3) phlogopite+calcite growth along foid-phases crystal edge, and in microveins and amygdalae, following fluidal directions.

On the basis of field data and mineralogical observations, this preliminary work points on incompatibility of such texture-fabric transition with intrusive path. An afterward emplacement of melilitolite magma from a cogenetic different pulse is rather improbably owing the following arguments: 1) venanzite is a volcanic rock, and it is unlikely to have been affected by intrusive bodies after its cooling at such a shallow level, 2) no structural control of intrusion has been observed, 3) the qualitative definition of Ol+Cpx evolution demonstrated a classical continue differentiation to Fe-richer phases.

In addition, we first report here the new finding inside the VNZ, at Pian di Celle crater, of a decimetric amygdale with similar uncomphagritic composition. Considering no connection between the two melilitolite bodies, and the general amygdale geometry, again it is quite complex to explain PEG as "intrusive" event.

In this view we reinterpret PEG as product formed by crystallization of an evolved melt derived through FC of hosting venanzite magma. PEG crystallized preferentially in upper cooling fronts of the lava pond (i.e. the 20m thick head of VNZ flow, or at emission vent where a rounded scoria convolute body was produced by the effusive activity). In this view, "pegmatitic" texture was developed by relative flux-enrichment in melt (PO₄, H₂O and CO₂ generating apatite, phlogopite and calcite respectively) that inhibited nucleation and viscosity and favored the rate of crystal growth. Considering the explosive-effusive monogenetic evolution, VNZ and PEG represent the evidence of a melt system separated in two immiscible phases in which pegmatitic bodies correspond to the one enriched in hydrate and carbonatite components.

Therefore, San Venanzo Lct-Ol-Melilitolite could not only be ascribed at flux compounds in originary melt, but also define typology of volatiles that, under overpressure conditions, triggered the initial explosive activity and controlled the dispersion of pyroclastics of this monogenetic ultrapotassic center.

Presenter e-mail: mmulas@unica.it

Key terms: welded; ignimbrite; peralkaline; rheomorphic; Sardinia

The Monte Ulmus ignimbrite (15.5 ± 0.5 Ma - Morra et al. 1994) is a high-grade, low-aspect-ratio rhyolitic to comenditic ignimbrite, related to the magmatic arc activity which developed in Sardinia between 32.4 and 13.8 Ma [Lecca et al. 1997; Savelli et al. 2002, and reference therein]. The overall deposit has a thickness varying between 8 to 98 m; it is locally rheomorphic and, spreads over an area of 300 km², representing one of the last eruptive events of the Oligocene-Miocene volcanic activity in the Sulcis area (Cioni et al. 2001). About 41 stratigraphic sections, sited in San Pietro, Sant'Antioco and Sulcis-Iglesiente areas, have been studied and described. The Monte Ulmus unit is constituted by a single cooling unit and has been subdivided into four main eruptive subunits: a basal fall-out deposit followed by three welded pyroclastic flow deposits (named A, B1 and B2). Sub-unit A is a 2 to 32m thick, reddish, fine grained, high-grade, rheomorphic ignimbrite that reaches its maximum thickness in Sant'Antioco island. Sub-unit B crops out mainly in San Pietro Island and Sulcis area where it reaches its maximum thickness. It is a 3 to 52 m thick, poorly porphyritic (Qtz+Sd-bearing), high grade ignimbrite constituted by two beds (B1 and B2) separated by a sharp contact. This sub-unit is locally rheomorphic and it is characterized by a high concentration of, randomly oriented, juvenile pyroclasts of three different lithotypes, possibly related to different physical conditions of deposition. Study of physical and petrographic features are focused on 23 samples collected from three representative stratigraphic sections, characterized by different post-emplacement history (Punta Senogio - San Pietro Island, Golfo di Mezzaluna-Sant'Antioco and Matzaccara-Sulcis area). Bulk density data show different vertical trends in relation to the presence of rheomorphic structures and respect to the paleotopography at deposition. At Punta Senogio, the ignimbrite deposits are not affected by post-emplacement

rheomorphic processes and they are localized on a topographic high. Vitrophyre has bulk density values varying between 1.75 and 2.25 gr/cm³ while the bulk ignimbrite has an average value of 2.16 gr/cm³. At Matzaccara, where rheomorphic ignimbrite thickness is lower than 8 meters, bulk densities range between 1.84 and 2.10 gr/cm³, and the vertical trend shows a discontinuity at the contact between unit A and B. Instead, at "Golfo di Mezzaluna", the Monte Ulmus unit is 23 to 30 m thick and it is located on a topographic low. Bulk density values range between 1.98 and 2.35 gr/cm³. The post-emplacement rheomorphism seems to affect the bulk density trend that decrease from bottom to three-quarters of deposit and increase in the upper portion. According to Schmincke (1974), this non linear correlation between bulk rock density and welding intensity could be related to post emplacement secondary vesiculation process that can cause the inflation of the hot tuff.

CHARACTERIZATION OF THE VULCANIAN SUCCESSION OF PALISI IN PANAREA, AEOLIAN ISLANDS. IMPLICATIONS FOR THE DETERMINATION OF THE ERUPTION STYLE.

REDOLFI Marco¹; DE RITA Donatella¹

1 - Università di Roma3 Dipartimento di Geologia

Presenter e-mail: amicored@gmail.com

Key terms: Panarea; Vulcanian explosions; Palisi succession

Panarea island, located in the eastern-central Aeolian Arc (Italy), is part of the most active coastal regions of the Mediterranean Basin. Its location between the western central sector of the Aeolian Arc and the active volcano of Stromboli is critical to the comprehension of the arc volcanism. During 2002-2003, the island has experienced a phase of gas unrest, in coincidence with paroxysmal explosions of Stromboli volcano. Despite, the explosive activity of Panarea is not well known. Recent studies have testified the young age of the pumice deposits present on the island and the related explosive activity has been constrained between 31± 7 to 20 ± 2 ka (Dolfi et al. 2007) and a new scenario for the evolution of the Panarea and surrounding islets have been proposed (Dolfi et al. 2007; de Rita et al. 2008; Cimarelli et al. 2008). For these reasons the characterization and the definition of the nature of the recent Panarea explosive activity may provide a contribution to the volcanic risk evaluation of the Aeolian archipelago. We have analyzed in detail the Palisi succession interpreted as derived by tephra fallout deposited from vent plumes of Vulcanian explosions (Cimarelli et al. 2008). The succession has been sampled every 20 cm and for each level grain size and component analyses have been made. In each level, 5-10 pumice clasts have been selected to determine density and vesicularity. Chemical analysis for each level have been also performed.

Results show reasonable congruence evidencing two main pulses, each of which is characterized by a gradual increase of the pumice clast size, of the juvenile component and of the vesicularity of pumice clasts, and a correspondent decreasing of the relative densities of the pumice clasts until to reach a maximum after that all the parameters register an inversion of the trend.

Data also evidence that the second pulse had a much more violent character reaching the maximum size of pumice and lithic clasts and a higher values of vesicularity.

If the general trend of the eruption may be interpreted as related to normal vulcanian type eruptions triggered by overpressure in the conduit, the character of the second pulse seems much more compatible with the participation of an external cause. The hypothesis of magma mixing processes is therefore discussed.

3 - UNIVERSITY OF BRITISH COLUMBIA, VANCOUVER, CANADA

Presenter e-mail: avona@uniroma3.it

Key terms: Multiphase; Rheology; bubble-bearing; crystal-bearing; Monte Nuovo

Rheology of partially crystallized trachytic magmas characteristic of the second stage of activity of the 1538 AD Monte Nuovo eruption, was investigated by a series of controlled deformation rate experiments using an unconfined uniaxial deformation apparatus. The overall crystal fraction

with respect to the solid matrix is $\Phi = 0.47$. Open porosity ranges between 39 to 47%. Experiments were performed isothermally by deforming crystal- and vesicle-bearing cylindrical specimen at constant displacement rates (CDR) or at constant load (CL). Both methods produce constant strain rates measurements. The experiments were carried out at T=600-800°C and applied strain rates between 10⁻² and 10⁻⁴ s⁻¹. The measurements are in the viscous regime and show non-Newtonian shear thinning behavior. Effective viscosity in the range of 10¹⁰-10¹³ were derived. Fitting of experimental data revealed that at the investigated conditions, no yield stress was ever observed and the fitting yielded a parameterization of the flow behavior in terms of consistency K and flow index n. Brittle and ductile failure were observed at T=600°C and strain rates of 10⁻⁵ s⁻¹ and at T=800°C for the higher applied strain rate (10⁻⁴ s⁻¹), respectively.

We derived the combined effect of solid and gaseous particles by normalizing the measured multiphase viscosity (liquid+crystal+bubbles) to the viscosity of the suspending liquid. To separate the net effect of vesicles from a crystal-bearing non-porous melt with the same crystal fraction and using recent parameterization of the effect of crystal on the multiphase rheology of magmas. The results reveal that the presence of vesicles has a major impact on the rheology of magmas and can lead to a marked decrease of the viscosity. At the same time, the presence of bubbles leads to a strong decrease in the shear strength of the magma inducing local and temporal variation in the deformation regimes (viscous vs. brittle). During lava flow emplacement, this may explain the origin of the flow banding textures observed in many silicic obsidian lava flows.

MN²⁺-DOMINANT TOURMALINE FROM PEGMATITE POCKETS OF GROTTA D'OGGI, SAN PIETRO IN CAMPO, ELBA ISLAND, ITALY: A NEW TOURMALINE MINERAL?

BOSI Ferdinando¹

1 - Dipartimento di Scienze della Terra, Sapienza Università di Roma

Presenter e-mail: ferdinando.bosi@uniroma1.it

Key terms: tourmaline; new mineral species; Elba island

Mn-rich tourmalines, structurally and chemically characterized by Bosi et al. (2005), occur in a druse of aplitic dike of Grotta d'Oggi (Elba island) associated with quartz, K-feldspar, plagioclase, elbaite and schorl. Among these Mn-rich tourmalines, there is one sample (Tsl2g) which could be considered as a new species in accord with the recommendations of Henry et al. (2011). In fact, the ordered empirical formula of this sample, approximated as

is consistent with a ²Al-dominant tourmaline belonging to the alkali-subgroup 1: Na-dominant at the X position and OH+F > O²⁻ at the W position of the general formula X₃Y₂Z₆T₆O₃₆(BO₃)₃V₃W. As the content of Mn²⁺ is larger than that of 2Li at the Y position (1.34 and 1.08 apfu, respectively) and because no tourmalines have yet been documented as ²Mn²⁺-dominant, this tourmaline could be classified as a new species. As the OH and F contents at W are statistically equal, 0.39±0.16 and 0.41±0.02 (respectively), the correct name can be assigned on the basis of inverse correlation between F and Mn²⁺. As such a correlation indicates that the F content decreases with increasing Mn²⁺, the excess of O²⁻ at the

W position can be related to the substitution ²Al + ²O²⁻ ⇌ ²Mn²⁺ + ²OH rather than to ²Al + ²O²⁻ ⇌ ²Mn²⁺ + ²F. Through the former substitution, ²O²⁻ is replaced by ²OH (as well as ²Al by ²Mn²⁺) giving a composition X(Na_{0.67}^{0.30})(Mn²⁺_{1.5}Al_{0.5}Li_{0.5})₂Al₆(Si₆O₁₈)(BO₃)₃(OH)₃(²OH_{0.6}F_{0.4}) that falls in the hydroxyl subgroup with ²OH > ²F.

Minor constituents can be related to the substitutions ²Na + ²Mn²⁺ ⇌ ²X + ²Al, 2²Mn²⁺ + ²OH ⇌ ²(Al + Li) + ²F and 2²Mn²⁺ ⇌ ²(Al + Li), which would lead to the end-member composition NaMn₂Al₆(Si₆O₁₈)(BO₃)₃(OH)₃OH.

ELECTRON MICROSCOPY INVESTIGATION OF A FLOWER-LIKE MINERALIZATION ON BI-SULFOLTS FROM ALFENZA (CRODO). A NEW BI HYDRATED SULFATE?

CAPITANI Giancarlo¹, GENTILE Paolo¹, MATTIOLI Vittorio²

1 - Università degli studi di Milano-Bicocca

2 - Via Keplero 5, Milano

Presenter e-mail: giancarlo.capitani@unimib.it

Key terms: Bi hydrated sulfate; SEM; TEM

A flower-like mineralization of white, micrometre-sized crystallites, occurs on Bi sulfosalts from the Alfenza Mine (Crodo). With a standard optical stereomicroscope each single crystal is hardly resolvable. At the scanning electron microscope (SEM), the crystallites show perfect, pseudo-hexagonal, randomly oriented platelets forming a hemispheric aggregate up to several tens of microns in radius. The EDS spectra show distinct S, Bi, O peaks, pointing to a Bi sulfate (or Bi hydrated sulfate). As far as we know, only two natural phases, cannonite [Bi₂O(OH)SO₄] and riomarinaitite [Bi(OH) SO₄·H₂O], have been reported with a composition that qualitatively match the observed one. However, available physical properties for these minerals (habit, color, cleavage...) do not match with those observed in our case.

In order to solve the puzzle, few mineral aggregates were peaked up with a knife tip, dispersed in ethanol, ultrasonicated, and pipetted on a holey-carbon Cu grid for TEM analyses. Preliminary results show a Pmm projected symmetry down the pole of the pseudo-hexagonal platelets consistent with a monoclinic or orthorhombic system, 2D cell parameters = 17.2(4) and b = 15.9(3) Å, (gamma = 90°), and systematic absences consistent with a 2₁ screw along the b-axis.

A comparison of the observed electron diffractions with those simulated for (synthetic) cannonite and riomarinaitite reveals substantial differences, excluding these two phases as possible and opening to the possibility for a new mineral. Deeper investigations are in progress.

THE M. MAZZOLU QUARRY: A NEW MINERALOGICAL LOCALITY

CUCCURU Stefano¹, GAMBONI Antonio², CASINI Leonardo¹

1 - DISBEG - Università di Sassari

2 - Mineral collector

Presenter e-mail: scuccuru@uniss.it

Key terms: Pegmatite; M. Mazzolu quarry; Corsica - Sardinia Batholith
Sardinia, due to its "geo-diversity", is rich of mineralogical localities. The minerals are mostly related to hydrothermal and/or pneumatolitic processes which mainly affect the low-grade metamorphic basement and the tertiary volcanites. The minerals associated with the granites of the Corsica-Sardinia Batholith are less known for their scarce economic relevance. However, the Batholith hosts a large variety of rare minerals related to the pegmatitic stage. Recently, detailed works allowed to

discover new mineralogical sites with rare minerals (Gamboni & Gamboni, 2006). This note focuses on the M. Mazzolu quarry, a location where several species of minerals, including some rare varieties, occur because related to the chemistry and to the emplacement level of the intrusion. Among the plutons until now identified, the Arzachena intrusion is the largest. It crops out in the north eastern sector of Sardinia and has a roughly ellipsoid shape, elongated NW - SE. Recent works Casini et al. 2008, Oggiano et al. 2005) allowed to identify the bulk geometry of the pluton, as well as its internal architecture. The apical zone was identified around the M. Mazzolu area, where the magmatic flow markers describe some circular trajectories matching the inferred shape of the pluton shell. This area is characterized by widespread pegmatitic pockets, aplitic dikes, wall-rock xenoliths, and biotite schlieren. The relatively low confining pressure and the occurrence of structural traps allowed the formation of pegmatitic pockets where centimetric quartz, K-feldspar, plagioclase, and "biotite" crystals occurs. Accessory minerals are: allanite-(Ce), babingtonite, bavenite, calcite, chabazite-Ca, clinzoisite-epidote series, epidote, apatite-(CaF), fluorite, "garnet" (almandine-spessartine), goethite (resulting from the weathering of pyrite), graphite, heulandite-Ca, laumontite, magnetite, molybdenite, monazite-(Ce), muscovite, opal, prehnite, "pumpellyite", pyrite, rutile, stilbite-Ca, titanite, zircon. Kaolinite, montmorillonite and some minerals of chlorite group results as alteration products.

The apical zone of the Arzachena intrusion due to the widespread occurrence of pegmatites is a new noticeable site for the occurrence of rare minerals of naturalistic and scientific relevance.

THE GUALTERONI COLLECTION: AN INTERIM REPORT

PAGANO Renato¹, PEZZOTTA Federico¹
1 - Museo di Storia Naturale - Milano

Presenter e-mail: renpagan@gmail.com

Key terms: history of mineralogy; mineral collections; mineral dealers

A significant mineral collection was assembled by Camillo Gualteroni (1861-1908), a gentleman of means who lived in Ornica, a small town on the mountains of the Bergamo area in Northern Italy. Most of Gualteroni's acquisitions were made between 1890 and 1900. In that year Gualteroni married and soon had children, so his mineral activity was greatly reduced, although the collection was carefully preserved. Gualteroni tried to obtain a sample of all the species known at the time. His collection, which today would be considered a species collection, included more than 2,000 mineral specimens; each of them was placed in a pasteboard tray with a concise external label and a neatly handwritten label with full details inside the tray. Original dealers' labels were also saved in the tray under the specimen along with Gualteroni's own labels. The collection was preserved in the original state in the residence of the Gualteroni family for almost 120 years, and was complete with its catalogue and original letters from most of the European dealers and Italian collectors of that time. Various other significant mineralogical items (Gualteroni's books, instruments, crystal models, etc.) were also kept with the collection.

The entire mineral collection, including the original cabinets, has been purchased by the Museum of Natural History of Milan from the Gualteroni family. The specimens and their labels are now being restored and studied.

The Gualteroni holdings provide a very unusual insight in the activity of a collector of that time - a real time capsule worthy of being preserved for the future generations.

NEW MINERAL SPECIES FROM VULCANO, AEOLIAN ISLANDS, SICILY, ITALY

CAMPOSTRINI Italo¹, DEMARTIN Francesco¹, GRAMACCIOLI Carlo Maria¹, RUSSO Massimo²
1 - Università degli Studi di Milano - Dipartimento di Chimica Strutturale e Stereochimica Inorganica
2 - INGV - Sezione di Napoli, Osservatorio Vesuviano

Presenter e-mail: italo.campostrini@unimi.it

Key terms: Vulcano Island; New minerals; Crystal structure

Since 2006 Vulcano Island was the object of a joint project concerning the study of fumarole minerals of Italian volcanoes, carried out in collaboration with Istituto Nazionale di Geofisica e Vulcanologia sezione di Napoli - Osservatorio Vesuviano.

At present, the mineral species found at Vulcano are over 100; the island is the type locality for 23 species, 17 of which were discovered by us, and is the unique occurrence for 20 of them. Besides the already IMA-approved "official" species, there are at least 38 potentially new minerals currently under examination. By far the main occurrence for these minerals are the fumaroles located at La Fossa crater which provide especially halides (fluorides, chlorides) and sulfides/sulfosalts together with abundant native sulphur and boric acid; there are however other localities, which are especially rich in sulfates, a few of them very rare and interesting. Another interesting locality is the "Grotta dell'Allume", a partially collapsed cavity whose walls are completely encrusted by sulfates of different colour.

In spite of the lowering of temperature of the fumaroles with respect to 1990, our research already in 2006 provided remarkable specimens of very interesting and new mineral species. The most important of these is the thallium lead chloride hephaestosite $TlPb_2Cl_5$, and three rare fluorides such as demartinite K_2SiF_6 , knasibite $K_2Na_2[SiF_6]_2[BF_4]$, and thermessite $K_2[AlF_7][SO_4]$. As a result of further trips to the island, considerable additions to the list of new minerals were made. These include a new series of sulfohalides: demicheleite-(Cl), demicheleite-(Br) and demicheleite-(I) BISX (X = Cl, Br, I) the lead-ammonium chloride

brontesite $(NH_4)_2PbCl_5$ as well as other interesting chlorides such as panichiite $(NH_4)_2SnCl_6$ and steresite Tl_2BiCl_6 and the sulphates aiolosite $Na_2(NaBi)(SO_4)_2Cl$, adranosite $NaAl(NH_4)(SO_4)Cl(OH)_2$, and pyracmonite $(NH_4)_2Fe(SO_4)_2$. Additional species recently approved by IMA are

coassaite $(Mg_{0.5}\square)Al_2(SO_4)_2(HSO_4)F_2 \cdot 36H_2O$, alunococquimbite, $AlFe(SO_4)_2 \cdot 9H_2O$, clinometaborite, HBO_2 and adranosite-(Fe), $NaFe_2(NH_4)_4(SO_4)_4Cl(OH)_2$.

NEW FUMAROLE MINERALS AT VULCANO: LUCABINDITE

GARAVELLI Anna¹, MITOLO Donatella¹, PINTO Daniela¹, VURRO Filippo¹
1 - Dipartimento Geomineralogico, Università degli Studi di Bari "Aldo Moro", via E. Orabona 4, I-70125 Bari, Italy

Presenter e-mail: a.garavelli@geomin.uniba.it

Key terms: lucabindite; new mineral; sublimates; fumaroles; Vulcano

Lucabindite is a new As(III)-oxygen phase, with ideal formula $(K,NH_4)As_2O_5(Cl,Br)$. It was found among medium-temperature fumarole encrustations ($T=170^\circ C$) collected in 1998 during a sampling field at the "La Fossa" crater of Vulcano island, Aeolian archipelago, Italy. Individual single crystals of lucabindite are very rare. Generally it appears in aggregates of minute, hexagonal, and platy crystals of micrometer-size

(up to $70 \times 70 \times 3 \mu m$) directly deposited on the surface of the pyroclastic breccia. In places, the lucabindite aggregates appears covered by a vitreous reddish crust containing mainly sulfur and arsenic. Associated minerals are arsenolite, salammoniac and realgar.

The new phase from La Fossa crater volcano is colorless to white, transparent, non-fluorescent, has a vitreous lustre and a white streak. The calculated density is 3.679 g/cm^3 . Chemical analyses were obtained by SEM-EDS methods. The ammonium content was deduced from the K content, taking into account the $(K,NH_4)As_2O_5(Cl,Br)$ stoichiometry ($K+NH_4=1 \text{ apfu}$). The presence of ammonium was confirmed by FTIR spectroscopy. Analytical data (in wt.%) are the following: K:O 3.67-6.70 (average 5.14, σ 0.70), As_2O_5 80.52-88.84 (average 84.62, σ 2.90), Cl 1.90-5.81 (average 3.63, σ 1.41), Br 3.70-10.31 (average 6.92, σ 2.24), F 0.27-1.21 (average 0.77, σ 0.27), $(NH_4)_2O$ 1.72-3.13 (average 2.51, σ 0.35), O=F,Cl,Br -1.84, total 101.75.

The empirical chemical formula, calculated on the basis of 5 anions per formula unit, is $[(K_{0.51}(NH_4)_{0.45})\Sigma_{0.96}As_2O_5]_{0.93}(Cl_{0.46}Br_{0.40}F_{0.19})_{0.97}$. The simplified formula is $(K,NH_4)As_2O_5(Cl,Br)$; the end-member formula is KAs_2O_5Cl , which requires: K:O 10.02, As_2O_5 84.15, Cl 7.54, O = Cl: -1.71, total 100.00 wt.%. Single crystal X-ray studies showed hexagonal symmetry, space group $P6_3/mmm$, with the following unit-cell parameters: $a = 5.2386(7) \text{ \AA}$, $c = 9.014(2) \text{ \AA}$, $V = 214.23(7) \text{ \AA}^3$, $Z = 1$. The strongest reflections in the calculated X-ray powder-diffraction data [d in \AA , (I relative to 100)] are: 5.20, (100); 2.62 (66.57); 4.51, (51.64); 4.54 (30.49); 1.98 (28.01); 1.485, (20.99); 1.60 (20.28); 2.26 (18.89).

The structure of lucabindite is topologically identical to that of the synthetic compounds MAs_2O_5X ($M = K, NH_4$; $X = Cl, Br, I$) described by Pertlik (1988). It consists of neutral As_2O_5 sheets arranged parallel to (001). Each As_2O_5 sheet is formed by AsO_3 pyramids ($As-O = 1.796(5) \text{ \AA}$) connected by shared oxygen atoms. The As atoms of two neighbouring sheets point at each other and the sheets are separated by interlayer M ($= K, NH_4$) and X ($= Cl, Br, F$) atoms. The M and X atoms show hexagonal prismatic coordination with twelve oxygen atoms and twelve arsenic atoms, respectively. Refinement of the occupancy of the M site gave $K_{0.52(4)}Na_{0.48}$, in good agreement with the chemical data. Occupancy of the site X was assigned as 0.5 Cl, 0.3 Br and 0.2 F on the basis of the results of chemical analyses.

The name is in honour of Luca Bindi (1971), head of the Division of Mineralogy of the Natural History Museum of the University of Florence. Both the mineral and the mineral name have been approved by the IMA-CNMNC commission (IMA 2011-010).

Presenter e-mail: a.garavelli@geomin.uniba.it

Key terms: adranosite-(Fe); new mineral; sublimates; fumaroles; Vulcano

Adranosite-(Fe), $(NH_4)_2NaFe^{3+}_2(SO_4)_2Cl(OH)_2$, is the Fe^{3+} -analogue of adranosite and corresponds to $(NH_4)_2K_2Fe_2(OH)_2(SO_4)_2 \cdot 9NaCl$, an anthropogenic product recovered from a burning coal dump at the Anna mine near Aachen, Germany (<http://www.mindat.org/min-38898.html>). Both the mineral and the mineral name have been approved by the IMA-CNMNC commission (IMA 2011-006).

The history of the discovery of adranosite-(Fe) is curious: it was independently and simultaneously identified by the two different research groups of the University of Bari and Milano in fumarole products collected at La Fossa crater of Vulcano (Aeolian Islands, Italy) in different years and around different high-temperature fumaroles. It's a long time that the two research groups are intensively studying rare or new fumarole minerals from Vulcano so, after exchange of information, the researchers were

happy to join the results and to work together at the characterization of the new phase.

The group of the University of Milano found adranosite-(Fe), in association with thermessite, pseudocotunnite and bismuthinite, on a sample collected in 2007 from fumarole F11; the group from Bari University found the new mineral, associated with barberite, salammoniac, anhydrite, sassolite and sulphur, in a sample collected in 1996 from the intracrater fumarolized area (IC area, T = 250°C). Besides the mineralogical association, the two occurrences mainly differ for the size of the crystals: up to 0.3 mm in the 2007 sample, micrometer-sized in the 1996 material. Due to the too small dimensions of crystals deposited in 1996 a complete determination of the physical properties could be possible only in the 2007 sample, which was consequently considered and described as the holotype material. The occurrence of adranosite-(Fe) in both the fumarole deposits of 1996 and 2007 is related to the reaction of fumarole vapours with rocks crossed by the fluids rising to the surface. Adranosite-(Fe) occurs around La Fossa crater fumaroles as a spray of pale-yellow, elongated, prismatic crystals covering the pyroclastic breccia. The mineral is tetragonal, space group: $I4_1/acd$ with a 18.261(2), c 11.562(1) Å, V 3855.5(7) Å³ and Z = 8. The strongest six reflections in the X-ray powder-diffraction pattern are: $[d_{obs}$ in Å(I/I₀)(hkl)] 9.134(100)(020), 4.569(83)(040), 3.047(79)(152), 6.462(36)(220), 3.232(29)(251) and 2.156(7)(660). The average result of chemical analyses (wt.%) is: Na₂O 5.01, Fe₂O₃ 15.77, Al₂O₃ 5.11, K₂O 0.82, (NH₄)₂O 15.76, SO₃ 50.96, Cl 3.71, H₂O 2.75, -O=Cl -0.84, for a total of 99.05. The measured density is 2.18(1) g/cm³, calculated density is 2.195 g/cm³. The mineral is uniaxial (-) with $\omega = 1.58(1)$, $\epsilon = 1.57(1)$ (l = 589 nm). Using single-crystal diffraction data, the structure was refined to a final R = 0.0415 for 670 observed reflections [$I > 2\sigma(I)$]. Building blocks of the structure are FeO₆ octahedra [Fe-O in the range 1.929(1)-2.034(1) Å] and SO₄ tetrahedra, which are linked together to form spiralling chains parallel to [001], and NaO₄Cl octahedra [Na-O 2.327(1), Na-Cl 2.891(1) Å], linked together by sharing the Cl corners. The ammonium ions occupy the voids in the resulting framework and interact with the Cl ions via hydrogen bonds.

SrV₃O₇·4H₂O, A NEW MINERAL FROM MOLINELLO MINE, VAL GRAVEGLIA, EASTERN LIGURIA, ITALY

CARBONE Cristina¹, BINDI Luca², CABELLA Roberto¹, LUCCHETTI Gabriella¹
 1 - Dip.Te.Ris, Università di Genova, Italy
 2 - Museo di Storia Naturale, Sezione di Mineralogia, Università di Firenze, Italy

Presenter e-mail: carbone@dipeteris.unige.it

Key terms: Liguria; new minerals; chemical composition; crystal structure

The sample containing the new mineral SrV₃O₇·4H₂O was collected at the Molinello mine, Val Graveglia, eastern Liguria, northern Apennines, Italy. In the Val Graveglia mines, Mn ores occur as braunite-bearing layered massive lenses, and boudins near the stratigraphic base of the cherts of the "Diapri di M. Alpe" Formation, overlying ophiolitic basement [1]. Mineralizations are characterized by a braunite + quartz association equilibrated under prehnite-pumpellyite facies conditions [2,3] during the tectono-metamorphic evolution which affected both ophiolites and cherts. Hydrothermal fluid circulation along later extensional fractures, at decreasing metamorphic conditions, induced the concentration of dispersed elements such as As, Ba, Cu, Sr, and V and the precipitation of great variety of uncommon minerals. The new mineral SrV₃O₇·4H₂O was found in association with rhodonite, pyroxmangite, quartz and braunite. Electron microprobe analyses carried out on the same crystal used for the structural investigation led to the following empirical chemical formula: (Sr_{0.97}Ca_{0.02}Na_{0.01})V₃O₇·4H₂O. H₂O was calculated by stoichiometry from the results of the crystal-structure analysis and its presence was confirmed by Raman spectroscopy. SrV₃O₇·4H₂O is monoclinic, space group P2₁/m, with a = 5.313(3), b =

10.495(3), c = 8.568(4) Å, $\beta = 91.14(5)^\circ$, V = 477.7(4) Å³ and Z = 2. Its crystal structure [R = 0.0209 for 1148 reflections with Fo > 4 σ (Fo)] consists of layers of VO₅ pyramids (with vanadium in the tetravalent state) pointing up and down alternately, with Sr between the layers (in nine-fold coordination). The mean bond distance for the VO₅ pyramids (range 1.871-1.906 Å) is in excellent agreement with those observed for synthetic AV₃O₇ (A = Ca, Sr) V⁴⁺-oxovanadates [4]. Despite the fact that the hydrogen atoms were not located in the difference Fourier maps, bond valence calculations clearly indicate that three oxygen atoms belong to water molecules which assure linking between the layers. The similarities of the crystal structure of SrV₃O₇·4H₂O with that of the anhydrous mineral cavitoe, CaV₃O₇[5], will be discussed.

CHURCHITE-(ND) FIRST WORLD OCCURRENCE FROM COSTA BALZI ROSSI, LIGURIA, ITALY: CHEMICAL DATA AND RAMAN SPECTROSCOPY

BERSANI Danilo¹, CADONI Marcella², BRACCO Roberto³, BALESTRA Corrado³, CIRIOTTI Marco E.³
 1 - Dipartimento di Fisica - Università di Parma
 2 - Dipartimento Scienze Mineralogiche Petrologiche - Università di Torino
 3 - AMI - Associazione Micromineralogica Italiana

Presenter e-mail: m.ciriotti@tin.it

Key terms: Churchite-(Nd); Discreditation; Costa Balzi Rossi; First world occurrence

Monoclinic churchites (formerly "weinschekite") are members of the gypsum supergroup which includes the phosphates brushite, Ca(PO₃OH)₂·2H₂O and churchite-(Y), Y(PO₄)₂·2H₂O, the sulfate gypsum, Ca(SO₄)₂·2H₂O, and the arsenate pharmacolite, Ca(As₅+O₃OH)₂·2H₂O. A mineral, which is included in the IMA list of the valid species as Rn (renamed) was described by Podporina et al. (1983) and considered the

Nd-dominant member of the churchites. Instead the chemical data in the above paper clearly demonstrate that the natural phase ("n. 2 Nd-churchite from Kazakhstan") is only a Nd-bearing variety of churchite-(Y). So the first, and at today the only described occurrence of churchite-(Nd) is not correct and the validity of the species (based on the Podporina et al., 1983 paper) must be reconsidered and discredited. All members of the gypsum supergroup has an isotopic layer structure, the layers being parallel to (010) face. The two sheets of sulfate ions are intimately bound together by calcium ions so as to form a strong double sheet. These double sheets are separated by sheets of water molecules. Each calcium ion is eight coordinated by six O atoms belonging to sulfate groups, and by two water molecules. The arrangement of the square-antiprismatic CaO₈ groups and sulfate tetrahedra consists of centrosymmetric pairs of chains along [101]. The tetrahedral sulfate group is not regular.

Due to the paucity and the micrometric size of the elongated needle crystal aggregates a diffraction for the new find of the natural Nd(PO₄)₂·2H₂O, from Costa Balzi Rossi, Magliolo, Savona, Liguria (Italy), resulted impossible.

The two specimens in which churchite-(Nd) occurs, always on xenotime-(Y) crystals, were used, the first for chemical analysis (semi-quantitative energy-dispersive electron-microprobe analysis on unpolished crystals) and the second for a Raman spectroscopy. The analytical results demonstrate the Nd-dominance on all REE and also on Ca and Sc. The stoichiometric formula (O = 4) is: (Nd_{0.31}La_{0.11}Sm_{0.10}Pr_{0.07}Ca_{0.05}Y_{0.05}M_{0.31})S₂=1(PO₄)₂·2H₂O (where M is exactly the sum of all other REEs and Sc, Al and Fe for which the values are between 0.04 and 0.01 apfu).

The comparison with the Raman spectrum of churchite-(Y) (Frost et al., 2010) would seem to be confirmed as Nd-dominant churchite. A similar comparison is provided with the synthetic Nd(PO₄)₂·2H₂O.

Costa Balzi Rossi is a recent well known locality in which the following REE minerals were found: aeschinite-(Y), allanite-(Ce), bastnäsite-(Ce), churchite-(Y), fergusonite-(Y), monazite-(Ce), parniite-(Y), thortveitite and xenotime-(Y) (Balestra et al., 2011).

If the IMA CNMNC will recognize the invalidity of the Kazakhstan occurrence, Costa Balzi Rossi should be the type-locality of the actually first natural churchite-(Nd).

A NEW MINERAL WITH A PYROCHLORE-RELATED STRUCTURE FROM EUGANEI HILLS, PADOVA (ITALY)

CAMARA Fernando¹, NESTOLA Fabrizio², BINDI Luca³, GUASTONI Alessandro³, ZORZI Federico², PEDRON Danilo²

- 1 - Università di Torino
 2 - Università di Padova
 3 - Museo di Storia Naturale, Firenze
 4 - Museo di Mineralogia, Padova

Presenter e-mail: fernando.camaraartigas@unito.it

Key terms: new mineral; pyrochlore-related structure; Euganei Hills

The mineral was found by Mr. B. Fassina at Monte delle Basse, Euganei Hills, Galzignano Terme, Padova (Veneto, Italy) in millimetric secondary vugs of a sanidine-bearing rock. These sanidinites are xenoliths hosted by calcisilicate rocks metamorphosed by the intrusion of syenitic-gabbros. Calcisilicate rocks are formed by wollastonite, gehlenite, grolite, hibschite, kilchoanite, pectolite, rankinite and sanidine. The new mineral forms fan-shaped groups of platy crystals, a few microns in thickness, brown-orange in color, and up to one millimeter in length. Minerals associated are colorless to grey titanite and dark yellow to dark brown hibschite garnet.

Electron microprobe analyses yield the empirical formula (Ba_{1.93}Ca_{1.20}Sr_{0.53}Na_{0.25}Fe_{2.70}Li_{0.27}Nb_{2.87}Ti_{2.05}Ta_{0.07}Zr_{0.01}V_{5.70}Si_{0.50}SiO₇[(P_{0.15}Si_{0.12}S_{0.07}O)_{0.64}(OH)_{0.64}][F_{0.09}(OH)_{0.27}]_{0.36}, on the basis of (18+2x)(O,F) pfu with x = [P+S+(Si-1)] < 0.5 apfu.

Single-crystal X-ray studies show that the mineral is orthorhombic, space group $Fmmm$, with a = 7.4105(4), b = 20.675(11), c = 21.4471(11) Å, V = 3189.4(5) Å³ and Z = 8. The structure was solved using Superflip. Weighted full-matrix least-squares refinement on F² was performed using SHELXL 97. The structure consists of a framework of Nb(Ti)-octahedra and BaO₇₍₊₂₎ polyhedra sharing apices or edges, and isolated Si tetrahedra sharing apices with Nb(Ti)-octahedra and BaO₇₍₊₂₎ polyhedra. There are three Nb(Ti)-octahedra, two of them are Nb dominant and one is Ti dominant. Chains of CaO₈ octahedra extend along [100] and are surrounded by Nb-octahedra. There are channels formed by six Nb(Ti)-octahedra and two tetrahedra, or four BaO₇ polyhedra, alternating along [100]. The channels are partially occupied by [PO₂(OH)]₂ in two mutually excluding positions, alternating with fully occupied Ca(Na)O₇ polyhedral pairs. Each P atom at the P sites of the [PO₂(OH)]-groups is coordinated with two (OH) groups and two different pairs of oxygen atoms, which are mutually exclusive, depending on the P site occupancy. Therefore, in terms of formula normalization, if the P site is vacant it means that there are 17 oxygen atoms per asymmetric unit plus one (OH) group, i.e. 18 anions. An occupation of the P site of x requires 2x additional oxygen atoms present. Thus, the total amount of anions is (18+2x), being x the occupation of the P site [i.e., P+S+(Si-1)]. x cannot be > 0.5, and therefore the maximum quantity of anions is 19 pfu. The observed structure is related to the pyrochlore structure with the addition of a slab of SiTiO₃ [PO₂(OH)]_{0.25}O_{0.25}(OH)_{0.25} every 0.5 b translation parallel to [110] of pyrochlore. Other pyrochlore-related structures have been described, although they have alternate one [K-nenadkevichite (Na,K)(Nb,Ti)₂[Si₂O₇](O,OH)₂ 1.6 H₂O], two [fersmanite (Ca_{5.49}Na_{2.37}Sr_{0.08}Fe_{0.06})(Nb_{1.6}Li_{1.2})(Si₂O₇)(O,OH)₂ 1.6 H₂O], or three [Na-komarovite Na₅Ca_{0.8}La_{0.2}Ti₁₀Nb₅Si₄O₂₆F₂·H₂O] octahedra-thick (100)-pyrochlore slabs with (SiO₄) groups showing different degrees of polymerization (four-membered rings being the most frequent unit). This new structure thus represents a novel type of pyrochlore-related structure, which includes further anionic groups other than (SiO₄).

4 - Institut für Mineralogie und Kristallographie, Universität Wien

Presenter e-mail: fabrizio.nestola@unipd.it

Key terms: Veneto; New minerals; Chemical composition; Crystal structure

The sample containing the new mineral here described was found in the Trentini mine, Mount Naro, Torrebelticino, Vicenza, Italy. The mine is in the Vicentine Alps metal-bearing district, exploited for lead, zinc, and silver from ancient times. From a genetic point of view, the mineralization is linked to Mid-Triassic calc-alkaline magmatism. Hydrothermal fluids related to volcanism deposited sulfides, barite, and Fe- and Mn-bearing minerals mainly at the boundary between Ladinic volcanites and carbonates of the Mount Spitz. Oxidation and hydrothermal alteration minerals are very common [1] and are represented by sulfates, carbonates and arsenates of Zn, Pb and Cu. The new mineral described here was found in association with galena, quartz, and anglesite. Electron microprobe analyses carried out on the same crystal used for the structural investigation led to the following empirical chemical formula $Pb_2.09C1.05S1.82O_6$ (based on 6 O apfu), ideally $Pb_2(CO_3)(S_2O_3)$. The presence of both carbonate and thiosulfate groups was confirmed by Raman spectroscopy.

The crystal structure of $Pb_2(CO_3)(S_2O_3)$ consists of rods of Pb-polyhedra that extend along the [010] direction. Among such rods there are, alternatively, CO_3^{2-} and the $S_2O_3^{2-}$ groups. The latter point alternatively left and right, considering the apex occupied by sulfur as the atom giving the direction. Pb atoms are nine-coordinated with 7 oxygen atoms (Pb-O 2.41-3.18 Å) and 2 sulfur atoms (3.22-3.31 Å). In the thiosulfate group, the central sulfur is linked to three O atoms at a mean distance of 1.48 Å and to a sulfur atom at 2.03 Å, the four anions forming a very distorted tetrahedron. Carbon makes two C-O bonds at 1.25 Å and one at 1.32 Å. Bond valence sums are 1.96 (Pb), 5.60 (S1), 4.13 (C), 2.02 (O1), 2.06 (O2), 1.87 (O3), 2.11 (O4), and 1.66 (S2).

To our knowledge, the new mineral here described is the third thiosulfate-bearing mineral known to occur in Nature (after sidpietersite [2] and steverustite [3]). There are other two minerals which are reported to contain the thiosulfate group, bazhenovite, $Ca_{55}CaS_{203}6H_2O_{20}H_2O$ [4], and viaenite, $(Fe,Pb)_4S_8O$ [5]. For bazhenovite, Bindi et al. [6], studying the type-sample, did not detect the presence of the thiosulfate group either by structural analysis or spectroscopic investigations. Viaenite was only poorly characterized because of the scarce amount of material available and its very low quality.

Natural $Pb_2(CO_3)(S_2O_3)$ was found in a matrix consisting of a mixture of fine-grained minerals with a strong predominance of galena. Together with $Pb_2(CO_3)(S_2O_3)$ it is possible also to find anglesite. $Pb_2(CO_3)(S_2O_3)$ is considered to be secondary after galena. We suggest that thiosulfate formation occurred during an intermediate stage of oxidation as the assemblage moved toward complete oxidation and subsequent formation of sulfate (anglesite) with decomposition of galena.

MINIERE E MINERALI DELL'ALTO VICENTINO - I MONTI D'OROPEGORARO Sergio¹

1 - AMI

Presenter e-mail: s.pegoraro@tin.it

Key terms: Alto Vicentino; Miniere; Minerali; Amalgama; Esplosivo in miniera

In the High Vicentino, the geological area that includes the adjacent valleys of Agno, Leogra and Posina, known as the "Recoarese", is the southernmost part of the Southern Alps (Sudalpino) and differs from all areas neighboring to the emergence of the so-called "Crystalline Basement". About 230 million years ago, in mid-upper Ladinic (Triassic), intense volcanic phenomena occurred in this area which led to the deposition of acid lava, forming the rocks now outcrop in the hills that surround the Mercanti Valley (Torrebelticino, Vicenza). This volcanic activity has resulted in a rich mining area with the formation of a series of metalliferous deposits of pyrite and polymetallic sulfides.

The Repubblica Serenissima di Venezia, where the Senate was particularly interested in the search for noble minerals like gold and silver for the supply of its brand and under whose rule, in the early 400, handed the territory of Schio, exercised careful control over mining activities in the Vicenza area, increasing the investigations and funding cultivations. The periods of most mining operations by the Serenissima covered the years ranging from 1450 to 1515. In the Sixteenth Century, the clash between the Emperor Maximilian and the Venetian Republic (War of Cambrai, 1509-1518), began Venetian mining in crisis with the result that all the mines were closed one by one, deliberately, hidden or abandoned. The most important mines opened, in this period, in the mountains that surround the Mercanti Valley were named Sant'Alvise, Santissimo Nome di Dio, San Martino, San Marco, Sant'Isidoro, San Giacomo, Madonna del Rosario, etc.

In these mines it can be found native elements, oxides, hydroxides, fluorides, carbonates, sulfates, arsenates, phosphates, wolframates, molybdates, vanadates and silicates. Monte Trisa is the type locality of cerussite and montetrisaite and studies are under way on possible new species.

In the early '500, in the field of mining technology, probably for the first time in the world, in the mining district of Schio, two historic innovations were implemented: i) in 1507 the use of amalgam to separate the silver from other minerals; ii) in 1572 the use of gunpowder in order to break the rock in the tunnels.

Vannoccio Biringuccio from Siena, who lived for more than two years in the Veneto, described that in the mining district of Schio was in use a new system to separate the silver: "the amalgamation".

The merit of this novel technique is of two Veronese men, Ioannes Antonius De Mauris and Thomaso de Cusano, who, on January 19, 1507, wrote to the Consiglio dei Dieci a plea for a twenty-five years deprivation in some mines of the Schio mining district, petition granted January 30,

1507.

According to literature, the amalgamation was first introduced in Europe around 1613 in Freiberg (Saxony) by Martin Weigold; this is the prevailing version, but according to others that use began in 1627 to Schemnitz, present-day Banská Štiavnica in Slovakia.

The documentation at the Archivio di Stato di Venice confirms that, without a shadow of doubt, in December 1572 in the Schio mining district, in the mines owned by Giovanni Battista Martiniengo, the use of the gunpowder in the tunnel for break the rock was currently. Unfortunately, these two important innovations, for some unknown reason, are not reported in the major publications.

WAKEFIELDITE-(Y) FROM MONTALDO DI MONDOVÌ (ITALY): NEW DATA AND CRYSTAL STRUCTURECADONI Marcella¹, CIRIOTTI Marco E.², FERRARIS Giovanni¹

1 - Università degli Studi di Torino - Dipartimento di Scienze Mineralogiche e Petrologiche

2 - AMI Associazione Micromineralogica Italiana

Presenter e-mail: marcella.cadoni@unito.it

Key terms: Wakefieldite-(Y); New data; Crystal structure; Zircon-type structure; Montaldo di Mondovì minerali

Wakefieldite-(Y) was first reported in quartz cavities from a zoned granite pegmatite of the Evans-Lou quarry [near Lac Saint-Pierre (Wakefield Lake), Val-des-Monts, Québec, Canada] as canary-yellow to tan pulverulent masses intimately associated with hellandite-(Y), quartz, kainosite-(Y), montmorillonite, thogorummite, Y-bearing fluorapatite, fine grained xenotime-(Y) and some unidentified compounds (Miles et al., 1971). The definition was based on X-ray powder diffraction (XRPD) and spectrographic chemical data obtained from a mixture of the new mineral with quartz, hellandite, kainosite-(Y) and montmorillonite. Following the identification in the XRPD pattern by comparison with synthetic YVO_4 , the authors assigned yttrium (Y) dominance to the chemical composition of the new species. This assignment was not obvious because in the studied mixture hellandite-(Y) and kainosite-(Y) were Y-bearing species too. Other three world finds of wakefieldite-(Y) are known, but all of them are verified by microprobe SEM-EDS tests only.

Wakefieldite minerals and dreyerite represent the vanadate members of a group of minerals with zircon-type structure that includes also arsenates (chernovite-(Y)), borates (behierite and schiavinatoite), chromates (chromatite), phosphates (pretulite, xenotime-(Y) and xenotime-(Yb)) and silicates (coffinite, hafnon, stetindite, thorite, thogorummite and zircon). Wakefieldite-(Y) with composition $(Y_{0.40}Nd_{0.15}Ce_{0.15}Ca_{0.15}Th_{0.15})(V_{0.92}As_{0.08})O_4$ is now reported as small group of vitreous reddish-brown microcrystals (up to 0.15 mm in size); the rhombododecahedral garnet-like crystals were implanted on quartz-calcite matrix and associated with tilasite (or, possibly, svabite), hematite and montmorillonite, from an abandoned Fe- and Mn-ores mine located at Borgata Oberti, Montaldo di Mondovì, Cuneo, Piedmont, Italy. The mine was operated since 1855 for about one century extracting Fe- and Mn-ores (Kolitsch et al., 2011). Due to the paucity and tiny dimensions of the available material, only semi-quantitative energy-dispersive electron-microprobe analysis could be carried out on unpolished crystals. The semi-quantitative data unambiguously indicate $Y > Nd \approx Ce \approx Ca \approx Th$ and V by far higher than As; minor quantities of La and Gd were detected. X-ray single-crystal diffraction data for wakefieldite-(Y) were collected on an Oxford Gemini R Ultra diffractometer equipped with a CCD area detector (50 μ m, 40 mA;

graphite-monochromated MoK α radiation). The zircon-type crystal structure (space group $I4_1/amd$; $a = 7.2591$ Å, $c = 6.4255$ Å) has been refined ($R = 0.017$ for 175 independent reflections) using X-ray diffraction data collected on a crystal from this locality. That confirms the validity of the species which previously had been only roughly defined using an impure pulverulent sample from Wakefield Lake (Québec, Canada). The substantial (30%) joint replacement of Ca^{2+} and Th^{4+} for Y^{3+} in the present wakefieldite-(Y) expands the cell volume of pure YVO_4 and could anticipate the existence of minerals with zircon-type structure and $A^{2+}A^{4+}T^{2+}O_4$ composition.

AMMINEITE, MATLOCKITE AND POST 1944 ERUPTION FUMAROLIC MINERALS AT VESUVIUSRUSSO Massimo¹, CAMPOSTRINI Italo²

1 - Istituto Nazionale di Geofisica e Vulcanologia sezione di Napoli | Osservatorio Vesuviano, Italy

2 - Università degli Studi di Milano - Dipartimento di Chimica Strutturale e Stereochimica Inorganica, Italy

Presenter e-mail: massimo.russo@ov.ingv.it

Key terms: Vesuvius; Eruption of 1944; Fumarolic minerals; Ammineite; Matlockite

The 1944 eruption of Vesuvius began on March 18th and ended on the 29th of the same month. It was the last eruption of Vesuvius and marked the transition from an open conduit to a closed conduit state.

The eruption took place during wartime so that nobody was interested to sample fumarolic minerals before and after the eruption. The only mineralogical work was made by Parascandola (1951), but most interesting were his comments on the temperature of the fumaroles and his observations about fumarolic minerals in the period between 1947 and 1960. Parascandola indicated the presence of about ten mineral species found on the fumaroles.

As a part of a joint project concerning the study of fumarole minerals of the Italian volcanoes, carried out in collaboration with the Università degli Studi di Milano - Dipartimento di Chimica Strutturale e Stereochimica Inorganica, a systematic investigation of old fumarole mineral samples was undertaken. Two old fumarolic sites, unfortunately almost completely destroyed by man and landslides has been identified and sampled. In

these sites several Vesuvius-rare and Vesuvius-new mineral species were found, many of which were not mentioned by Parascandola, probably because of the inadequacy of the analytical instruments of the time or/and because some of these minerals could have formed later. The first site is a fumarole that was active in 1944 and has currently a temperature of 70-80° C; the second one is a fumarole with a temperature of about 100° C and the occurrence of H₂S, located at the bottom of the crater. Ammineite, CuCl₂(NH₃), is one of the most interesting minerals found; this species was recently described for the first time in a guano deposit, in contact with plutonic rocks at Pabellón de Pica in Chile by Bojar et al. (2011), therefore the finding at the fumaroles of Vesuvius represents not only the second occurrence of this species in the world, but also the first in a totally different environment. The mineral occurs in bluish crusts associated with altered tenorite, opal and artroite. Matlockite, PbFCl, was identified as colorless platy crystals up to 1 mm, together with artroite, tenorite and calcioaravaipite. Other species of great interest, new for Vesuvius, are gearksutite, hemimorphite and caledonite.

On post-eruption fumaroles the following minerals have been found: alum-(K), ammineite, anglesite, antlerite, artroite, baryte, calcioaravaipite, calcite, caledonite, cerussite, chalcocolloite, cotunnite, chrysocolla, cumengeite, erythrosiderite, fluorite, gearksutite, gypsum, halite, halotrichite, hematite, hydrozincite, linarite, matlockite, metatolite, mimetite, opal, pickeringite, salammoniac, sassolite, sulphur, sylvite, tenorite and, on the scoriae, siderazot.

Key terms: Lafossaite; Vesuvius; Thallium chloride

As a part of a joint project concerning the study of fumarole minerals of the Italian volcanoes, carried out in collaboration with the Istituto Nazionale di Geofisica e Vulcanologia sezione di Napoli - Osservatorio Vesuviano, a systematic investigation of old fumarole mineral samples was undertaken. The presence of natural thallium chloride lafossaite, first described at La Fossa crater, Vulcano Island by ROBERTS *et al.* (2006), was detected on two small samples from "Atrio del Cavallo" dated 1906 and obtained together with other fumarole material from an old collection belonging to the "Istituto Geomineralogico Italiano", a mineral-dealer society active in the '20s of the past century. In our samples lafossaite forms small aggregates or colorless cubic crystals, up to 0.05 mm, associated with realgar, dimorphite in small orange-yellow crystals, anhydrite and an unknown thallium mineral containing S, Cl, K, As. Differently from that of Vulcano, lafossaite from Vesuvius contains only small amounts of bromine. The unit-cell parameters obtained by least squares method from X-ray powder diffraction are also in good agreement with those of pure TlCl.

Presenter e-mail: maddalena.delucia@ov.ingv.it

Key terms: Museum; Somma-Vesuvio; Minerals; Osservatorio Vesuviano

The Istituto Nazionale di Geofisica e Vulcanologia, sezione di Napoli | Osservatorio Vesuviano began actions for the acquisition (by donation) of the mineral collection of Mariano Carati, Neapolitan collector of Somma-Vesuvius minerals. The collection, set up in about forty years, consists of both personal findings and acquisitions of parts of existing collections, such as the important one (60 samples) of Antonio Parascandola, who was professor of mineralogy at the faculties of Science and Agriculture at the University of Naples, and the one (27 samples) of Roberto Palumbo, a well known Roman collector, as well as of specimens got by exchange with other collectors.

The collection consists of 444 mineral specimens of great scientific value, four medallions of lava, two lava samples incorporating a coin, two cases containing thin sections of minerals, one of which belonged to Eugenio Scacchi, professor of mineralogy at the University of Naples and son of the famous Arcangelo, "the father of mineralogy of Vesuvius", and another belonged to Ferruccio Zambonini, mineralogist known throughout the world and great scholar of Vesuvius mineralogy, and other rarities from the world of mineralogy.

Samples of minerals found by Carati were collected in a period between 1970 and 1994, mostly in caves and ravines of the volcano Vesuvius. The collection includes about 130 of the 230 mineral species currently known at Somma-Vesuvius.

Extremely rare species are represented: apthitalite, avogadrite, bassanite, cotunnite, hematite, euclorine, hauyne, lazurite-lapislazuli, litidionite, magnesioferite, mallardite, millerite, rinneite, vesuvianite, and others.

Many of the Carati collection minerals are not present in the section "Vesuvius minerals" of the prestigious Museum of Mineralogy of the

University of Naples; for this reason, with this acquisition, the museum of the Vesuvius Observatory aims to become a valuable complement of the major Neapolitan museum, in the field of mineralogy. Examples of such minerals are: åkermanite, albite, artroite, chabazite-K, chrysocolla, ettringite, fluoborite, fluoro-potassicrichterite, geikelite, gismondine-Ca, hibschite, magnesite, marialite, montesommaite, natrolite, norbergite, pargasite, piypite (ex caratiite), quadridavyne, thaumasite, thortite, tremolite, zirconolite. The Museum of Vesuvius Observatory will display the collection in a permanent exhibition, in specifically made cabinets, using criteria inspired by educational and scientific needs of the museum itself, which has an audience mainly composed of middle and high school students.

Key terms: Minerals of Campania; Campi Flegrei; Roccamonfina; Fiano; gypsum-sulphurous and sedimentary formations

After the completion, in 2004, of the monography: Russo, M. and Punzo, I. (2004): I Minerali del Somma-Vesuvio, by the Associazione Micromineralogica Italiana (AMI), the authors are finishing a new book which deals with the mineralogy of the whole Campania area, excluding Vesuvius, again for the AMI.

The mentioned areas are many and many of them are of remarkable scientific interest, though always overshadowed by one of the most famous volcanoes in the world: the Somma-Vesuvius. For example, Campi Flegrei are type locality for misenite of the Grotta dello Zolfo, for marialite of Pianura, for nacholite of Stufe di Nerone and the alum-(K), dimorphite and voltaite of Solfatarà di Pozzuoli.

Other areas of interest are those of Fiano, close to Salerno, for fluoborite (ex nocerite), Roccamonfina for leucite, etc. It is a modern work, whose release is scheduled for 2013, suitable to both professionals, and collectors, and learned readers.

Presenter e-mail: robertorizzo@parcogeominerario.sardegna.it

Key terms: mineralogical heritage; abandoned mining site; Sardinia

In recent decades, the birth of Geoparks focused the need to protect and enhance the abandoned mining heritage. In the experience of the Authors, the knowledge of the mineral species in the abandoned mining sites, in terms of study and scientific disclosure, can provide a great contribution to their enhancement. In scientific and popular ambit good results were obtained in the past twenty years, which led to the definition of new mineral species and the publication of valuable monographs. This justifies the possibility of a regulated access to the collection and study of minerals in the abandoned mining areas, even to amateur mineralogists. The present study compares the increase of knowledge of the mineralogical species from some "classic" sites with others until recently nearly forgotten, precisely thanks to the collaboration between professional and amateur mineralogists.

Presenter e-mail: mauscacchetti@alice.it

Key terms: natural preserve; ophiolite; pillow-lavas; datolite

The Natural Preserve of Campotrera, in the Enza river valley (Reggio Emilia province, Northern Apennine), was established in 1999 and its management was entrusted to Canossa municipality, where the preserve is present. This Natural Preserve includes a huge ophiolitic outcrop, composed by pillow-lavas basalts and subordinately by polygenic and ophiolitic breccias.

Campotrera ophiolitic block, together with nearby Rossena and Rossenella ones, represents an ophiolite (Campotrera ophiolite) belonging to the External Ligurian Units, composed by ophiolitic slide-blocks embedded in a sedimentary melange that marks the base of flysch-like sequences of Cretaceous-Eocene age. These basalts underwent a low-grade metamorphism (oceanic metamorphism), represented by prehnite-pumpellyite to greenschist-facies assemblages. The main chemical effect of this transformation is silica liberation and calcium mobilization. In ophiolitic basalts plagioclase is transformed into albite+prehnite±epidote±pumpellyite association, clinopyroxene is partially replaced by chlorite+amphibole (actinolite) and Fe-Ti oxide phases are frequently converted into titanite. Many hydrothermal veins, up to 30 centimetres in thickness, are hosted in basalt-pillows and breccias, and here several minerals occur: datolite, calcite, prehnite and to a lesser extent natrolite, analcime, barite, hematite, magnetite. Sometimes these minerals can occur as well-faceted crystals. Indeed, Campotrera is one of the most famous places in Italy for the beauty and the size of its minerals, especially centimetric red datolite crystals. Since 2000, the SRSN has been cooperating with Canossa municipality in order to reconstruct the quarrying history of these ophiolitic bodies (Borghi

& Scacchetti, 2002) and to investigate their mineralogy. For this purpose, the SRSN established a collaboration with the University of Parma (Department of Physics and Department of Earth Sciences) and with the Department of Applied Geological Sciences and Geophysics of Leoben (Austria).

At the beginning of this collaboration, according to the Canossa municipality provisions, we sampled and then identified by micro-Raman spectroscopy the major number of mineralogical phases (Bartoli et al., 2003). Afterward, several rock samples from Campotrera ophiolite were analyzed by electron microprobe and a fluid inclusion study (Zaccarini et al., 2008) along with a crystal chemistry characterization (Rinaldi et al., 2010) were carried out on datolite crystals. Micro-Raman spectroscopy enabled the discovery of new minerals in the ophiolite, such as magnetite, pumpellyite, and hematite. The latter is present as solid micro-inclusions in datolite and analcime crystals. Thin sections obtained from a single datolite vein show a symmetrical structure with coarse grained datolite in the vein core, characterized by mosaic texture, triple junctions, and palisade-like aggregates of minute datolite crystals typically elongated normally to the contact with the wall rock.

Two-phase (L+V) fluid inclusions were observed, texturally identifiable as primary and secondary. Microthermometry analyses suggested a NaCl-H₂O system for all inclusions. The calculated salinity is in the range of 10-16 wt% NaCl equivalents. Paragenetic considerations and mode of occurrence of datolite from these ophiolitic basalts indicate that the mineral precipitated from hydrothermal fluids circulating through the ophiolitic rocks during some post-magmatic stage.

The chemical analyses show no significant site substitution. The single-crystal structure refinements confirm the structural model of

datolite previously reported (with $a \sim 4.83$, $b \sim 7.61$, $c \sim 9.63$ Å, and $\beta \sim 90.15^\circ$, space group P2₁/c).

THE HISTORY OF THE DISCREDITED MOHSITE (OF COLOMBA)

COSTA Emanuele¹, GALLO Lorenzo Mariano²

1 - Università degli Studi di Torino - Dipartimento di Scienze Mineralogiche e Petrologiche

2 - Museo Regionale di Scienze Naturali - Sezione di Mineralogia Petrografia e Geologia

Presenter e-mail: emanuele.costa@unito.it

Key terms: Mohsite; Colomba; Chrichtonite; Mineralogy; Museology

Mohsite is a discredited mineral, and is now recognized as a member (chrichtonite) of the sénéaite-chrichtonite series, but the history of its description and identification is of notable interest for the mineralogy of the Susa Valley. The authors had the opportunity to examine and investigate the samples of "mohsite" described by Colomba, an Italian eminent mineralogist, in 1902. These samples were lost during years and found again some years ago, after more than a century, in the historical mineralogical collection of the Turin University, now in the Piedmont Council Museum of Natural Science of Turin. These new analysis proves that the mohsite of Colomba has a high Sr content, and should thus be identified as chrichtonite.

Mohsite was first reported by Lévy in 1827, on material probably from the Dauphiné Region, in France. The chemical composition was unknown, and the description was mainly morphological. The original samples of Lévy was never traced again. In 1901 Lacroix found some other samples in the Haute Alpes, again in the Dauphiné. This material was not chemical analyzed because of its very small amount but, being these samples morphologically similar, they became neotype.

In 1902 Colomba found similar material from near the Dora Riparia, Oulx, Italian Alps, some ten km from the previous locality but in the Italian sector of the mountain chain. Some qualitative analysis performed at that time showed that the samples contained titanium and iron, as well as small quantities of Ca and Mg, and for this reasons Colomba identified these small black crystals as mohsite.

Kelly et al (1979) obtained a sample of Lacroix's specimen from the Museum National d'Histoire Naturelle de Paris, and they found that the main cation was Sr and so identifying the samples as chrichtonite, and in the same time discrediting the name "mohsite" due to temporal priority of the name "chrichtonite" (De Bournon, 1813).

The authors, as a consequence of the rediscover of the Colomba's samples, submitted these 1902's specimens to SEM-EDS and micro-XRF analysis, and found that the small crystals were made of a complex oxide of titanium, iron and vanadium with Sr as main bivalent cation, followed by Y and small amount of U and Yb. The formula of this oxide as mean of many analysis could be written, as (Sr_{0.9}Y_{0.7}U_{0.2}Yb_{0.1})(Ti_{13.7}Fe_{7.3}V_{0.3})O₃₈ on the basis of 38 oxygens. This formula is close matching with the one of chrichtonite (Sr,Y,U,Yb)₂₁(Ti,Fe,V)₂₁O₃₈, the Sr-bearing term of the group (the other important terms being senaite if Pb is the main large cation, davidite for REE, landauite for Na and loveringite for Ca). Thus, the mohsite of Colomba is in fact a sample of chrichtonite, and probably Colomba may have misidentified Ca with Sr in the old analysis, or these analysis were performed on dirt samples with interference from others minerals.

Key terms: FTIR spectroscopy; Hydrogen; Imaging; FPA detectors; HT-FTIR

Hydrogen can be a major, a minor or a trace constituent of a large variety of minerals. It is usually bonded to oxygen to give H₂O, OH⁻, or more rarely H₃O⁺, H₂O², H₂O⁺ units, but also NH₄⁺ or organic compounds. It can be a structural component in stoichiometric hydrates, hydroxides, and in many silicate minerals, or can be non-stoichiometrically present as a major extraframework component in microporous minerals (e.g. zeolites). Hydrogen also occur as a minor constituent in structural defects of nominally anhydrous minerals (NAMs) [1]. H exerts a strong influence on the chemical and physical properties of minerals; hence it has a controlling effect on many high-temperature geological processes (e.g. magma genesis, kinetic of phase transformations, etc.), as well as low-temperature alteration processes. Unfortunately, H is a rather elusive element, specially when it occurs in very low amounts, as in NAMs. Conventional micro-analytical techniques (EMPA) and X-ray diffraction are generally unsuitable to characterize this element; secondary ion mass spectrometry (SIMS) and neutron diffraction are not easily accessible and requires complex, time-consuming, analytical procedures. A possible alternative is offered by spectroscopy: Raman, Fourier-transform infrared (FTIR) and nuclear magnetic resonance (NMR). FTIR is particularly suitable for hydrogen, since the O-H (C-H and N-H) bond absorbs the infrared radiation very efficiently. The relatively low cost, ease of use and ease of sample preparation makes the FTIR technique an extremely powerful tool for the study of H-bearing minerals [2]. Using FTIR spectroscopy we can: a) quantify hydrogen, b) study its distribution [3], c) distinguish its speciation, d) define the structural orientation of the O-H dipole, e) study phase transitions associated with H loss, and f) study thermal processes [4]. We present here the recent developments of the FTIR activities at Roma Tre and describe the new facilities which are currently available in our laboratories (high temperature stages, Focal Plane Array detectors). We will use, as examples, the most recent results obtained by our group, including studies on beryl, cordierite, feldspaths, phosphates and hydrocarbons-bearing materials.

WATER IN ZEOLITES: RELATIONSHIPS BETWEEN THERMAL STABILITY AND ENERGETICS

CRUCIANI Giuseppe¹

1 - Dipartimento di Scienze della Terra, Università di Ferrara

Presenter e-mail: cru@unife.it

Key terms: zeolites; thermal behaviour; structural modifications; thermodynamic properties; stability index

The relation between heat and water in zeolites has attracted great interest since their discovery as 'boiling stone' minerals, being able to dehydrate reversibly. The contribution of water to zeolite thermodynamic properties has been matter of debate. In fact, it is generally assumed that zeolites are thermodynamically metastable phases. On the other hand, it has been suggested that hydrated aluminosilicate zeolites can have true stability fields near room temperature because the exothermic enthalpy of hydration more than compensates for the metastability of the anhydrous framework. Nevertheless, due to the large differences in the enthalpy values determined by different techniques, no consensus exists about the magnitude of the total energetic stabilization imparted by H₂O. In any case, zeolite thermodynamic stability is limited to T < 400-500 K by the large positive entropy of dehydration. As far as the effect of water on the thermal behavior and stability of zeolites it is known that zeolite structures subjected to dehydration by heating give rise to several intriguing phenomena from crystallographic, chemical, and physical viewpoints. Understanding the zeolite thermal stability from both the kinetic and thermodynamic standpoints is of particular importance in order to model, optimize, and design zeolite-type materials with promising performances in many fields (industry, environment, energy). As a first attempt to quantify and predict the zeolite behavior upon heating, it was recently introduced a stability index (S.I.) ranging from 1 to 5 as a function of increasing thermal stability [1]. This index displays systematic correlations with chemical composition of both the zeolite framework and extraframework (EF) cations.

The present study aims to improve the quantitative relationships established between the zeolite thermal stability index and the zeolite chemical and structural features, and to explore the possible correlations existing with the thermodynamic data taken from the literature.

The critical review of experimental data, in particular those from in situ X-ray diffraction studies, for thermally induced transformations in zeolites has been extended starting from previous work [1]. As discussed in the latter paper, several intrinsic chemical and structural factors have been suggested to control the thermal behavior of zeolites, affecting the dehydration and collapse/breakdown temperatures: i) the framework Si/Al ratio; ii) the (weighted) ionic potential (Z/r) and size of EF cations; iii) the coordination of bare cations after H₂O expulsion; iv) the framework topology. In addition, the temperature at which dehydration and structural collapse/breakdown occur can be affected by several extrinsic factors. In fact, the structural modifications occurring in the same zeolite framework can be different when heated in 'near-' or 'far-equilibrium' conditions. The present study enforces the previously found generalizations [1]:

zeolites with $Si/(Si+Al) \leq 0.6$ ($Si/Al \leq 1.3$) or/and $Z/r \geq 0.187$ always

have S.I. < 3 (poor thermal stability), while zeolites with $Si/(Si+Al) \geq 0.8$

($Si/Al \leq 4$) or/and $Z/r \leq 0.072$ are very stable (S.I. ≥ 3). The largest

group of zeolites do not show definite trends as simple functions of Si/Al and Z/r. However, the definition of a 'combined factor' which accounts for both the latter two variables plus a parameter newly introduced to quantify the ring/channel size and geometry in different zeolite topologies, greatly improves its relationship with the S.I. and allows to recognize a correlation, never reported before, with zeolite thermodynamic data.

WATER IN BERYL: A CONTRIBUTION FROM THEORETICAL CALCULATIONS AT THE AB INITIO LEVEL, AUGMENTED BY AN EMPIRICAL DISPERSION TERM

PRENCIPE Mauro¹

1 - University of Torino, Torino

Presenter e-mail: mauro.prencipe@unito.it

Key terms: beryl; water; dispersion forces; quantum mechanical calculations

Dispersion forces can be modeled by none of the *ab initio* Hamiltonians currently available, either at the purely DFT level (no matter if LDA or GGA), or at the hybrid HF/DFT one. The reason is related to the fact that DFT functionals are specifically designed to deal with *short* range electron correlation effects (dynamic correlation), whereas *long* range effects (static correlation), which encompass dispersion energy, are not taken into account [1]. It is possible to augment the *ab initio* Hamiltonian by a London type empirical term, which is parametrised in such a way to properly deal with dispersion energies [2]. The approach has been applied to the case of beryl, to model the behaviour of water inside its structural channels. Calculations confirmed previous findings which located the water molecule at the 2a Wyckoff position (Space Group *P6/mcc*), with a type I orientation having the H-H axis parallel to [001] (see for instance [3]). The calculated hydration energy (-20 Kcal/mol) is in reasonable agreement with experimental measurements (-13 Kcal/mol, [4]). The activation energy for the diffusion of the molecule through the structural channels has also been calculated, and it amounts to 38 Kcal/mol: a result which is not far from the experimental datum of 32 Kcal/mol [5]. The approach can thus reliably be used to model the position of the water molecule in minerals, and the involved hydration energy, even in cases of weak bindings of dispersive type.

DEHYDRATION AND REHYDRATION OF BIOTITE DURING ANATEXIS: CONSTRAINTS FROM MICROSTRUCTURALLY-AIDED SIMS ANALYSIS OF HYDROGEN

CESARE Bernardo¹, MELI Sandro², CRUCIANI Giuseppe³, SILVESTRI Mirko³, VALERIANI Lorenzo²

1 - Geoscienze, UNI-Padova

2 - Scienze della Terra, UNI-Parma

3 - Scienze della Terra, UNI-Ferrara

Presenter e-mail: bernardo.cesare@unipd.it

Key terms: anatexis; biotite; dehydroxylation; SIMS

The SIMS-based study of Ti-H relationships in biotite during the prograde and retrograde phases of HT metamorphism and anatexis (Cesare et al., 2008) has been expanded with the addition of three new case studies that help providing a coherent scenario for metapelitic rocks. Two of the three sample suites are enclaves or xenocrysts in lavas, which have been demonstrated to be the ideal setting for the preservation of the primary composition of biotite from high-grade anatectic metapelites (Cesare et al., 2003).

In a Spl-Crd enclave from El Hoyazo, Spain (Alvarez-Valero et al., 2005) biotite shows TiO₂ contents ranging from 2.5 to 7.5 wt.%. The Ti contents are microstructurally controlled: small biotite inclusions in the core of garnets have the lowest contents, whereas the coarser grained crystals toward the garnet rims have the highest. Biotite in the matrix outside garnet shows intermediate Ti contents. Like in the samples of Grt-Bt-Sil enclaves from the same lavas, the measured H contents are negatively correlated with Ti along a trend that provides further support to the Ti-oxy exchange. Furthermore, the decrease of H₂O contents from 4 to 2.5 wt.% show the progressive dehydroxylation of biotite associated to the growth of garnet which records the development of partial melting of the rock with increasing temperature.

Biotite inclusions have been studied also in garnet and cordierite xenocrysts and in enclaves of the Crd-bearing lavas from Lipari (Aeolian arc, Italy; Di Martino et al., 2011). Here the range of Ti contents (3 to 11 wt% TiO₂) includes the highest reported values in the literature, whereas analysed H contents include the lowest (from 1.9 down to 0.2 wt.% H₂O). These data extend the occurrence of a Ti-oxy exchange to Ti contents not previously investigated. In addition, they suggest that the (OH+F+Cl) content of extremely Ti-rich biotites may decrease to almost zero.

The third case study is represented by the metapsammite granulites (*leptynites*) of the Kerala Khondalite Belt (India), in which Cesare et al. (2008) suggested the occurrence of retrograde hydroxylation and fluorination during the slow cooling of these regional anatectic rocks. SIMS

profiles at high spatial resolution (1.8 μm spot size, 2-4 μm scan step) combined with EMP traverses demonstrate that H, Ti, Fe, Mg, and F

diffusion profiles are preserved in the outermost 50 μm of biotite in contact with garnet. These patterns indicate an increase of H, F and XMg, and the simultaneous decrease of Ti, in accordance with an inverse Ti-XMg relationship and the Fe-F avoidance.

The new data integrate and confirm previous findings or inferences, showing that:

- Ti-oxy is the dominant exchange mechanism over the entire TiO₂ range so far investigated in biotite from metapelitic rocks;
- during prograde heating and continuous melting biotite is progressively dehydroxylated mainly through Ti uptake, until it may eventually become OH-free;
- in most granulites and migmatites the halogen and hydrogen contents of micas are probably increased by retrograde diffusion, and biotite may

preserve evidence of such reequilibration in thin (a few tens of μm) rims at the contact with garnet.

THE TEMPERATURE BEHAVIOUR OF WATER IN LEUCITE

DELLA VENTURA Giancarlo¹, BELLATRECCIA Fabio¹

1 - Università Roma Tre

Presenter e-mail: dellaven@uniroma3.it

Key terms: leucite; nominally anhydrous minerals; FTIR; thermal behaviour

Naturally leucite crystallizes in the cubic phase, with space group *Ia3d* (Pearce, 1968). On cooling below $T = 625^{\circ}\text{C}$ it undergoes a phase transition to a tetragonal *I4/a* form (Mazzi et al. 1976); there are indications, however, that an additional tetragonal phase is stable over a narrow temperature interval (Lange et al. 1986). Palmer et al. (1997) have shown that the displacive phase transition to tetragonal symmetry is due to twisting of tetragonal prisms of corner-linked (Al,Si)O₄ tetrahedra about [001] and a collapse of the [111] structural channels with concomitant volume reduction. Although nominally anhydrous (NAM), leucite typically contains significant amounts of water; this feature was reported for samples from Roccamonfina (Balassone et al., 2006) and the Alban Hills volcano (Della Ventura et al., 2008). Della Ventura et al. (2008) have shown in addition that H₂O may be significantly zoned, thus providing a potential tool to monitor the evolution of the magmatic conditions with time. More recently, Martucci et al. (2011) studied the dehydration of synthetic B-substituted leucite (KB₅SiO₈) by synchrotron powder diffraction and concluded that the structural modifications accompanying the tetragonal - cubic transition is associated with the migration of H₂O molecules through the [111] channels.

We relate here a single-crystal high-T in situ FTIR study of a set of natural inclusion-free leucite phenocrysts occurring within lava flows, pyroclastic rocks or ejecta in the Roman Comagmatic Province. The spectra show broad absorptions in the 4000-3000 cm⁻¹ region consisting of overlapping components around 3604, 3500 and 3250 cm⁻¹. Interestingly, two different types of spectra are observed in the H₂O stretching region, indicating that water molecules may be trapped in leucite in two different environments (hereafter "type I" and "type II"). These different H₂O types are systematically associated with samples from different volcanic areas, thus suggesting a possible role of the petrological conditions (pressure, temperature) of crystallization on the H₂O entrapment in leucite.

FTIR-FPA images show significant H₂O zoning across the samples; crystals with homogeneously-distributed water were selected for the dehydration experiments, done using a Linkam T600 heating stage fitted under a NicPlan FTIR microscope at University Roma Tre. The evolution of the water loss as a function of T was monitored by measuring the principal H₂O water absorption. The data indicate a continuous water loss with a break in the trend; in "type I" leucite the slope change occurs at ~ 500°C, and dehydration is complete at T > 600°C, probably close to the transition temperature. In "type II" leucite, the slope change occurs at ~ 350-400°C, and dehydration is complete at ~ 500°C. This behaviour is compared with isostructural materials like analcime or pollucite.

THE QUANTITATIVE ANALYSIS OF H₂O AND CO₂ IN CORDIERITE USING SINGLE CRYSTAL POLARIZED-LIGHT FTIR MICROSCOPY

RADICA Francesco¹, BELLATRECCIA Fabio¹, DELLA VENTURA Giancarlo¹,

CAVALLO Andrea², CAPITELLI Francesco³, HARLEY Simon⁴

1 - Dipartimento di Scienze Geologiche, Università degli Studi RomaTre, Roma

2 - Istituto Nazionale di Geofisica e Vulcanologia, Roma

3 - Institute of Crystallography, CNR, Bari

4 - School of GeoSciences, University of Edinburgh

Presenter e-mail: fradica@uniroma3.it

Key terms: Cordierite; Volatiles; FTIR; Microspectroscopy

Cordierite is a unique case of a microporous mineral stable under geological conditions spanning from the amphibolite facies to UHT metamorphism to crustal anatexis (Harley et al., 2002; Bertoldi et al., 2004). Because of its structural channels, it is able to trap H₂O and CO₂ (Armbruster and Bloss, 1980), and for this reason the analysis of the volatile constituents of cordierite may help constraining the geological conditions and the composition of coexisting fluids during its formation (Vry et al., 1990; Harley et al., 2002). It follows that the quantitative evaluation of the channel constituents is crucial in petrologic studies. We address here this point by studying, using a multidisciplinary approach, a set of cordierite samples from different occurrence and with different H₂O/CO₂ content. The aim of the study was a calibration of reliable absorption coefficients to be used for the quantitative microanalysis of H₂O and CO₂ in cordierite based on single-crystal polarized-light FTIR spectroscopy. The specimens were fully characterized by a combination of techniques including optical microscopy, single-crystal X-ray diffraction, EMP (electron micro probe), SIMS (secondary ion mass spectrometry), and FTIR

spectroscopy. All cordierites are orthorhombic *Cmm*; the 2V_∞ optic axis angle is linearly related to the CO₂ content. According to the EMP data, the Si:Al ratio is always close to 5:4; X_{Mg} ranges from 76.31 to 96.63 and additional octahedral constituents occur in very weak amounts. Extraframework K and Ca are negligible, while Na may reach values as high as 0.84 apfu. SIM spectrometry shows H₂O up to 1.52 and CO₂ up to 1.11 wt.%. Optically transparent single-crystals were oriented using a spindle-stage and examined under polarized light. On the basis of the literature data and the polarizing behaviour, the observed bands were assigned to water molecules in two different orientations and to CO₂ molecules in the structural channels. The spectra also show the presence

of ^{13}C and ^{18}O , and weak amounts of CO in the samples. FTIR imaging

done using the novel FPA detector system clearly shows that at a μm -scale the distribution of H and C in this mineral may be significantly inhomogeneous, and this must be taken into account when collecting analytical data for petrological purposes. This feature is probably less important for carbon molecules than it is for H_2O , whose distribution within the crystal can be strongly affected by the geological history of the mineral after its formation.

TI-GARNETS: INVESTIGATION BY EPMA, SIMS, SCXRD AND MÖSSBAUER SPECTROSCOPY AND QUANTIFICATION OF THE HYDROGARNET COMPONENT

SCHINGARO Emanuela¹, SCORDARI Fernando¹, LACALAMITA Maria¹, OTTOLINI Luisa²

1 - Dipartimento Geomineralogico, Università degli Studi di Bari, I-70125 Bari (Italy)

2 - CNR-Istituto di Geoscienze e Georisorse, Sezione di Pavia, I-27100 Pavia (Italy)

Presenter e-mail: schingaro@geomin.uniba.it

Key terms: Ti-rich garnets; crystal chemistry; SIMS; substitution mechanisms; hydrogarnet component

Ti-garnets commonly occur as accessory phases in silicocarbonatite and carbonatitic rocks. They are believed to be tracers of magma evolution [1, 2] and the speciation of Fe and Ti is of relevant petrological interest [3, 4]. In Ti-garnets, hydrogen may be incorporated via the hydrogarnet substitution, where a SiO_4 unit may locally be replaced by a H_2O_4 tetrahedron. However, more complex mechanisms have also been proposed [5]. In the present work, a crystal chemical study was undertaken on a suite of Ti-bearing garnets of different origin (igneous and metamorphic). The garnet samples underwent multiple technique investigation, which consisted in the combination of chemical (EPMA, SIMS), structural (SCXRD) and spectroscopic (Mössbauer) techniques. In particular, SIMS has been used to analyse hydrogen (quantified conventionally as H_2O , wt%), fluorine and lithium. Salient chemical analytical data (wt%) are: CaO (31.34 - 33.23), FeO_{tot} (18.01 - 20.53), Al₂O₃ (0.86 - 2.46), TiO₂ (5.57 - 17.10), ZrO₂ (0.01 - 2.87), SiO₂ (25.70 - 32.89). SIMS investigation yielded: H₂O 0.091(7) - 0.46(4) wt%; Li 11.3(1.6) ppm; F 42(8) - 483(28) ppm. Mössbauer analysis provided spectra with different complexity, which could be fitted with a number of components variable from one ($^{57}\text{Fe}^{3+}$ (Y)) to five ($^{57}\text{Fe}^{2+}$ (X), $^{57}\text{Fe}^{2+}$ (Y), $^{57}\text{Fe}^{2+}$ (Z), $^{57}\text{Fe}^{3+}$ (Y), $^{57}\text{Fe}^{3+}$ (Z)). However, the $^{57}\text{Fe}^{2+}$ (Z) component has been

reinterpreted by some authors ([6]) as due to $^{57}\text{Fe}^{2+}$ (Y) \rightleftharpoons $^{57}\text{Fe}^{3+}$ (Z) electron hopping. From X-ray data, such garnets were expected to have tetrahedral substitutions and a hydrogarnet component. FTIR preliminary spectra in the OH⁻ stretching region evidenced that the samples were characterized by various degrees of hydration.

The comparison with data obtained by X-ray site scattering refinement and Mössbauer spectroscopy allowed to ascertain that the combination of $^{57}\text{Ti}^{4+}/^{57}\text{M}^{3+}$ ($^{57}\text{Fe}^{3+}/^{57}\text{Si}^{4+}$ (schorlomite substitution) and $^{57}\text{M}^{2+}/^{57}\text{Ti}^{4+}/^{57}\text{Fe}^{3+}$ (morimotoite substitution), with $\text{M}^{3+} = \text{Fe}^{3+}$, Al^{3+} , and $\text{M}^{2+} = \text{Fe}^{2+}$, Mg^{2+} , Mn^{2+} , can explain most of the chemical variation of tetrahedral and octahedral sites.

In our samples the hydrogen is incorporated uniquely via the hydrogarnet substitution. In all cases excellent agreement was found between charge balance and SIMS determined OH⁻ groups per formula units (g.p.f.u.). Specifically, in igneous garnets samples the OH⁻ content ranges from 0.08 to 0.20 g.p.f.u. Out of the two metamorphic garnets considered, one has low OH⁻ content (0.05 g.p.f.u.), while the other has the highest OH⁻ content of the suite (0.26 g.p.f.u.). Fluorine was considered as OH⁻ substituent following the recent literature [7].

PROBING THE DYNAMICS OF MATTER BY TIME-RESOLVED DIFFRACTION WITH SYNCHROTRON RADIATION: STATE-OF-THE-ART AND TRENDS

CRUCIANI Giuseppe¹

1 - Dipartimento di Scienze della Terra, Università di Ferrara

Presenter e-mail: cru@unife.it

Key terms: X-ray diffraction; synchrotron radiation; non-ambient conditions; time-resolved studies; transient states

The intense, tunable and highly collimated synchrotron X-ray sources have opened the possibility to investigate the dynamics of condensed matter under perturbed states (e.g. chemical gradients, magnetic or electrical fields, etc.) or at non-ambient conditions (increasing temperature or pressure). In particular, time-resolved X-ray scattering experiments performed at in situ conditions are increasingly attracting the interest of crystallographers, chemists, physicists, Earth and material scientists. The paramount importance of recording transient and non-quenchable states

of perturbed matter in order to obtain a deep understanding of its properties is documented by a selection of recent studies performed by 'in situ' time-resolved diffraction in order to follow processes in a continuous way at different time-scales (from hours, to minutes, to seconds, to picoseconds). Among those, the study of the structural modifications upon heating of zeolites and zeolite-like microporous materials in far-from-equilibrium conditions has allowed to shed light on water confinement and diffusion processes, and to discover phenomena like the 'trap door' and 'molecular gate' effects which are exploited in ton-scale industrial applications. Similarly the 'breathing effect', recognized by time-resolved diffraction experiments in the new class of metal-organic frameworks, makes these materials very promising for hydrogen and carbon dioxide storage/capture. The structural tracking of molecular reactions or electronically excited states in solution, with time-scale of pico-seconds, has been achieved in a number of systems by the pump-probe time-resolved X-ray scattering experiments performed at synchrotron light sources. All the above studies show that there is still plenty of justification to design and build synchrotron radiation beamlines dedicated to multimodal time-resolved experiments. These stations will fruitfully complement the forthcoming free-electron laser based instruments.

Key terms: Co-spinel; raman spectroscopy; Cr-spinel

Raman spectroscopy, like other spectroscopies, provides a mean to investigate the local environment in different crystallographic sites. This is useful when the local structure in solid solution has to be investigated. In the case of spinels, it was observed by changes in UV-VIS-NIR absorption spectroscopy of Cr (Halenius et al. 2010) that only partial relaxation occurs at the Cr site in solid solutions along the join MgAl_2O_4 - MgCr_2O_4 . It is expected that such feature should be apparent also from Raman spectra, and likely found in several spinel solid solutions involving transition elements. We have therefore undertaken Raman analysis of twelve synthetic spinels of the series MgAl_2O_4 - MgCr_2O_4 and ten of the series MgAl_2O_4 - CoAl_2O_4 . The spinels were previously analyzed by electron microprobe. Raman spectra were collected with a Jobin Yvon LabRam micro-spectrometer using two different laser wavelengths. A 632.8 nm He-Ne laser was used for the samples with high Cr content, while in the samples containing Co and in those with the lower Cr content the spectra were recorded with a 473.1 nm wavelength from a solid state laser, to avoid the fluorescence. The spectral resolution was about 2 cm^{-1} at 473.1 nm and 1.5 cm^{-1} at 632.8 nm. The laser power on the sample was selected by inserting a neutral density filter to avoid heating effects (2-5 mW).

Along the MgAl_2O_4 - MgCr_2O_4 series a marked change in intensity and position of the Raman peaks is observed. A peak at 410 cm^{-1} is evident in the Al richest portion of the series and disappears at about the 50% of the series (corresponding to Cr 1.00 atoms per formula unit, apfu): according to the existing literature, it is ascribed to Al ion bending (Cynn et al., 1992). A peak at 685 cm^{-1} dominates the Cr richest portion of the series and increases its wavenumber with a step by 15 cm^{-1} up to 730 cm^{-1} for Cr decreasing and sample composition approaching Cr 0.70 apfu (that is, corresponding to Al:Cr ratio of 2:1). Furthermore, another signal at about 650 cm^{-1} appears in intermediate compositions only. The observed sudden change in the peak at 650-730 cm^{-1} is likely related to a change in the O site local environment, represented by one tetrahedron and three octahedra. Given that the tetrahedron is (almost completely) centered by Mg, the observed Raman spectra modifications must be ascribed to the progressive substitution of Al by Cr in the octahedra. Along the MgAl_2O_4 - CoAl_2O_4 two distinct profiles of Raman spectra may be observed. Up to intermediate compositions the spectra show the peaks at 410 cm^{-1} , 670 cm^{-1} and 770 cm^{-1} , typical of the spinel s.s. (Cynn et al., 1992), whereas in the Co-richest region all spectra have a Raman band at ca 530 cm^{-1} which is attributed to the Co-O stretching vibration (Kock and De Waal, 2007). This trend is due to both compositional change

($\text{Co}^{2+} \rightarrow \text{Mg}$ substitution) and cation distribution. Indeed Co^{2+} strongly prefers the tetrahedral coordination with respect to Mg and only starts to disorder into the octahedrally-coordinated sites after 50% of the series. CATION DISTRIBUTION AND OPTICAL PROPERTIES OF MGAL₂O₄-COAL₂O₄ FLUX-GROWN SINGLE CRYSTALS

D'IPPOLITO Veronica¹, ANDREOZZI Giovanni B.¹, BOSI Ferdinando¹, HÄLENIUS Ulf²

1 - Sapienza Università di Roma, Italy

2 - Swedish Museum of Natural History, Stockholm, Sweden

Presenter e-mail: veronica.dippolito@uniroma1.it

Key terms: cobalt-spinel; cation distribution; optical absorption; blue colour

Co-spinels are important compounds for many different uses as ceramic pigments, catalysts, and gemstones. Studies of cation distribution in these spinels are of considerable interest for a better understanding of relationships between structure and physical properties (such as colour). Spinel single crystals having different compositions along the MgAl_2O_4 - CoAl_2O_4 series were synthesized by flux growth method with $\text{Na}_2\text{B}_2\text{O}_7$ as solvent. Low cooling rates (2°C/h) and linear temperature profiles were applied in the temperature interval 1200-800°C, and a continuous flow of CO_2 -H₂ in the ratio of 100/4 cm^3/min was adopted to obtain a reducing atmosphere (with the oxygen fugacity ranging from 10^{-8} to 10^{-15} bars at 1200 and 800 °C, respectively). Selected crystals were analysed by single-crystal X-ray diffraction (CCD detector), electron microprobe and

optical absorption spectroscopy. The crystals obtained were found to be chemically homogeneous, with the Co^{2+} content ranging from 0.06 to 1.00 atoms per formula unit, and varied in colour from light blue to intensely dark blue with increasing Co^{2+} content. The progressive substitution of Co^{2+} for Mg causes a large increase of tetrahedral bond length (from 1.919 to 1.944 Å), which is responsible for the observed increase of both unit cell parameter (from 8.079 to 8.100 Å) and oxygen positional parameter (from 0.2622 to 0.2635). Optimized structural formula show that the cation inversion between tetrahedrally- and octahedrally-coordinated sites is directly correlated with equilibration temperature. At the constant temperature of 800 °C, the inversion degree decreases from 0.23 to 0.14 with increasing Co^{2+} content. With respect to Mg, Co^{2+} shows a higher preference for tetrahedral coordination, and its site preference for octahedral coordination (e.g., ${}^{\text{V}}\text{Co}^{2+}/\text{Co}^{\text{VI}}$) increases from zero to 0.14 with increasing Co^{2+} content. The optical absorption spectra, measured between 4000 and 35000 cm^{-1} , show a set of three bands at ~ 4300 , 7200 and 17,000 cm^{-1} marking spin-allowed electronic d-d transitions of Co^{2+} in tetrahedral coordination. The absorption bands of Co^{3+} are absent, in agreement with the highly reducing conditions imposed during crystal growth. The observed transitions are due to Co^{2+} in tetrahedral coordination, and are the only responsible for the characteristic blue colour of cobalt spinels.

Key terms: synthesis; spinel; cuprospinel; solid-solution; spectroscopy

This work aims at exploring the character and mechanisms of structural relaxation in minerals, through a detailed spectroscopic study of the real structure and compositional dependence of T-O and M-O bond distances of Cu centered TO_4 and MO_6 polyhedra in synthetic spinel-cuprospinel single crystals.

Large (up to mm-sized) spinel single crystals with variable composition in the binary $\text{Mg}_{(1-x)}\text{Cu}_x\text{Al}_2\text{O}_4$ were synthesized by the flux-growth method. This method employs a mixture of nutrient oxides (MgO , Al_2O_3 and CuO , in this case) and $\text{Na}_2\text{B}_2\text{O}_7$ as flux compound as starting material, which was put in a Pt crucible. The synthesis experiments were conducted in air in a muffle furnace. The temperature was first raised to 1200°C and then left constant for 24 hours, to allow complete dissolution of the nutrient oxides and homogenization of the melt. The temperature was then decreased by 4°C/hr down to 800°C, and subsequently cooled more quickly to ambient conditions. The proportions of the nutrient oxides and the flux compound were changed in order to obtain spinel single crystals of different compositions, aiming to cover the entire range between the two end members spinel *stricto* MgAl_2O_4 and cuprospinel CuAl_2O_4 . Up to now, we have successfully synthesized single crystals in the $\text{Mg}_{(1-x)}\text{Cu}_x\text{Al}_2\text{O}_4$ series with nominal compositions in the range $x = 0 - 0.7$. Single crystal optical absorption spectroscopy in the UV/VIS-NIR spectral range confirms that Cu actually entered the crystal structure. Furthermore, the optical absorption spectra demonstrate that Cu^{2+} is present in both T and M sites of the spinel structure, with a strong preference for the T sites. Absorption bands, resulting from spin-allowed electronic d-d transitions in Cu^{2+} at T and M sites, were observed at $\lambda = 6900 \text{ cm}^{-1}$ and $\lambda = 13900 \text{ cm}^{-1}$, respectively. The intensity of these bands increase with the Cu content of the spinel. The crystal field splitting energy for Cu^{2+} at the tetrahedrally coordinated T site is predicted by ligand field theory to correspond to 4/9 ($\lambda = 0.44$) of the splitting energy for octahedrally coordinated Cu^{2+} at the M site. Considering that Cu^{2+} -O distances are somewhat shorter than M-O distances in Cu-substituted spinel, the experimentally derived value of 0.49 is in excellent agreement with theory. In addition, the fact that no significant composition dependent energy shifts of the absorption bands caused by Cu^{2+} at T and M sites are observed in the present spectra indicates that MO_6 and TO_4 polyhedra are structurally strongly relaxed in this solid solution series. Both the synthesis experiments and the spectroscopic measurements were performed at the Department of Mineralogy of the Swedish Museum of Natural History (Stockholm). This project (SE-TAF_893) received support from SYNTHESIS which is financed by the European Community - Research Infrastructure Action under the FP7 "Capacities" Specific Programme.

NI-FREE, BLACK CERAMIC PIGMENTS BASED ON CO-CR-FE-MN SPINELS: A REAPPRAISAL OF CRYSTAL STRUCTURE, OPTICAL PROPERTIES AND TECHNOLOGICAL BEHAVIOUR

Key terms: ceramic; pigment; spinel; crystal structure; optical properties

The pigments used to impart black shades to ceramic wares are mostly synthetic spinels. The best colouring performance in the industrial practice is ensured by complex mixed oxides (Cr, Fe, Mn, Co, Ni, and sometimes further transition elements). This turns the black pigments as the most expensive ceramic colorants after those based on noble metals or cadmium selenide. The design criteria followed in the industry basically consist in admixing different transition metal oxides in order to get into the spinel structure as much ionic species as possible (e.g. Cr^{3+} , Fe^{2+} , Fe^{3+} , Mn^{2+} , Mn^{3+} , Co^{2+} , Co^{3+} , Ni^{2+}) each able to absorb in the visible spectrum, so contributing to achieve the best black colour. From the colourimetric viewpoint, the target is a minimal brightness without significant chroma contributions. Besides spinels have been deeply investigated and the relationship between crystal structure and properties is well known for binary (and to some extent ternary) compositions, the complex systems used in ceramic pigments are not modelled and the

application of conventional XRD and spectroscopic approaches is complicated by the occurrence of several transition metals. Both health regulations (preventing the use of carcinogenic compounds like Ni-bearing oxides) and technological innovation (digital decoration and particularly ink-jet printing) are changing the market demand towards high performance and safe pigments. This is not an easy task, because some pigment properties are ensured by the undesired elements (e.g. Ni was used to improve the chemical resistance in Zn-rich glazes). From this standpoint, a reappraisal of crystal structure, optical properties and technological behaviour of black spinels is needed to define the best compositions in the Co-Cr-Fe-Mn system and disclose the pigment-glaze interactions affecting the final crystallochemical features after the ceramic process. For this purpose, 21 ternary and quaternary spinel formulations were designed, using the crystallochemical criterion of Cr³⁺ occupancy of the octahedral site (with Co, Fe and Mn sharing the tetrahedral site): progressive decreasing of chromium (from 2 to 1.5, 1, 0.5, and 0). Spinel pigments were prepared from these batches, simulating the industrial processing (firing at 1300°C) and characterizing the powder samples through XRD (Rietveld refinement); optical and Raman spectroscopy; technological testing (in different glazes). Spinel pigments are monophasic (but when the sum Cr+Fe exceeds the occupancy of the octahedral site, resulting in spinel+hematite assemblages). The colour ex synthesis is uniformly black (but when Cr occupancy=2). The colouring performance depends on the chemical composition and firing temperature of the glaze: black shades are kept when Cr occupancy is between 1 and 1.5 apfu, while for values <1 the spinel reacts with the glass causing bubble formation and eventually bloating phenomena. Suitable black spinels exhibit unit cell parameter in the 8.35-8.40 Å range and anionic parameter in the 0.258-0.262 range. The best colouring performance in glazes rich in alkaline-earth elements correspond to quaternary batches; in particular, the best behaviour in zinc-rich glazes is ensured by high cobalt amounts (nominally half occupancy of the tetrahedral site). More suitable for high temperature glazes (rich in alkalis) are spinels richer in Fe and/or Mn. Therefore, the mechanisms controlling the colouring performance seem to be the partial occupancy of the octahedral site by Cr³⁺ and the amount of cations with a strong affinity to the tetrahedral site to contrast the formation of solid solution with Mg and Zn that would turn the colour to brown shades. Preliminary Raman observation has shown that samples with best colour are heterogeneous, with strong local spectral differences, and highly disordered, with large Raman peaks, prompting for further EDS and XRD characterization (run within the PRIN project SPIN GEO-TECH).

Key terms: ceramic; pigment; hibonite; crystal structure; optical properties

Hibonite, with general formula $[\text{12}]\text{A}[\text{6}]\text{M}[\text{1}][\text{5}]\text{M}[\text{2}][\text{4}]\text{M}[\text{3}][\text{6}]\text{M}[\text{4}][\text{2}][\text{6}]\text{M}[\text{5}]\text{O}[\text{19}]$, is the natural counterpart of the synthetic calcium hexa-aluminate (CaAl_2O_7) which crystallizes with the magnetoplumbite-type structure (space group P63/mmc, Z=2). Calcium occurs in a 12-fold coordination site (A), whereas Al³⁺ ions are distributed over five different sites, including three distinct octahedra (M1, M4, and M5), a tetrahedra (M3), and an unusual trigonal bipyramid (M2) that gives rise to a fivefold oxygen-coordinated site. Minerals of the magnetoplumbite-group habitually contain significant amounts of metals with different valences (e.g. divalent as well as tetravalent and pentavalent cations). Of great importance is the tendency of these metal ions to be hosted at definite sites. As a matter of fact, M2+ ions are usually hosted at M3 site, while M4+ and M5+ ions are preferentially accommodated at the M4 site. The ions of different charges tend to improve the local charge balance in the crystal structure. Therefore, the introduction of divalent ions is thought to be achieved by co-incorporation of tetravalent or pentavalent cations which are mainly ordered over the octahedral sites in the face-sharing interlayer doublet. This ability to accommodate such a wide variety of ions, with different valence and coordination, makes the hibonite structure very interesting to be used as a ceramic pigment. In this work, the electroneutrality of the hibonite lattice

was ensured by the following coupled substitution: $2\text{Al}^{3+} \rightarrow (\text{Ni}^{2+} + \text{Ti}^{4+})$. Hibonite ($\text{CaAl}_{12-2x}\text{Ni}_x\text{Ti}_x\text{O}_{19}$ where $x=0.1-2.0$) is a refractory phase hard to synthesize by the conventional solid state reaction. Therefore, kinetic hindrances were overcome through a combustion synthesis performed at 400 and 1200 °C. In order to maximize the exothermic effect, fuel mixtures (urea, glycine, beta-alanine) were selected, based on their compatibility with metal nitrates used as raw materials. These synthesis strategies allowed the formation of hibonite structure directly during the combustion reaction, without any further annealing. The behavior during combustion was monitored by thermal analysis, which revealed that highly exothermic redox processes are responsible for the formation of the designed oxide compound. The hibonite characterization was performed by X-ray powder diffraction, microstructure analysis (SEM), and diffuse reflectance spectroscopy (DRS). At the lower combustion temperature, the hibonite structure is the main phase, but secondary phases were also detected, such as spinel (NiAl_2O_4), perovskite (CaTiO_3), and gamma alumina ($\gamma\text{-Al}_2\text{O}_3$). With the increasing of the combustion temperature to 1200°C, the XRD profile exhibits sharper peaks and a better peak to background ratio. The hibonite structure shows an expansion of lattice parameters that is proportional to the degree of nickel and titanium substitution for the smaller aluminium ion. In terms of optical parameters, Ni²⁺ is incorporated at two different coordination sites, M3 and M4, preferentially in tetrahedral coordination up to saturation of the M3 site. The crystal field strength of nickel in tetrahedral coordination is regularly decreasing implying an elongation of the local Ni-O distance, coherent with the volume increasing from AlO₄ to NiO₄ tetrahedra. Ti⁴⁺ ions are accommodated at the octahedral site M4, in competition with Ni²⁺, and secondarily at the 5-fold coordinated site M2. The combined XRD+DRS approach allows to understand the mechanisms of dopant incorporation into the $\text{CaAl}_{12}\text{O}_{19}$ structure and the origin of its colour on the right track for engineering of hibonite ceramic pigments.

STRUCTURAL PROPERTIES OF $Al_{1-x}Cr_xNbO_4$ JOIN: A XRPD AND EAS COMBINED APPROACH

ARDIT Matteo¹, DONDI Michele², CRUCIANI Giuseppe¹

1 - Dip. Scienze della Terra, Univ. Ferrara

2 - CNR-ISTEC, Faenza

Presenter e-mail: rdtmtt@unife.it

Key terms: $AlNbO_4$ -type structures; Crystal structure; Optical properties; Structural relaxation

Nb and Ta are geochemically related elements which typically give rise to isomorphous series of oxides as accessory minerals in granitic pegmatites (e.g. columbites, pyrochlores, fergusonites, etc.). However, in spite of the natural occurrence of orthorhombic aluminantite ($AlTaO_4$), its Nb counterpart is only known as a synthetic product. $AlNbO_4$ crystallizes with monoclinic symmetry (s.g. $C2/m$) and was early described with a strict ordering of Nb and Al, respectively over M1 and M2, the two non-equivalent octahedral sites in the structure [1]. This model was revised by successive refinements showing that a partial disorder occurs in $AlNbO_4$ with a ~20% inversion degree [2,3]. $CrNbO_4$ is a disordered $MM'O_4$ compound, crystallizing with the rutile structure (s.g. $P4_2mm$)

while $FeNbO_4$ crystallizes with wolframite (s.g. $P2_1/c$), orthorhombic Cc - PbO_2 -type, rutile, or $AlNbO_4$ -type structure as the temperature increases. This brief review shows that, even at room conditions, the chemical nature of the metal cations M3+ strongly affects the crystal structure of $MM'O_4$ -type oxides. In order to better understand the substitution mechanisms, the cationic ordering, the structural stability, and the phase transition processes for $(M3+)(Nb5+)_2O_4$ compounds, six samples along the $(Al_{1-x}Cr_x)NbO_4$ join (x: 0.0-0.5) were synthesized by the solid-state reaction process and investigated by means of a X-ray powder diffraction (XRPD) and electron absorption spectroscopy (EAS) combined approach.

Monophasic up to $x(Cr)=0.125$ apfu ($AlNbO_4$ -type structure), the samples along the join become biphasic (the former plus the $CrNbO_4$ -type structure) for $x(Cr)>0.125$ apfu, indicating the impossibility to have a complete solid solution between $(Al,Cr)NbO_4$ oxides. The lattice parameters increasing with the Al-Cr substitution defines a structural expansion limit ($x(Cr)>0.24$ apfu) that is ascribed to the maximum chromium content that the structure can accept. The samples up to $x(Cr)=0.25$ also exhibit the typical optical spectra of Cr^{3+} in 6-fold coordination, involving d-d electronic transitions. Ascertained that the proposed octahedral ordering models were corrected [2,3], through different refinement strategies, the global instability index, GII [4], was calculated over the un-doped structure by varying the Al/Nb ratio in the two metal sites. Unpredictably, even the minimal values of GII obtained are very close to the limit of 0.20 v.u. that implies strained structures. With a crystal field strength that decreases moving from $x(Cr)=0.06$ to 0.50 apfu, and both the Racah parameters and the nephelauxetic trends nearly constants, no significant change in the degree of covalency and polarization of the Cr-O bond are found. The 10Dq decreasing suggests an elongation of the local Cr-O distance for Cr^{3+} increasing at site M2 and to a minor extent at site M1, fitting well the structural data on the long-range mean bond distances. The degree of structural relaxation around Cr^{3+}

was also assessed by means of the relaxation coefficient ϵ , until the structure will maintain the same symmetry. The $AlNbO_4$ lattice has a limited propensity to relax ($\epsilon=0$) and the $AlNbO_4$ structure follows the Vegard's law. In contrast with the well known Al-Cr joins in garnets, spinels, perovskites and corundum, the $AlNbO_4$ structure is strongly constrained by other factors, like cation ordering and electrostatic charge balance. Indeed, the M2 site hosting Al^{3+} is underbonded and Cr^{3+} can be accommodated at this site without significant strain for that the lattice does not need to relax around the bigger ion.

A COMPARISON OF THE STRUCTURAL AND MICROSTRUCTURAL FEATURES DETERMINED FROM RIETVELD REFINEMENTS AND PAIR DISTRIBUTION FUNCTION ANALYSES OF IRON OXIDE NANOPARTICLES

CAMETTI Georgia¹, SADUN Claudia², BALLIRANO Paolo¹

1 - Sapienza Università di Roma, Dipartimento Scienze della Terra

2 - Sapienza Università di Roma, Dipartimento Chimica

Presenter e-mail: georgia.cametti@uniroma1.it

Key terms: Pair Distribution Function; maghemite nanoparticles; Rietveld analysis

Rietveld method is by now the conventional crystallographic method for structural analysis. However, in the past few years total scattering technique has become increasingly important for crystalline materials that show reduced long-range periodicity. Data are evaluated by the Pair Distribution Function technique, that allows analyzing simultaneously Bragg and diffuse scattering, revealing short and intermediate range order of the material. This function is defined in real space, in terms of atomic coordinates. The aim of this work is to compare the results from Rietveld and Pair Distribution Function analyses applied to powder diffraction data on iron oxide nanoparticles. Diffraction data were obtained from the ADXD (Angular Dispersive X-Ray Diffraction) method, using a parallel beam Bruker AXS D8 Advance diffractometer operating in transmission mode in $\theta-\theta$ geometry, and from a non conventional EDXD (Energy Dispersive X-Ray diffraction) diffractometer characterized by a $\theta-\theta$ vertical geometry. ADXD data were analyzed by the Rietveld method while EDXD data were evaluated by the PDF method using PDFFITGui (Farrow *et al.*, 2007) software. Samples are maghemite nanoparticles of different nominal size (10nm, 7nm, 5nm, 3.5nm). They were synthesized by condensation in aqueous medium by controlling temperature, Ph and system composition ($Fe^{2+}/Fe^{3+} + Fe^{3+}$).

Both techniques (Rietveld and Pair Distribution Function analyses) apply least-squares full profile refinements: the first operating in reciprocal space and the second in direct space. Cell parameter, atomic displacement parameters, x coordinate of the oxygen site, and size of nanoparticles

were common parameters refined with both approaches. A big problem to be faced of with ADXD data was the very large absorption. Two different series of refinements were performed using GSAS&EXPGUI (Larson and Von Dreele, 2004; Toby, 2001) and TOPAS v.4.2 (Bruker AXS, 2009) programs. TOPAS implements the Fundamental Parameters Approach FPA (Cheary and Coelho, 1992), a convolution approach in which the peak-shape is synthesized from a priori known features of the diffractometer and the microstructural features of the specimen. This approach is believed to provide more accurate microstructural parameters than a conventional Rietveld refinement. In the case of the Rietveld refinements, individual isotropic displacement parameters were refined with the full ionization model (Ballirano, 2003) for the oxygen atom. The PDF technique allowed the refinement of the individual anisotropic displacement parameters that were found systematically larger than those from the Rietveld analyses possibly because of correlations among parameters. Only FPA provided a meaningful analysis of the microstrain. As expected, strain decreases with the increase of the particles diameter due to the reduction of the specific surface. The cell parameter a obtained from Rietveld refinement (ca. 8.353 Å) was very similar for all analyzed samples: it was slightly smaller than that reported for other nanocrystalline maghemite (Di Marco *et al.*, 2009, 2006), and greater than that of microcrystalline sample (Greaves, 1983; Shmakov *et al.*, 1995). The x coordinates of the oxygen site obtained from the Rietveld refinements (ca. 0.254) didn't show any significant difference from reference data as well as those from PDF analyses. Therefore both conventional and FPA Rietveld and PDF approaches can provide reliable information on the atomic displacement parameters and on the x coordinate of the oxygen site. Moreover, nanoparticles size has been reliably estimated only by PDF and FPA Rietveld analyses.

SYNTHESIS AT ROOM AND HIGH PRESSURE OF PYROXENES ALONG THE JOIN $CaCoSi_2O_6-Co_2Si_2O_6$

Key terms: Co-pyroxene; Synthesis; X-ray diffraction; Raman spectroscopy

The study of pyroxenes along the join $CaCoSi_2O_6-Co_2Si_2O_6$ has an interest in mineralogy and in ceramic sciences. As for ceramics, Co-bearing silicates can act as blue to pink pigments. Blue color stems from Co in tetrahedral coordination, like in $CoAl_2O_4$ spinel (blue cobalt), whereas higher coordination drives to a pink hue. In $CaCoSi_2O_6-Co_2Si_2O_6$ pyroxenes the substitution occurs in two different sites M1 and M2 at different coordination, being M1 a regular octahedron and M2 a distorted polyhedron with 6-8 fold coordination, and the effect of Co for Ca substitution on the pyroxene color can therefore be investigated. As for mineralogy the series is an analogue to the series diopside-enstatite ($CaMgSi_2O_6-Mg_2Si_2O_6$) and hedenbergite-ferrosilite ($CaFeSi_2O_6-Fe_2Si_2O_6$) of quadrilateral pyroxenes. The comparison on the crystal chemistry and phase transitions of the effect of the solid solution of Ca for Co on the M2 site, vs that of Ca for Mg and for Fe, can provide the basis for an extensive model of solid solutions in pyroxenes. Preliminary results on the synthesis and characterization of $CaCoSi_2O_6-Co_2Si_2O_6$ pyroxenes are here reported.

Previous experimental data on $CaCoSi_2O_6-Co_2Si_2O_6$ pyroxenes are confined to the end members, $CaCoSi_2O_6$ which was synthesized at room pressure, and $Co_2Si_2O_6$ which was synthesized above 3 GPa and 7 GPa in the orthorhombic and monoclinic polymorphs respectively. In the present study eleven compositions along the series, at step of 10 mol % of the $CaCoSi_2O_6$ component, were synthesized at room and high pressure. Room pressure syntheses were achieved by calcinations at 1000 °C for 12 hours of stoichiometric mixtures of the oxides. Combined SEM/EDS, Raman and XRD investigation gave evidence of an incomplete reaction for the starting materials, with the presence of residual amorphous silica. Clinopyroxene, with a composition close to $(Ca_{0.9}Co_{0.1})CoSi_2O_6$, was found in all samples except that with stoichiometric composition $Co_2Si_2O_6$, where an assemblage of Co-olivine (Co_2SiO_4) and silica was found. Co-olivine was observed in all samples, less in Ca-richer compositions. Co-ackermanite ($Ca_2CoSi_2O_7$) was observed between $CaCoSi_2O_6$ and $(Ca_{0.6}Co_{0.4})CoSi_2O_6$. The color changes from pink to blue together with increasing ackermanite and decreasing olivine.

To obtain wider pyroxene solid solution, high pressure synthesis on the same starting materials was carried out with piston cylinder apparatus at P = 3 GPa and T = 1200 °C, for 4 to 20 hours. XRD and Raman analyses show that between $CaCoSi_2O_6$ and $Ca_{0.4}Co_{0.6}Si_2O_6$ a clinopyroxene solid solution is the only phase. In the sample with starting composition $Ca_{0.2}Co_{0.8}Si_2O_6$ we obtain the coexistence of clinopyroxene, orthopyroxene and quartz, and in $Co_2Si_2O_6$ only olivine and quartz, without formation of a pyroxene phase.

Cell parameters follow the same trend with composition previously observed in $C2/c$ pyroxenes along the series diopside-enstatite and hedenbergite-ferrosilite. Changes observed in Raman spectra may be interpreted as in pyroxenes along the diopside-enstatite. Single crystal XRD and optical spectroscopy investigations, as well as attempts to synthesize $Co_2Si_2O_6$ clinopyroxene by means of a multi-anvil apparatus, are in progress.

Key terms: omphacite; high-pressure; high-temperature; single crystal; X-ray diffraction

Omphacite shows an intermediate composition along the binary jadeite-diopside join of the Na-pyroxene solid solution. Most of the interest in this mineral has been focused on the order-disorder

phenomena which it undergoes, causing a $P2/n \leftrightarrow C2/c$ phase transition [1]. Although omphacite plays a key role in high-pressure and high-temperature geological environments, *in situ* studies on its thermo-elastic behaviour under non-ambient conditions are definitively scarce. Some experimental results have been reported on the omphacite high-pressure *in situ* behaviour [2,3] and, more recently, the thermal expansion and the thermal equation of state were studied by [4] and by [5] respectively. However all these data were collected using different experimental conditions, by both powder materials and single crystals and often off the omphacitic composition. Therefore they do not provide a systematic on the high-pressure and high-temperature behaviour. In order to constrain the correct value of the compressibility and thermal expansion of omphacite we have studied a natural sample by high-pressure and high-temperature *in situ* single crystal X-ray diffraction (in two separate experiments). Two twin and inclusion-free single crystals of $P2/n$ omphacite from the Münchberg Mass (Bavaria) eclogitic rock were selected for this study. Its composition, $Jd_{0.5}Di_{0.5}Hd_{0.5}En_{0.5}CaTs_1$, is very close to pure $Jd_{0.5}Di_{0.5}$ omphacite. In order to obtain fully disordered $C2/c$ omphacite crystals, isothermal annealing at 1000 °C for 300 hrs was carried out using a vertical temperature control furnace. Intensity data collections were performed to verify the absence of the $h+k = 2n+1$ reflections, and data were refined in the $C2/c$ space group. Unit-cell parameters were determined by SCXRD at 16 different pressures up to about 7 GPa. A continuous decrease of the unit-cell parameters and volume was observed as a function of pressure up to the maximum P reached (volume decreases about 5.2% up to 7 GPa). A third order Burch Purnaghan equation of state was used to fit the experimental pressure-volume data. We obtained the following coefficients: $V_0 = 421.04(7) \text{ \AA}^3$, $K_{T=0} = 118.65(1.84) \text{ GPa}$, $K' = 5.7(6)$. The compressibility

scheme $b > c > a$ is similar to that of other clinopyroxenes. High-temperature experiments were carried out measuring lattice parameters at intervals of 50°C in the 25-800°C T range both on increasing and decreasing temperature. Continuous increasing of the unit-cell parameters and volume was observed as a function of temperature with a volume increase of about 2.3% up to 800°C. The thermal expansion obtained using the approach by [7] yielded $\alpha = 3.03(3) \times 10^{-5} \text{ K}^{-1}$.

We obtained two different behaviours as a function of pressure and temperature: 1) even if further experimental data are necessary for intermediate compositions, our data show that the bulk modulus value for disordered omphacite is in very good agreement with a linear combination of the bulk moduli of the Jd and Di end-members; 2) otherwise the thermal expansion value is slightly higher than that expected for a linear combination of the volumetric thermal expansion of the two end members.

Key terms: Epidote; Low Temperature; High Temperature; Neutron single-crystal diffraction; X Ray single-crystal diffraction

The effects of temperature on the crystal structure of a natural epidote from the intrusive/metamorphic complex of Val Sissone, Valmaenco, [Ca_{1.925}Fe_{0.795}Al_{1.265}Ti_{0.000}S₃037O₁₂ (OH), $a=8.8924(7)$, $b=5.6214(3)$, c

$=10.1547(6) \text{ \AA}$ and $\beta = 115.396(8)^\circ$ at room conditions, Sp. Gr. $P2_1/m$) have been investigated with a series of structure refinements at low T (293 - 100 K) by means of single-crystal X-ray diffraction (SC-XRD) and at high T (293 and 1070 K) by means of neutron single-crystal diffraction. The low- and high-T experiments confirm that epidote is stable within the whole T range investigated (i.e. 100 K-1070 K) and that the space group $P2_1/m$ is maintained. At high T, a positive thermal expansion is observed along all the three crystallographic axes (with $\Delta a/a \sim 0.55\%$, $\Delta b/b \sim 0.91\%$, $\Delta c/c \sim 1.00\%$ and $\Delta V/V \sim 2.4\%$ between 293-1070 K). At low T, within the precision and accuracy of our CCD data, the unit-cell constants do not vary significantly, and only a slight decrease of the monoclinic angle is observed.

The refinements performed on the whole T range confirm that Fe³⁺ occupies, along with Al³⁺, the M(3) site [%Fe(M3)100K = 69.6(4)% X-ray data, %Fe(M3)1070K = 74(2)% neutron data]. In other words, the M(1) and M(2) sites are fully occupied by Al. Moreover, the high-T structural refinement shows that no dehydration effect occurs.

Over the whole T range investigated, the structure behaves without any drastic change on most of the geometrical parameters; only little variations on inter-atomic bond distances, thermal vibration of all the atomic sites, and inter-polyhedral tilting occur. The main low-T effect is observed on the vibrational regime of the atomic sites; a significant monotonic reduction of the magnitude of the thermal displacement ellipsoids, with a variation of U_{eq} (defined as one third of the trace of the orthogonalised U_{ij} tensor) by $\sim 40\%$ is observed for both the Ca-sites between 293 and 100 K. However the vibrational regime of the two Ca-sites is slightly different within the T-range investigated: the Ca(1) site shows a lower U_{eq} and a less pronounced anisotropy, (represented by the ratio R1/R3 respectively the longest and the shortest components of the root-mean-square components of the thermal ellipsoids) with respect to Ca(2) at any temperature. This is basically due to the different coordination shell of the two cationic sites, with longer bond distances for Ca(2).

Within the T range investigated, the thermal displacement ellipsoids of the oxygen sites are only slightly pronounced; the most significant anisotropy is observed for the three oxygen of the two corner-sharing T-sites [O(3), O(8) and O(9) oxygen sites, with R1/R3 < 3 at low T and R1/R3 ~ 2 at high T]. This effect might be driven by rotation of the Si(2)-tetrahedron

due to the presence of Fe³⁺ at the M(3) site. The nuclear refinements show that two possible hydrogen bonds, with O(2) and O(4) as acceptors [i.e. O(10)-H(1)¹⁰⁰⁰O(2) and O(10)-H(1)¹⁰⁰⁰O(4)] occur. However, the topological configuration of the bonds suggests that the O(10)-H(1)¹⁰⁰⁰O(4) is energetically more favourable, as H(1)¹⁰⁰⁰O(4) = 1.9731(28) Å, O(10)¹⁰⁰⁰O(4) = 2.9318(22) Å and O(10)-H(1)¹⁰⁰⁰O(4) = 166.7(2)°, whereas H(1)¹⁰⁰⁰O(2) = 2.5921(23) Å, O(10)¹⁰⁰⁰O(2) = 2.8221(17) Å and O(10)-H(1)¹⁰⁰⁰O(2) = 93.3(1)° (at 293 K). The O(10)-H(1) bond distance at 293 K corrected for "riding motion" is 0.9943 Å.

Key terms: Northern Victoria Land (Antarctica); mantle xenoliths; metasomatism; oxygen fugacity; spinel

Northern Victoria Land (Antarctica) mantle, sampled by spinel peridotite xenoliths found in basalts of Mt. Melbourne Volcanic Province, brings evidence of a metasomatic event related to Cenozoic volcanism. This metasomatic signature varies across the volcanic province: at Baker Rocks (BR) metasomatism is characterized by the occurrence of amphibole as disseminated grains or in veins hosted in lherzolite and harzburgite xenoliths carried by alkali basalt; at Greene Point (GP, about 80km north of BR) cryptic metasomatism provides variable enrichments of incompatible elements in clinopyroxenes from lherzolite/harzburgite xenoliths that were transported to the surface by a nephelinite-basanite lava.

In this work we check the effects of the two styles of metasomatism on oxygen fugacity, estimating the redox state of anhydrous xenoliths with different metasomatic signatures, by means of the spinel-orthopyroxene-olivine oxybarometer. At BR, we estimated also the redox state of the metasomatic agent (the crosscutting amphibole-bearing veins) by applying the Popp et al. (2006) method to the crystal-chemical data obtained from amphiboles crystallized in the veins.

Xenolith mineral chemistry was determined by electron microprobe, and the ferric iron content of spinels and amphibole were measured by 57Fe Mössbauer spectroscopy. Amphiboles were also characterized by single-crystal X-ray structure refinement, which allowed quantification of dehydrogenation by the method proposed by Oberti et al. (2007).

Results show that oxygen fugacities recorded by the xenoliths range from -0.2 to -1.6 log-bar units ($\Delta \log fO_2$) with respect to the

fayalite-magnetite-quartz (FMQ) buffer. The $\Delta \log fO_2$ values calculated from amphiboles are about -0.6 log-bar units, thus in the range found for metasomatic amphibole of mantle xenoliths from the same area of

northern Victoria Land ($\Delta \log fO_2 = -1.4 : -0.4$ log-bar units, Nazzareni et al. 2010).

In detail, fO_2 data shows that i) beneath Greene Point, metasomatism

increased fO_2 by $\sim 1 \Delta \log fO_2$ log-bar units, whereas in Baker Rocks lithospheric mantle the metasomatic melt/rock interactions did not produce any significant change in fO_2 ; ii) within each suite, there is no evident correlation between fO_2 and the degree of mantle depletion, as indicated by spinel Cr#; iii) in GP xenoliths no direct correlation is found between fO_2 and the enrichment in incompatible elements in clinopyroxenes.

In conclusion, as evidenced by Baker Rocks xenoliths, mantle metasomatism leading to amphibole formation does not necessarily imply mantle oxidation; in contrast, the variability of fO_2 obtained for Greene Point xenoliths highlights that the silicate melts responsible for the last metasomatic event recorded by xenoliths acted as an effective oxidiser of the depleted shallow upper mantle.

HIGH-PRESSURE PHASE TRANSITIONS IN ALKALINE-EARTH FELDSPARS

BENNA Piera¹, CURETTI Nadia¹, NESTOLA Fabrizio², BRUNO Emiliano¹

1 - Dipartimento di Scienze Mineralogiche e Petrologiche, Università di Torino
 2 - Dipartimento di Geoscienze, Università di Padova

Presenter e-mail: PIERA.BENNA@UNITO.IT

Key terms: high-pressure studies; alkaline-earth feldspars; phase transitions

While the structural and thermodynamic behaviour of the phase transitions induced by temperature in feldspars was subject to several investigations and is now well described, their high-pressure behaviour has been investigated only in more recent times.

At room conditions, in alkaline-earth feldspars, a triclinic $P\bar{1}$ symmetry is observed with Ca as M cation, whereas the symmetry becomes monoclinic I2/c when the larger Ba or Sr cations replace Ca, as in celsian (BaAl₂Si₂O₈, Cls) and Sr-feldspar (SrAl₂Si₂O₈, SrF). High-pressure investigations on anorthite (CaAl₂Si₂O₈, An) were performed by Angel (1988), that observed a reversible first-order phase transition

from $P\bar{1}$ to $I\bar{1}$ between 2.6 and 3 GPa. Along the An-SrF join, with increasing pressure, the An₂₀SrF₈₀ feldspar shows a displacive first-order $I\bar{1}$ -I2/c phase transition at about 4.3 GPa,

analogous to the displacive second-order $I\bar{1}$ -I2/c transition observed with increasing temperature at room pressure for the same feldspar. Both high-pressure and high temperature I2/c monoclinic structures are characterized by an increase of the coordination number of the Ca/Sr cations, which can be ascribed to an increase of the r_1/r_2 ratio, where r_1 is the ionic radius of the non-tetrahedral cations and r_2 is the ionic radius of

oxygen. In particular, the triclinic-monoclinic $I\bar{1}$ -I2/c high-pressure transition can be justified by the higher compressibility of the oxygen atoms with respect to the non-tetrahedral cations, causing the increase of the r_1/r_2 ratio. At about 7.3 GPa, the $An_{20}Sr_{80}$ feldspar shows a further first-order transformation from monoclinic I2/c to monoclinic P2₁/c (Nestola et al. 2004; Benna et al. 2007). In pure Sr-feldspar, Pandolfo et al. (2011) observed the same I2/c-P2₁/c phase transition at about 6.6 GPa.

In the present work the results obtained in celsian, by single-crystal *in situ* high-pressure X-ray diffraction up to 6.5 GPa, show the same I2/c-P2₁/c transition between 5.5 and 5.9 GPa. The results highlight the significant reduction of the transition pressures in comparison to $An_{20}Sr_{80}$ and Sr_{100} feldspars. This allows to correlate the decrease in the transition pressures with the increase of the average ionic radius in alkaline-earth feldspars along the An-SrF and SrF-ClS joins. Considering the well known morphotropic phase transitions occurring at room condition with changing composition, the results obtained on celsian allow to draw, along the Ca-Sr and Sr-Ba-feldspars joins, the stability fields of the observed phases between 0 e 7.5 GPa.

Key terms: phyllosilicate; inosilicate; liquid phase deposition; nanostructures; magnetic anisotropy

In recent years, many efforts have been made on the synthesis of new self-assembled materials, and on scientific understanding of the formation mechanism from building molecules. With the aim to develop new functional materials, layered inorganic compounds recently attracted considerable interests for the preparation of nanoscale organic/inorganic hybrids. A large class of minerals presents inherently nanostructured morphologies. Within this group, we cite, to name a few, chrysotile, crocidolite, and montmorillonite, being examples of crystalline aggregates of nanotubes, nanorods, and nanosheets, respectively. On this basis, synthetic "geo-inspired" materials are being developed, with the aim to enhance their possibility to be employed as nanomaterials in technological applications. On the other hand, the surface of such minerals is rich of chemical groups which can bind covalently or electrostatically organic compounds capable to confer technological functionalities to the ultimate hybrid system. In order for a transition from bare mineral to functional material to be achieved, the development of processes for the deposition of highly-oriented thin film phases of such mineral nanoparticles are mandatory. Indeed, their marked anisotropic morphology influences also their physical properties, which may vary to a great extent depending on the probed direction. Here, we show the results of a scanning probe and electron microscopy, X-ray diffraction, and IR optical analysis of nanostructured thin films of natural and synthetic minerals obtained by liquid phase deposition of colloidal solutions. By assisting the deposition process with a static magnetic field, we demonstrate the possibility to induce a preferential orientation of the deposited nanoparticles, thanks to the anisotropy of their diamagnetic or paramagnetic susceptibilities. This effect is also studied in minerals deliberately doped with paramagnetic species such as Fe(II) and Fe(III) ions. Hybrid inorganic-organic colloids are synthesized by reacting chrysotile nanotubes with ionic derivatives of metal-phthalocyanines, organic molecules which display semiconducting character in the solid state. The structure, morphology and optical properties of the magnetically driven ordered deposits of hybrid nanoparticles are analyzed and compared with those of the bare minerals. Some conclusive remarks for their technological application and perspectives are drawn.

² - Dipartimento di Geoscienze, Università di Padova

Presenter e-mail: nadia.curetti@unito.it

Key terms: crystal structure; high-pressure studies; phase transitions

Single-crystal *in situ* high-pressure X-ray diffraction was performed at P = 0.0001, 2.1, 4.2, 5.5, 5.9 and 6.5 GPa on celsian ($Ba_{0.97}K_{0.03}Al_{1.95}Si_{2.04}O_8$) from Jakobsberg, Sweden. The evolution of the unit-cell parameters as a function of pressure shows a discontinuity at pressure between 5.5 and 5.9 GPa (mainly in β angle and b parameter) and highlights a displacive

first-order transformation.

The data collections between 0 and 5.5 GPa show only a-type and b-type reflections (a: h+k=even, l=even; b: h+k=odd, l=odd) confirming the I2/c space group of celsian. The I2/c structures show only minor modifications mainly involving a shortening of the average < M-O > distances.

The data collections at 5.9 and at 6.5 GPa show the presence of also c-type and d-type reflections (c: h+k=even, l=odd; d: h+k=odd, l=even) indicating a primitive lattice. As in the high-pressure P2₁/c configurations of the feldspars of composition $Ca_{0.2}Sr_{0.8}Al_2Si_2O_8$ ($An_{20}Sr_{80}$) and $SrAl_2Si_2O_8$ (Sr_{100}) (Benna et al. 2007; Pandolfo et al. 2011), in celsian the scheme of intensity of the different reflections is: $a > d > b \geq c$. Only reflections h0l, 00l and 0k0 with l and k even were observed, confirming the P2₁/c space group. At pressure between 5.5 and 5.9 GPa, the I2/c-P2₁/c phase transition involves a reduction of the symmetry with the loss of the two-fold axes and of one-half of the centers of symmetry. In the P lattice the numbers of independent atomic sites is doubled and pairs of atoms related by the pseudo-body centering (a+b+c)/2 vector are present. The most significant changes in the P2₁/c configuration are: the deformation in the Ba polyhedra and the variation in the T-O-T angles. In particular, the T2(00)-OC(0i)-T1(0i) angle decrease to 112.24° at P = 6.5 GPa. The very small value of this angle in celsian at P = 6.5 GPa is related to the large changes in the OC oxygens in the M(0)-polyhedron.

HIGH ANGLE ANNUAL DARK FIELD (HAADF) MICROSCOPY: A NEW LOOK INTO CRIPTED SUB-NANO DOMAINS IN MINERAL SCIENCES

FERRARIS Cristiano¹

¹ - Muséum National d'Histoire Naturelle, Laboratoire de Minéralogie et Cosmochimie, CP 52, 61 Rue Buffon, 75005 Paris, France

Key terms: HAADF; HRTEM; nanodomains; mineralogy; crystallography

A major challenge to the development of a full understanding of mineral and ceramic nano-structures, including unit cell defects and distortions and local charge balance problems, is to identify contaminant (<10 ppm) elements and characterize their environment at the nano-scale.

Atomic-scale techniques, such as conventional transmission electron microscopy, although powerful, are limited by the extremely small amounts of material that are examined. However, recent advances in electron microscopy provide a number of new analytical techniques that expand its application in environmental studies, particularly those concerning trace elements with high atomic number compared to those of the hosting phase.

High-angle annular dark field scanning transmission electron microscopy (HAADF-STEM), STEM-energy-dispersive X-ray spectrometry (EDX), and energy-filtered TEM (EFTEM) can be effectively used to identify and characterize these elements.

The technique of high-angle annular dark-field (HAADF) imaging, allows forming images by collecting high-angle scattered electrons using an annular dark-field detector in a dedicated scanning transmission electron microscopy (STEM) instruments. This technique, in contrast to common TEM ones, is not limited to fully electron transparent sample areas, but also slightly thicker sample volumes are good for investigations. The contrast of HAADF images is i) strongly dependent on the average atomic number of the scatterer encountered by the incident probe, ii) not strongly affected by dynamical diffraction effects, iii) not strongly affected by defocus and, finally, iv) not strongly affected by sample thickness variations; the spatial resolution is limited by the size of the focussed incident probe.

Furthermore, the high sensitivity of HAADF image contrast to the average Z-number of the specimen atomic columns has allowed the use of this methodology to study the presence of single atoms of dopants in a crystal structure, or to derive the chemical profile of buried layers in a host matrix.

As examples, both gold nano-crystals in olivine and iridium nano-clusters in rutile have been identified by HAADF-STEM and STEM-EDX mapping and subsequently characterized by high-resolution TEM (HRTEM). The combined use of these techniques greatly expands the effective application of electron microscopy in mineralogical studies, especially when applied to heavy elements of very low concentrations. Examples of how this electron nano-beam technique can be used to characterize a low concentration of heavy metals (a few ppm) on nano-scale particles are discussed.

FIBROUS ORTHOPYROXENE IN THE ETNEAN VOLCANICS FROM S. MARIA DI LICODIA (SICILY, ITALY).

GIANFAGNA Antonio¹; MAZZIOTTI TAGLIANI Simona¹

¹ - Dipartimento di Scienze della Terra, Sapienza Università di Roma

Presenter e-mail: antonio.gianfagna@uniroma1.it

Key terms: Fibrous orthopyroxene; Mineralogy; Etnean volcanics

The south-western area of the Mt. Etna volcano has been studied because the presence of peculiar mineralogical association. In our previous study we investigated the Biancavilla area, a dome and dyke system with auto-brecciated portion. In the Biancavilla volcanic system the metasomatic process led to the formation of new minerals, fluoro-edenite and fluorogopite [1] [2], and some rare minerals, such as pseudobrookite and As-apatite(Ca, F) (under study).

In this work we studied the Santa Maria di Licodia area, a dome located on the East side of the Biancavilla volcanic area. Some significant differences are present respect to the Biancavilla, such as the presence of a fibrous orthopyroxene instead of fibrous fluoro-edenite. Fibrous orthopyroxene is rare, and was found in ultramafic xenoliths and interpreted as an autometasomatic product of hydrous magmas [3].

With the aim to investigate a possible metasomatic process in S. Maria di Licodia area, a detailed sampling was executed on both the unaltered lava portion (massive rocks) and the altered portion (massive and brecciated rocks) of the dome. Combining mineralogical and petrographic data the presence of fibrous orthopyroxene in both massive and brecciated portion was evidenced. Besides the fibrous opx, the secondary mineral phases also include alkali-feldspars (Na), augitic clinopyroxene, apatite, Fe-Ti oxides.

Orthopyroxene show different morphology, such as prismatic, acicular and fibrous. In the massive rocks, fibrous orthopyroxene appears at the expense of probable olivine, in veins and in reaction rim. Here the orthopyroxene forms radiating aggregates totally replacing the previous crystal. The acicular morphology is only present in the pores of the rocks. Finally, in the brecciated portions the orthopyroxene is characterized by loose fibers.

Different morphology correspond to differences in composition, in particular in the iron content. The EMPA analyses on the orthopyroxene from the massive rocks evidenced high content of FeO (until 18 wt%), while SEM-EDS micro-analyses on the fibers of the brecciated portion highlighted a more large variability, ranging from 4 to 14 wt % FeO. X-ray investigation on brecciated (fine) portion allowed to individuate and identify the orthopyroxene as an enstatite ferroan, as also confirmed by the EDS micro-analyses. Further mineralogical investigations are in progress to better define and characterize this rare fibrous orthopyroxene.

Key terms: crystal chemistry; synthetic spinels; single crystal XRD; electron microprobe analyses; Mössbauer spectroscopy

Single crystals along the hercynite-chromite join were synthesised using a flux-growth method. Analytical grade Al_2O_3 , Cr_2O_3 , Fe_2O_3 powders were dehydrated and dried at 900 °C for 12 h before mixing with $Na_2B_4O_7$, used as flux compound. Around 6 g of starting material was ground under acetone in an agate mortar and mixed with flux/nutrient ratio ranging from 1.3 to 2.0 depending on nutrient compositions. The mixture was loaded in a 10cc Pt/Au (5%) crucible with a lid. For thermal runs an ENTECH vertical tube furnace equipped with programmable temperature controller and controlled atmosphere flow system was used. In order to obtain a homogeneous melt, the load was heated at 1200 or 1300 °C for 24 h. Subsequently the temperature was linearly decreased by 300 °C with a cooling rate of 4°C h⁻¹. A reducing atmosphere was provided by a continuous flow of high-purity CO₂ and H₂ gases through the furnace. The CO₂:H₂ ratio was maintained by TYLAN flow controllers and was kept constant at 1:2. Oxygen fugacity ranged from 10⁻¹¹ to 10⁻¹³ bars at 1200 and 900°C, respectively. The thermal runs were ended turning off the furnace and the product was allowed to cool more rapidly to room temperature.

For single-crystal XRD analyses, synthetic spinels were mounted on an automated KUMA-KM4 (K-geometry) diffractometer, using MoK α radiation monochromatized by a flat graphite crystal. The unit cell (a_0) was determined by 24 equivalent reflections of (12 8 4) (about 90° of 2 θ), accurately centred at both sides of 2 θ . Data collection was made according to Della Giusta et al. (1996) up to 2 θ = 55°. Structural refinement was carried out against F_o^2 in the Fd-3m space group (with origin at -3m), without chemical constraints, using the SHELX-97 program (Sheldrick, 1997). Cell edges varies within the range 8.1534 (6) Å - 8.3672 (1) Å, while the oxygen positional parameter is comprised between 0.2645 (2) and 0.2628 (1).

Structural parameters a_0 , T-O and M-O increase with chromite content while u decreases.

Mössbauer spectra were acquired at room-temperature using a conventional spectrometer system operated in constant acceleration mode. The spectra are dominated by a relatively broad absorption envelope consistent with ferrous iron. Several samples show also weaker contributions from ferric iron, despite the strongly reducing conditions prevailing during the synthesis procedure. The amount of ferric iron appears to increase with the chromite component of the samples.

Key terms: high pressure; arsenic sulfide; X-ray diffraction

Arsenic sulfides are widely studied for their great technological potential and $\bar{A}S_2S_4$ compounds in particular are of interest to material scientists owing to their high infrared transparency, photo-structural sensitivity and doping ability [1, and references therein]. Most of them consist of a packing of cage-like, covalently bonded $\bar{A}S_4$ ($n = 3, 4, \text{ and } 5$) molecules held together by van der Waals forces, and the investigation of their thermodynamic properties, such as thermal expansion and compressibility, can usefully contribute to the understanding of the interactions governing the structure and its stability.

The crystal structure of the \bar{A} modification of $\bar{A}S_2S_4$ (i.e., the mineral realgar) has been recently investigated by *in situ* X-ray single-crystal and powder diffraction methods up to 43 GPa [2]. On the other hand, no data

on the compressibility and structural behaviour of $\bar{A}S_2S_4$ at high pressure have been reported in the literature so far.

Under ambient-pressure conditions, $\bar{A}S_2S_4$ crystallizes in the C2/c space group with $a = 9.957(3)$, $b = 9.335(4)$, $c = 8.889(5)$ Å, $\beta = 102.48(4)^\circ$ [3]. The structure consists of $\bar{A}S_4$ cage-like molecules, characterized by a D_{2d} molecular symmetry, with each As atom bonded to one As and two S

atoms. Crystals of $\bar{A}S_2S_4$ were obtained by heating crystals of realgar under vacuum at 295 °C for 24 hours. The quenched product was used to collect single crystal intensity data at pressures up to 4.8 GPa using two different diamond anvil cells loaded with different crystals in a methanol-ethanol (4:1) mixture. Unit-cell measurements have been performed in a ETH-type DAC using a STOE STADI IV four-circle diffractometer equipped with a point detector (University of Padova). The measurement of unit-cell parameters became impossible beyond 2.8 GPa because of a dramatic broadening of reflections. The whole intensity data collections were carried out at different pressure steps up to 2.7 GPa using an Oxford Diffraction Xcalibur2 diffractometer equipped with a CCD detector (Bayerisches Geoinstitut) using a Bolher-Almax DAC. The diffraction study has been combined with a microRaman investigation throughout the whole experiment. The compressibility data were fit through a Birch-Murnaghan equation of state truncated at the 3rd-order with resulting bulk modulus $K_0 = 10.9(2)$ GPa, and its first pressure derivative $K'_0 = 8.9(3)$. These values are substantially identical to those found for the low temperature polymorph [2] which is characterized by the same kind of molecule. The response to pressure is almost isotropic and the dramatic decrease of the unit-cell volume (from 805.17 to 702.7 Å³ at 2.7 GPa) is mainly due to the reduction of intermolecular distances, whereas molecules remain substantially unchanged. In particular, the volume of the $\bar{A}S_4$ disphenoidal group does not decrease significantly while the molecular volume contracts by approximately 1.6 %, due to the shortening occurring along the S3-S3 [30-1] and S1-S2 [010] directions. Further experiments, carried out at higher pressures with a thinner crystal, only led to a rough measurement of the unit-cell parameters

showing that $\bar{A}S_2S_4$ does not undergo any phase transition in the whole pressure range investigated, in spite of a compression to about 80% of the initial volume.

Key terms: berthierite; lone electron pair; high-pressure; sulfosalts

Berthierite is a sulfosalt with composition $FeSb_2S_4$ (space group $Pbam$) presenting several interesting aspects like magnetic properties (Winterberger et al., 1990) and phase transition in the temperature range 323-365 K (Lukaszewicz et al., 2001). Moreover, berthierite structure features antimony in a trivalent state and is characterized by its lone electron pair (LEP) with pronounced steric effect. In this study, high-pressure single crystal X-ray diffraction experiments have been performed on a natural sample of berthierite in order to determine its equation of state (EoS) and high-pressure crystal structure evolution. Structural relation to stibnite and galenobismutite is also presented and the high-pressure development of the three structures compared. The purpose of this work is to contribute to the compressibility systematic for LEP compounds with the aim to outline a mechanism of their structural deformation and to define better the changes in the LEP activity as a function of pressure.

Two needle-like single-crystals of berthierite were selected from a natural sample collected in the Herjia deposit (Romania), the first one for

high-pressure unit-cell determination (183 x 80 x 40 μm^3) and the other

one for intensity data collection (175 x 75 x 40 μm^3). High-pressure single-crystal diffraction experiments were performed for each sample in an ETH-type diamond-anvil cell (DAC), equipped with diamond culets of

600 μm in diameter and diamond backing plates. Stainless steel gaskets

preindented to a thickness of 90 μm and with a spark eroded hole of 250 μm in diameter were used. A mixture of methanol and ethanol (4:1) was used as a pressure-transmitting medium and a single-crystal of quartz as an internal pressure standard. For the EoS determination, the measurements were performed using a four-circles STOE STADI IV diffractometer equipped with a point detector and controlled by the SINGLE software. No phase transitions were indicated in the investigated pressure range. The third-order Birch-Murnaghan equation of state calculated using high-accuracy volume-pressure data up to 8.046(12) GPa gave the following coefficients: $V_0 = 608.78(7)$ Å³, $K_0 = 37.2(2)$ GPa and $K'_0 = 7.0(1)$. The crystal selected for structure analysis was measured from room pressure up to 7.408 GPa, including one measurement on decompression. Complete intensity data collections were performed using a STOE STADI4 four-circle diffractometer, equipped with an Oxford Diffraction CCD detector.

As in the case of stibnite and bismuthinite, the crystal structure can be divided into rods comprising the short Sb-S bonds and the intervening space, which is sterically affected by the lone electron pairs of Sb. In all three structures the latter space accommodates most of the compression. The LEP activity has been quantified by the eccentricity of the Sb coordination polyhedra. With increasing pressure the eccentricity decreases indicating a reduction of the LEP activity. The Fe octahedron, which is the stiffest coordination polyhedron in berthierite, increases its distortion between 3 and 5 GPa exhibiting an increasing in the Jahn-Teller effect with a more clear distinction between two shorter and four longer bonds.

OUTLIER RECOGNITION AND ROBUST WEIGHTING PROCEDURES APPLIED IN CATION ORDERING-DISORDERING KINETIC DATA PROCESSING.

SCIASCIA Luciana¹, PARISI Filippo², PRINCIVALLE Francesco², MERLI Marcello¹

1 - Dipartimento di Scienze della Terra e del Mare (DiSTeM), Via Archirafi 36 I-90123 Palermo

2 - Università di Trieste - Dipartimento di Geoscienze, via Weiss 8, 34127 Trieste, Italy

Presenter e-mail: princiva@units.it

Key terms: intersite cation exchange; kinetics; least squares processing; outliers; leverage analysis

An efficient protocol, based on advanced statistical diagnostics and robust fitting techniques applied to the least-squares processing of cation ordering-disordering kinetic data, is here presented and discussed. The study of the intersite cation exchange in rock-forming minerals constitutes a powerful tool for modeling the thermal history of the host rocks. In recent decades many experiments have been conducted on cation ordering-disordering in different rock-forming silicates with the aim of quantifying cation ordering as a function of chemical composition, equilibration temperature, and time. This makes it possible to estimate both the closure temperature and the cooling rate of silicates from terrestrial rocks and meteorites. The kinetics of cation ordering in minerals is less well known than the thermodynamics. This is mainly due to the scarcity of experimental data and to difficulties in interpreting the kinetic data. Moreover, as a consequence of a number of factors, kinetic data are often affected by the presence of strong outliers, i.e. data points markedly distant from the main part of the system. This fact turns into a large discrepancy between the observed and calculated data points and into an incorrect modeling of the experiment. The effect of trying to fit an outlier is to make the fits of all other data points a little bit worse with consequent biasing of the parameter estimates. This is particularly true when the outlier is also an influential point (i.e., a point that remarkably affects the model).

Bearing in mind these considerations, we proposed a protocol for processing cation ordering-disordering kinetic profiles aimed at obtaining a greater accuracy of the estimates of the least-squares optimizing procedures. The procedure, which consists in the identification of the outliers that remarkably impair the fitting by means of the so-called "leverage analysis" and some related diagnostics, has been applied to different set of synthetic data generated on the basis of the Mueller kinetic model. Random errors taken from a normal population with mean and standard deviation comparable to those obtained from experimental measurements have been added to the calculated data points. The effect of the number of experimental data points and of the distribution of them across the kinetic profile, on the reliability of the procedure and on the parameter estimates, has been also investigated. It has been found that the proposed approach allowed the elimination of the actually aberrant observations from the data set and/or their robust weighting to inhibit the negative effects induced on the data fitting, with consequent reduction of the bias introduced into the parameter estimates and a significant improvement in the regression results.

FeCr2O4 SYNTHETIC SPINEL: HEATING EXPERIMENTS AND OXIDATION KINETICS.

PARISI Filippo¹, LENAZ Davide¹, PRINCIVALLE Francesco¹

1 - Università di Trieste - Dipartimento di Geoscienze, via Weiss 8, 34127 Trieste, Italy

Presenter e-mail: princiva@units.it

Key terms: CHROMITE SPINEL; HEATING EXPERIMENTS; SXRD DIFFRACTION; EMPA-SEM EBS; IRON OXIDATION

Single crystals of FeCr2O4 were synthesized using a flux-growth method. Analytical grade Cr2O3 and Fe2O3 powders were dried at 900°C for 12 h before mixing with Na2B4O7, used as flux compound. About 5-6 g of starting material was ground under acetone in an agate mortar and mixed with flux/nutrient ratio.

The mixtures were loaded in 10 cc yttria-stabilised Pt/Au (5%) crucibles and covered with a lid. For thermal runs, an ENTECH muffle furnace with programmable temperature controller were used.

In order to obtain a homogeneous melt, the load was heated at 1,200°C for 24 h. Subsequently the temperature was linearly decreased to 900°C with a 4°C h⁻¹ cooling rates. The thermal runs were ended turning off the furnace and the product was allowed to cool rapidly to room temperature. The reducing atmosphere was provided by a continuous flow of high-purity CO2 and H2 gasses into the furnace. The CO2 :H2 ratio was maintained by TYLAN flow controllers and was kept constant at 1:2 Oxygen fugacity ranged from 10⁻¹¹ to 10⁻¹⁷ bars at 1200-900°C, respectively, which is ca. -0.1 log units from the iron-wüstite solid buffer.

Additional details on the spinel syntheses can be found in Lenaz and Skogby (2003).

Previous studies (Lenaz et al. 2004) showed that Cr completely fills the octahedral site, and that iron occurs almost exclusively as tetrahedral Fe2+.

As Cr should not be oxidized in spinels, we would expect that heating affects only the iron cations present in the T site. Heating in hercynite spinels, FeAl2O4, causes exchange of the Fe and Al cations between the two non-equivalent sites and oxidation of Fe2+ to Fe3+ (Lavina et al. 2005).

Consequently, as Cr cannot fit into a tetrahedral site, the only possible effect is the oxidation of Fe2+ to Fe3+ and, possibly, the formation of T

site vacancies.

To reach this purpose crystals were put in a thin-walled quartz tube and heated in a vertical tube furnace at different temperatures from 600 to 1000°C. Heating runs were performed at room pressure in air. Run temperatures were accurately measured and controlled by means of a calibrated Pt/Pt-Rh thermocouple located near the sample; the uncertainty is estimated to be about ±5°C.

Since the cell parameter (a) and the oxygen positional parameter (u) changes with time and temperature, a strongly correlated relationship between the heating process and the iron oxidation was supposed. At the end of the oxidation process the crystals were polished to about the median plane in order to see if and how the oxidation develops into the crystals.

In order to verify the presence of ferric iron and the formation of vacancies, SEM EBS as well as EMPA analyses have been performed and successively compared with previously performed data obtained from single crystal XRD, EMPA and Mössbauer spectroscopy.

ELECTRONIC, MAGNETIC AND STRUCTURAL PROPERTIES OF NiO AND FeO THIN FILMS EPITAXIALLY GROWN ON SURFACES OF Cu(001) : AN AB-INITIO DENSITY FUNCTIONAL STUDY

GUARCELLO Claudio¹, GELARDI Franco Mario¹, MERLI Marcello¹, SCIASCIA Luciana¹

1 - Università degli Studi di Palermo

Presenter e-mail: luciana.sciascia@unipa.it

Key terms: epitaxial growth; ab-initio; magnetic properties; Bader's theory

In the present project we have simulated the properties of ultrathin layers of nickel and iron oxide epitaxially grown on copper (001), which represent a new class of materials with potential applications in microelectronics, magnetic tunnel junctions, flat panel displays, model supports of catalytic systems, etc. The interest in these systems comes mainly from the theoretical possibility to tune the electronic and geometric properties of the films so as to obtain new desired properties by simply varying the lattice parameter through a proper choice of the appropriate metal substrate, by modifying the film thickness or the nature of the interface, by selectively introducing hetero-atoms or defects in the structure. On the other hand, the fact that sometimes the films possess a different geometric and electronic structure is one of the fascinating aspects of these materials, and opens new perspectives for their use in various applications. Another property of interest is related to the magnetic behavior. This can be modified in principle by interfacing a nonmagnetic metal with a magnetic oxide or simply by changing the lattice mismatch. The nature of the bonding at the interface is essential in determining the final magnetic properties of the system.

Bearing in mind the great interest in this field, we decided to undertake the present study where the properties of ultrathin layers of nickel and iron oxide epitaxially grown on copper (001) have been determined, by adopting a periodic slab model, consisting of five layers of Cu covered on both sides with NiO and FeO monolayers.

The choice of the metallic substrate was dictated by the need to improve and further develop applications based on copper, in view of recent advances in microelectronics and other advanced technologies. The electronic, magnetic and structural properties of the oxides and of the complex systems have been determined. Moreover, the topological analysis of the investigated structures in the framework of the Bader's theory has been performed.

The calculations have been performed by exploiting the ab-initio CRYSTAL09 program at the HF/DFT level. Different Hamiltonians and basis sets have been tested in order to choose the computational setting which better reproduced the experimental observations.

The present studies have shown that the presence of the copper substrate modifies indeed the structural and electronic properties of an epitaxial oxide monolayer; for example, it has been noted that the conductive properties of the materials change significantly, as shown by the analysis of the density of states and band structures. Moreover the antiferromagnetic properties of the films supported by the metallic substrates don't differ significantly from those of the unsupported ones; both unsupported and supported films show an antiferromagnetic ordering.

Fe-Mg SUBSTITUTION IN PIGEONITE: A STUDY BY RAMAN SPECTROSCOPY

TRIBAUDINO Mario¹, MANTOVANI Luciana¹, BERSANI Danilo¹, LOTTICI Pier Paolo¹

1 - Università di Parma

Presenter e-mail: mario.tribaudino@unipr.it

Key terms: pyroxene; pigeonite; Raman spectroscopy; meteorites; peak position-composition relations

The Raman spectra of 10 samples containing the mineral pigeonite, a Ca poor P21/c variety of the mineral pyroxene, were measured. Seven of the studied samples come from the achondritic meteorites belonging to the family of ureilites, two are from volcanic rocks, and one is synthetic; the studied samples have an mg content [mg = 100Mg/(Mg+Fe)] between 52 and 100. The differences in Raman spectra with C2/c and Pbc21 pyroxenes are highlighted; the peak position of the main peaks changes linearly with mg, whereas, likely for the small difference in Ca content, no correlation is present with Wo. Changes in peak position with mg of the major peaks at 340 and 670 cm⁻¹ are significantly lower in C2/c compared to Pbc21 and P21/c pyroxenes. This feature is interpreted as changes in the major peaks are most related to major structural modifications in the M2 polyhedron; such structural modifications are lower in C2/c pyroxenes. Peak width in natural pigeonite is higher than in synthetic one, owing to the defective texture of the former.

The present results may provide a basis for on site analysis of pyroxenes by means of Raman spectroscopy of planetary bodies in space exploration.

NUMERICAL MODELING EXPERIENCE APPLIED TO CO2 POTENTIAL GEOLOGICAL RESERVOIRS IN ITALY

MOIA Fabio¹, GUANDALINI Roberto¹, CIAMPA Giuseppina¹
1 - RSE S.P.A.

Presenter e-mail: fabio.moia@rse-web.it

Key terms: CCS; CO2 FATE; GEOLOGICAL/NUMERICAL MODELING; RESERVOIR CO2 CAPACITY

As argued by the European Commission - Directorate General for Energy and several international bodies, like among the others the Carbon Sequestration Leadership Forum (CSLF), the Carbon Capture and Storage (CCS) is accepted as a reasonable solution for reducing greenhouse gas emissions, figuring in perspective as a countermeasure against the climate change. In particular, there is a general agreement to consider the CO2 storage in geological formations as a feasible technique and Weyburn-Midale CO2 Project (Canada Saskatchewan) and Sleipner Project (Norway-North Sea) seem to demonstrate it. Yet the safe and effective approach in a long-term perspective (500-1000 years) is still largely not proven. Thus the understanding of the long-term transport and fate of CO2 and associated physical processes is still a crucial issue in view of the deployment of the technology.

CO2 can be stored in different geological reservoirs as: depleted oil and gas fields, unminable coal seams and deep saline aquifers. The porous rocks with salt waters offer the highest CO2 storage potential and the injection should take place in geological reservoirs located at least 800 meters of deep where the conditions of temperature and pressure are suitable for injecting CO2 in supercritical conditions and with the characteristics of a fluid. The reservoir must be covered by a clay (or equivalent) geological formation, which can prevent the leakage of CO2 into geological formations above.

The characterization of the caprock-reservoir system for CO2 geological storage includes several processes as for example: well integrity, chemical reaction, thermal flux, multiphase flow and transport, stress/strain change, induced fracturing and fault reactivation. In this complicated contest, it is undeniable that the numerical modeling is the only tool available for predicting the long-term behavior of CO2.

The paper describes the geological models created for three different potential reservoirs in Italy: a) Offshore Sibari basin (denominated Calabria Ionica) where the geological caprock is represented by a thick clay formation (Pleistocene) locally with thin silt or sand layers and the reservoir is represented by high porosity and salt water arenaceous/gravel-sand formation (upper Miocene), b) Offshore North Adriatic sea where the caprock is represented by clay with silt and thin layers of sand (Pleistocene) and the reservoir is represented by high porosity and salt water sands with few thin clay intercalation (Pleistocene-Middle Pliocene), c) Area onshore around Malossa oil and gas field in Lombardia region in which the caprock is represented by a clay formation known as Santerno Clay of Pliocene age and the reservoir is a conglomerate formation with salt water known as Serignano Gravel of upper Messinian age.

The numerical modeling results of CO2 injection and fate by using the Integrated System for Modeling Analysis (SIAM) developed by RSE Company are also shown with particular relevance to CO2 plume extension during the 30 years of supposed injection and extended to more than 500 years after the start of the CO2 injection process itself. The stress conditions generated around the injection wells, inside the reservoirs and at reservoir-caprock interfaces are also shown to verify the safety pressure criteria. The injection of 1 Mton/year of CO2 for a 30 years period is considered for case a) and b) while, for case c) we considered a CO2 injection rate of 0,3 Mton/year. The CO2 storage capacity of each saline-aquifer reservoirs has been estimated by using the method proposed in the EU Geocapacity Project with different values of the storage efficiency factor and compared with the more sophisticated procedures related to numerical modeling.

REMAINING GAPS FOR A "SAFE" GEOLOGICAL STORAGE OF CO2: THE CO2GAPS VISION CHALLENGES OF "LEARNING BY DOING"

QUATTROCCHI Fedora¹, VINCIGUERRA Sergio¹, CHIARABBA Claudio¹, BUTTINELLI Mauro¹, CANTUCCI Barbara¹, IMPROTA Luigi¹, NAZZARI Manuela¹

1 - Istituto Nazionale di Geofisica e Vulcanologia, Roma, Italy

Presenter e-mail: fedora.quattrocchi@ingv.it

Key terms: CO2 Gaps; geochemical-geochemical data; public acceptance

CO2GAPS vision of the INGV (which is jointed recently with other research groups of CNR, ETHZ, EUCENTRE, etc.... by an European Proposal still confidential and under evaluation, as a whole) intends to fill key GAPS concerning the main risks associated to the storage of CO2 and the consequent liability of the "storage" part in the entire Carbon Capture and Storage (CCS) process. These still constitute a real obstacles for the large scale industrial development of CCS. A better "site specific" risk assessment and the development of reliable multi-disciplinary monitoring protocols will be then supported by "peer reviewed" processes and patented analytical procedures and techniques. The outcome results should be also embedded in the updating of the Annex 2, EU Dir. 2009/31/EC. The vision of the INGV group, as part of the partnership, is to apply a multidisciplinary approach, integrating geochemical-geochemical data with seismic tomography and crustal rocks anisotropy, induced/triggered seismicity, gravimetry, EM techniques, and "early alarm" procedures for leakage in shallow geo-spheres and abandoned wells.

Moreover geochemical and geochemical data are necessary for a reliable 3D-Earth modelling and a full merging with reactive transport codes, as well as the improvement of numerical modeling codes itself (updating "site specific" siting - Annex 1). CO2GAPS vision will apply and verify these themes working on several European selected sites, taking

also into account complex systems such as "inland" active faulted blocks close to the off-shore storage sites, ECBM faulted prone-areas, "inland" injection test site, and CO2 natural analogues. The purpose of these future activities will focus on the study of long-term fate of stored CO2, leakage mechanisms through the cap-rock/abandoned wells, geochemical/geochemical reactivity of cement wells, as well as the effects of impurities in the CO2 streams, their removal costs, the use of tracers and role of biota.

RADON AND THORON EMISSIONS FROM HIGH TO LOW POROSITY ROCKS UNDER INCREASING DEFORMATION

Presenter e-mail: tuccimei@uniroma3.it

Key terms: radon emission; rock deformation; seismic surveillance; rock porosity

Anomalous radon and thoron emissions are regarded as valuable precursors of earthquakes and volcanic eruptions and are related to increasing damage of the medium. However both positive and negative anomalies are observed in the field prior ruptures, thus indicating competing deformation mechanisms. Initial porosity (P) plays a key role for natural lithologies in controlling damage accumulation and strain localisation processes. Thus investigating how elastic properties of low to high porosity rocks are affected from increasing loading is required to quantitatively interpret the positive and negative anomalies observed. Here we present an experimental dataset where measurements of radon (²²²Rn) and thoron (²²⁰Rn) emissions are carried out on low to high porosity lithologies incrementally loaded up to failure. The following samples are investigated: a high porosity lithophyse-rich tuff (P = 47.0 %) and a low porosity phonolitic lava flow (P = 3.6%). Cylindrical samples of 120 (length) x 60 (diameter) mm, have been uniaxially loaded at constant strain rate in servo-controlled uniaxial machines. Samples have been either 1) mechanically damaged to the end of the elastic phase, before the onset of dilatancy or 2) loaded up to the failure. Radon and thoron exhalation rates are carried out by using a solid-state alpha detector, connected to a small accumulation chamber kept at the constant temperature of 60°C. Measurements are performed on two samples at once to achieve stronger signals and repeated several times in order to verify their reproducibility. Results show that a decrease of radon and thoron emissions are evidenced at the end of the 'damage phase' for the high porosity tuff, while a slight increase is observed for the low porosity lava flow. At the end of the elastic phase the tuff reduces its radon and thoron exhalation rates, because of pervasive pore collapse of the macropores, with a P reduction up to 40.1%. In contrast, for the lava flows the loading slightly increases the crack damage and, consequently, P increases up to 5.1%. This change does not significantly affect the radon exhalation. At the failure, new rupture surfaces are generated. The total exhaling surface of the samples increases and an increase of radon emission is observed for both lithologies.

Presenter e-mail: alba.zappone@sed.ethz.ch

Key terms: CO2 geological storage; porosity; permeability; physical properties; Swiss Molasse Basin

The potential for storage of CO2 in geological formations in Switzerland has recently been evaluated by Chevalier et al. (2010). A score was assigned to each aquifer/seal pair in the Swiss Molasse basin and Jura mountains, based on an international reference scale (Bachu, 2003). The upper Muschelkalk/Gipskeuper aquifer/seal pair scored highest.

However, the spatial heterogeneity of this aquifer, combined with lack of data coverage, warrants a more thorough investigation of the potential aquifer/seal pair, with emphasis on the following questions:

- 1) How is porosity and permeability spatially distributed in the Muschelkalk?
- 2) Can we use existing geophysical data (i.e., seismic lines) to provide information about the physical properties of the Muschelkalk?
- 3) How has the physical properties of the Muschelkalk developed over geological time?

To answer these questions we aim to compile existing published data and gather new data by laboratory measurements, where it is needed. Several sources for information are available at present, including academic literature and industry records.

Laboratory investigations on elastic properties, density, porosity and permeability are ongoing, using experimental equipment at the rock deformation laboratory in Zurich.

The work will present a state of the art of the of these studies in the perspective of a feasibility study of a pilot project of Carbon capture and Storage in the Swiss Molasse Basin.

 4 - Institute of Geological Sciences, University of Berne, Berne, Switzerland

Presenter e-mail: alba.zappone@sed.ethz.ch

Key terms: CO₂ geological storage; injection induced seismicity; mineral carbonation; Laboratory experiments; Switzerland

The CARMA project aims to explore the potential for and the feasibility of Carbon Capture and Storage (CCS) in Switzerland within the framework of future energy scenarios. We aim to exploit the available expertise to develop new CCS technologies and know-how, which might be applied in Switzerland and worldwide. We intend to evaluate the economic, environmental, societal, and institutional implications of CCS and to assess the potential CO₂ geological storage capacity in Switzerland. We also intend to build on the strengths, experience and available equipment of the research groups involved, focusing on mineral carbonation, as a means of fixing CO₂ in stable, mineral form. CARMA brings together the research groups from various universities and industries in Switzerland. The project started in January 2009, with a total runtime of 4 years. This poster reports the achievements with respect to geological storage of CO₂ in Switzerland during the first half of the project.

An estimate of the theoretical storage potential in the subsurface was completed in August, 2010. The methodology followed an existing evaluation scheme developed in Canada, based on geological criteria only. Modifications were introduced to suit the geological setting and available data in Switzerland. The study relies on quantitative and semi-quantitative attributes derived from analysis of existing laboratory, drill-hole, geological, and geophysical data. The weighted combinations of these attributes have been ranked in order to visualize Switzerland's storage potential in the form of a contour map. The theoretical storage capacity of the suitable sandstone and limestone aquifers is approximately 2.6 Gtons of CO₂, i.e. 65 times Switzerland's current annual CO₂ emissions.

Through geological investigations, laboratory testing and one or multiple field tests would be imperative to prove its feasibility and safety. The potential seismic hazard related to CCS operations is carefully assessed within CARMA. The activities that have been carried out focused on the compilation of known cases of induced seismicity due to fluid injection. The compilation includes enhanced geothermal systems, passive geothermal plants, liquid waste disposal, and CCS projects. A classification methodology has been proposed according to the type of operation, operative plant parameters, tectonic regime, state of stress and background seismicity of the injection area.

An alternative approach to that offered by subsurface storage is ex-situ mineral carbonation in a controlled industrial setting. This involves the dissolution of CO₂ into an aqueous phase, leaching of magnesium/calcium from a natural mineral feedstock and the precipitation of Mg-/Ca-carbonates, thus fixing CO₂ in a stable, environmentally benign form. The reactions involved are exothermic overall, but their kinetics is slow under ambient conditions. This makes an energy intensive, mechanical or thermal activation of the mineral feedstock inevitable. While this adds to costs, mineral carbonation offers the possibility of fixing CO₂ directly from an industrial off gas stream, thus obviating the costly capture step. Within CARMA, we are investigating an aqueous process, where a flue gas is bubbled through a stirred tank containing the mineral feedstock in suspension. We have built a set-up to perform mineralization experiments under a variety of temperature, pressure, gas composition and solution chemistry conditions, using several optical and physicochemical analytical techniques to monitor the different phases in-situ and online further downstream. Currently, the dissolution behavior of thermally activated serpentine is being studied. Hitherto, olivine was found to be the natural silicate feedstock exhibiting fastest dissolution kinetics. When directly compared to olivine, we found that activated serpentine dissolves 2 to 3 orders of magnitude faster under identical conditions.

MECHANICAL CHARACTERIZATION OF THE SERGNANO RESERVOIR BY ULTRASONIC WAVE VELOCITY MEASUREMENTS

APUANI Tiziana¹, GIANI Gian Paolo¹, VIGANI Giulia¹
 1 - Università degli Studi di Milano - Dip. Scienze della Terra

Presenter e-mail: tiziana.apuani@unimi.it

Key terms: Ultrasonic wave velocities; elastic properties; Santerno Shale; Sergnano oilfield

Proper design and planning of gas storage in natural reservoirs takes advantage of the numerical modeling of the injection process. The numerical simulation must be supported not only by a thorough knowledge of the geological and structural features of the concerned area, but also by an adequate geomechanical characterization of the involved units. Static and dynamic methods can be applied, by in situ tests or at laboratory scale.

With the final goal to furnish the input data for numerical modeling, the mechanical properties of the rocks making up the Sergnano oilfield were preliminarily investigated by ultrasonic wave velocity measurements on rock samples.

The Sergnano oilfield (CR-Italy) is located in the Pliocene-Quaternary foredeep of the Po basin; discovered in 1953, it was converted into a methane gas storage tank in 1965. The reservoir rocks belong to the "Ghiaie di Sergnano unit", overlying the Gallare marl (Marne di Gallare). The cap rock is represented by the Santerno shale (Argille di Santerno).

Samples were collected from the two cores gently offered by Eni s.p.a.: six in the cap rock at the depth between 1330-1340 m, and two at the base of the reservoir at about 1710 m b.s.l.. The mineralogical clay nature of the Santerno shale was derived from x-ray diffraction analysis and their behavior defined by the Atterberg limits. The physical properties of bulk and specific unit weight were measured and porosity calculated, both for the cap rock unit then for the bottom one.

P and S high frequency wave velocities, measured in different directions, normal and parallel to the bedding plane, allowed to define a poor anisotropic behavior. The effect of increase confining pressure, up to 290 MPa, was explored and correlation equations between wave velocity and pressure were attempted. The dynamic elastic properties were then calculated: Bulk modulus (K), Elastic modulus (E), Shear modulus (G),

Poisson's ratio (ν).

Presenter e-mail: punturo@unic.it

Key terms: textural and seismic anisotropy; mineralogical changes; Kavala shear zone

Mylonitic shear zones represent the binary which drives the structural evolution of mountain belts; for this reason they can be considered as "natural laboratories" where it is possible to observe and concentrate the investigation on microstructural and textural characteristics related to the changes in physical and mineralogical properties of progressively deformed rocks.

Our attention focussed on the Kavala (Symvolon) pluton, which crops out in north-eastern Greece and is mainly composed of early-Miocene granodiorite deformed at various extents during syn-shearing emplacement. According to the Authors, it represents the south-western termination of the Rhodope Core Complex, which was exhumed as a result of large scale extension from mid-Eocene to mid-Miocene times.

Structural features of mylonitic textures highlighted the presence of a NE-SW monotone stretching lineation consistent with the shape elongation of the outcropping pluton, with intensity in deformation increasing towards the contact with the host gneiss. Despite gneiss rocks experienced a longer deformation history, any previous fabric was completely reworked by the Alpine mylonitic shearing activity. Such a peculiar outcrop conditions set aside samples to be collected by taking into account progressive deformation.

Bulk rock geochemical and petrographic investigation allowed the characterisation and selection of representative samples for both Kavala granitoid and country gneiss rocks. They mostly classify as metaluminous to weakly peraluminous granodiorite and strongly peraluminous granite, respectively, and define distinct parallel trends in specific major and trace element variation diagrams. Geochemical trends have been used to check for any possible modification of the different rock types associated with mylonitization, as well as to identify original magmatic compositions. Mineral chemistry investigation accompanied by multivariate statistical analysis of multispectral X-ray maps highlighted well preserved original porphyroblast zoning within low strain domains, whereas a complete compositional re-homogenisation was observed in widespread high-strain domains. Moreover, several generations of syn-mylonitic mineral growth inducing local strength-softening have been detected. Quantitative microstructural investigation was performed on thin sections cut parallel to the stretching lineation. Optical assisted-image technique analysis on quartz grains (800 ca. grains per sample) revealed a mean axial ratio (AR, i.e. the ratio between major and minor axis of particles) ranging between 2.2 and 3.2 (AR max = 15) and average grain size of 20

μm . 2. Calculated flow-law equation describing the rheological properties of quartzite suggests a mean shear strain rate value of $4.87 \times 10^{-12} \text{ (s}^{-1}\text{)}$ for the studied samples.

Finally, petrophysical investigation on progressively deformed granodiorite at confined pressure conditions (up to 400 MPa) highlighted that Vp are distributed with the highest and lowest values orientated within and normal to the main foliation plane, respectively. Vp related seismic anisotropy ranges from 2.16 to 6.92%. Vs related acoustic birefringence shows its maximum along the stretching lineation direction. Vp/Vs ratios are in the range of 1.67 - 1.70.

Preliminary correlation between petrophysical and quantitative microstructural features opens new perspectives in the calculation of strain rate estimates of progressively natural sheared rocks.

CAN CARBONATE FAULTS BE MELT-LUBRICATED?

VIGANÒ Alfio¹, TUMIATI Simone², MARTIN Silvana³

- 1 - Università degli Studi di Trento
 2 - Università degli Studi di Milano
 3 - Università degli Studi di Padova

Presenter e-mail: silvana.martin@unipd.it

Key terms: Carbonate pseudotachylite; Fault lubrication; Earthquake; Grigna Massif

There is natural and experimental evidence that faults are normally lubricated during seismic faulting. In particular, carbonate fault lubrication is thought to be driven principally by decarbonation reactions. Here we present the natural example of the Canalone Porta fault (Grigna Massif, Southern Alps, Italy) which shows the existence of carbonate pseudotachylites, suggesting that low-viscosity melts can promote melt lubrication processes.

The Canalone Porta fault, developed within dolomitic and marly limestones, hosts fault- and injection-veins of dominant carbonate composition. Vein texture is characterized by a fine-grained reddish matrix supporting millimetre-sized clasts. This matrix is composed of micrometre-sized globular aggregates of micrometre- to nanometre-sized calcite and dolomite crystals, bound together by a K-bearing aluminosilicate glass. Bulk-rock geochemical compositions of veins are very similar to those of the host fault-core rocks. However, veins display a Mg/(Ca+Mg) ratio (XMg) definitely lower than the host rocks.

In the calcite-dolomite system, carbonate melting occurs in the ~660-1100 °C range of temperature, depending on the water content. The estimated melting temperature of the studied rocks falls within this temperature range (~700 °C). Besides, the average XMg of the matrix (0.26) is in keeping with the theoretical value (0.2-0.3) for similar compositions at crustal pressures. The observed aluminosilicate glass can be derived from disequilibrium melting of muscovite.

Structural, chemical, mineralogical and petrological observations suggest that the Canalone Porta veins have not been formed by simple mechanical comminution, but are the quenching product of friction-induced

carbonate-rich melts (i.e., carbonate pseudotachylytes) produced at $T \approx 700$ °C and $P \approx 0.1-0.2$ GPa. The existence of pseudotachylytes of dominant carbonate composition along faults implies the presence of low-viscosity melts promoting fault lubrication during those earthquakes nucleating in the carbonate sedimentary levels of the shallow crust.

Key terms: *Petrophysics; Elastic properties of rock; Ultrasonic emission; Fiber optic-based sensors; Rock landslides*

The analysis of stress accumulation and crack-induced vibrations of an unstable slope before failure is considered an effective tool in rock-fall disaster forecasting. The national project SMILAND (Innovative Integrated Systems for Monitoring and Assessment of High Risk Landslides) aims at development of innovative solutions for rocky landslides early-warning based on optical fiber sensors. Within this project, a petrophysical characterization, based on different laboratory methods aims to detect the elastic properties, has been carried out on different type of rock samples. The acoustic emissions (AEs) released during the rock fracturing of laboratory samples has been also studied. Nowadays, the implemented AE monitoring techniques, used both in laboratory and in the field, are mainly based on seismometers, geophones or also microphone arrays. These devices, although accurate and reliable, may be difficult to install in the field and are liable to lighting and electromagnetic interference (EMI). In recent years, the interest in fiber optic-based sensors (FOS) has experienced a rapid increase, fostered by the advantages that these sensors offer in comparison with the classical ones. In particular, their intrinsic robustness to EMI and lightning, their remote operability and distributed sensing ability, make the FOS suitable to the distributed monitoring of several parameters (e.g. strain and temperature) in hard environment conditions too. The application of such sensors to landslides and cliff collapses is nowadays mainly limited to displacement measurements.

Nonetheless, the application of fiber sensors to the characterization and monitoring of seismic precursory patterns of unstable rocks or cliffs is still an unexplored research field.

Interferometric sensors have shown very high sensitivity, that consists an extremely important feature for detecting small wave amplitude precursor AEs related to initial rock cracking development.

Considering that the correlation between the rock behavior to different stress conditions and internal resistance variation is principally due to the mechanical properties of the rock mass, different rock types samples (marble, dolomite and trachyte) has been used in laboratory tests to detect the elastic properties of rocks related to mineral composition, fabric, structure and porosity.

Elastic properties of rock samples have been measured by using different laboratory methods such as uniaxial apparatus, ultrasonic static and dynamic multifrequency instrument. The comparison of data results have shown a substantial homogeneity from elastic modulus obtained by different methods.

In this frame, all the rocks involved in the testing phase have been characterized from the mineralogical-petrographical and structural point of view. Such a complete characterization has been carried out on three mutually perpendicular sections with respect to the macroscopic fabric elements of the rock. Grain and bulk densities of the rocks will be also measured.

Laboratory testing of FOS have been carried out coupling the developed sensors with several rock samples, having different lithological, structural and mechanical features.

Key terms: *MICAS; GIXRD; AXANES; NEXAFS; P-EXAFS*

Intercalation means the reversible insertion of a guest chemical species (atom, ion, molecule) in a virtually unchanged host crystal structure. Any type of layer-structured material may give rise to intercalate compounds, the guest species being inserted between the host sheets without loss of their planarity. Layer silicates, in particular, may be considered intercalated structures in which interlayer guest species and complexes are inserted between the silicate layers. The most common guest species is water, which is generally present under natural conditions in layer silicates such as smectites, vermiculite and halloysite. From the outset, attention was focused on their swelling/shrinking behaviour with respect to water, and also on the non-stoichiometric, heterogeneous complexes they formed with organic liquids such as ethylene glycol and glycerol. At present, the unique combination of the layer-silicate features (small crystal size, high surface area) and the low concentrations necessary to effect a change in the matrix, both coupled with the advanced characterization techniques now available, have generated much interest for the special field of nanocomposites, as far as for graphene, which can also be considered as an intercalated layered structure. In general, any guest material inserted into an interlayer space causes a main modification in the structure, with size changes in a particular crystallographic direction (d-spacing). After a brief introduction on conventional and synchrotron-based X-ray techniques used to define crystal size and thickness, the essentials of the grazing-incidence diffraction (GIXRD) technique will be given. The additional, complementary information arising from X-ray absorption spectrometry (XAS) such as short-range order and detailed local information on atomic positions by angle-resolved X-ray near-edge structure (AXANES), polarized extended X-ray absorption fine structure (P-EXAFS), and near-edge extended absorption fine structure (NEXAFS) spectroscopies will also be analyzed and discussed.

CRYSTAL CHEMISTRY OF TRIOCTAHEDRAL MICAS-2M: FROM BUNYARUGURU (SW UGANDA) KAMAFUGITE

LACALAMITA Maria¹, SCORDARI Fernando¹, SCHINGARO Emanuela¹, MESTO Ernesto¹

1 - Dipartimento Geomineralogico, Università degli Studi di Bari, I-70125 Bari (Italy)

Presenter e-mail: M.LACALAMITA@GEOMIN.UNIBA.IT

Key terms: *Ugandan 2M-phlogopites; crystal chemistry; substitution mechanisms; Mössbauer; FTIR*

In trioctahedral micas, polytype 2M occurs less frequently than 1M one. For such a reason, trioctahedral 1M-polytype has been extensively studied up to date whereas studies on 2M-polytype are relatively rare. In several cases 2M-micas have been reported as coexisting with 1M-micas [1, 2, 3, 4, 5]. Other studies were focused on the characterization of phlogopite-anite 2M micas with peculiar composition [6, 7, 8, 9, 10]. The crystal chemistry of 2M micas from Bunyaruguru (south west Uganda) kamafugite was studied by Electron Probe Microanalysis, Single Crystal X-ray Diffraction, Mössbauer and Fourier Transform Infrared spectroscopy. To the best of our knowledge, this is the first integrated crystal chemical study of phlogopite from Ugandan kamafugites, and was undertaken to get an insight into the crystal chemistry of the trioctahedral mica 2M-polytype.

Chemical analyses showed that the studied crystals are Ti-rich, F-poor phlogopites with an annitic component, $Fe_{\text{total}}/(Fe_{\text{total}} + Mg)$, ranging from 0.15 to 0.23. Unit-cell parameters from single crystal X-ray data are in the range: $5.3252(1) \leq a \leq 5.3307(1)$, $9.2231(3) \leq b \leq 9.2315(3)$,

$20.1550(6) \leq c \leq 20.1964(8)$ Å and $94.994(2) \leq \beta \leq 95.131(2)^\circ$.

Anisotropic structure refinements, in the space group $C2/c$, converged to

$2.80 \leq R_1 \leq 3.56$ % and $2.91 \leq wR_2 \leq 4.08$ %. Mössbauer spectroscopy showed that the studied sample has: $^{57}Fe^{2+} = 60(1)$ %, $^{57}Fe^{3+} = 24(1)$ % and $^{57}Fe^{3+} = 16(1)$ %. FTIR investigations pointed to the occurrence of Fe³⁺-oxy substitutions and ruled out the presence of vacancy mechanisms. The overall crystal chemical features are consistent with the following substitutions: tetraferriphlogopite; Ti-oxy and Al, Fe³⁺, Cr-oxy; Al, Fe³⁺-Tschermak; kinoshitalite and $^{IV}K^{+} + ^{VI}Al^{3+} \leftrightarrow ^{IV}Si^{4+} + ^{VI}Al^{3+}$.

The estimation of the OH⁻ content for Ugandan mica-2M was obtained, for the first time, from the linear regression equation $c = 0.20(2) \times OH^- (\text{gpfu}) + 19.93(2)$ derived from literature data of 2M-samples with known OH⁻ content.

The orientation of the O-H vector with respect to c^* was found in the range from 2.8 to 12.6°, consistently with literature values [11].

THE PHYLLOSILICATE LAYERS: AN OVERVIEW ON TOPOLOGY AND MODULARITY

FERRARIS Giovanni¹, CADONI Marcella¹

1 - Università degli Studi di Torino - Dipartimento di Scienze Mineralogiche e Petrologiche

Presenter e-mail: giovanni.ferraris@unito.it

Key terms: *Phyllosilicates; Layers; Topology; Modular structures; Crystal Chemistry*

On the basis of the specific purposes of Symposium J7, the keynote aims to present an introductory overview on the structural characteristics of the phyllosilicate layers. With particular reference to the TOT layer, emphasis will be given to the features that support complex crystal chemistry, polytypism, polysomatism and twinning.

Key terms: paragonitic muscovite; crystal chemistry; surface

The paragonitic muscovite considered $[(K_{1.722}Na_{0.255}Ba_{0.010})^{VI}(Fe^{2+}_{0.140}Al^{3+}_{0.789}Cr^{3+}_{0.003}Mg_{0.074}Ti_{0.012}Mn_{0.002})^{IV}(Al_{1.89}Si_{1.103})O_{20}(F_{1.09}OH_{1.891})]$ came from Antarctica, it is monoclinic, 2M₁ polytype, with symmetry C2/c and unit

cell parameters $a = 5.1969(1)$, $b = 9.0138(3)$, $c = 20.0835(7)$ (Å) and $\beta = 95.763(2)$ (°).

By using a multi-analytical approach this study describes the crystal chemical features of muscovite determined both in the bulk and on the uppermost surface layers.

The bulk structure was refined by single crystal X-ray diffraction and the final refinement yielded the following agreement factor $R = 0.0299$. The

two tetrahedral sites, T1 and T2, present similar distances ($\langle T1-O \rangle =$

1.643 Å and $\langle T2-O \rangle = 1.647$ Å) and distortion parameter values, thus evidencing a disordered distribution of ^{IV}Si and ^{IV}Al in tetrahedral sites.

Tetrahedral ring is significantly distorted ($\alpha = 11.2^\circ$) and the tetrahedral basal oxygen atoms plane is remarkably wavy ($\Delta z = 0.224$ Å). tetrahedral ring distortion affects not only the topology of the cleavage plane, but also the coordination of the interlayer cation, which reduces from twelve to eight.

Crystal chemical modifications at mineral surface were investigated via X-ray Photoelectron Spectroscopy (XPS), by comparing data related to surface to the ones characterizing the bulk.

A peculiarity of muscovite from Antarctica is a limited Na for K interlayer substitution, which was found in the bulk as well as on the mineral surface. It is well known that in micas the coordination of the interlayer cation can vary from twelve to six, depending on the distortion of the hexagonal tetrahedral ring, as measured by α angle, as observed and predicted by Weiss et al. [1].

The interlayer cation K (binding energy = 293.36 eV) is confirmed to be eight-fold coordinated [2]. Na (binding energy = 1071.02 eV) substitutes K both in the bulk and at the surface. Na coordination, at mineral surface, reduces from eight to six. The six-fold coordination presented by Na is consistent with $\alpha \approx 16^\circ$, which is typical for paragonite, whose interlayer is completely occupied by Na. Chemical composition at the surface was compared to bulk chemical composition obtained by electron microprobe analysis. This comparison highlights a decrease in K content, which can be explained by its location on the cleavage surface, since the cation is expected to be distributed equally along the two surfaces generated after cleavage, and an increase in Na which can be related to Na domains close to the cleavage surface.

These aspects may relate muscovite cleavage processes to the presence of "defects", or better inhomogeneities in layer crystal chemistry. This fact may thus suggest that Na content in paragonitic muscovite could not be only attributed to a solid solution mechanism, where this cation substitutes for K, but rather to the presence of Na-dominant clusters.

MULTIMETHODIC INVESTIGATION OF COEXISTING 1M- AND 2M₁-MICAS FROM KASENYI (SW UGANDA) KAMAFUGITE

SCORDARI Fernando¹, MESTO Ernesto¹, SCHINGARO Emanuela¹, LACALAMITA Maria¹

1 - Dipartimento Geomineralogico - Università degli Studi di Bari

Presenter e-mail: mesto@geomin.uniba.it

Key terms: Ugandan 1M-2M₁ phlogopites; crystal chemistry; comparison in the 2M₁ setting

Several diffraction studies on coexisting 1M and 2M₁ polytypes have been carried out to date [1, 2, 3, 4, 5, 6] in order to draw informations on their differences by comparing unit layer structure and/or the crystal chemical details of the two polytypic forms. Some of the quoted studies contain implications on polytype formation in micas [1, 2].

In the present work, the crystal chemistry of 1M and coexisting 2M₁ micas from Kasenyi (south west Uganda) kamafugite was investigated by Electron Probe Microanalysis, Single Crystal X-ray Diffraction and Mössbauer spectroscopy. The aim of the present study is to compare crystal chemical and unit layer structural features of the coexisting polytypic forms and to make comparisons to literature data.

EPMA investigation yielded similar composition for 1M and 2M₁ polytypes. They are Ti-rich, F-poor phlogopites with an anionic component, $Fe^{2+}/(Fe^{2+} + Mg)$, of about 0.14. The room temperature Mössbauer spectrum of the sample yielded three Fe-species: $^{57}Fe^{2+} = 58(1)\%$, $^{57}Fe^{3+} = 23(1)\%$ and $^{57}Fe^{3+} = 19(1)\%$. A typical crystal chemical formula is: $(K_{0.96}Na_{0.04}Ba_{0.01})(Mg_{2.22}Al_{0.09}Fe^{2+}_{0.21}Fe^{3+}_{0.08}Ti_{0.28}Cr_{0.04}Ni_{0.01})(Si_{2.87}Al_{1.06}Fe^{3+}_{0.07}O)_{10.65}F_{0.05}OH_{1.30}$.

Average cell parameters are $a = 5.326$, $b = 9.224$, $c = 10.231$ Å, $\beta =$

100.06° for polytype 1M and $a = 5.325$, $b = 9.223$, $c = 20.206$ Å, $\beta = 95.08^\circ$ for polytype 2M₁. The interatomic distances are similar for the two polytypes and consistent with the relevant site chemistry.

The comparison among atomic coordinates of 1M and 2M₁ micas from this study and from the literature in the 2M₁ setting evidenced a remarkable agreement between all atomic coordinates, with the exception of the y values of the octahedral oxygen atoms. Specifically, the difference between y values was 0.004 in the study samples, 50 times the estimated standard deviations. Similar differences were found for the literature data [1].

Key terms: phlogopite; high pressure; compressibility; single-crystal X-ray diffraction; synchrotron powder diffraction

The crystal chemistry and the elastic behaviour under isothermal conditions up to 9 GPa of a natural, and extremely rare, 3T-phlogopite from Traversella (Valchiusella, Turin, Western Alps) $[(K_{0.99}Na_{0.05}Ba_{0.01})(Mg_{2.66}Al_{0.28}Fe^{2+}_{0.21})[Si_{2.71}Al_{1.29}O_{10}](OH)_2]$ space group P3₁12, with $a = 5.3167(4)$, $c = 30.440(2)$ Å, and $V = 745.16(9)$ Å³ have been investigated by electron microprobe analysis in wavelength dispersion mode, single-crystal X-ray diffraction at 100 K and in-situ high pressure synchrotron radiation powder diffraction (at room temperature) with a diamond anvil cell. The single-crystal refinement confirms the general structure features expected for tri-octahedral micas, with the inter-layer site partially occupied (using the potassium scattering curve alone), iron almost homogeneously distributed over the three independent octahedral sites, and the average bond distances of the two unique tetrahedra suggesting a disordered Si/Al-distribution (i.e. $\langle T1-O \rangle \approx 1.658$ and $\langle T2-O \rangle \approx 1.656$ Å). The location of the H-site confirms the orientation of the O-H vector nearly perpendicular to (0001). The refinement converged with $R(F) = 0.0382$, 846 unique reflections with $F_o > 4\sigma(F_o)$ and 61 refined parameters, and not significant residuals in the final difference-Fourier map of the electron density (+0.77/-0.37 e-/Å³). The high-pressure experiments showed no phase transition within the pressure range investigated. The P-V data were fitted with a Murnaghan (M-EoS) and a third-order Birch-Murnaghan equation of state (BM-EoS), yielding: 1) M-EoS, $V_0 = 747.0(3)$ Å³, $K_{T0} = 44.5(24)$ GPa and $K' = 8.0(9)$; 2) BM-EoS, $V_0 = 747.0(3)$ Å³, $K_{T0} = 42.8(29)$ GPa and $K' = 9.9(17)$. A comparison between the elastic behaviour in response to pressure observed in 1M- and 3T-phlogopite is carried out.

Key terms: Fluorophlogopite; 1M twin; single crystal X-ray refinement; EPMA; volatile-induced differentiation

In the present study, a systematic investigation of fluorophlogopite from Mt. Etna volcano (Italy) was performed. The mica sample studied here is among the most Fe- and Ti-rich fluorophlogopite found in nature. It occurs in a bonemoreitic lava from the prehistoric volcanic activity of Mt. Etna (post-caldera phase of the "Ellittico" volcano; ~15 ka BP)[1]. Fluorine-rich minerals are important indicators of the halogen activity in magmatic systems, so that their investigation offers the opportunity to get important information on the processes of magma differentiation acting in the shallow portions of the volcano plumbing system. This study was based on electron probe microanalyses (EPMA), and single-crystal X-ray diffraction (SCXRD).

EPMA data yielded the following chemical formula for the mineral under consideration: $(K_{0.817}Na_{0.148}Ca_{0.003})(Fe^{2+}_{0.535}Fe^{3+}_{0.004}Mg_{2.223}Al_{0.003}Ti_{0.227}Mn_{0.008})(Al_{0.958}Si_{3.042})O_{10}(Cl_{0.010}F_{1.388}OH_{0.152}O_{0.450})$. The X-ray analysis indicated that the sample represents an example of twinning of 1M polytype simulating the diffraction patterns of a 3T polytype [2]. Structure refinements, which was performed on three crystals using twin laws, converged at $R = 0.03-0.04$, with cell parameters in the range $a = 5.323-5.324$, $b = 9.219-9.222$, $c = 10.116-10.119$ Å, $\beta = 100.13-100.25^\circ$. Major substitutions are $OH \rightleftharpoons$

F^- , and the Ti-oxy substitution: $^{VI}M^{2+} + 2(OH)^- \rightleftharpoons ^{VI}Ti^{4+} + 2O^{2-} + H_2 \uparrow$. The replacement of OH with F⁻ affects mainly the octahedral sites reducing the misfit between tetrahedral and octahedral sheets. The short c parameter is due to the reduced repulsion between the interlayer cation and the hydrogen depleted anion site in O4. In the studied sample the structural effects due to the high-F content are enhanced by those due to oxy-type substitution. The crystal chemical features of this fluorophlogopite from the summit portions of Mt. Etna are intermediate between those from Biancavilla [3] and the Ti-rich fluorophlogopite from Presidente Olegario, Brazil [4]. Although the fluorophlogopite from Biancavilla and that studied here were found in products of the same eruptive period at Mt. Etna, the different structural and chemical features may reflect distinct physico-chemical conditions of crystallization. The Biancavilla fluorophlogopite occurs as phenocryst together with the "classical" Etnean mineral assemblage, whereas those of the summit portion crystallized inside the lava vesicles during the post-eruptive phases [1]. In the last instance, the fluorine available during crystallization of fluorophlogopite crystals should be lower than that of the active Biancavilla lava domes, where the continuous volatile flux by halogen-rich fluids may have brought to such fluorine enrichment. The anomalous high Fe content of the studied fluorophlogopite may have been inherited by the lower degree of differentiation of the hosting lava than that of the Biancavilla volcanic rocks.

INFLUENCE OF UNCERTAINTIES AFFECTING ELASTIC PARAMETERS ON THE GIBBS ENERGY CALCULATION: THE CASE OF 3T - 2M₁ PHENGITEPAVESE Alessandro¹, DIELLA Valeria²

1 - Dipartimento di Scienze della Terra, Università degli Studi di Milano, Italy

Key terms: elastic parameters; deformation energy; 3T-2M₁ phengite

The stability of 2M₁ (S.G. C</>2/c) versus 3T (S.G. P3:12) polytype is dependent on the P/T ratio of formation: large P/T values are supposed to promote crystallisation of 3T phengite, presumably because of 3T having a more flexible structure than 2M₁ to arrange cations in the octahedral sheet. In fact, the trigonal polytype provides two symmetry-independent octahedral sites (M2 and M3), against only one in 2M₁. (Ferraris and Ivaldi 2002 and references therein). All this is related to the occurrence of cation order, which Pavese et al. (2003 and references therein) have extensively investigated by neutron powder diffraction. However, the stability of 3T vs. 2M₁ phengites is still an open question. On the basis of experimental works (Curetti et al. 2006, Gatta et al. 2010) we infer that the stability of 3T increases as a function of P, though the Gibbs energy difference between the two polytypes still keeps small. Such a behaviour is due to that K'(3T) < K'(2M₁), and K₀(3T) is very similar to K₀(2M₁): at sufficiently high pressures 2M₁ becomes less compliant to P than 3T, and therefore the deformation energy contribution to the Gibbs energy is supposed to favour the latter. The relative stability between trigonal and monoclinic polytypes remains a matter of thermodynamic inference. In this view, hence, the ability to fix the uncertainty on the elastic properties, and to determine how it propagates onto the calculated deformation energy, is a fundamental step to support any prediction of stability of a given polytype at high pressure. In a study about the accuracy of the calculated Gibbs energy, depending on the uncertainties on elastic parameters (bulk modulus, its first derivative versus pressure and molar volume) we revised the relative stability, controlled by pressure, between 3T-2M₁ phengite. Above a few GPa the uncertainty due to the deformation energy and dependent on the parameters governing the equation of state grows the dominant contribution to the total uncertainty on G(T,P), and it is imperative to make efforts to abate the uncertainties on K₀ and K' so that one can achieve fully distinguishable deformation energy contributions. Using another approach to discuss on how to manage the role of the elastic properties in the relationship between polytypism and stability for phengite 2M₁ and 3T, we developed the general concept of "distinguishability" between sets of elastic parameters used to calculate the contribution of deformation to the Gibbs energy. This notion bases on that different contributions of deformation are actually observed if the related elastic parameters sets lie in the K₀-K' spaces sufficiently apart, in terms of a variational principle formulated using the experimental uncertainties. The results of the comparison between the two polymorphs of mica showed that a P increase does favour their distinction and promote the stabilization of 2M₁: even if this behaviour is appreciable only in the high pressure, a regime very different from the actual field of stability of micas but that stresses the role of pressure in differentiating the two polytypes. Once more the large errors that affect the elastic observables and the relevant proximity between the elastic parameters are responsible of the difficulties in distinguishing the behaviours of the considered polytypes off ambient conditions.

Key terms: 3T trioctahedral mica polytype; Single crystal X-ray refinement; crystal chemistry

3T trioctahedral micas are rarer than it is thought. This is likely due to the occurrence of apparent polytypism, so that 1M polytype twins result in a diffraction pattern simulating a 3T periodicity [1, 2]. Most of the 3T trioctahedral micas found in nature to date belong to muscovite-polythionite-annite system [3, 4, 5, 6]. X-ray diffraction studies on these micas have often reported partial tetrahedral ordering and/or different patterns of octahedral ordering [3, 6]. In the present work, a 3T trioctahedral mica from Kasenyi (south west Uganda) kamafugite was studied via Electron Probe Microanalysis (EPMA) and Single Crystal X-ray Diffraction (SCXRD). Main EPMA data gave: SiO₂ = 38.7(2), Al₂O₃ = 13.08(9), MgO = 20.4(2), TiO₂ = 4.8(1), FeO_{tot} = 5.51(9), Cr₂O₃ = 0.90(7), K₂O = 9.64(5), Na₂O = 0.29(1), BaO = 0.15(5) and F = 0.13(5) wt%. The analysed crystal may be classified as a Ti-rich, F-poor mica with a composition intermediate between the annite and phlogopite end members. Anisotropic single crystal X-ray refinement was performed in the P3:12 space group and converged to R₁ = 4.34 and wR₂ = 3.33 %. Unit cell parameters were: a = b = 5.3235(3) and c = 30.188(2) Å. Mean bond length distances of M1, M2 and M3 follow the pattern M1 = M2 < M3, suggesting partial octahedral cation ordering. Conversely, mean bond

lengths of T1 and T2 point to a disordered cation distribution over tetrahedral sites.

Finally, the overall crystal chemical features indicates the occurrence in the studied sample of the following substitution mechanisms: tetraferriphlogopite; Ti-oxy and Al, Fe³⁺, Cr-oxy; Al, Fe³⁺-Tschermak;

kinoshitalite and $^{39}K^{+} + ^{27}Al^{3+} \rightleftharpoons ^{29}Si^{4+} + ^{39}Ca^{2+}$. Such substitutions are the same as those found in 1M-2M₁ coexisting micas from the same rock sample [7].

LAYER CHARGE LOCATION IN LAYER SILICATES AND ITS IMPLICATIONSELMI Chiara¹, BRIGATTI Maria Franca¹, Malferrari Daniele¹

1 - Dipartimento di Scienze della Terra, Università di Modena e Reggio Emilia, Largo S. Eufemia 19, 41121 Modena, Italy

Presenter e-mail: chiara.elmi@unimore.it

Key terms: Layer charge; muscovite; heterovalent substitutions

Layer charge value and location are commonly considered key factors for predicting interaction of layer silicates with external agents, such as, for example, pollutants, bio-molecules, and, more generally, ionic complexes. Several methods are discussed in literature for the experimental determination of layer charge, always, however, giving an average value from the different micro-crystals used for the analysis. The most commonly used methods are: the structural formula method [1, 2], the alkylammonium method [3] and the potassium saturation method [4]. The purpose of this paper is to demonstrate that the determination of the average value of the layer charge can sometimes lead to inconsistent results, as not correctly representing the layer charge location at mineral surface. This goal was achieved by analyzing crystal chemical results obtained from different crystals of muscovite characterized by a different content of celadonitic substitution. Muscovite sometimes presents heterovalent substitutions both in tetrahedral (e.g., Al³⁺ for Si⁴⁺) and in octahedral sites (e.g., Mg²⁺, Fe²⁺, and vacancies for Al in octahedral sites). Our results seem to demonstrate that these substitutions can be ascribed to trioctahedral cells, all occupied by cations different than Al, in a dominating dioctahedral pattern, with *cis*-octahedral sites entirely occupied by Al and the *trans*-site vacant. This interpretation suggests that mean layer charge may not represent effective layer charge at mineral surface because it refers not to randomly distributed substitution, but to domains showing different chemistry which can be locally charge-neutralized. Furthermore, also distortion parameters which affect tetrahedral topology and that can also affect the formation of surface complexes, such as α angle and Δz oxygen plane flattening, can be different inside a same structure and locally not corresponding strictly to the determined mean value via single crystal diffraction.

Key terms: lizardite; ophiolite; crystal chemistry; exchange mechanisms; metasomatism

This study investigates the crystal chemical features of six lizardite-17 crystals sampled in four ophiolitic outcrops (Pompeano, Sassomorello, Varana, and Santa Scolastica) in the Modena Apennines (Italy). Notwithstanding the extensive contributions already present in literature, this is the first study dealing with lizardites from Modena ophiolites. As evidenced by one of our samples, the whole rock composition affects lizardite composition, which results to be sensible to the overprint of secondary, metasomatic events. In our study, particular attention was devoted to the effects of octahedral Fe for Mg and of Si-Al(Mg,Mn,Fe)²⁺¹ (Al,Cr,Fe)³⁺ exchange mechanisms on the structure. Our results suggest that Fe for Mg substitution induces an increase in the octahedral M-04 length, and a decrease in the octahedral site distortion. Both these effects are also observed to influence unit-cell parameter c. The effect of the Si⁴⁺

Al(Mg,Mn,Fe)²⁺-(Al,Cr,Fe)³⁺ substitution is a decrease in the M-O1 distance and a concomitant increase in the T-O1 distance.

ADSORPTION OF WATER MOLECULES ONTO 1:1 DIOCTAHEDRAL CLAY MINERALS: A BADER'S TOPOLOGICAL ANALYSIS OF THE AB-INITIO ELECTRON DENSITIES

SCIASCIA Luciana¹, PARISI Filippo², GUARCELLO Claudio³, PRINCIVALLE Francesco³, PAVESE Alessandro³, MERLI Marcello¹
 1 - Università degli studi di Palermo
 2 - Università degli Studi di Trieste
 3 - Università degli Studi di Milano

Presenter e-mail: luciana.sciascia@unipa.it

Key terms: kaolinite; dickite; adsorption; ab-initio; Bader's topological analysis

The interaction between water molecules and clay minerals has been investigated by means of ab-initio computational methods. The interest in this field comes from the considerations that water-clay systems play a central role both in natural and industrial processes. Clays, as natural inorganic component of soils, significantly affect transport, distribution, and stability of dissolved chemical species. In this context, special focus has to be paid to toxically active species, such as radionuclides, pesticides, heavy metals. Clays also found a lot of industrial applications as effective storage materials for nuclear waste or as potential catalysts for refining processes used in the oil industry. In many of the above processes, water plays a crucial role as a natural solvent and as a transport medium for chemical species, therefore the understanding of the structure and chemistry of the water-clay interface is of considerable importance. In spite of the great number of experimental investigations in this field, a thorough understanding of clay mineral-water interactions is still lacking. Computer simulation techniques can provide interesting insight concerning a structural characterization of adsorption sites and of interactions between surfaces and adsorbed molecules at the molecular level. In the light of these considerations, the present computational study has been undertaken in order to make a theoretical characterization of each compound and then to get strategic information in predicting its behavior. In particular, we decided to investigate two polytypes of the kaolinite group, namely kaolinite and dickite, since it is well known that the holes in the tetrahedral and octahedral surfaces of these structures are favorable interactions sites for adsorption of different molecules.

Bulk and slab geometry optimizations have been performed and the topology of the electron density and its Laplacian distribution have been studied on the basis of Bader's 'Atoms In Molecules' (AIM) theory to determine the conditions required for the adsorption of different organic molecule on the tetrahedral and octahedral surfaces of the mineral. The analysis of the Laplacian critical points allowed to recognize the reactive sites of the structures and provided an efficient tools that guides in the determination of the sites of adsorption and of the geometry of the reactant relative to the surface site. The results of this analysis indicated that the octahedral and tetrahedral holes in both basal surfaces are favorable interaction sites for adsorption of small polar molecules and that the electronic reactivities of the two different polytypes are very similar, which means that the chemical behavior of the analyzed structures is comparable.

In a second step, in order to test the possibility of absorbing water in each position predicted by the topological analysis the geometrical optimization of mineral-water system has been performed.

The information coming from both the theoretical prediction of the reactivity of the molecules involved and the simulated structural and energetic features of the investigated system actually represent an engineering approach that can allow to "calibrate" the experimental work as well as to explain the experimentally observed behaviors. Moreover, this kind of data base actually represents a good "launching pad" for all the subsequent theoretical simulations of the interactions between clay minerals and different guest molecules of interest.

CHARACTERIZATION OF GENTAMICIN-BENTONITE COMPLEX

BELLINI Alessia¹, BELLINI Massimiliano¹, IANNUCELLI Valentina¹, ZANCHETTA Olmo¹, MALFERRARI Daniele¹
 1 - UNIVERSITY OF MODENA AND REGGIO EMILIA

Presenter e-mail: dmalf@unimore.it

Key terms: MONTMORILLONITE; BENTONITE; GENTAMICIN; THERMAL ANALYSES; DRUG CARRIER

Clays are common ingredients in pharmaceutical and cosmetic formulations, used as active substances (gastrointestinal protector, osmotic oral laxatives, anti-diarrhoeals, topical antibacterials and anti-inflammatories) and excipients in solid (tablet, capsules, powder), liquid (suspensions, emulsions) or semisolid (ointments, creams) forms. The present work aims to evaluate the intercalation of gentamicin molecules into a montmorillonite rich clay (i.e., bentonite, here after BNT) to obtain a drug delivery carrier for antibiotic treatment in a perspective to decrease gentamicin side effects and to improve systemic adsorption. In addition clay antibacterial activity could produce a synergistic effect. BNT-gentamicin complexes, obtained via a batch treatment, were characterized by chemical analyses, thermal analyses (thermogravimetric and thermo-differential) coupled with evolved gasses mass spectrometry, and X-ray powder diffraction at non-ambient temperature conditions. Chemical analyses indicates that gentamicin is adsorbed by the clay in a percentage varying between 2.0 and 2.3 (weight %) in relation to the pH of the treating solution. Thermal analyses show that the gentamicin treatment influences both the dehydration and the dehydroxylation reactions of montmorillonite and, in particular, highlights that in the treated sample the dehydroxylation reaction related to cis-vacant sites is shifted to an higher temperature respect to the natural clay. Basal periodicity was measured via XRPD diffraction on (001) oriented mounts of the air-dried samples in the temperature range 25- 400°C (heating rate 2 °C/min) using a powder diffractometer equipped with an area detector. In the natural sample the layer periodicity reach the closest 2:1 packing (i.e., 0.99nm) at about 160°C, whereas this value in the gentamicin treated sample is reached only after 400°C (i.e., after the thermal decomposition of the organic molecule).

SODIUM HEXAMETAPHOSPHATE INTERACTIONS WITH ILLITE AND MONTMORILLONITE: PRELIMINARY OBSERVATION ON THERMAL BEHAVIOR

CASTELLINI Elena¹, BERT Matteo¹, BERTHOLD Christoph², BRIGATTI Maria Franca¹, MALFERRARI Daniele¹
 1 - UNIVERSITY OF MODENA AND REGGIO EMILIA
 2 - UNIVERSITY OF EBERHARD-KARLS

Presenter e-mail: dmalf@unimore.it

Key terms: DEFLOCCULANT; ILLITE; MONTMORILLONITE; SODIUM HEXAMETAPHOSPHATE; THERMAL ANALYSES

The interaction of an efficient deflocculant, sodium hexametaphosphate (NaHMP), with two different illites (IMt-1 from Silver Hill, Montana USA and from Schwäbisch Hall, Württemberg Germany) and two different Ca-montmorillonites (STX-1 from Gonzales County, Texas, USA and from Santa Rita, New Mexico, USA) was investigated.

Adsorption measurements of the NaHMP anion were performed on Na-exchanged illite IMt-1 as a function of temperature by means of inductively coupled plasma technique (I.C.P.). The thermodynamic parameters of the adsorption process, together with an estimation of the maximum adsorbed amount on the Na-illite were obtained and compared to the corresponding data previously obtained for Na-kaolinite.

The effect of NaHMP on the natural illites and montmorillonites was analyzed using different techniques. I.C.P. measurements of the concentration of P, Na, Si, Al, Ca, Mg, and K of the deflocculant solutions in contact with the clays were performed in order to detail the adsorption, dissolution and exchange phenomena which accompany the deflocculant activity.

Thermal analysis (thermo-gravimetric, thermal-differential) and XRD measurements at non ambient temperature conditions were used to characterize the clay solid samples after the interaction with NaHMP. Thermo-gravimetric analyses indicate that NaHMP-treated illites and montmorillonites are less hydrated than natural samples, whereas the dehydroxylation reaction seems to be not influenced by the NaHMP treatment. Basal periodicity was measured via XRPD diffraction on (001) oriented mounts of the air-dried samples in the temperature range 25 - 400°C (heating rate 2 °C/min) using a powder diffractometer equipped with an area detector. No significant variation of layer periodicity was observed, thus indicating that NaHMP molecules are adsorbed on the edge and/or in the interlayer without modifying natural layer periodicity.

TEXTURAL STUDY OF METAMORPHIC ROCKS BY MEANS OF A CONVENTIONAL X-RAY SOURCE

MALFERRARI Daniele¹, BRIGATTI Maria Franca¹, LAURORA Angela¹, SASSI Raffaele¹, SASSI Francesco Paolo²

1 - Dipartimento di Scienze della Terra, Università degli Studi di Modena e Reggio Emilia

2 - Dipartimento di Geoscienze, Università degli Studi di Padova

Presenter e-mail: mariafranca.brigatti@unimore.it

Key terms: morphological preferred orientation; metamorphic rocks; textures; X-ray diffractions; phyllosilicates

The aim of this study is the textural characterization of very low to greenschist facies metamorphic rocks by means of a conventional X-ray source, possibly establishing a relationship between the extent of morphological orientation of mineral grains and metamorphic degree. For a long time geologists investigated the morphological orientation of mineral grains in polycrystalline rocks by means of petrographic microscope equipped with a Universal stage. More recently diffraction of conventional X-ray sources as well as diffraction (or transmission) of hard X-rays, electrons and neutrons has been applied to these kind of study. However, whereas X-ray conventional sources can be regarded as a routine technology, hard X-ray, electron and neutron sources are only available in a few facilities around the world.

Phyllosilicates such as smectite, illite, muscovite, chlorite and biotite play a key role in the textural characteristics of the mineral assemblages of rocks characterized by increasing metamorphic degree. The present study is focused on the variation of the X-ray intensities of selected reflections of these phases. In short, if a morphologic orientation of the grains of a certain phyllosilicate is present, a variation of the intensity of these reflections will be measured when the rock sample is rotated in a goniometer keeping constant both the incident beam angle and the position of the detector.

The samples selected for the study are the following: 1) a Ms, Chl, Qtz, Pl fine grained metapelite from Frassenetto (UD, Italy) (very low grade metamorphism, Anchizone) with some detrital muscovite flakes recognizable by their coarser grain size; 2) Ms, Chl, Qtz, Pl fine grained metapelite from Chiadenis (UD, Italy) (low grade metamorphism, Epizone) with some detrital muscovite flakes recognizable by their coarser grain size; 3) a Ms, Chl, Ilm, Qtz, Pl layered phyllite from Villabassa (BZ, Italy) (Greenschist facies metamorphism, Ms-Chl-Bt), with crenulated main foliation and axial planes defining a second spaced foliation; 4) a Ms, Bt, Grt, Ilm, Qtz, Pl layered phyllite from Luson (BZ, Italy) (Greenschist facies metamorphism, Ms-Bt-Grt), with crenulated main foliation and axial planes defining a second spaced foliation.

DIAGNOSTIC AND PETROGRAPHIC INVESTIGATIONS FOR THE RESTORATION AND SEISMIC REHABILITATION OF THE CHURCH OF S. AUGUSTINE IN OFFIDA (AP, ITALY)

MASSACCI Giovanna¹, ESPOSITO Enrico², MARONI Annalisa³

1 - University of Camerino, Faculty of Ascoli Piceno

2 - Artemis Srl, Ancona (Italy)

3 - Municipality of Offida (Ascoli Piceno, Italy)

Presenter e-mail: giomassac@libero.it

Key terms: materials; mortar; non destructive diagnostics; thermography; sonic tests

This work deals with the petrographic and archaeometric studies and the non destructive and non invasive diagnostic tests done on the S. Agostino church in Offida (province of Ascoli Piceno, Italy); these activities are propaedeutic to strengthening structural interventions to improve the building seismic response.

The Church is a large building, made of bricks, whose construction started in 1338 and finished in 1441 and, as a first step, its history has been fully studied and an architectonic survey conducted.

Petrographic and archaeometric study of stone and lithoid materials (bricks and mortars) has been conducted to investigate the composition and conservation state of the travertine employed for the main portal, and of terracotta romanico-gothic decorative elements positioned on the upper part of the north façade; beside this, the lithological typology of materials and their provenience have also been investigated, in order to increase the historical and artistic knowledge of the building. Also the characteristics of inerts and binders employed for the mortars have been analyzed, along with the employed raw materials (mainly clays, sands and other incoherent substances). A methodology has thus been developed that has led to a high resolution screening of materials and a detailed determination of provenience areas. In the end, comparative analysis of geo-materials and lithoids has made possible to identify alteration processes and to individuate best conservative actions, procedures and materials for gradual cleaning and restoration interventions. Physical/mechanical diagnostic tests have been addressed to the evaluation of both the structural consistency of the building and the presence of excessive humidity; tests have been conducted inside the building, with an extensive thermographic survey and localized evaluations of masonry humidity content, and outside the building, again with a thermographic survey and sonic tests, the latter ones applied on important cracks on the main and north façades. Tests have thus revealed the presence of critical structural areas, rain infiltrations from the roof and a diffused presence of raising dampness; the integration of these investigations with the petrographic ones and with the historical and architectonic surveys has thus been possible to formulate an accurate plan for the restoration and the seismic response improvement of the ecclesiastical building.

A VIRTUAL RESTORATION OF THE MAIN FAÇADE OF ST. GIULIANA CASTLE (UMBERTIDE, ITALY) THE USE OF COMPUTER APPLICATIONS IN RESTORING A CULTURAL HERITAGE

GIAMMARTINI Barbara¹

1 - University of Perugia

Presenter e-mail: barbara.giammartini@unipg.it

Key terms: virtual restoration; archaeometric analysis; medieval castle; N-W Umbria (Italy)

Virtual restoration, is the set of calculations performed with the help of two-dimensional or three-dimensional computer graphics for reconstructing an artwork or building. This can provide a set of hypothesis for actual intervention.

The medieval castle of St. Giuliana (XIII-XIV century A.D.), is one of the best examples of a fortified settlement located on Mt. Corona (708 m a.s.l.), situated near the town of Umbertide (N-W Umbria, Italy). The virtual restoration performed on the main façade shows us how the archaeometric analysis of the building is essential for a correct restoration of it.

The analysis of macroscopic, microscopic and geochemical characteristics was carried out on samples of the materials in place on the façade of the castle. This allowed a precise identification and characterization of these materials and of their provenience (in the Municipality of Umbertide). On such a basis it was possible to propose a proper active restoration through the use of materials compatible with the original.

The main façade built with stones of local origin, shows the use of sandstone and limestone belonging to the Umbria-Marche stratigraphic succession.

A lithological mapping of the materials of the façade has allowed a quantitative estimate showing that the prevailing natural stones, are represented by limestone belonging to the Scaglia Rossa and Maiolica formations. In addition, there are also samples of Scaglia Variegata and Marnoso Arenacea formations which, together with bricks, were used in the various stages of restoration, carried out over the years. These casual materials, or those readily available locally, changed the original look of the façade.

An important part of the wall was altered by the misuse of mortar that was literally "spread" over a few ashlar. This was used as gap filler replacing the original stones. Part of the wall has succumbed to alteration phenomena such as black crusts, and some ashlar show fractures by climbing plants.

The virtual restoration, using CAD "Computer Aided Design" and graphic processing of the images software, has allowed the creation of a digital clone of the monument on the basis of the archaeometric studies that were carried out.

A working hypothesis regarding a project intervention was made, which involves the exchange of mortar and materials improperly used with the original ones and the cleaning of masonry surfaces from black crusts and climbing plants. It appears that similar processes of study and analysis are essential today for restoration work.

PETRO-ARCHAEOLOGY OF MEDIEVAL ORNAMENTAL MATERIALS FROM THE NORMAN-GOTHIC MESSINA CATHEDRAL (SICILY, ITALY)

CARABETTA Maria Teresa¹, MACAIONE Elisa¹, MESSINA Antonia¹

1 - Dipartimento di Scienze degli Alimenti e dell'Ambiente - Sezione Scienze della Terra, Università di Messina - Messina (Italy)

Presenter e-mail: mtcarabetta@yahoo.it

Key terms: Norman-Gothic Messina Cathedral; original lower order of façade; Middle Age ornamental materials; sedimentary and metamorphic rocks; petro-archaeometry

The present research has enabled the determination of the petro-archaeometry of the ornamental slabs and mosaics characterizing the lower order of the Messina Cathedral façade. This paper also discusses the origin of these decorative materials which have never been documented in the historical reconstruction.

This Basilica, only second in majesty to the Palermo Cathedral in Sicily, was erected between 1120 and 1168. It was rebuilt many times because of several anthropic and natural calamities, with continual stylistic and architectural modifications.

The present edifice, reconstructed in 1929, exhibits a Latin Cross plant in the three naves.

The façade is divided into two orders: the upper is sober and completely restructured, the lower exhibits three Norman-Gothic portals with Renaissance decorative elements, and a Late-Middle Age polychrome ornamental covering.

The sculptures of column-bearing lions situated on both sides of the central portal are ascribed to the Romanic Epoch, the ornamental covering to 1320, and the elements of the portals (bas-reliefs, aedicles, string-courses and statues) realized between 1468 and 1640.

In the covering, characterized by a geometrical ornament, there is a 9 repetitive pattern of 1 to 4 horizontal cross-sectional bands of rock slabs and floral polychrome inlays of heterogeneous tesserae. The pattern has been also used in the lateral arcs, and in two old portals. The same decorative materials are used on the landing and the entrance steps to the Cathedral.

In the ornamental stones, mesoscopic and microscopic features allow carbonates, metacarbonates, metaultramafics and metamafics to be recognized.

Among the 11 types of green to grey-greenish metaultramafics and green to pale-green metamafics characterizing the slabs and mosaic tesserae of bands 2 and 4, respectively, three petrographic groups were selected for a first chemical investigation (mineral chemistry and Major oxides and trace element analyses). Data indicates that the first two groups are Tholeiitic Within Plate metaperidotites and metahornblendites. Metaperidotites record three metamorphic processes, documented by forsterite+enstatite+magnetiteI, antigorite+antophyllite+magnetiteII and tremolite+Fe-antigorite+clinochlore parageneses. Metahornblendites are made up of Fe-pargasite+titanite. The third group consists of Na-Alkaline Within Plate Pl-metahornblendites, characterized by Mg-hastingsitic hornblende+oligoclase+quartz.

The compositional and evolutive history recognized in each group supplies important constraints for their geological provenience. This has been confirmed by the petrographic and chemical comparisons with similar rock types of the Peloritani Mts. (Calabria-Peloritani Arc), and specifically with metaperidotites and metahornblendites of the Aspromonte Unit and Pl-metahornblendites of the Mela Unit, sampled in specific relict quarry sites near Messina.

Among the four types of carbonates characterizing slabs and mosaic tesserae of bands 1 and 4, respectively, three petrographic groups were selected: two limestone groups and a dolostone one. The reddish limestones have been classified as micritic wackestones containing re-crystallized bioclasts, ankerite and iron oxides and hydroxides; the grey carbonates are dolostones. Both rock types come from the Mesozoic carbonatic platform of the San Marco d'Alunzio Unit (Pliensbachian), according to comparisons made with analogous rocks sampled in known quarry sites around San Marco d'Alunzio village (W Peloritani Mts.). The whitish limestones are sparitic grainstones which come from the Mesozoic cover of the Piraino Unit, sampled in meter-thick Mesozoic slice sites to the west of Ali (south of Messina).

The whitish metacarbonates characterizing slabs and mosaic tesserae of bands 3 and 4, respectively, are fine-grained muscovite marbles from the Mela Unit basement, as indicated by comparisons with similar rocks sampled in old caves in the Mela Valley (NE Peloritani Mts.).

ARCHAEOLOGY OF ROCK TESSERAEE FROM THE MOSAICS, MORTARS AND PLASTERS OF THE ARCHAEOLOGICAL SITE OF GRUMENTUM (BASILICATA, ITALY)

MASSACCI Giovanna¹, MESSINA Antonia¹, PERRONE Vincenzo², RENZULLI Alberto²

1 - Dipartimento di Scienze degli Alimenti e dell'Ambiente - Sezione Scienze della Terra, Università di Messina - Messina (Italy)

2 - Dipartimento di Scienze della Terra, della Vita e dell'Ambiente - Università degli Studi di Urbino "Carlo Bo" Campus Scientifico - Urbino (PU - Italy)

Presenter e-mail: giomassac@libero.it

Key terms: mosaics; opus tessellatum; sedimentary and volcanic rocks; mortar; archaeometry

This study is dealing with archaeometry of the rock tesserae from mosaics (opus tessellatum), mortars and plasters characterizing the archaeological site of Grumentum (Alta Valle D'Agri, Basilicata, Italy), a Roman settlement with orthogonal roads and protected by walls, dating back to the III century BC (Grumentum I, Regio III; Lucania et Bruttii).

Grumentum represented for the Romans an important military centre during the Sannitic wars, being located in a strategic area between the Tyrrhenian and Ionian Seas, at the intersection between Via Herculea (coming from Venusia and Potentia to Taranto) and Via Popilia (towards Reggio Calabria). According to the archaeological literature, the main monumental complexes are represented by the "Domus of Mosaics" (a typical Roman house with opus tessellatum, atrium and peristyle dating back to the first half of the II century AD) and the thermae of Republican and Imperial age. Although the chronological reconstruction of the archaeological site is not yet well defined, the thermae utilization should have spread from the second half of I century BC to V century AD. The main entry of the thermae was constituted by an apodyterium with a black and white opus tessellatum, showing numerous fish species, tritons and a marine monster (Scylla) at the centre of the mosaic. Through the apodyterium it was possible to get to the frigidarium, a wide rectangular room with polychromatic opus tessellatum showing plants and geometric patterns. The thermae were also constituted by three rooms heated by two tepidaria and one calidarium where a two-color opus tessellatum with geometric patterns is still visible on the floors.

Preliminary petrographic and archaeometric investigations were mainly focused on the the rock tesserae from the mosaics (sedimentary and volcanic lithotypes), mortars and plasters. As concerning the white sedimentary tesserae from the mosaics, they consist of micrites coming from the Mesozoic limestone platform of the Alburno-Cervati Unit. Gray sedimentary tesserae are represented by microsparitic marly limestones coming from the chert-bearing limestones of the Lagonegro Units,

belonging to the Upper Trias. Red to pink tesseræ are of sedimentary origin as well, represented by a slightly marly, fine-grained limestone which can be classified as a pelagic, fossil-rich, micritic lime-mudstone also containing fine-grained detrital grains of quartz, clay minerals, iron oxide and hydroxides. Red to pink tesseræ should come from the fine-grained calcareous turbidites which characterize, among the Lagonegro Units, the Cretaceous-Oligocene "Red Flysch" Formation. Black volcanic tesseræ consist of leucite-bearing tephrite lavas with low porphyritic index, probably belonging to the Vesuvius or Vulture volcanoes, respectively 135 km to WNW and 75 km to NNW from Grumentum. Major oxides and trace element analyses of the volcanic tesseræ are in progress and should define, according to their chemical fingerprint, the belonging to one of these two volcanoes. Cocciopesto-bearing mortars of the "Domus of Mosaics" were also studied. This allowed a comparison between the red mortar of the Republican thermæ, mainly consisting of volcanic fragments and various types of cocciopesto and that of the Imperial thermæ, constituted by clots of lime putty, quartz and carbonatic fragments. FT-IR spectrophotometry investigations of the red and yellow plasters of the Republican thermæ pointed out the presence of As, Cu, Sr e Mn. Orpiment (As₂S₃) and realgar (As₂S₂) should therefore represent some of the raw materials used in the plasters to obtain the yellow and red colours respectively.

SAFEGUARD OF THE UNDERGROUND ENVIRONMENT, AS A PART OF THE CULTURAL HERITAGE: NEW PERSPECTIVES IN APULIA

FIORIO Antonio¹, PARISE Mario²

1 - Basin Authority of Apulia

2 - Institute of Research for Hydrogeological Protection, National Research Council, Bari

Presenter e-mail: antonello.fiore@adb.puglia.it

Key terms: caves; safeguard; monitoring; cultural heritage; exploitation

The Apulia karst region shows as main peculiarity the presence of a high number of underground caves, both of natural and anthropogenic origin. Many caves are a significant, if not remarkable, part of the cultural heritage, for their historical and archaeological importance, and/or due to the remains they host. The latter range from man's artifacts, to palaeontological and anthropological remains as the burial in the S. Maria di Agnano cave at Ostuni (a woman in advanced state of pregnancy, dated back to Musterian time) or the bones entirely covered by speleothems of the pre-Neanderthal Altamura Man in the Lamalunga Cave. In addition, many anthropogenic caves are of great importance too, having been for centuries worship sites, decorated with hundreds of frescoes representing saints and holy figures and themes. These are only a few of the many examples which are present in Apulia, and represent a huge value of the local cultural heritage.

Safeguard of this heritage is not an easy task to be reached, due to many reasons, including but not limited to complexity of the underground environment, which results often in heavy difficulty in properly monitoring its main parameters. The recent regional code, established in 2009 by Apulia Region, entitled "Safeguard of the geological and speleological heritage" (Regional Law no. 33) marks an important date in the perspective of protection and exploitation of the underground caves, including (for the first time in an Apulian regional law) those of anthropogenic origin. As a matter of fact, the law allows the possibility of cave exploitation, once their stability conditions, and therefore the safety of likely visitors, had properly been taken into account.

To obtain this goal, monitoring of the cave conditions is mandatory to any activity. Monitoring should include measurements of the main micro-climatic parameters (temperature and relative humidity), plus control of the presence of gases such as carbon dioxide and radon, and of their variations as well. In case of on going or potential stability problems, a specific monitoring program should also be considered, aimed at controlling the discontinuities and/or sectors of the cave identified as the most dangerous. Choice of the monitoring type (manual versus automatic), the sensors to be used (type, sensitivity, measurement ranges, etc.), and the selection of the points to monitor is extremely delicate. Design of the monitoring system has to be carefully planned, possibly following a preliminary collection of data which might help in better defining the final system.

Some considerations about this matter, which is still at a very initial stage of development in Apulia, are presented in the paper, as a first contribution to the best definition of monitoring standards and rules to be adopted in a very peculiar setting as the underground environment.

LANDSLIDE RAPID ASSESSMENT IN THE SIQ OF PETRA, JORDAN

DELMONACO Giuseppe¹, MARGOTTINI Claudio¹, SPIZZICHINO Daniele¹

1 - ISPRA Italian National Institute For Environmental Protection And Research, Geological Survey Of Italy, Via Vitaliano Brancati 48, 00144 - Rome

Presenter e-mail: d.spizzichino@gmail.com

Key terms: Landslide; Petra; rock fall

Rapid onset natural phenomena, such as earthquakes, floods and landslides, pose a major threat to cultural heritage and visitors in Petra. In 1963, 24 tourists died as a result of a sudden flash-flood in the Siq. Assessing the percentage of losses caused by each specific event is very difficult, and whereas earthquakes and floods cause damage to large expanses of land, landslides act more locally, affecting only a specific area and in this the Siq, hence the focus of this research. The Siq is a 1.2 km naturally formed gorge in the sandstone mountains that served, during the Nabataean times, and still serves today as the main entrance to the site of Petra (Jordan), from the urban area of Wadi Musa. It is formed by very steep slopes with variable height from the ground level, from few meters at the entrance to several tens of meters in some areas of the path. The Siq and the hand-carved monuments of Petra are constituted by the sandstones of Umm Ishrin and Disi Cambrian-Ordovician formations, in the form of massive and/or poor stratified rocks. The structural setting of the rock-forming slopes are characterised by discontinuities of various type, mainly related to stratigraphical setting (bedding, generally horizontal), tectonic activity (faults and joints, vertical and inclined), geomorphological evolution of the slope (sub-vertical joints). Such a structural condition determines a rock-fall potential activity that may

involve unstable volumes that may range from from 0.1m³ up to over 1000m³. The latter can be catastrophic according to evolution of the movement (extremely rapid) and involved rock mass volumes. Recent events has involved the rapid deformation of a block located on the south slope of the Siq, approximately 300m from the entrance in a particularly narrow stretch of the Siq, requiring that visitors walk very close to the high risk area. Additionally, during May 2009 a smaller rock (approx. 150kg) detached from the slope and fell to the ground in the area of the Camel Caravan relief. The collapse occurred during the night and fortunately did not result in injuries or fatalities. Due to the acceleration of crack deformation and consequent increasing of rock-fall hazard conditions in the Siq, UNESCO and Jordan local authorities have promoted a project focused on the implementation of a landslide hazard and risk analysis of the Siq as a fundamental tool for the conservation strategy of the site. The first stage of the project has provided the definition of the structural and geological typologies of decay as well as actual and potential instability conditions of the geological formations and selected monuments. The study has been based on data collection by accurate field survey and data analysis and mapping. The first stage has been focused on an in-depth assessment of landslide risks that affect the Siq and its monuments based mainly on engineering geology field survey techniques. All data have been analysed by implementing structural modelling that will provide landslide types identification and kinematics as well as a landslide hazard map. Several thematic maps have been produced such as potential rock-fall inventory map, rock-fall hazard map, vulnerability and risk maps vs. slope instability. The main outputs of the above mentioned investigations have detected unstable slope areas and/or single monuments that necessitate to be consolidated and reinforced. This last objective is aimed at providing the local authorities with a guideline for consolidation works to be implemented in the most hazardous sectors of the Siq and feasible techniques for analysis and conservation of monuments vs. rock-slope instability considering priorities and urgency. A preliminary consolidation works project has been implemented for the reinforcement of unstable blocks located in risk areas whereas guidelines have been provided for other relevant unstable areas to be mainly controlled with long-term monitoring.

THE BROKEN ARCHITRAVES: STONE CONSOLIDATION IN A ROMAN SITE IN TUNISIA

RIZZI Gionata¹, VOLTA Stefano²

1 - Studio Rizzi Milano

2 - Impresa di restauro Parma

Presenter e-mail: gionatar@gmail.com

Key terms: stone conservation; sunken courts; multidisciplinary approach

Bulla Regia, Tunisia: a site famous for its mosaics (stylistically very close to those of Piazza Armerina in Sicily) and for the subterranean houses. When a collaborative project between the World Monuments Fund and the Institut Nationale du Patrimoine started in 2008, the most beautiful of the "sunken courts" giving light to these houses was so deteriorated that collapse could have occurred at any moments. This paper tells the story of the international effort to save it. The success of this intervention lie, in our opinion, in the multidisciplinary approach that, throughout the project, led an architect, a conservator, a structural engineer, an archaeologist and a geologist to discuss together all the steps of consolidation: from the identification of the causes of decay, to the development of the most appropriate strategy, to the final, extremely difficult, implementation. Use of modern materials and techniques, such as carbon fibers strapping and fiberglass 2 meters long stitching are also described.

ARCHITECTURAL SURFACES IN SHEKHAWATI REGION (INDIA)

TONINI Lisa¹, CAVALLO Giovanni², PANDIT Manoj Kumar³

1 - Conservator of architectural surfaces

2 - Institute of Materials and Constructions DACD SUPSI

3 - University of Rajasthan, Dept. of Geology

Presenter e-mail: lisa_tonini@yahoo.it

Key terms: Shekhawati; architectural surfaces; Fresco lustro

The study is a consistent part of the project From the Geosciences to the Material Culture supported by Swiss Agency for Cooperation and Development (KfH) and SUPSI.

The research, developed in Shekhawati region (NE Rajasthan India) aims to identify the material and techniques used considering the entire sequence of the architectural surfaces from the masonry to the final paint decoration. Four different type of structures were selected: Havelis (house palace), temples, wells and cenotaphs. These historical building date to 18th-19th centuries

On the basis of in situ observations, samples were taken and analyzed through optical microscopy (OM) integrated with microanalysis (SEM-EDS). Infrared spectroscopy (FTIR). The results were compared with the consulted bibliography which reports meticulous macroscopic observation referring mainly to local oral tradition.

The results indicate the use of local available materials both for the masonries (calcrete, bricks, lime-based mortar with the addition of cocciopesto) and the renders.

The painted decorations were executed adopting a dry technique, contrary to what is stated in the reference literature.

The identification of the organic binder used for the pictorial layers was not possible as it was completely transformed into calcium oxalate; this patina acted as a protective coating allowing murals preservation in an extreme climatic region.

There were no substantial difference between the different types of structures analyzed.

The complete absence of protection largely contributed to the decay of the studied monuments.

ACTIVITIES IN COLLABORATION WITH THE NATIONAL MUSEUM IN DAMASCUS, SYRIA

FABBRI Bruno¹, GUALTIERI Sabrina¹, MACCHIAROLA Michele¹
 1 - CNR, Institute of Science and Technology for Ceramics, Faenza, Italy
 Presenter e-mail: bruno.fabbri@istec.cnr.it

Key terms: Ceramics; Cuneiform tablets; Damascus Museum; Diagnostics; Mortar

During the years 2009-10, the Institute of Science and Technology for Ceramics (CNR, Faenza) has managed a project for the organization and starting up of restoration and diagnostic laboratories in the National Museum of Damascus (Syria). The activity was subdivided into theoretical and practical lessons with reference to a wide range of architectonic and archaeological materials. During the practical lessons, some research experiences were done taking into account architectonic structures of Syrian General Directorate for Museums and Antiquities (DGAM) and archaeological objects of the Museum. Of course, it deals with the beginning of wider projects, but the idea was to continue them after the end of the above training project. Unfortunately, the current political situation forced us to suspend the collaboration with the hope that it can profitably continue as soon as possible. In the present paper some examples are given on the work done, in order to demonstrate the importance of the issues and topics covered in the short period of collaboration with DGAM, and the direction of future research.

A lot of mortars samples were collected from different structures of the Citadel complex in Damascus downtown and some of them were analyzed (OM, XRD, DTA-TGA). The results revealed that all the samples had hydraulic characteristics due to the presence of volcanic granules (pozzolana) or fragments of terracotta (cocciopesto) among the aggregate. In addition in two samples the binder was obtained by mixing lime and gypsum, while the presence of traces of magnesite in a sample clearly indicated that the lime used in this case was obtained by calcination of a dolomitic limestone. Finally different quantities of charcoal fragments were recognized in all the samples, as a consequence of the calcination technique used for producing the lime. Of course only a systematic study of a large number of samples will be able to identify the raw materials and technologies used for preparing the mortars in the different periods.

In order to identify the binder used for fixing the colours of a wall painting, in bad conservation state, coming from an ancient house (19th century) in Damascus, and to recognise the product/s used in a restoration work made in the seventies of the last century, some small fragments were analysed by means of FT-IR instrumentation both in transmittance and in ATR system. The analyses highlighted the presence of egg yolk as binder of the colour, and paraloid as restoration product. The data obtained were useful for planning a new and necessary conservation intervention.

An investigation was referring to Syrian painted pottery of the 8th century BC. The main problem was to define the processing technique used for obtaining objects with a surface lighter than the internal parts of the body. At the present state of investigations, we are convinced that they treated the surface with sea water, without applying any slip layer. But some technical questions are open: Did they apply a layer of dehydrated clay in order to obtain a flatter and smoother surface? At which stage of the manufacturing cycle did they treat the surface?

A very interesting experience was developed for the search of conservation methodologies of cuneiform tablets without cooking the artifacts. First of all, it was retained opportune to go into the issue of the degradation causes, taking into account thousands of small clay tablets dated back to the beginning of the II millennium B.C., recovered at Tell Mari, Hariry (Syria). It was realized that in these tablets superficial radial cracks form in correspondence with the growth of gypsum crystals just under the surface. Therefore, now the question to face is the formation mechanism of gypsum: does it form at present inside the deposits of the museum? Or it formed inside the ground in the archaeological site from which the tablets come?

STONES USED IN THE ARCHITECTURAL HERITAGE OF SYRIA

CANTISANI Emma¹, DE LUCA Daniele², GARZONIO Carlo Alberto², RICCI Marilena², VETTORI Silvia²

1 - CNR-Institute for Conservation and Enhancement of Cultural Heritage, Florence

2 - Department of Construction and Restoration, University of Florence

Presenter e-mail: silvia.vettori@unifi.it

Key terms: limestone; mortar; architectural heritage of Syria; degradation conditions; Tartous Citadel

Some sirian buildings of the Tartous Citadel (main walls, galleries, Donjon, Knight's Chapel, Hall of the Knights) and the surrounding areas (Arwad Island and the archaeological site of Amrit) have been investigated in the frame of the Euromed Heritage IV project "Mare Nostrum. A Heritage Trail along the Phoenician maritime routes and through the historic port cities" founded by European Union. Main object of this project is to provide data on the systematic analysis (chronological phases, construction techniques, state of preservation) required for preparing conservation guidelines. In Tartous most of the attention was directed at the Citadel which presumably has corresponded with the pre-Roman city and has been redeveloped during the Constantine and Byzantine eras. The phoenician structures along the coasts of Arwad are linked to subsequent constructions through re-use and building taking place over thousands of years, including the period of Islamic control and the Crusades, right down to the more recent traditional architecture in the Ottoman era.

Many archaeological and historical sites are also representative of the geological features and the geo-materials. The main geostructural features of the western Syria are the platform blocks, the anticlines and others sedimentary units, which are mainly composed of limestones (predominantly of marine origin, ranging in age from Triassic to Miocene - with a prevalence of Cretaceous limestone). Lava covers Syria and Jordan (Hawran), and also the architecture used basalts in symbiosis with the limestone, particularly where this is an alternation of sedimentary structures and volcanic soils just as close to the Syrian coast. After identification construction processes that could be considered homogeneous, a representative sampling, of the construction material, on the basis of a schematization of the architectural system of the Citadel into blocks, has been performed.

The petrography, mineralogy, and chemistry of several mortars and stones and their degradation conditions were investigated with the aim of collecting information before planning conservative interventions.

The field analyses, and the laboratory measurements, have allowed us to distinguish at least two different types of limestone. Blocks belonging to inner walls and buildings are constituted by fossiliferous grainstones with carbonatic cement and trace of quartz and with different degree of porosity (due to the loss of carbonatic cement) and major/minor presence of terrigenous component (clay minerals). Blocks, instead, which belong to the outer walls of the Citadel are mainly constituted by carbonatic rocks at highly widespread recrystallization of calcite, that makes the rock very compact. The fossil species are almost entirely replaced by reprecipitated calcite.

Also ancient and restoration mortars have been analyzed and classified on the basis of binder and aggregate composition.

RESEARCH AND EDUCATION FOR THE CONSERVATION OF CULTURAL HERITAGE IN GEORGIA

CAVALLO Giovanni¹, JANJALIA Mzia², KUPRASHVILI Nana²
 1 - Institute of Materials and Constructions DACD SUPSI, Canobbio (Switzerland)

2 - Tbilisi State Academy of Art, Faculty of Restoration, Art History and Theory, Tbilisi (Georgia)

Presenter e-mail: giovanni.cavallo@supsi.ch

Key terms: Gelati monastery; architectural surfaces; education; conservation

Georgia has a huge religious cultural heritage suffering the lacking of adequate conservation works. The project, granted by the Swiss National Science Foundation, intends to develop and improve the research and education establishing high standards in the field of conservation and providing high quality of the curricula of the Georgian faculty.

Since 1970s, Tbilisi State Academy of Arts is the single training centre for the conservation in Georgia. The Institutional Partnership project will help the Georgian partner to improve the research at their Faculty also considering the implementation of the scientific laboratory: all the conservation-restoration projects need preliminary scientific investigation aimed at establishing the appropriate procedures for the interventions.

The main goal of the project is the training of young and senior Georgian researchers and the study of architectural surfaces (stones, plasters and wall paintings) for the conservation of Gelati Monastery applying methodologies internationally recognized. This site, located near the city of Kutaisi in western Georgia, is one of the UNESCO sites and preserve wall paintings and decorative stones from 12th to 17th century and has great importance for the historical, religious, cultural tradition of the country.

Georgian partner has no relevant experience in the field of natural stones deterioration and conservation procedures. This is particularly relevant considering that many monuments have historical reliefs and decorative stones, in many cases dated back to the 4th-5th century, relevant for the cultural expression of the country. The stones mainly used (sandstones and tuffs) exhibit serious damages and an adequate strategy is required for their preservation.

The project based on comprehensive approach considering architectural structure as a whole and aiming at the detailed examination of architectural surfaces and elaborating practical solutions, is of urgent importance. Implementation of the project will essentially change the situation in the country as in Georgia there is absolutely no experience in the field of stone conservation and examination. Knowledge obtained through the joint work will be of key importance not only for the Georgian Faculty but the whole scientific society. The project can be considered a start point for the field of stone conservation in Georgia.

10.1474/Epitome.04.0829.Geoitalia2011

THE ANCIENT MOSQUE OF HAJI PIYADA IN AFGHANISTAN: THE INVESTIGATION FOR THE PRESERVATION OF A FORGOTTEN MONUMENT.

TONIETTI Ugo¹, ROVERO Luisa¹, FRATINI Fabio², PECCHIONI Elena³

1 - Construction and Restoration Department -University of Florence

2 - I.C.V.B.C -C.N.R. Florence

3 - Earth Sciences Department - University of Florence

Presenter e-mail: elena.pecchioni@unifi.it

Key terms: earthen mortars; gypsum mortars; restoration mortars; Afghanistan mosque

The work explains the stages of a structured survey, conducted on the mosque of Haji Piyada in northern Afghanistan by researchers of the University of Florence and ICVBC-CNR of Florence, as part of an international project aimed at the recovery and protection of the monument.

The mosque is located near the ancient city of Balkh in the Mazar al Sharif province, not far from the borders with Uzbekistan, in a flat and quite fertile area. The mosque is almost in ruins, but it is still enclosed on three sides by a perimetral wall and it conserves a system of big columns on which two unsafe arches are still standing. A tripartite arrangement of the sides, thanks to the six central columns (of which only four still standing), was the support for a covering made with nine domes, unfortunately collapsed, but mentioned by the name Noh-Gombah still used in the Dari language. The construction dates from the VIIIth century AD, that is just over one hundred years after the Hijra, and it is therefore the oldest Islamic temple in Afghanistan. A special value of the monument is given not only by the gigantism of drums and arches, but also by a rich plaster coating of all the internal parts, finely carved with motifs of Sassanid ancestry. The mosque is at present filled to a depth of 150 cm, from the debris produced by the collapse of part of the domes and arches and shows signs of gradual deterioration with the risk of collapse for the arches still standing.

A call to rescue of the remaining integrity began in 2007 by the French Archaeological Delegation in Afghanistan (DAFA) which involved, in an international team (France, Iran, Afghanistan), experts in consolidation of ancient buildings belonging to the University of Florence and to ICVBC-CNR. The Italian coordination of the cooperation project is curated by Giovanni Secco Suardo Association, competent for restoration activities in developing countries. The Afghan contacts are the offices for the Protection of Archaeological and Cultural Heritage. In its development the

project has seen successive support of the World Monument Fund and of AKTC (Aga Khan Trust for Culture), the latter being particularly useful for the preparation of an intervention in a region known to be complex and even dangerous, where the local roots is essential, taking into account the fact that the organization of a restoration yard can take a very long time. The mosque complex consists of three building systems: 1. the columns and arches, which are the main load-bearing elements, made of baked bricks, the first walled with gypsum mortar and the second with earth mortar; 2. the first containment wall perimeter, close to the system described, including the filling volume of the vaulted system, made of mud-brick; 3. the outer perimeter, degraded and largely crumbling, made of on site pressed earth.

In order to plan a consolidation intervention of the remaining structures, it has been necessary to analyse samples of material, collected in different missions (2007-08-09) and transported to Italy with the help of French and Italian armies. The samples, representing the various types of bricks, gypsum and earth mortars and the rammed earth of the outer perimeter, were analysed in order to determine the mineralogical, physical and mechanical characteristics. These investigations are essential for the identification of suitable restoration mortars (injection, sealing, filling gaps, masonry mortar) useful to give consistency to the walls, but still compatible with the widespread presence of gypsum and degraded earth mortars. This study will develop a restoration plan that provides for the reinforcement of the building part, the consolidation of the arcs, the elimination of an incongruous support of an arc and the restoration the gypsum decorations.

COMPOSITION AND DISTRIBUTION OF SOLUBLE SALTS IN WALL REMAININGS OF THE IMPERIAL PALACE IN ISTANBUL

FABBRI Bruno¹, MACCHIAROLA Michele¹

¹ - CNR, Institute of Science and Technology for Ceramics, Faenza, Italy
Presenter e-mail: bruno.fabbri@istec.cnr.it

Key terms: Brick walls; Imperial Palace; Istanbul; Soluble salts

The Imperial Palace in Istanbul is a complex of buildings that constituted the seat of the Roman Empire. The capital of the Roman Empire was in fact moved in the fourth century AD by Constantine the Great to the ancient Byzantium, which from that moment became known as Constantinople. The first unit of the imperial palace was built on the Golden Horn, the promontory that overlooks the Sea of Marmara, which controls the Bosphorus, a strategic position to control the trade. The Imperial Palace underwent significant changes and additions, especially in the period of Justinian (sixth century AD), during which the port Boukoleon was added. The imperial complex in that period included, as well as buildings used for habitation, by buildings for the cult and for the administration of justice, a thermal complex, a hippodrome and a port area with storage facilities.

In the eleventh century, the emperor's seat was moved and the complex began gradually to decay, so that at the time of the Ottoman conquest in 1453, there were only ruins of the Palace. Currently, the remains of the complex occupy a large area of the Golden Horn, an area that has been proposed for the creation of a historical-archaeological park. This area will be subjected to archaeological recovery, followed by restoration of the structures to make them accessible to tourists. The complex is mostly underground, and many structures are currently almost entirely below the ground level, such as the Apse, a building, probably used to the cult, whose access is permitted only through the windows of the upper level.

The project of creating a historical and archaeological urban park also includes the characterization of construction materials used, including all information necessary for restoration of the walls. The present paper fits into this context through the study of soluble salts in bricks taken from four sites of the ancient complex: Apse, Boukoleon, Sea walls, Tekke. The type and concentrations of soluble salts in the bricks examined were analyzed by ion chromatography. The results indicate that the concentrations of salts vary widely, from less than 1% to over 10% by weight. Nitrate prevails between the anions, followed by chlorine, while calcium and sodium emerge between the cations. Both the total amount of salts and their composition appear to be influenced by different variables, including distance from the sea, the height above ground, exposure to air, local circumstances. On the contrary, nature and distribution of salts appear little influenced by the composition and age of the bricks.

SESSIONE L1

Le Alpi dal break up della Pangea alla strutturazione della catena: una sessione in onore di Luciano Cortesogno e Mario Vanossi

L1-1 Orale Dallagiovanna, Giorgio

FROM FIELD GEOLOGY TO PALEOGEOGRAPHIC AND GEODYNAMIC RECONSTRUCTIONS: THE SYNERGY OF LUCIANO CORTESOGNO AND MARIO VANOSSÌ

DALLAGIOVANNA Giorgio¹, GAGGERO Laura², SENO Silvio¹

¹ - Università di Pavia

² - Università di Genova

Presenter e-mail: dallagio@unipv.it

Key terms: Ligurian Alps; Penninic nappes; structural and metamorphic evolution

This session is jointly dedicated to the memory of Luciano Cortesogno and Mario Vanossi who passed away in 2005 and 2008 respectively. Since 1970, Luciano Cortesogno developed investigations addressed to primary, ocean floor and orogenic processes in the oceanic lithosphere. In those years, starting from extensive, accurate, interpretive field survey and mapping, through deep and exhaustive mineralogical, petrographic, petrological analyses, he elaborated original petrogenetic and geodynamic interpretations and resulted a first rank contributor to the Alpine and Tethyan ophiolite geology. A distinctive character of Lucio was the capacity to collaborate and integrate the contribution from other disciplines than petrography: stratigraphy, structural geology, geochemistry and mineralogy. His scientific interests spread then to the

Paleozoic petrogenetic processes in the continental crust of the Ligurian Penninic terranes: Lower Palaeozoic stratigraphy and metamorphic evolution, Late Variscan volcanism, plutonism, stratigraphy, Triassic volcanism. His research, in a fruitful collaboration with Pavia colleagues and friends, firstly Mario Vanossi, was developed across many years of field and laboratory work.

Mario Vanossi has been one of the most complete geologists in the national and international scientific community, endowed with great abilities of analysis and synthesis and helped by a formidable power of concentration. He wrote about 150 publications as only author or in collaboration with Italian and foreign colleagues. In about twenty years, between the 'sixties and the end of the 'seventies, he collected a huge amount of stratigraphic and structural data, then expressed in more than forty scientific publications, edited in ten years only, as well as in several geological maps. One of these was the second edition of the Albenga-Savona Map of the C.G.I., 1:100.000 scale, printed in 1970, which he managed as survey co-director. At the same time, ranging from the Helminthoid Flysch to the Briançonnais and Piedmont successions, and everytime dealing with different topics, from the stratigraphic-sedimentologic to structural, paleogeographic and geodynamic ones, he outlined a general framework for this sector of the Alpine belt which is, up to now, a milestone. As from the early 'eighties the collaboration Vanossi-Cortesogno started and continued for over twenty years producing basic contributions about the genesis and metamorphic evolution of the Paleozoic basements, the stratigraphy of the late-Variscan successions of the Ligurian Briançonnais and their metamorphic Alpine evolution. Even during the draft of his last paper, co-authored with colleagues and friends in the University of Pavia, Mario Vanossi still addressed the structural evolution of the Penninic nappes of the Ligurian Alps, and honoured his scientific engagements, but also accomplished his teaching commitment, another face of his great passion towards the Earth Sciences.

GEOLOGY OF THE LIGURIAN ALPS: THE HERITAGE OF LUCIANO CORTESOGNO AND MARIO VANOSSÌ

CAPPONI Giovanni¹, CRISPINI Laura¹, FEDERICO Laura¹

¹ - Dip.Te.Ris. - Università di Genova

Presenter e-mail: capponi@dipters.unige.it

Key terms: Ligurian Alps; Voltri Massif; mélange

In this work we want to show the present-day advancements on the geology of the Ligurian Alps, with emphasis on central Liguria. A major contribution to the knowledge of the geology of this area is due to Lucio Cortesogno and Mario Vanossi: the present state of the art could not have been the same without their contributions and we want to dedicate to Lucio and Mario this work.

Central Liguria, i.e. the Voltri Massif and the Sestri - Voltaggio Zone, is in a key geological position, as it represents the easternmost part of the Ligurian Alps, and the physical link with the northern Apennine belt. On the basis of twenty five years of geological mapping and structural analysis, here we want to focus on the structural architecture and the mutual relationships between the main tectono - metamorphic units that characterize this area: the Voltri and the Palmaro - Caffarella units. They derive from mantle and oceanic crust and show different peak metamorphic conditions: the Voltri Unit (as defined by Capponi & Crispini, 2008) re-equilibrated in the eclogite facies, whereas the Palmaro - Caffarella Unit shows blueschist facies peak metamorphic conditions. According to the recently published Geological Map of the area (Foglio 213-230 "Genova" of the CARG project, Capponi & Crispini, 2008), the eastern sector of the Voltri Unit largely consists of serpentinites that enclose bodies of eclogitized metagabbros, metasediments and serpentinitized peridotites, that achieved slightly to severely different P-T conditions, even if they attained peak conditions within the metamorphic eclogite facies.

On the whole, at the regional scale, the Voltri Unit is limited to the east by the Palmaro - Caffarella Unit, in contact along folded and sheared boundaries; nevertheless detailed geological mapping and structural analysis revealed a more complex architecture, showing that disrupted portions of the blueschist Palmaro - Caffarella Unit are boudinated and sheared along the regional foliation inside the Voltri Unit. The result is that highly sheared serpentinites and metasediments of the Voltri Unit host various HP rock slices re-equilibrated at different P-T peak conditions. Metagabbro and peridotite bodies display strong strain partitioning, being much less deformed than the country rocks.

Such evidence indicates that bodies with different metamorphic (eclogite vs blueschist facies) and tectonic evolution float in a low competence "matrix" and therefore suggests that the Voltri Massif, at least its eastern sector, matches the requirements of a tectonic mélange. In particular the Voltri Massif displays a strong strain partitioning, with low deformed rock bodies inside highly sheared country-rocks; such bodies (from m-scale to km-scale) show heterogeneous metamorphic peak conditions, ranging from eclogite to blueschist facies.

The occurrence of a tectonic mélange in the Voltri Massif has been proposed by Federico et al. (2007) that interpreted in this way an hectometric outcrop of foliated chlorite-actinolite enclosing lenses of less deformed metabasites and metasediments, at Cascine Parasi, in the western part of the Voltri Massif. We like to recall that we were introduced to the geology of the Cascine Parasi area by Lucio Cortesogno, who also led the petrographic studies during our Geological Mapping of the CARG project.

NATURAL FOOTPRINTS OF THE TRANSITION FROM VARISCAN COLLISION TO CONTINENTAL BREAK-UP IN THE ALPS

GOSSO Guido¹, SPALLA Maria Iole¹, MAROTTA Anna Maria¹

1 - Dipartimento di Scienze della Terra "A. Desio" Università degli Studi di Milano and C.N.R. - I.D.P.A., Milano, Italy

Presenter e-mail: guido.gosso@unimi.it

Key terms: Variscan Convergence; Permian-Triassic extension; HT-LP

In the European Alps the exposure of Variscan structural and metamorphic imprints within the present-day Alpine structural domains indicates that before the Pangaea break-up, the continental lithosphere was thermally and mechanically perturbed by Variscan subduction and collision. When continental rifting does not develop on a stable continental lithosphere, geodynamic interpretation of igneous and metamorphic records, as well as structural and sedimentary imprints of rifting-related lithospheric extension, can be highly ambiguous since different mechanisms can be responsible for regional HT-LP metamorphism. While the metamorphic and igneous records of Variscan orogeny are widespread in the European continental crust, a diffuse igneous activity associated with HT metamorphism accounting for a Permian-Triassic high thermal regime is peculiar to the Alpine area. The overprint of HT Permian-Triassic evolution on the HP relics of the Variscan subduction and collision has been interpreted as induced either by late-orogenic collapse or by lithospheric extension and thinning leading to continental rifting (e.g. Lardeaux & Spalla 1991; Diella et al. 1992; Ledru et al. 2001). Even the interpretation of the geodynamic environment responsible for the development of intracontinental basins hosting the Permian volcanic products allows two possible alternatives: one envisaging a strike-slip dominated regime (Arthaud & Matte 1977; Cassinis & Perotti 1994), which is compatible with the evolution of a mature collisional setting (Molnar & Lyon-Caen 1988), the other a continental rifting tectonic setting (Siletto et al. 1993; Selli 1998; Staehle et al. 2001). In both cases the continental rifting promoting Mesozoic opening of the ocean in a lithosphere thermally softened and thinned by slab break-off processes is generally accomplished in the final stages of continental collision. Recently the integrated use of geological data and numerical modeling shows that active extension is required to achieve the thermal conditions allowing partial melting of the crust accompanying gabbroic intrusions and HT-LP metamorphism (Spalla & Marotta, 2007; Marotta & Spalla, 2007; Marotta et al., 2009).

Key terms: late variscan basins; granite; thermometamorphism; Sardinia

In North Sardinia a volcano-sedimentary succession made of clastic sediments and by a thick stack of pyroclastic flows crops as remnant of a Permo-Carboniferous basin. The outcrop to the south is buried by the Tertiary sediments of the Castelsardo basin, whereas to the north it rests on granitoids that intrude the Variscan High Grade Metamorphic Complex, which mainly consists of migmatites. Among the different intrusions in touch with this late Variscan basin, a small intrusion consisting of intergradational, quartzose gabbro-diorite, diorite and voluminous mafic-to-felsic granodiorite is the closest to the best exposition of its infilling.

The clastic sediments consists of fine-grained quartzites, arcoses with silty intercalation and conglomerates; these consist of mud-sustained angular to sub-rounded clasts, derived from the metamorphic basement. The facies of the deposits recall that of some Stephano-Autunian basin of southern Sardinia. The clastic succession is capped by tuffs and by welded lava-like ignimbrites with an exposed thickness of 700m.

The intrusive relationships between the plutonic rocks of the area with the late variscan deposits were already evidenced by Del Moro et al. 1996, who evidenced some metamorphic assemblage in the Permo-Carboniferous sediments.

Actually, the fine-grained sedimentary rocks in contact with the intrusives are deeply transformed, in place resembling those of the High Grade Metamorphic Complex. In any case in thin section they show abundant

andalusite ± cordierite, graphyte and decussate aggregates of muscovite and biotite. Graphyte is particularly abundant in some dark beds as metamorphic product of carbonaceous matter.

New U/Pb zircon analyses on the gabbroic portion of the composite intrusion yielded an age 285.8 ± 1.9 Ma. Such an age is coherent with both the Rb/Sr blocking ages and newly performed Ar/Ar ages - which resulted few hundred thousand years younger - on muscovite and biotite with decussate texture of the thermometamorphic sediments. Moreover amphibole thermobarometry confirmed the shallow emplacement level (2-3 Km) for the composite granodioritic intrusion.

Taking in account that the High Grade Metamorphic Complex on which the Lu Falzu sediments rest is affected by the neo-Variscan HT/LP (≈ 4 Kb - 650 °C) event at about 303 Ma (Macerà et al. 1989) and that erosion and sedimentation must have occurred before the gabbro emplacement, uplift and exhumation of the migmatite that equilibrated

at least 13-14 Km occurred within a time span as short as ten million years.

POST- AND LATE COLLISIONAL VOLCANISM IN SOUTHERN VARISCIDES: A KEY TO COLLAPSE AND DISRUPTION OF AN OROGEN

Key terms: orogenic collapse; Variscan; crust-mantle; volcanism; Permian

The late to post orogenic evolution in southern Variscides is characterized at the Early Permian, by a transtensional geodynamic regime developed along the southern Palaeoeuropean margin, as a result of a dextral megashear between Gondwana and Laurasia. In West-Mediterranean southern Variscides, magmatism and tectonics interplayed during the opening of intracontinental alluvial to lacustrine basins.

The most significant issues to address in the characterization of post-orogenic succession in Southern Variscides are the following: i) within the generalized orogenic collapse, sediment- or volcanic-dominated series develop as a consequence of local tectonic and lithospheric setting.

The volcanic units are characterized by a common stratigraphic succession, beginning with early calc-alkaline andesites and rhyolites, followed by conspicuous rhyolites, and by dacites infilling fault-bounded pull-apart basins. Both andesites and rhyolites show K-normal and high-K calc-alkaline character. However, in different regions and settings, differences in timing, areal distribution and outpoured volumes arise.

ii) opening of pull apart basins is associated with strike slip basins

iii) when tectonic unroofing is active, the volcanism could be associated with HT /LP metamorphism

iv) along with areal distribution of the volcanic field, a chemical zonation is possible parallel to the orogen axis. This character has been evidenced in the Ligurian Alps and also in the collapse of the Balkan orogen (Bulgaria)

v) the relationships between calcalkaline and alkaline volcanism have been demonstrated to occur as subsequent or coeval. In the Ligurian Alps, the volcanic activity is confined between calc-alkaline rhyolites dated 285.6±2.6 Ma and rhyodacites-rhyolites aged 272.7±2.2 Ma (U/Pb LA ICP MS on zircon). In between, intermediate lavas and associated tuffites that have been interpreted as the result of mixing and fractional crystallization originated in partial melting at boundary between lithospheric mantle and lower crust. The interaction with the overlying thickened crust was constrained at ~34 % crystallization by adding ~27 % of contaminant to the parental magma. The final volcanic event is represented by K-alkaline rhyolites at 258.5 ± 2.8 Ma after a Mid-Permian amagmatic and sediment-starved time gap of c. 14 Ma.

Conversely, in Nurra, a mildly alkaline activity occurs at Santa Giusta at 291 Ma; here the basement was a structural high bounded by E-W trending faults since the Late Carboniferous-Lower Permian, and also controlled the development of Mid Permian and Lower Triassic successions. The Lower Paleozoic medium- to high-grade metamorphic basement, the Sardinia-Corsica batholith and the Stephano-Autunian calc-alkaline effusives are cut by transitional dolerite dikes with a N-S trend and subvertical dip. 40Ar-39Ar ages on amphibole at 253.8±4.9 and 248±8 Ma probably represent the emplacement interval.

Finally, a role of volcanic dominated series in plate reorganization has been envisaged: the end of calc-alkaline magmatism and the gap in the sedimentary record may correspond to the major displacement along the megashear zone between Laurussia and Gondwanaland as supported by palaeomagnetic constraints. In the Ligurian Alps, the age of the alkaline volcanic rocks matches the end of the plate reorganization and the onset of the Alpine cycle.

Key terms: U-Pb dating; late/post-Variscan tectonics;

Carboniferous-Permian magmatism; Ligurian Alps

The Alpine chain comprises two major rock groups: one of these only experienced tectonics related to the Alpine cycle, while a second shows pre-Alpine relict metamorphism. The latter recorded a polyphase ante-Alpine history, both Variscan or pre-Variscan in age. The Alpine overprint on the Variscan relict units in general obscures our interpretation

of the preceding history. In particular, the Penninic nappes of the Western Alps comprise several gneissic units, whose age, origin, pre-Alpine metamorphism and tectonic significance are debated. In the Ligurian Alps, one of the basement units of the Briançonnais domain (Barbassiria massif) is made up of orthogneisses derived from K-rich rhyolitic protoliths and, subordinately, rhyolitic dykes cutting a main igneous body. The pervasive Alpine metamorphic and tectonic overprint under blueschist facies conditions on the Barbassiria Orthogneisses preserves little evidence of the Variscan metamorphism. New U-Pb excimer laser ablation ICP-MS dating on zircon separates from the orthogneisses and dykes has been undertaken to unravel the relationships between effusive emplacement and Variscan metamorphic overprint. The results suggest an age for the eruption of the rhyolite protolith of the Barbassiria Orthogneisses of ~ 320 Ma (i.e. Late Carboniferous), and a subsequent dyke emplacement at 260.2 ± 3.1 Ma. The Variscan high-temperature metamorphic event (amphibolite-greenschist facies) is thought to be related to a mechanism of tectonic burial associated with the compressive tectonics during the uppermost Carboniferous late stage of the Variscan collision. The dykes cutting the Barbassiria Orthogneisses at ~ 260 Ma belong to the diffuse K-rhyolite volcanism emplaced at 258.5 ± 2.8 Ma. This age represents the end of the orogenic phase in this segment of the southern Variscides, and enhances the evidence of a ~ 10 - 15 Ma Mid-Permian sedimentary/magmatic gap in its volcano-sedimentary cover.

Key terms: Permian Gabbros; lithospheric thinning; Austroalpine domain; Western Alps

Gabbro emplacement in the continental lithosphere is a marker of lithospheric thinning: association of mantle peridotites, gabbros and continental crust is an important key for the understanding of passive margins. Gabbros included in continental units of orogens are therefore basic tools to infer duration and mechanisms active during ocean opening. Moreover gabbro compositions are diagnostic to develop critical parageneses in subduction-collision environment.

In the Austroalpine domain several gabbro bodies have Permian ages and are often intruded into metamorphic rocks deformed under high-temperature and intermediate- to low-pressure conditions. They are interpreted, with the contemporaneous metamorphism often developed in their country rocks, as signals of a positive thermal anomaly associated to lithospheric thinning, indicated by some authors as precursor of the continental rift that led to the Mesozoic ocean opening (Marotta et al., 2009 and refs therein). Amongst these, mainly in the western portion of the Austroalpine, numerous bodies underwent HP-LT Alpine metamorphic re-equilibrations but still preserve, at places, relicts of pre-Alpine evolution. Corio and Monastero and Sassa gabbro bodies are here investigated to reconstruct their structural and metamorphic evolution in order to decipher the geodynamic scenarios characterizing their pre-Alpine and Alpine tectonic history.

The polyphase Alpine deformation of these gabbros is highly heterogeneous; our detailed structural investigations allow to discriminate between emplacement structural levels: the Sassa body maintains at best the igneous characters over huge weakly deformed volumes and the pre-Alpine subsolidus evolution accounts for an exhumation from the intermediate crust. The Corio and Monastero gabbro is pervasively eclogitized but few low strain domains preserve pre-Alpine fabrics and mineral assemblages pointing to a deep crustal emplacement. Similarly the Alpine evolution differs in the two bodies: Sassa gabbro underwent Tertiary blueschist facies re-equilibration whereas Corio and Monastero gabbro underwent Upper Cretaceous - Paleocene eclogite-facies conditions.

Differences in the P-T paths characterizing the pre-Alpine and Alpine evolutions are the key to unravel differences in the thermal state affecting pre-Alpine continental crust during lithospheric thinning and the Alpine evolving thermal state of the subduction zone.

Key terms: Ligurian Alps; Geodynamics; Prepidmont; Briançonnais

The renewed interest that has arisen around passive margins leads us to reconsider the stratigraphy and geodynamics of this peculiar and misunderstood sector of the Italian Alpine belt. The Western Italian Alps comprise one of the most extensively studied areas in geological sciences, but the Ligurian Alps, are left out from recent debates and are rarely cited in papers on pre-collisional geodynamic reconstructions. In our opinion this is due to the scarcity of international literature on this Alpine sector, and to the widespread metamorphism and tectonic displacement affecting almost all the sedimentary covers, discouraging field research. Nevertheless, once the complex puzzle of tectonic units has been restored, the Ligurian Alps represent one of the best places to observe a complete section of a Mesozoic passive margin. In addition, in the Ligurian area there is no field evidence of multiple oceans (as in other sectors of the Western Alps), giving the researcher an opportunity to pass directly through the margin towards its transition to the undeformed foreland and to the oceanic domain. Furthermore, the preserved geological records pertain to two distinct orogeneses, the late-Variscan and the Alpine events. The Early-Middle Permian tectonics, considered as the product of a megashear zone evolution or as a response to a changed geodynamic context, affected the Ligurian Alps, as we can see in the Briançonnais

domain, with the rejuvenation or birth of new faults bordering graben/half-graben or pull-apart structures during the emplacement of the different volcanic bodies. During Late Permian-Early Triassic times, the Ligurian sectors underwent extensional tectonics only. At first, graben/half-graben structures filled by Upper Permian K-rhyolites developed, followed by the establishment of suitable gradients for erosion and transport of clastic components of the Verrucano Formation. From the Middle Triassic onwards, the Ligurian Alps area was affected by diffuse extension caused by southeastern subduction of Palaeotethys which led to the opening of multiple oceanic troughs (i.e. Pindos, Maliac and Meliata). At these times, the study area was located in a sector approaching the convergence of the axes of basins, opening like a fan toward the East. The climax of this activity occurred in the Ladinian. Nevertheless, our data show that the extensional basin axes at this time were markedly different from the Alpine Tethys ones that overprint the whole pre-Jurassic geological record. The Late Carnian to Norian was a key point in the evolution of the Mediterranean area: in the Ligurian Alps it represented the transition between the Middle Triassic back-arc/rifting stage and the Alpine Tethys rifting s.s. Field evidence is in favour of an overlap of the two extensional mechanisms rather than a complete switch-off of the first. The Alpine Tethys rifting developed from the Norian and reached its climax in the Early Jurassic, when subsidence increased until the collapse of the margin. This led to the formation of emerged rifting shoulders and deeper inner domains, creating the Briançonnais-Prepidmont differentiation. It follows the oceanisation and successive cooling of the margins. Our research highlights that the Ligurian Alps were a domain in which for over a hundred million years orogenesis, rifting and oceanisation strongly affected the integrity of the upper crust. The rare volcanic effusions testify to a complex chemistry, sometimes apparently in contrast with the supposed geodynamic environment. This may be related to the heterogeneity of the crust that was affected by multiple mantle uplifts, partial melting and extensive faulting over a long period. Thus the last and most important rifting (the Alpine Tethys) developed around a narrow, elongated area of crustal weakness generated by multiple geodynamic events.

THE "URBE" 212-2 QUADRANGLE: NEW GEOLOGICAL MAPPING IN THE HP POLYDEFORMED VOLTRI MASSIF (WESTERN ALPS)

FEDERICO Laura¹, TORCHIO Silvia¹, POGGI Eugenio¹, VIGO Andrea¹,

CRISPINI Laura¹, CAPPONI Giovanni¹

1 - Dip.Te.Ris - Università di Genova

Presenter e-mail: federico@dipterial.unige.it

Key terms: geological mapping; structural setting; HP metaophiolites; Voltri Massif; Western Alps

We performed a new geological mapping of the western part of the Voltri Massif at 1:10.000 scale, between autumn 2009 and 2010. The investigated area is approximately 160 Km² and covers a hilly to mountainous region in Liguria (spanning the Savona and Genova provinces), with the highest peak of Mt Beigua (1287 m) at only about 8 Km from the Ligurian Sea.

The mapped area falls inside the HP metaophiolitic Voltri Massif of the Western Alps and thus encompasses rocks belonging to the Ligurian-Piemontese Domain. The bedrock is made up of serpentinites and metasediments, with minor occurrence of metabasite, ilherzolite and metagabbro. Metagabbros frequently crop out as lenses and bodies inside serpentinites and are either eclogite-facies Fe-Ti-oxide gabbros or Mg-rich HP gabbros, largely retrogressed in greenschist facies.

Along the contacts between serpentinites or metabasites and metasediments, levels of hybrid rocks (schists containing chlorite + actinolite/tremolite \pm carbonate \pm ores) often occur, resulting from shearing and metasomatic exchanges; such rocks are schists containing chlorite + actinolite/tremolite \pm carbonate \pm ores

Metabasites encompass rocks with either a magmatic ("Prasinite" Auct.) or metasedimentary origin (pristine mafic breccias or greywackes), completely retrogressed in greenschist facies conditions.

The bedrock is covered by late- to post-orogenic deposits, either belonging to the basal horizons of the Tertiary Piedmontese Basin (TPB) or to Pliocene marly sediments.

The metamorphic rocks are commonly highly deformed and the more evident foliation in the field is a composite fabric (CF) that is parallel to the lithological contacts. More than 2200 CFs have been measured, together with axes and axial planes of folds. The structural analysis and the development of mesoscopic fold interference patterns point out to the occurrence of at least three phases of folding.

The older deformation event (F1+2) is characterized by tight to isoclinal transpositive folds, with generally subhorizontal axial planes and subhorizontal axes; the second one (F3) is characterized by open folds with E-W to NE-SW trending and low plunging axes, that don't produce an axial plane cleavage. Dispersion of AP3 suggests the occurrence of a further folding event (F4) with N-S to NW-SE subhorizontal axes. The resulting interference patterns are both of type 2 and 3, that occur also at the cartographic scale.

In general the CF dips 40-50° towards E-SE in the eastern side of the mapped area, whereas it is subhorizontal in the western part. This structural feature, combined with the fact that further to the east the CF in the Voltri Massif is commonly steeply dipping (CAPPONI & CRISPINI, 2008), points to a general recumbent geometry already depicted in literature but variably interpreted (e.g. CAPPONI & CRISPINI, 2002; VIGNAROLI et al., 2010). This 3D-structural architecture is going to be discussed on the basis of our analysis.

In the studied area brittle structures are widespread and associated to mappable fault rocks. We measured fault surfaces and associated kinematic indicators in the field and mapped the tectonic lineaments resulting from photo-interpretation as well.

Even if lithologic boundaries generally follow the CF, they are locally reworked by brittle tectonics, that in places can be constrained in time by the occurrence of the Pliocene sediments (in the southeastern part of the map) and of the TPB deposits in the northwestern corner.

The new detailed mapping and structural analysis allowed us to make a direct comparison with data recently collected in adjacent areas (CARG Project - CAPPONI & CRISPINI, 2008) to obtain a better insight into the structural setting of the Voltri HP-ophiolites.

Key terms: Prepidmont; Ligurian Alps; Lias; Volcanics; Rifting

Cortesogno et al. (1981) pointed out the presence of rhyodacite lavas and pyroclastics that form metre-thick layers interfingering with the M. Galero Breccia near Albenga, SV (Case Morteo rhyodacites). Two volcanic events can be recognised: the first led to the deposition of altered acid lava, about 4 metres thick, the second event is formed by 5-6 metres-thick level of altered acid lava that overlies a breccia horizon, reworking and engulfing its clasts, testifying to the true stratigraphic position of the volcanics. The original mineralogical composition of massive lava and pyroclastics was interpreted (Cortesogno et al., 1981) to be formed by plagioclases, amphibole, biotite and quartz and thus considered to be an alteration product of a primary felsic suite that ranges from rhyolite to dacite. The age of volcanics remained unsolved due to both the uncertainty of the chronostratigraphic position of the embedding breccia (traditionally referred by regional comparison to Dogger s.l.) and to the lacking of minerals for the radiometric datation (zircons were searched but not found). Recently, a revision on the stratigraphy of this sector of the Ligurian Alps, (Decarlis & Lualdi, in press) leads to the definition of new lithostratigraphic unit that allow to reconsider the chronological position of some units also by comparison with key-successions in the Western Alps used as geodynamic markers. On this base, the M. Galero Breccia, i.e. megabreccias produced by the dismantling of northern margin of Tethys, has been referred to a Late Liassic age rather than Dogger s.l. Since the opportunity to date this huge amount of clastics (and their equivalent in the Western Alps, e.g. Formation Detritique Rousse, Breche s.l. of the Breccia Nappe) that marks the paroxysmal phase of rifting that closely predates the oceanisation. The relevance of these volcanics is also to be a unique witness of synrift flow on continental crust on the whole Western Alps. The existence of these outflows may prove their run-up in Liassic times along pre-existing faults and their mixing with the falling blocks. As a consequence, they can be considered to be strictly linked to the geodynamic context of the pre-oceanic rifting of the Prepidmont sector of the European margin. It is worth considering that similar pyroclastic product emplacements took place during the Pliensbachian to Toarcian in the Betic cordillera, preceding the effusion of basic lava associated with the western Tethys preanisanion. Unfortunately, the U/Pb radiometric analyses on zircon separates by the EL-ICP MS (excimer laser ablation inductively coupled plasma mass spectrometry) method (CNR - IGG Pavia) did not provide a reliable age due to the alteration of the volcanics and to high normal-Pb content. The latter is probably due to a late hydrothermalization associated with rifting and emplacement of the oceanic crust, recorded by the complex vein network affecting the overlying radiolites. Recently, a detailed sampling has been performed on the coarser grained fraction of the flow that provided a few zircon crystals. Further U-Pb analyses on zircons in progress by SHRIMP (Sensitive High Resolution Ion Microprobe) are aimed to improve the response in order to achieve regional scale correlations. Key terms: Oceanic anoxic event; Oceanic red bed; Poggio le Guaine core; Aptian-Albian interval

A continuous core extending from the Albian-Cenomanian boundary down to the uppermost Barremian (~99.5-127 Ma) was drilled at Poggio le Guaine, where the most continuous, complete and best preserved Aptian-Albian succession throughout the Umbria-Marche Basin (northern Apennines, central Italy) is exposed.

The Poggio le Guaine core penetrated 98.72 m of pelagic sediments consisting mainly of limestones, calcareous marls, marls, clays and black shales. The core was continuously drilled with essentially 100% recovery of excellent quality material and completely logged. The cored sequence

records both OAE1a to OAE1d and regional equivalents of widely distributed Aptian-Albian oceanic anoxic events. The Poggio le Guaine core can be considered as a tightly constrained "reference section" for the Aptian-Albian interval at low latitudes and is designated to provide high-ranking informative records for that critical time interval through high-resolution multiproxy studies.

The dataset collected will supply the framework for 1) computing a high-resolution relative paleointensity reference curve for the Aptian-Albian interval of the long normal Cretaceous superchron that would allow us to correlate relative paleointensity curves from other places in the world, 2) building up, at high resolution and using astronomical tuning and absolute dating, a unique and original age model to which refer the sequence of the geological, biogeochemical, oceanographic and climatic events as recorded throughout the Aptian-Albian critical time, and 3) defining the causal linkages among these events as well as their consequences.

Key terms: CHLOROBIACEAE; CENOMANIAN-TURONIAN; BLACK SHALES; NORTHEASTERN SICILY

The Chlorobiaceae, also known as green sulphur bacteria, are strictly anoxygenic photoautotrophic prokaryotes that inhabit the photic zone of euxinic basins usually at the interface between well-oxygenated surface layers and anoxic waters rich in H₂S. Chlorobiaceans fix carbon through a reductive Krebs cycle and play a key role in marine ecosystems acting as an ecological barrier to the diffusion of H₂S in surface layers, thereby allowing the presence of nektonic organisms. These bacteria are adapted to sustain photosynthesis at very low light intensities (Overmann et al. 1992) and produce characteristic pigments, including some aromatic carotenoids. Molecular fossils derived from such pigments can be used to document the distribution of these photosynthesizing prokaryotes in the fossil record, as well as to provide evidence of the occurrence of photic zone euxinia in ancient depositional environments (Summons & Powell 1986; Sinninghe Damsté et al. 1993; Koopmans et al. 1996). A vast array of diagenetic and catagenetic products derived from the pigments characteristic of the Chlorobiaceae have been documented in sediments ranging from Ordovician to Miocene (Koopmans et al. 1996). Examination by gas chromatography/mass spectrometry of Cenomanian-Turonian ichthyolithiferous black shales of Argille Varicolori of northeastern Sicily revealed the presence of isorenieratane and chlorobactane, two sedimentary derivatives of aromatic carotenoid pigments (isorenieratene and chlorobactene) specifically produced by chlorobiaceans. The presence of isorenieratane and chlorobactane is accompanied by a carbon isotopic anomaly (enrichment of ¹³C; Scopelliti et al. 2008), which may be attributable to the unusual carbon metabolism of these bacteria (Siveråg et al. 1977). Aromatic carotenoids, including isorenieratene, are generally labile compounds not very resistant to transport over long distances (Sinninghe Damsté & Koopmans 1997). Therefore, the presence of their derivatives in the sedimentary rocks must be considered as autochthonous.

In summary, the analysis of molecular fossils in the black shales of northeastern Sicily has provided unambiguous evidence of the activity of microbial communities that recorded the development of euxinic conditions at shallow depths along the north African shelf at the Cenomanian-Turonian boundary (Sinninghe Damsté & Köster 1998).

Key terms: STTE; ELPE; Hyperthermal; Paleogene; Contessa Road (Gubbio)

A ~250-kyr long-lasting dissolution interval during the Paleocene, here named Selandian-Thanetian Transition Event "STTE" has been recognized at Western Tethys Contessa Road section (Gubbio, Italy). The uppermost part of the "STTE" includes the short-lived suspected hyperthermal event known as the early late Paleocene event (ELPE, Bralower et al., 2002; Petrizzo, 2005) or mid-Paleocene biotic event (MPBE, Bernaola et al., 2007), which therefore would become part of a more complex scenario. Here we present and discuss high-resolution biochronostratigraphic and geochemical records, and magnetic susceptibility and environmental magnetism data from the western Tethyan Contessa Road section (Gubbio, Italy). The "STTE" falls within the middle-lower part of the planktonic foraminiferal Zone P4b and calcareous nannofossils Zone NP6 with its onset placed in the uppermost part of Chron C26r. The "STTE"

constitutes a precursor for the ELPE that is marked by a drop in $\delta^{13}C$ bulk carbonate and carbonate content accompanied by prominent peaks in low-field magnetic susceptibility. At Contessa Road, the STTE and ELPE exhibit peculiar stressed ecological responses among calcareous nannofossils and foraminifera, which highlight marked environmental perturbation affecting the geobiosphere. Further studies are needed to understand whether the "STTE" represents a regional or global event. However, an abrupt environmental perturbation close to the Selandian-Thanetian transition has been observed in other Tethyan as well as open ocean sites suggesting that the "STTE" might be a possible global prelude to the PETM.

EVOLUTIONARY ORIGIN OF THE FORAMINIFERAL GENUS HANTKENINA FROM THE MIDDLE EOCENE CONTESSA HIGHWAY SECTION (GUBBIO, ITALY): MAGNETOBIO-CHRONOSTRATIGRAPHIC, CHRONOLOGIC AND PALEOENVIRONMENTAL IMPLICATIONS

COCCIONI Rodolfo¹, BANCALA' Giuseppe¹

¹ - Dipartimento di Scienze della Terra, della Vita e dell'Ambiente dell'Università degli Studi di Urbino

Presenter e-mail: giuseppe.bancala@uniurb.it

Key terms: *Hantkenina*; evolutionary trend; morphotypes; Middle Eocene; Gubbio

One of the most distinctive and enigmatic bioevents in Cenozoic planktonic foraminifera evolution is the origin of the genus *Hantkenina*, which evolves gradually from the genus *Clavigerinella* by the acquisition of particular morpho-structures called "tubulospines". This evolutionary trend, firstly restricted to the deep water of Tethyan region, occurred during a dramatic climatic change from the extremely warm conditions of early Eocene to the initial rapid phase of Cenozoic cooling between 50 and 48 million years in unusual hydrographic conditions associated with restricted circulation, involving periods of low oxygenated waters follow by upwelling (Zachos et al., 2001). *Hantkenina* origin and speciation might involve divergence from the ancestral genus *Clavigerinella* within deep, cold oxygen starved, nutrient-rich but food-poor environment (Coxall et al., 2003). In this scenario, *Hantkenina* was probably originated through competition for limited food resources and the tubulospines may represent a structural adaptation to this new trophic strategy, allowing the organism to harvest a greater volume of water at minimal metabolic cost (Coxall et al., 2003). In this context, a high-resolution study was carried out on the middle Eocene hard lithologies of the Western Tethys Contessa Highway Section (Gubbio, Italy). The cold acetolysis method enabled the extraction of foraminifera even from indurated limestones, offering the possibility of accurate taxonomic determination and detailed analysis of the foraminiferal assemblages.

We collected numerous and readily identifiable specimens that allow us to build up a continuous and complete evolutionary record, which includes the evolutionary transition forms between *Clavigerinella* and *Hantkenina*. In particular, we recognized a large number of specimens of *Hantkenina gohrbandti*, which is considered to be the real ancestor of the genus *Hantkenina* (Rögl and Egger, 2010, 2011). For the first time, we were able to distinguish three discrete morphotypes of *Hantkenina gohrbandti*, which first appear at different times and would testify a further evolutionary lineage within this species. Based on the recent Contessa Highway astronomical calibration of Jovane et al., (2010), we also provide the timing of the evolutionary steps from *Clavigerinella* to *Hantkenina*.

PERTURBATION AT THE SEA FLOOR ACROSS THE MIDDLE EOCENE CLIMATIC OPTIMUM AS RECORDED BY BENTHIC FORAMINIFERA IN THE ALANO DI PIAVE SECTION (BL, NORTH-EASTERN ITALY)

BOSCOLO GALAZZO Flavia¹, GIUSBERTI Luca¹, LUCIANI Valeria²

¹ - Dipartimento di Geoscienze, Università di Padova

² - Dipartimento di Scienze della Terra, Università di Ferrara

Presenter e-mail: flavia.boscolagalazzo@studenti.unipd.it

Key terms: Middle Eocene Climatic Optimum; Benthic foraminifera; Alano di Piave section

The Middle Eocene Climatic Optimum (MECO; Bohaty & Zachos, 2003) is a prominent (~500 Kyr) warming episode that, at 40 Ma, interrupted the overall cooling trend of the middle Eocene (Tripathi et al., 2005; Sexton et al., 2006; Edgar et al., 2007a; Bohaty et al., 2009). MECO is recorded worldwide by pronounced changes of both $\delta^{13}C$ and $\delta^{18}O$ values and is marked by coeval oscillations in global CCD (Bohaty et al., 2009).

The middle bathyal Alano di Piave section (northeastern Italy, central-western Tethys) provides an excellent record of the MECO, offering the opportunity to investigate this event in detail with multi-proxy, high-resolution approaches (e.g. Spofforth et al., 2010). At Alano, a peculiar sapropelic interval, characterized by excursions in both the carbon and oxygen bulk-carbonate isotope records, represents the lithological expression of the post-MECO event. Such organic-enriched interval follows

the $\delta^{18}O$ negative shift, interpreted as the peak of MECO warming (Spofforth et al., 2010). Previous studies on the Alano section, based on calcareous plankton, suggest increased nutrient input and surface ocean water productivity in response to the environmental perturbation associated with the MECO (Luciani et al., 2010; Toffanin et al., 2010). In order to improve our knowledge about the benthic ecosystem response to the MECO, we investigated benthic foraminiferal assemblages of the Alano di Piave section through the analysis of the $\geq 63 \mu m$ fraction and, for

selected samples (e.g. sapropelic interval), of the $\geq 125 \mu m$ fraction. The combined quantitative study of these two different size fractions allowed a detailed reconstruction of the sea-floor conditions during the environmental perturbations associated with the MECO.

Our results of the $\geq 63 \mu m$ fraction show a benthic foraminiferal assemblage characterized by small bolivins (*Bolivina* spp.) which show a cyclical pattern abundance throughout the section. Moreover there are some remarkable peaks of other opportunistic taxa as *Globobuccidulina* spp., *Bulimina thanetensis*, *Bulimina semicostata*, *Oridorisalis umbonatus* and small uvigerinids as *Uvigerina farinosa*.

Within the sapropelic intervals, the study of the $\geq 125 \mu m$ fraction better evidence increased abundance of abnormal big-sized *Uvigerina*, a taxon common in oxygen-depleted, organically enriched settings and other big-sized taxa which peak in these intervals (e.g. *Hanzawia ammophila*, *Plectinella dalmatina*). All these faunal modifications, compared with planktonic foraminiferal and geochemical data (Luciani et al., 2010; Spofforth et al., 2010), were interpreted as a response to remarkable food transfer to the sea-bottom and to the development of dysoxic waters at the sea-floor just above the peak of the MECO warming. Such peculiar conditions were an effect of eutrophication of surface waters, as consequence of the modified, enhanced hydrological cycle in response to the MECO warming.

Within the framework of the "Paleogene Integrated Stratigraphy" (PALIS) project we have reassessed the Paleogene bio-, chrono-, and magnetostratigraphy and chronology of the Umbria-Marche Basin (central Italy), building up a ~42.5-Myr continuous, undisturbed and well-preserved composite section belonging to the Scaglia pelagic sediments and based on the Contessa, Massignano and Monte Cagnero key sections.

It should serve as the Paleogene reference section for the Western Tethys, which will provide a template for future progress to the Cenozoic time scale as well as constraints for on-going paleoenvironmental, paleoceanographic and paleoclimatic studies.

Presenter e-mail: mattia.vallefucio@iamc.cnr.it

Key terms: planktonic and benthic foraminifera; oxygen stable isotope; southern Tyrrhenian Sea; maunder event; human impact

High-resolution study of southern Tyrrhenian marine record (core C90-1m,

40°35,76'N;14°42,48'E, water depth of 103.4m) from continental shelf of Salerno Gulf, provides a good opportunity to detect the anthropogenic impact on sedimentation during the last 600 years. Based on ²¹⁰Pb and ¹³⁷Cs measurements, the sedimentation rate results of 0.20 cm/yr for the last 100 years. The high resolution of sample investigation (1 cm sample spacing) provide a time resolutions of data around 5 years. Quantitative changes in the planktonic and benthic foraminifera

assemblages combined to ¹⁸O_{carb} variation allows to recognize different paleoenvironmental intervals linked to the global and regional climatic and oceanographic changes. A significant turnover between herbivorous and opportunistic species and carnivorous planktonic foraminifera after the Maunder event reflects changes in river runoff and/or an increase in coastal flood events in the studied area. Human impact induces variations in the microfauna since 1940 AD associated to the building of the dam on the Sele river.

1 - CNR - National Research Council of Italy, ISMAR - Institute of Marine Sciences in Bologna

2 - CNR - National Research Council of Italy, IAMC - Capo Granitola

Presenter e-mail: caterina.bergami@ismar.cnr.it

Key terms: Foraminifera; sapropel; temperature; salinity

The youngest sapropel S1 has been investigated by a multiproxy study on a core (ET99-M11) collected in the western Ionian Sea at a water depth of 2800 m, which is considered to represent anoxic conditions in the eastern Mediterranean at the time of sapropel formation.

Planktonic foraminifera have proven to be excellent indicators of sea surface temperature, salinity, food availability and they have been used for the detection of long- and short-term climate changes in the Mediterranean Sea.

Quantitative and qualitative characterization of the planktonic

assemblages, stable isotopes (¹⁸O and ¹³C) and trace elements measurements on the planktonic foraminifers Globigerinoides ruber and Globigerina bulloides have been performed to reconstruct Sea-Surface Temperatures (SST), Sea Surface Salinities (SSS), and riverine inputs at the time of sapropel S1 deposition.

The beginning of S1 is marked by a significant decrease in SSS and by a change in the planktonic foraminiferal assemblage with the increase of warm waters taxa, near absence of Globorotalia inflata and the significant decrease of Neogloboquadrina pachyderma. The ecosystem composition suggest a rising riverine input at the onset of the sapropel deposition and during the sapropel interruption linked to the African monsoon system. The sapropel S1 interval was characterized by a general increase in water temperatures (documented by calculated isotopic temperatures) both at surface and in the sub-surface layers. In addition, several short-term cold oscillation can be correlated with millennial scale climate events in the North Atlantic region. This indicates a possible atmospheric connection between the central Mediterranean and the North Atlantic region and the strong relation between climate and oceanographic changes during the sapropel deposition.

In addition, it is noteworthy that the cold periods can be correlated with intervals of weak Asian southwest monsoon suggesting that the Holocene climate changes in the North Atlantic can be have counterparts in the Asian southwest monsoon system.

Discrepancies between Mg/Ca ratios and calculated isotopic temperature suggest that these ratios during sapropel intervals may be significantly influenced by other factors such as seawater carbonate chemistry, lower salinity, and possibly diagenetic effects.

ENVIRONMENTAL PARAMETERS CONSTRAINT ON DISTRIBUTION OF BENTHIC FORAMINIFERA IN THE STRAIT OF BONIFACIO (MEDITERRANEAN SEA)

BUOSI Carla¹, CHERCHI Antonietta¹, ARMYNOT DU CHÂTELET Eric²

1 - Dipartimento di Scienze della Terra, Università di Cagliari

2 - Université Lille 1, FRE 3298 Géosystèmes, UFR Sciences de la Terre, Villeneuve d'Ascq

Presenter e-mail: cbuosi@unica.it

Key terms: Benthic foraminifera; Environmental parameters; Currents; Strait of Bonifacio

The Strait of Bonifacio is located between the Isles of Sardinia and Corsica (Mediterranean Sea), its maximum depth is about 100 m. The Strait is the exchange zone between the waters of the Tyrrhenian and Ligurian-Provencal basins and is strongly affected by high current action. Benthic foraminifera were identified in 31 samples collected during an oceanographic cruise ("Bocche 2003" - P.I.C Interreg III Project) that provided new geomorphological and sedimentological data on the western continental shelf of the Strait of Bonifacio.

Several biotic parameters were calculated (species diversity, density, Fisher's α index, Shannon-Weaver index, and Dominance) and multivariate analyses (Cluster Analysis, Principal Component Analysis and Canonical Correspondence Analysis) were performed to identify foraminiferal assemblages in the context of environmental parameters.

Strong current, bathymetry, grain-size, organic matter and food availability are the main factors exerting control on the spatial distribution of benthic foraminifera in the Strait of Bonifacio.

Three groups of assemblages were differentiated according to several sampling sites, which varied mainly due to degrees of energy. The first group included the shallowest station, close to the islands of Corsica and Sardinia, while the two other were typical of high-energy environments and were localized in the central area of the Strait. Cluster C concerns those located at a central position, while cluster B includes those in a more lateral position at the deepest part of the Strait. Elphidium crispum, Eponides concameratus and Textularia agglutinans appeared to be the more adapted species in this high-hydrodynamic system. The dominance of the epibenthic foraminifera (e.g. Lobatula lobatula and Planorbina mediterraneensis), permanently attached to sea grasses (Posidonia oceanica) and algae has been related to both the greater current velocities in the sampled area. The occurrences of Miliolinella subrotunda,

Neonorbina nitida, Quinqueloculina stelligera, Rosalina globularis, R. vilardeboana and Sigmoinella costata appear to be closely related to the abundance of organic carbon and higher C/N ratios. The distribution of S. sagittula appear closely linked with bathymetry. Interaction between multiproxy ecological factors (oxygen, food, toxic substances, biological interactions, transport, light penetration, turbidity, etc.) characterize peculiar microenvironments in the sediment-water interface, allowing different species to occupy different niches within a relatively small area. A detailed understanding of environmental parameters that influence benthic foraminifera distribution in natural systems is a necessary prerequisite for the use of foraminifera as useful tools for ecological and environmental interpretations.

FIRST DATA ON THE DISTRIBUTION AND MORPHOLOGICAL ABNORMALITIES OF THE RECENT FORAMINIFERS IN THE MARANO AND GRADO LAGOON (NORTHERN ADRIATIC SEA).

MELIS Romana¹, COVELLI Stefano¹, JELENA Bugarski¹, GABRIELLA Varagona¹

1 - Dipartimento di Geoscienze, Università di Trieste

Presenter e-mail: melis@units.it

Key terms: lagoon; foraminifers; test deformation; bioindicator; mercury

The Marano and Grado Lagoon along the northern Adriatic coast, is an environment of naturalistic but also economic value, since it is exploited by man for industrial, farming and fishing activities. At the present, this area is constantly under quality control in accordance with the recent environmental directives.

This environment historically experienced a significant input of mercury (Hg), carried from the Isonzo River draining the cinnabar deposits of the world's second largest Hg mine at Idrija (Slovenia), which has been in activity for 500 years. Recent studies indicate that Hg it is the most common contaminant in the sediments and previous studies have also revealed its presence in the aquatic food chain.

Benthic foraminifers were investigated in the recent sediments collected during the "Miracle Project" (AA.VV., 2010). The diversity index is lowest in the stations in front of the Aussa-Corno River mouth, which is the area mostly affected by environmental stress (mercury pollution and/or natural salinity variations). Here, a greater dominance of brackish forms such as Ammonia tepida, Elphidium granosum, E. gunterii and Haynesina germanica has been recognized. Conversely, slightly higher values of diversity appear in less restricted areas of the lagoon or, at least, where physical parameters such as temperature and salinity are less variable (or more constant). Here, the association is characterized by more thalassic taxa, such as miliolids and arenaceous species.

The greater frequency of E. granosum, E. gunterii and H. germanica is recorded in the western sector of the lagoon (Marano), which is more affected by industrial activities. On the contrary, the greater dominance of A. tepida is recognized in the eastern lagoon (Grado), where the sediments are enriched in Hg, mainly in mineral form.

The deformation tests, carried out mainly on dead specimens, showed very high FAI (Foraminiferal Abnormality Index) values in the lagoon areas highly affected by riverine tributaries compared to the low values found in less restricted areas. However, the types of deformation are very often those involving only limited dimensional changes of the chambers. Concerning the study of some cores, higher FAI index coincides with the highest concentrations of Hg_{tot} in the recent sediments, whereas the index decreases with depth in agreement with the decreasing Hg content. Plotting the concentration values of Hg_{tot} and the deformation of the shell according to the calendar age scale, calculated on the basis of the ²¹⁰Pb activity log distribution (AA.VV., 2010), a sharp increase of pollution and tests deformation following the period of great industrial expansion of 1950 is observed.

AA.VV., 2010 - Messa a punto di un metodo per l'individuazione delle aree da destinarsi alla venericoltura (Tapes philippinarum) a minor rischio di contaminazione da mercurio in Laguna di Marano e Grado. A TETHYAN PLANKTONIC FORAMINIFERAL AND STABLE CARBON ISOTOPE RECORD OF THE EARLY EOCENE CLIMATIC OPTIMUM (POSSAGNO SECTION OF NORTHEASTERN ITALY)

LUCIANI Valeria¹, BACKMAN Jan², GIUSBERTI Luca³, RIO Domenico³

1 - UNIVERSITY OF FERRARA

2 - UNIVERSITY OF STOCKHOLM

3 - UNIVERSITY OF PADOVA

Presenter e-mail: valeria.luciani@unife.it

Key terms: PLANKTONIC FORAMINIFERA; PALEOGENE; CLIMATE; EVOLUTION

The Earth experienced in the Early Paleogene a pronounced warming trend that peaked during the Early Eocene Climatic Optimum (EECO; ca. 50-52 Ma) that records the highest global temperature of the past 70 Ma within an extended interval of greenhouse-climate regime (e.g., Zachos et al., Science 2001, Nature 2008). Peak Cenozoic warmth reached during the EECO was followed by a long-term cooling trend through the middle-late Eocene leading to the modern icehouse world at the base of the Oligocene (Miller et al., Journ. Geoph. Res. 1991). A critical issue of the studies of early Paleogene climate is to demonstrate which is the role of climate on the biotic evolution. Woodbourne et al. (PNAS 2009) document dramatic plant and mammal faunal turnover related to the EECO, thus supporting a direct primary evolutionary control played by the EECO warmth. In the marine realm, new evolutionary trends in calcareous nannofossil communities appear linked to the EECO and set course toward modern structure (Agnini et al. EPSL 2006).

The EECO has been recently identified by Agnini et al. (EPSL 2006) in the classical early Paleogene section of Possagno (Venetians Pre-Alps of northern Italy; Bolli, Schweiz. Palaeont. Abhand. 1975) that accounts a reliable magnetostratigraphy and calcareous nannofossil record. This continuous section, deposited in a bathyal setting, provides an exceptional record of the Lower-middle Eocene transition as occurring in a marginal basin of the central-western Tethys. Given the importance of planktonic foraminifera that are extremely sensitive to environmental modifications, the quantification of their changes is an excellent proxy for the

comprehension of past surface-water variations during this interval of extraordinary warmth and for evaluating possible evolutionary pressures on this group across the EEOC.

The quantitative analysis performed at the Tethyan Possagno section highlights significant changes in abundance within the planktonic foraminiferal assemblages. The most marked variations well correlate the geochemical expression of the EEOC event, consisting of a pronounced, composite negative stable carbon isotope perturbation, thus suggesting a planktonic foraminiferal response to the Paleogene maximum warmth. Dominance of the warm-indices acarininids during the EEOC interval coupled with decrease of the cold-indices subbotinids can be straightforwardly interpreted as a consequence of the extreme warmth. The most negative stable carbon-isotope values are mainly associated to high fragmentation of planktonic foraminiferal tests thus suggesting some carbonate dissolution. The synchronicity of the EEOC event and deep-sea carbonate dissolution provides arguments that this was linked to a transient increase in atmospheric carbon dioxide pressure that caused the rise of the carbonate compensation depth and deep-water acidification. Nevertheless, we cannot totally exclude that carbonate dissolution may have differently affected the foraminiferal assemblages.

The most important information that emerges from the Possagno record is the decline of the symbiont-bearing morozovellids that appears as irreversible after the EEOC. Occurring against the profound climatic change represented by the EEOC, the morozovellid decline which correlates with evolution in other planktonic clades, e.g., calcareous nanofossils (Agnini et al., *EPSL* 241, 2006) may allude to critical steps in the reorganization of Eocene pelagic ecosystems that passes from the greenhouse to the doobthouse/icehouse regime. The consequent modification in the water column structure and the reduced carbon-dioxide pressure following the EEOC might have negatively affected the ecological niches of the highly specialized muricate forms and biased the complicated mechanism of the morozovellid symbiosis processes.

CALCAREOUS NANNOFOSSIL PRESERVATION STATE AS A DISSOLUTION PROXY: A CASE STUDY FROM THE EOCENE-OLIGOCENE TRANSITION AT ODP SITE 1090 (AGULHAS RIDGE, SOUTH ATLANTIC OCEAN)

PEA Laura¹; BOHATY Steven M.²; VILLA Giuliana¹

1 - Dipartimento di Scienze della Terra, Università degli Studi di Parma, Parma, Italy

2 - School of Ocean and Earth Science, University of Southampton, Southampton, UK

Presenter e-mail: GIULIANA.VILLA@UNIPR.IT

Key terms: CALCAREOUS NANNOFOSSIL; EOCENE-OLIGOCENE; SOUTH ATLANTIC; DISSOLUTION

The Eocene-Oligocene Transition (EOT) (~34 Ma) is characterized by global cooling and Antarctic ice-sheet expansion, sea level fall, deepening of the calcite compensation depth (CCD), and significant turnover in marine and terrestrial biota. CCD deepening at the EOT is interpreted worldwide based on an increase in carbonate accumulation at multiple deep ocean sites. In the South Atlantic, the CCD is interpreted to have deepened by ~1 km, but a detailed CCD history across the EOT has not been previously developed for this region. In this study, quantitative analysis of calcareous nanofossil assemblage was carried out within the EOT interval at ODP Site 1090 (42°S; Agulhas Ridge; South Atlantic). The primary goals of this work were: (1) to assess the degree of dissolution affecting nanofossil assemblages; (2) to use the nanofossil dissolution signal as proxy for CCD variation; and (3) to characterize surface-water temperature and nutrient changes during the EOT using paleoecological information provided by nanofossils.

Within the EOT interval of ODP Site 1090, two indices of dissolution were calculated using the preservation state of two common taxa: *Coccolithus pelagicus* and *Reticulofenestra umbilicus* group. A third dissolution index was calculated using characteristics of the entire assemblage. Comparison between the nanofossil indices and carbonate content shows a striking correspondence, indicating that dissolution was a major factor controlling carbonate sedimentation and nanofossil preservation/assemblage composition in the EOT interval at this site. Additionally, there is a good correspondence between carbonate content and *Blackites* and *Clausicoccus* abundance, suggesting that dissolution is also a major factor in controlling the stratigraphic distribution of these taxa.

Variation in nanofossil dissolution indices and carbonate content through the EOT interval of Site 1090 are interpreted to reflect CCD fluctuations. The CCD at this site markedly oscillates in the latest Eocene and then deepens in the earliest Oligocene in correspondence with oxygen isotope ($\delta^{18}O$) Step 2 (coincident with Oi-1). An intense dissolution interval is observed in the latest Eocene immediately prior to oxygen isotope Step 1. Within this dissolution interval, however, only one sample is totally barren of nanofossils and the total abundance varies with carbonate content, suggesting that nanofossil assemblages are good dissolution indicators even in extreme conditions of carbonate under-saturation. Nanofossil dissolution indices also define an interval of carbonate dilution just prior to oxygen isotope Step 2, which results from an increase in bioliteous sedimentation.

A selection of well-preserved samples was used for the paleoecological interpretation of nanofossil assemblages across the EOT at Site 1090. A major assemblage change is observed near the E/O boundary (~33.6 Ma) and is interpreted to reflect an increase in sea-surface nutrient availability, possibly in conjunction with cooling. This event is followed by a gradual increase in fertility associated with cooling which culminated at Step 2. Following Step 2, nanofossil assemblages at Site 1090 indicate nutrient-enriched cold waters during the earliest Oligocene.

THE TRIPOLI FORMATION OF THE PIETRAPERZIA SECTION (SOUTHERN SICILY, CL). REGIONAL COMPARISON

MUSCA Claudio¹, DI STEFANO Enrico¹, SPROVIERI Rodolfo¹, LENA Gabriele²

1 - Università degli studi di Palermo

2 - Università degli studi di Perugia

Presenter e-mail: claudiomusca@hotmail.it

Key terms: Tripoli Formation; Southern Sicily; Messinian

The stratigraphic interval preceding the beginning of the evaporitic sedimentation (pre 5.96 Ma), in the central Sicily (Caltanissetta basin

Auct.) consists of the well know Tripoli formation.

This unit, between the silico-clastic late-miocenic deposits and the messinian evaporites, is made of a "triplet" of (Decima and Wezel, 1971): a) marly layer, b) brown-red laminites "sapropel" and c) white diatomitic laminites. Each triplet is developed in response to a single precessional cidity (about 21.000 years, Sprovieri et al., 1996).

We describe the results of a detailed lithologic and bio-stratigraphic study performed in the frame of regional research on Tripoli in Sicily (Catalano et al., unpublished). The stratigraphic section outcrops at Serra di Mezzo (SRM, Pietraperzia, CL) and was compared to the Falconara section (FNA, Southern Sicily), is studied by Sprovieri et al., (1996), to underline similarities and differences. The FNA section is considered the representative and complete Sicilian Tripoli section. It is characterized by a deep marine environmental succession, where 40 precessional cycles have been recognized. The biostratigraphic analysis, carried out by Sprovieri et al., (1996), highlighted the presence of well diversified and preserved microassociations, almost for the whole section, and a progressive worsening from cycle 36.

The Pietraperzia section lithologic analysis includes about 14 m below the base of evaporitic limestone. The analysis highlighted a triplet layer organization for each of the 16 precessional cycles. The local base of the Tripoli doesn't outcrop. The detailed sampling (about 2 samples/m) allowed to characterize the studied section from a biostratigraphic point of view and to correlate them with the upper part 16 cycles FNA section. The first 4 cycles of the SRM section (25-28 FNA cycles), are characterized by the presence of a rich assemblage of planktonic foraminifera, containing *Globigerinoides obliquus* s.l. and a few *Globigerina* bulloides. The calcareous nanofossil association is well diversified, but without index forms. Siliceous remains (Diatoms and Silicoflagellate), and fish have been found, sometimes abundant. The middle-upper part of the SRM section, 5 to 16 cycles (equivalent to 29-40 Falconara cycles) showed very different features compared to Falconara. In particular, towards the upper part of the succession the flora and fauna microassociations progressively disappears, until the total sterility. The calcareous nanofossil assemblages occur up to 4th cycle as well the Planktonic foraminifera assemblages disappear in the 3th cycle. The siliceous assemblages decrease in abundance and diversity upwards. Along the whole studied section, there are frequent amber elements, more or less dark, associated with well preserved sporomorphs. Possibly suggesting a proximal depositional environment until isolation from continental supply. In conclusion, the SRM stratigraphic section, is correlated with the upper portion of the complete FNA section. The litho- and biostratigraphic data, obtained from the two compared sections, put evidenciate that within the SRM section, the disappearance of flora and fauna microassociations, would anticipate about 9 cycles (about 190 ky) the same event recorded in the FNA section. The data are explained by hypothesizing that immediately before the Messinian salinity crisis, the paleoenvironmental condition progressive worsening and the isolation of some depositional areas, from the marine areas, was a diachronous, from the present day North to the South (Catalano et al., 2010). This hypothesis is supported by the presence within the SRM section of continental contribution remains, totally absent in the FNA section.

Presenter e-mail: donata.violanti@unito.it

Key terms: Calcareous microfossils; Siliceous microfossils; Upwelling; Early Pliocene; Piedmont, Northwestern Italy

Massive whitish silty-clayey to sandy silts, yielding mixed calcareous (mainly foraminifers, ostracods, echinoid fragments) and siliceous (sponge spicules, diatoms and radiolarians) were discontinuously recovered in an area of about 40-45 km² of the Monferrato (Piedmont, Northwestern Italy). The diatomaceous silts are local members of the Argille Azzurre (Blue Clay) Formation (Zanclean, Lower Pliocene) (Dela Pierre et al., 2003). Micropaleontological assemblages (diatoms, foraminifers, calcareous nannoplankton, ostracods and radiolarians) were quantitatively studied in the natural section of Castelcebro and La Torretta and in an abandoned quarry near Calliano (Asti). On the basis of foraminifers, they have been dated to the MPI3 biozone (Zanclean) and therefore are the first documentation of Pliocene mixed calcareous and siliceous assemblages in the Piedmont, where only Miocene diatomites or diatomaceous silts were previously described (Bonci et al., 1990; Bonci et al., 1991). The occurrence of rare *Nitzschia jouseae* both at La Torretta and Castelcebro allows the correlation to the *Nitzschia jouseae* diatom biozone (upper Early Pliocene to Late Pliocene). Calcareous and siliceous microfossils show often opposite abundances and suggest conditions of moderate, probably seasonal upwelling on shelf bottoms. Planktonic foraminifers are mainly represented by phytoflagous, eutrophic taxa as *Globigerina* bulloides and *Neoglobobulimina acostaensis*; the infaunal, opportunistic *Bulimina* spp., *Cassidulina carinata*, well adapted to abundant trophic resources and to dysaerobic bottoms, are dominant. Diatoms are more frequent and well preserved at La Torretta, meroplanktonic forms (*Paralia sulcata*, *Thalassionema* group) and *Chaetoceros* resting spores are common to abundant. Stress tolerant taxa are common to dominant also between ostracods (*Costa edwardsi*) and radiolarians (*Dictyocorynids*, *Rhopalastrium zitteli*). Within the calcareous nanofossils, the absence of *Discoaster* spp. is inferred to be due to high nutrient availability in surface waters.

The quantitative micropaleontological study documents rather high productivity episodes and enlightens an Early Pliocene palaeoenvironment more complex and diversified than previously known in the region, where only calcareous assemblages are documented.

SOUTHERN SINAI STROMATOLITES AND ONCOLITES

BASSO Daniela¹, FAVALLI Andrea Noemi¹, BRACCHI Valentina Alice¹
1 - Dip.to Scienze Geologiche e Geotecnologie - Univ. Milano-Bicocca
Presenter e-mail: daniela.basso@unimib.it

Key terms: microbialites; stromatolites; oncolites; cyanobacteria; Red Sea

Stromatolites are rare today in modern marine, freshwater or hypersaline systems, but occur widely as fossils in many calcareous or dolomitic sedimentary sequences. Stromatolites have been long time defined as layered accretionary structures formed in shallow water by biofilms of microorganisms, primarily cyanobacteria, that trap, bind and cement the sediment in a more or less rhythmic fashion. Recent studies show that the processes of stromatolite formation are both abiogenic (sediments trapping in bacterial mucilaginous) and biogenic (microbially-induced mineralization), and consequently the accepted definition of stromatolite is going to be considerably widened. In agreement with Riding (2009) stromatolites are "subaqueous authigenic crusts, formed by abiotic precipitation and/or by biogenic lithification of microbial mat".

However, the correct interpretation of fossil stromatolites genesis - biogenic or abiogenic - and mechanisms of formation is constrained by the occurrence of specific environmental conditions and thus yields unequivocal palaeoenvironmental information. Although stromatolites are significant in Earth palaeoenvironments that are poorly comparable with the modern ones, present-day stromatolites structure, composition, growth mechanisms and favourable environments remain a substantial source of knowledge for palaeobiologists.

Samples of modern microbialites were collected in Nabq Bay and in Ras Mohamed (southern Sinai, Egypt) in a marine intertidal tropical environment. The studied material included agglomerated, unconsolidated sand, oncolites and crusts at different levels of consolidation/lithification. The sand was analyzed with light microscopy, oncolites were observed with SEM (Scanning Electron Microscopy) and crusts were studied throughout SEM and thin sections. Thin sections were staining with Alizarin Red.

Thin sections of poorly lithified crusts show evidence of bacteria (cyanobacteria and purple sulphur bacteria) among the constituent grains in the form of gelatinous filaments (green and red sheaths), while fully-lithified crusts show presence of microalgal colonies along the outer edge, accompanied by a very high degree of diagenetic alteration. In addition, at the surface and/or inside some crust samples we observed the alternation of planar or irregular dark, superposed layers and clastic layers.

Southern Sinai microbialites show evidence of both sediment trapping in bacterial mucilaginous sheaths and microbially-induced mineralization, supporting the hypothesis of their biogenic nature. In particular we observed widespread filaments of Schizothrix (?) among grains, EPS (Extracellular Polymeric Substance) sheaths connecting particles, calcareous tubes possibly grown around cyanobacteria cells and acicular aragonite. Fringes of acicular aragonite occur around particles and appear locally dissolved. Staining with Alizarin Red confirms the calcareous composition of constituent grains. The presence of magnesium has been confirmed by EDS (Energy Dispersive Spectrometer) analysis. Investigation on cement occurrence and mineralogy are in progress.

ITALIAN CONTRIBUTION TO THE CHRONOSTRATIGRAPHIC SUBDIVISION OF THE CAMBRIAN SYSTEM.

BAGNOLI Gabriella¹
1 - Dipartimento di Scienze della Terra Università di Pisa
Presenter e-mail: bagnoli@dst.unipi.it

Key terms: Cambrian; Ordovician; Chronostratigraphy

Traditionally, the Cambrian was subdivided into three series: Lower, Middle, and Upper. However, the International Subcommission on Cambrian Stratigraphy has recommended a four-fold subdivision of the Cambrian System to accommodate a thick pre-trilobite interval in the lower part of the system. The base of the Cambrian has been established formally at the base of the Tricophycus pedum Zone, and the base of the Ordovician has been established at the base of the Iapetognathus fluctivagus Zone. However, internal subdivisions of the Cambrian into two or three stages for each series are not yet accomplished. To date, the Terreneuvian Series and Fortunian Stage at the base of the Cambrian System, the Drumian Stage (at the base of the Ptychagnostus atavus Zone), the Guzhangian Stage (at the base of the Lejopyge laevigata Zone), and the Furonian Series and Paibin Stage (at the base of the Glyptagnostus reticulatus Zone), have been ratified.

The Italian contribution to the chronostratigraphic subdivision of the Cambrian included the study of conodont associations from several Chinese sections, in particular the Paibi section (GSSP of the Furonian Series and Paibin Stage), the Luoyixi section (GSSP of the Guzhangian Stage, the last stage of an unnamed series, provisionally termed Series 3), and the Duibian B section (proposed GSSP of Stage 9, the second stage of the Furonian Series, recently approved by the International Subcommission on Cambrian Stratigraphy).

Even though agnostoid trilobites are the primary tools, conodonts helped to constrain the definition of these chronostratigraphic units and proved to be useful for correlation with other areas.

In 2000 the International Union of Geological Sciences (ratified the decision to place the GSSP for the base of the Ordovician System in the Green Point section, Newfoundland, Canada, at a point coinciding with the first appearance datum of the conodont Iapetognathus fluctivagus. Since then search for the taxon and the fixing the boundary in many other

places in the world has been in vain, because firstly the taxon is indeed rare, secondly the chosen taxon does not appear at the boundary but much later and finally the taxon has been misidentified at the Green Point GSSP section.

A re-study of the specimens assigned to Iapetognathus fluctivagus from the stratotype revealed, however, that the primary correlation marker is not present in the boundary interval of the stratotype section. In consequence, the section does not fulfil the biostratigraphic requirements of a GSSP.

This problem is a result of the previous efforts, where different genera and species have been allocated to the same genus i.e. Iapetognathus and distinct different species have been synonymized to become the same species.

A recent re-evaluation of the taxon shows that the genus as previously interpreted is polyphyletic and is composed of at least three lineages, which are Iapenodus (two species), Iapetognathus (three species) and two new unnamed genera both of which represented by one species. As a consequence, a restudy of the GSSP section and the other sections in the Cow Head Group is needed and a revised biostratigraphic definition of the boundary is necessary.

10.1474/Epitome.04.0857.Geoitalia2011

LATE ORDOVICIAN CONODONT FAUNA FROM THE CARNIC ALPS: WHAT ELSE?

FERRETTI Annalisa¹
1 - Dipartimento di Scienze della Terra, Università degli Studi di Modena e Reggio Emilia
Presenter e-mail: ferretti@unimore.it

Key terms: Ordovician; Carnic Alps; Cellon Section; conodont biozonation; Amorphognathus evolution

Biostratigraphy alone, even if integrated with information derived from diverse faunal groups, has been shown to be insufficient for identifying with precision any subdivision of a stratigraphic interval.

Chemostratigraphy in primis now plays a dominant role, as in the Late Ordovician where the subdivision of the Hirnantian stage into the two

stage slices H1 and H2 is marked by the end of the global Hirnantian $\delta^{13}C$ excursion (HICE; Bergström et al., 2009).

Conodonts have long been used as important biostratigraphic tools. The Cellon Section of the Austrian Carnic Alps played a prominent role when the original Silurian conodont biozonation was introduced by Walliser (1964). The section is equally significant for the Ordovician, as documenting one of the most continuous Late Ordovician successions preserved in Europe covering both the Katian and Hirnantian stages. At this locality two distinctive stratigraphic sequences are present. The Uggwa Limestone Formation is approximately 4 m thick and consists of limestone strata with intercalated siltstones at the top. The overlying Plöcken Formation, approximately 6 m thick, consists of siltstones with interbedded bioclastic limestone lenses at the base from which the Hirnantia brachiopod fauna has been documented and impure pyrite-rich limestones and sandstones at the top.

Most published biostratigraphic schemes for the Carnic Alps area were based on single group organisms, such as conodonts or graptolites. The recent documentation of the HICE spike event at the Cellon Section (Schönlaub et al., 2011) has renewed interest in checking and comparing the most important biostratigraphic markers present by resampling of the area. These studies are complemented with a precise calibration by identification of chronostratigraphic markers.

As regards conodonts, within the Late Ordovician the appearance of Amorphognathus ordovicicus marks in the Katian the start of the Ka3 stage slice. The same apparatus is known to span through the Late Ordovician up to the Ordovician/Silurian boundary. In the Carnic Alps the Amorphognathus genus is equally present in the Katian and in the overlying Hirnantian glacial deposits of the Plöcken Formation (Ferretti & Schönlaub, 2001). A thorough analysis of the numerous lineages of Amorphognathus reveals how the conodont signature contained within this genus may be highly informative with respect to the biostratigraphic subdivision of this final part of the Ordovician. Thus, a revised conodont biozonation, easily correlated across several paleocontinents and additionally constrained by data from graptolites, chitinozoans and shelly faunas in this stratigraphically significant area, may be derived from the species present. Integrated biostratigraphic data for the Cellon Section have been recently proposed based on the published literature and ongoing fieldwork (Schönlaub et al., 2011).

THE EARLY TO MIDDLE PALEOZOIC REVOLUTION (IGCP 591): CHRONOSTRATIGRAPHY AND BIOSTRATIGRAPHY OF SILURIAN SEQUENCES IN THE CARNIC ALPS

HISTON Kathleen¹
1 - Dipartimento di Scienze della Terra, Università degli Studi di Modena e Reggio Emilia, Largo S. Eufemia 19, I-41100 Modena (Italy)
Presenter e-mail: catherine.histon@unimore.it

Key terms: Carnic Alps; Silurian; chronostratigraphy; biostratigraphy; lithostratigraphy

The Late Ordovician to Early Devonian interval contains several of the most significant paleoclimate and paleobiological events in Earth history including paleobiodiversity events and/or perturbations to the global

carbon cycle. IGCP Project 591 (www.igcp591.org), of which the author is a co-leader, is designed to provide a forum for the Early to Middle Paleozoic global community to investigate this dynamic and important interval in the history and evolution of life and our planet. Research in progress in the Carnic Alps falls within the framework of the above project and a short overview regarding in particular chronostratigraphic and biostratigraphic studies will be presented so as to highlight the outstanding importance of this area for global correlation. Among the many geological sections located in the Central and Southern Alps those of the Carnic Alps, in particular the Cellon Section, serve as reference sections for the Silurian within this middle paleolatitude North Gondwana Sector. Since the Great War up to the present day scientists from both Austria and Italy have studied the area. The comprehensive study carried out by von Gaertner is of particular importance as he focused his work on the Cellon section and introduced a formal lithostratigraphic subdivision which has partly been in use until the present with most of his Silurian divisions now being formally recognized: Kok, Cardiola and Alticola Formations (Histon et al., in prep). A valuable multidisciplinary data set is now available for the study area across a broad facies range from proximal to basinal settings (Nöbling and Bischofalm Formations).

Biostratigraphical studies on conodonts, graptolites, chitinozoans and bivalves are all important for global correlation and the standard index fossils for Upper Ordovician to Lower Devonian biozones have been identified in the Carnic Alps sequences. Faunal assemblages of brachiopods, nautiloids, ostracods, acritarchs, trilobites and corals provide valuable data with regard to paleoenvironmental and paleobiogeographical reconstructions using both benthic and pelagic faunas. The data facilitate detailed correlation on a global basis and are complemented by a range of studies on sedimentology, microfossils, and C and O isotope analyses that aid in deciphering climatic and eustatic changes on a regional scale. Sequence stratigraphic methods applied to the Silurian sequences highlighted eustatic changes which may be traced across four palaeocontinents (Brett et al., 2009).

K-Bentonites of Upper Ordovician to Lower Devonian age have been correlated with coeval occurrences in other parts of Europe. The ash layers originated from a subduction-related volcanism of an active plate margin, dominated by calc-alkaline mafic lavas of a volcanic arc setting with andesitic-rhyolitic/dacitic magmatism (Histon et al., 2007). The data are of important significance with relation to geodynamics and palaeogeographical reconstructions of the Peri-Gondwanan Terranes as such findings are rare within this middle paleolatitude sector for this interval. Radiometric dating and precise geochemical profiles of these levels will provide significant time-lines for chronostratigraphy and correlation of the full data-set available from the area with regard to global timing of major events identified there during the Early to Middle Paleozoic.

TOWARDS THE DEFINITION OF THE GSSP OF THE NORIAN STAGE: REPORT ON THE ONGOING ACTIVITIES OF THE ITALIAN WORKING GROUP

BALINI Marco¹

¹ - Dipartimento di Scienze della Terra "Ardito Desio", Università degli Studi di Milano, Via Mangiagalli 34, 20133 Milano, Italy.

Presenter e-mail: marco.balini@unimi.it

Key terms: Upper Triassic; Norian; GSSP; Chronostratigraphy; Integrated stratigraphy

The completion of the chronostratigraphic scale of the Triassic System still requires the definition of 4 GSSPs, namely those for the Olenekian, Anisian, Norian and Rhaetian stages. Some Italian specialists are active in all the Working Groups of the Subcommission on Triassic Stratigraphy, but the contribution of Italian stratigraphers is especially important in the Carnian/Norian and Norian/Rhaetian WGs. For these two intervals some sections located in Italy are also under discussions as GSSP sites. In order to better integrate the activities of the Italian specialists, few years ago research teams from Milano, Padova, Ferrara, Perugia and Palermo universities grouped together under a PRIN entitled "Upper Triassic integrated stratigraphy: GSSP and auxiliary sections in Italy". The project was funded in 2010 and a first international meeting was organized in Palermo (September 12-18, 2010). Here we summarize the activities carried out on the Carnian/Norian boundary during the first year of the project.

The PRIN research units have been working on Carnian-Rhaetian successions in the Southern and Eastern Alps, Lagonegro basin and western Sicily with two major aims. The first is to study in great detail the best sections with potential interest for the definition of the GSSPs. The second is to test their stratigraphic significance and usefulness by means of correlations with as many sections as possible. Ammonoids, halobiids, conodonts and radiolarians, are the best tools for a high resolution bio-chronostratigraphy, that is integrated with sedimentology, sequence stratigraphy, stable isotope variation and, when possible, radioisotopic dating.

As regard the definition of the GSSP of Norian stage, three sections are under study: Pizzo Mondello and Pizzo Lupo (Sicily), and West Union Canyon (central Nevada, USA).

Pizzo Mondello section (Sicani Mountains) was discovered in the 1990s by researchers from Palermo University. This section is one of the two candidate sections for the definition of the GSSP of the Norian stage, together with Black Bear Ridge in British Columbia (Canada). Magnetostratigraphy has been published few years ago (Muttoni et al 2001, and 2004) and in the last 3 years the section has been studied for sedimentology, nannofossils, conodonts, halobiids and ammonoids. Several contributions have been submitted for publication in the proceedings of the Palermo workshop. Magnetostratigraphy and its integration with halobiids, conodonts, ammonoids and radiolarians bio-chronostratigraphy are the main pros of this section.

Pizzo Lupo section (Sicani Mountains). This new site is located in an

quarry and is under study by a team lead by P. Di Stefano. The section has been sampled for ammonoids and halobiids and the study of conodonts is in progress. The section is easily correlated with Pizzo Mondello not only by biostratigraphy, but even by bedding. The preliminary results will be presented in this session by Tripodo et al. West Union Canyon (central Nevada, USA). This site shows the best Late Carnian-Early Norian ammonoid record in North America and is of great importance for the correlations with the Tethys. The last two ammonoid zones of the Carnian of the North American standard scale were defined on the Luning Formation of this area. Moreover this formation also records the first zone of the Norian. Surprisingly, this site has been never studied in the last 50 years, therefore neither conodont nor halobid data are available. For this reason a preliminary sampling of this site was carried out in Fall 2010. Preliminary ammonoid data are presented by Balini et al. in the session GEO/01.

Acknowledgments

The anonymous reviewers who supported the PRIN 2008 "Upper Triassic integrated stratigraphy: GSSP and auxiliary sections in Italy" are here very warmly thanked.

Presenter e-mail: angelo.tripodo@unipa.it

Key terms: Carnian/Norian boundary; Sicily; ammonoids; pelagic bivalves; Sicilian basin

A well preserved section of Halobia limestones has been recently studied near Castronovo di Sicilia in central Sicily in the framework of a project aimed at the identification of the historical localities where G.G. Gemmellaro (1904) has collected the Triassic ammonoids described in his outstanding monograph "I cefalopodi del Trias Superiore della regione occidentale della Sicilia". This section, that we indicate as "Pizzo Lupo", occur along the abandoned slope of an active quarry. It represents the lower zone of a pelagic succession of Carnian to Cenozoic age pertaining to the Sicilian Basin and occurring as a thrust sheet in the external zone of the Apenninic-Maghrebian fold and thrust belt.

The section exposes about 200 m of slightly folded Halobia limestones (also known as cherty limestones or Scillato Fm. Auct.). The studied zone consists of about 50 m of thick-bedded (30-50 cm) calcilutites, sometimes with chert and irregular marly intercalations. Wackestone or mudstone with radiolarians, halobiids and calcispheres are the common microfacies in this zone. A shelter porosity provided by halobid isorotation is frequent. This section has been sampled for ammonoids and halobiids. Ammonoids are rare, but several well preserved specimens have been so far collected. Late Carnian ammonoids are relatively common, and consist of the short ranging "Anatomites", *Projuvavites* and *Microtropites*, together with long ranging *Hypocladiscites* and *Arcestes*. Higher up in the section the Early Norian *Dimorphites* has been found from levels yielding *Halobia austriaca* Mojsisovics, 1874.

As in other sicilian sections, the halobiids are rather frequent, in terms of both number of fossil-bearing beds and number of specimens. They allow a better identification of the Carnian/Norian boundary. *Halobia radiata* Gemmellaro, 1882, *H. austriaca* and *H. styriaca* (Mojsisovics, 1874) have been so far recognized in succession, from the levels yielding Late Carnian to Early Norian ammonoids.

The new data emphasize the stratigraphic significance of *H. austriaca* and *H. styriaca* as markers of the Lower Norian in the western Tethys, as suggested in literature. Preliminary test samples for conodont biostratigraphy are positive and the study is in progress.

The collected bed-by-bed litho- and biostratigraphic data allow high resolution correlations with the succession exposed at Pizzo Mondello (Bivona), a well known locality at about 15 km to the South West, especially as regard the Carnian/Norian boundary interval and make it possible to consider Pizzo Lupo as an auxiliary section to support Pizzo Mondello as the GSSP of the Norian stage.

PROGRESSES ON CRETACEOUS STRATIGRAPHY

PREMOLI SILVA Isabella¹

¹ - Università degli Studi di Milano

Presenter e-mail: isabella.premoli@unimi.it

Key terms: Cretaceous; Stratigraphy e GSSPs; Italian contributions

A wealth of data on various aspects of Cretaceous stratigraphy had continued to be published up to now providing a continuous amelioration of the multiple stratigraphic framework that today spans the whole Cretaceous in high to frequently very high resolution. Increasing knowledge on carbon isotope stratigraphic patterns and magnetostratigraphy from continuous pelagic successions, including from deep-sea perforations, through the Cretaceous, provoked an increase of interest in the scientific community for a more traditional stratigraphic aspects.

The Italian scientific community in the past decades provided the first order calibration of the magnetic time scale based on calcareous nannofossils and to minor extent calpionellids in the Early Cretaceous interval prior to the Cretaceous Superchiron (Early Aptian) and on nannofossils and planktonic foraminifera after it (Campanian-Maastrichtian).

Recent work, still ongoing, in search of the Berriasian GSSP, extended the calibration across the Jurassic/Cretaceous boundary mainly based on high resolution nannofossil biostratigraphy from the Southern Alps. Specialists on planktonic foraminifera were/are deeply involved in several projects, the most important ones dealing with (1) the taxonomic revision of genera and species and their distribution from Early Cretaceous on-land and in deep-sea successions; (2) the taxonomic description of the planktonic faunas found for the first time across the Aptian/Albian boundary in a new section surveyed in Vocontian Basin nearby that previously proposed as base Albian GSSP (not suitable); (3) the studies in

search of base Campanian GSSP and refinement of Campanian biostratigraphy.

A CONTRIBUTION TO THE BARREMIAN AND APTIAN GEOCHRONOLOGY FROM ORBITAL CHRONOSTRATIGRAPHY OF SHALLOW-MARINE CARBONATES

AMODIO Sabrina¹, FERRERI Vittoria², D'ARGENIO Bruno²

1 - Università degli Studi di Napoli Parthenope, DiSAM
2 - IAMC, CNR, Napoli

Presenter e-mail: sabrina.amodio@uniparthenope.it

Key terms: shallow-marine carbonates; cyclostratigraphy; orbital time scale; Barremian; Aptian

The duration of the geological time intervals, biostratigraphically bracketed, can be calculated by a combination of methodologies (orbital cyclostratigraphy, paleomagnetism, and stable isotope stratigraphy), that are independent from those based on the decay of radiogenic isotopes. At present the idea of high-frequency cyclicity dominated by conditions external to the depositional environments (alloycyclicity) has been widely accepted, especially for the pre-Quaternary intervals. In this context the Earth's orbital periodicities (Precession, Obliquity, short and long Eccentricity) recorded in both pelagic and shallow marine carbonates, have been often used to determine time length and accumulation rate of given intervals, as well as to assemble the related orbital chronostratigraphy based on the long eccentricity cycles, the latter interpreted in terms of depositional sequence equivalents. In the last twenty years, high-resolution (cm scale) studies of several Cretaceous carbonate platform successions in central-southern Italy have demonstrated that they carry clear evidence of astronomically controlled eustatic oscillations on their hierarchical stacking pattern (elementary cycles, bundles and superbundles). Moreover, these deposits, widely outcropping in the Periadriatic Region as thick stratal successions, exhibit a sequence-stratigraphic configuration, that is well evident in their superbundles (long eccentricity cycles) as well as in the composite mode of their aggradational pattern, laterally consistent also at more than 100 km distance.

Based on cyclostratigraphy and sequence stratigraphy criteria and using appropriate biostratigraphic, isotopic and paleomagnetic markers, high-resolution physical correlations (precision 100 ky) have been traced at regional scale among several lower Cretaceous sections from Southern Italy. In particular, detailed carbon-isotope curves from Barremian to Aptian intervals of S. Maria core (east of Maiella Mountain), Serra Sbragavittelli (Matese Mountains), Monte Faito (Lattari Mountains) and Monte Tobenna (Picentini Mountains) have been correlated with the palaeomagnetically and biostratigraphically dated carbon-isotope stratigraphy of the longest Monte Raggeto (Maggiore Mountain) reference section.

For each of the above sections a chronostratigraphic diagram has been assembled, based on the following sequence-cyclostratigraphy assumptions: (a) superbundles (400 ky cycles) are considered as depositional sequence equivalents, (b) maximum flooding surfaces of the coeval superbundles are isochronous at the scale of the bundles (100 ky cycles); (c) bundles are used as basic chronostratigraphic units. By correlating coeval sections, orbital chronostratigraphy allows: (a) to locate missing bundles or superbundles (if any) along the analyzed successions, (b) to calculate for each superbundle, as well as for each succession, the average accumulation rate, regardless of the gaps occurring in the sedimentary record and (c) to estimate the minimum time required for each succession to accumulate.

On these bases, a numerical estimate of the Barremian and Aptian stage duration is proposed. Taking into account the number of superbundles for each interval, a duration of 5.6 my for the Barremian stage (14 superbundles) and of 8.0 my for the Aptian stage (20 superbundles) has been calculated. These numerical estimates are compared with the "floating" geological time scales available for the above stages (e.g. Gradstein et al., 1994, 2004; Ogg et al., 2008), showing that cyclostratigraphy of carbonate platform sequences, integrated with other stratigraphic methodologies and high precision long distance correlations is a valid tool for the above assessments.

Key terms: Lutetian/Bartonian boundary; magnetobiostratigraphy; Contessa Highway section; Italy

An accurate magnetobiostratigraphic definition and astrochronological dating of the Lutetian/Bartonian boundary is provided at the Contessa Highway section (Gubbio, Italy). According to the International Commission on Stratigraphy guidelines, this section represents an excellent GSSP candidate for the base of the Bartonian Stage. The criteria proposed as reliable for driving the "golden spike" that should define the Lutetian/Bartonian boundary are: (1) the first occurrence of planktonic foraminifer *Turborotalia cerroazulensis* that occurs in the upper part of Chron C19r, (2) the last occurrence of planktonic foraminifer *Guembelitroides nuttalli*, which is found just below the base of Chron C19n, (3) the base of Chron C19n, (4) the top of Chron C19n or (5) the first occurrence of calcareous nanofossil *Reticulofenestra reticulata* that falls in the lower part of Chron C18r. Given the apparently close

association of criteria (2 to 5), and also in agreement with the current Geologic Time Scale, we propose the top of Chron C19n as the most useful and best potential for global correlation with an astronomically calibrated age for that event of 41.25 Ma.

K-FELDSPAR HYDROCHRONOMETRY

VILLA Igor¹, HANCHAR John M²

1 - Università di Milano Bicocca, Milano, Italy; Institut für Geologie, Universität Bern, Bern, Switzerland

2 - Memorial University of Newfoundland, St. John's, Canada

Presenter e-mail: igor.villa@unimib.it

Key terms: Geochronology; Isotope systematics; Diffusion; Petrology; K-feldspar

Microclines are sometimes used to infer cooling rates of rocks by modelling their 39Ar-40Ar systematics. In this study, we present multi-isotopic, imaging, and microchemical data on microclines from the Aar metagranite (Swiss Central Alps) in order to understand what controls their isotope record. One sample displays a staircase-shaped 39Ar-40Ar age spectra that can be modelled following conventional "thermochronology", assuming that 39Ar is the only isotope of interest. However, thermochronological modelling results in a paradox, as overdetermined independent paleothermometry constrains the peak T quite reliably to 430-450 °C and implies that the mylonite zone ca. 1 m away from our sample was apparently active for < 40 years. This leads to a geologically unrealistic slip rate of > 500 mm/a. Alternatively, multiple isotope systematics (Pb and Sr stepwise leaching, 37Ar/39Ar and 38Ar/39Ar ratios) reveal that two diachronically grown K-feldspar generations coexist: Kfs-1 (≥ 35 Ma old, Ca-poor, Rb-Cl-rich, low

87Sr/86Sr, high 206Pb/204Pb) and Kfs-2 (≤ 10 Ma old, antithetic isotopic signatures). Kfs-1 retained its chemical and isotopic signature at 450 °C. The shape of the spectrum and the Arrhenius trajectory are not causally related as asserted by thermochronological modelling. Staircase spectra reflect mixing of distinct feldspar generations rather than within-grain diffusive gradients. Arrhenius rates reflect a sum of unrelated processes, none of which has an a priori linear dependence on 1/T. Chemically heterogeneous microtextures were imaged by cathodoluminescence, back-scattered electrons and element mapping by electron microprobe. Quantitative microanalyses confirm hetero-chemical replacement, such as the addition of water-soluble Ba transported by a fluid, and confirm the heterogeneity predicted by the multi-isotopic systematics. This combined strong chemical and microtextural evidence argues for fluid-dominated recrystallization. The stepwise release of Ar, Pb and Sr must not be modelled as diffusion from a single inert matrix. What feldspars can be used for is to constrain the fluids that interacted with them by multi-isotopic analyses, rather than to model a "cooling history" from 39Ar release alone, ignoring microtextures and the context of all other isotope systems.

PALEOBATHYMETRIC SIGNATURES OF MOLLUSK ASSOCIATIONS FROM FRONTE SECTION (TARANTO): A CANDIDATE GSSP FOR THE BASE OF THE TARENTIAN (LATE PLEISTOCENE)

SCARPONI Daniele¹, VAI Gian Battista²

1 - Dipartimento di Scienze della Terra - Università di Bologna

2 - Museo Geologico Giovanni Capellini, Università di Bologna

Presenter e-mail: daniele.scarponi@unibo.it

Key terms: Late Pleistocene; Taranto; GSSP; Mollusk; Paleocology

Taranto area is chronostratigraphically very important, as it is one of the few areas in the world where Upper Pleistocene marine successions, uplifted very recently, are well exposed. This area is currently under investigation, in order to find suitable marine sections for defining Late Pleistocene GSSP (Tarentian).

Fronte section is a suitable candidate for the GSSP (or in alternative a parastratotype), cropping out at the gulf of Taranto (Mar Piccolo). This section and two nearby drilled cores (Cimino and Cantoro) were densely sampled for paleobathymetric reconstruction and yielded relatively diverse mollusk associations (263 species and >8.000 specimens distributed in 50 sample), dominated by extant mollusk species with known bathymetric distribution.

Mollusk samples were analyzed with multivariate ordination techniques (Detrended Correspondence Analyses and Correspondence Analyses). The DCA outputs were then calibrated using extant species depth information and provided good estimates of bathymetry.

The bathymetric range of sampled successions seems bracketed between 140 and 0 meters. In particular the Fronte section record a meter scale cyclicity characterized by a deepening upward trend followed by a shallowing upward trend superimposed to an overall shallowing upward tendency.

The results are consistent with the bathymetric interpretation of the DC axis 1 postulated previously for the fossil record, and will be used to implement sequence-stratigraphic interpretations.

PLEISTOCENE CORALLIGENOUS BUILD-UPS AND ASSOCIATED BIOCLASTIC DEPOSITS OF LE CASTELLA AND CAPO COLONNA MARINE TERRACES, CALABRIA, SOUTHERN ITALY.

BRACCHI Valentina Alice¹, BASSO Daniela¹, NALIN Ronald², MASSARI Francesco³

- 1 - Department of Geological Sciences and Geotechnologies, University of Milano-Bicocca
 2 - Geoscience Research Institute, Loma Linda University, California, USA
 3 - Department of Geosciences, University of Padova

Presenter e-mail: v.bracchi@campus.unimib.it

Key terms: *Coralline red-algae facies; Coralligenous build-ups; Pleistocene; Marine terraces; Crotona*

Autochthonous carbonate build-ups are mainly formed by encrusting coralline algae, which are one of the most important carbonate sediment contributors in the benthic communities of the Mediterranean area. They represent one of the most productive ecosystems in temperate regions and currently develop on Mediterranean hard and soft bottoms with a patch distribution along the coast. Light, salinity and temperature seem to be the main environmental factors influencing their distribution. Several types of assemblages have been described so far, due to the high heterogeneity of coralline growth-forms, distributed from the intertidal down to 160 m water depth, from rhodolith-beds to coralligenous build-ups.

In particular, coralligenous build-ups are frameworks with three-dimensional structure that serve as shelter and provide storm protection by buffering wave action along coastlines.

Coralline red-algae build-ups have high potentiality to be conserved in the fossil record. However, few fossil examples have been described in the literature and their evolution in the context of a stratigraphic cycle has seldom been modeled in detail.

Wide marine terraces are preserved in the area of the Crotona peninsula, Ionian Calabria, southern Italy. They are related to the interplay between Pleistocene sea-level changes and the progressive uplift of the Calabrian arc from the middle Pleistocene onwards. These terraces overlie a Plio-Pleistocene slope succession (Cutro Marly Clay Fm).

The two youngest marine terraces have been correlated with Marine Isotopic Stage (MIS) 3 and 5.1.

Many authors have already studied the deposits of these terraces, defining their major stratigraphic features and facies, but very few details exist on their paleontological content.

The deposits up to 10 m thick consist of mixed carbonate and siliciclastic sediments, in which red-algal reefs (= coralligenous build-ups) and other red algal facies are dominant.

Stratigraphic sections in both terraces have been measured and sampled in order to obtain a complete spatial description of the terrace deposits. Samples have been collected both in the red algae facies and in the grainstone and sandstone that occupy the cavities within the main algal bodies.

Thin sections have been prepared for red algae identification. A statistical analysis has been performed on the diagnostic anatomical microfeatures of the algal thalli.

Bio-calcareite have been disgregated in order to separate particles in a conservative way and conduct the quantitative paleontological analysis of the molluscan shell assemblages along with grain-size and chemical analyses. Species identification of bryozoans has been provided for facies dominated by this taxon.

The coralligenous build-ups are dominated by *Mesophyllum alternans* (Foslie) Cabioch & Mendoza and *Titanoderma pustulatum* (Lamouroux) Nägeli usually alternated with bryozoans crusts. Other red algae species like *Lithophyllum stictaeforme* (Areschoug) Hauck, *Phymatolithon calcareum* (Pallas) W.H.Adey & D.L.McKibbin and *Neogoniolithon* sp. rarely occur.

The molluscan assemblages in the grainstone associated to algal build-ups vary from typical coralligenous (C) to coastal detritic (DC), whereas they record an infralittoral environment in the uppermost unit.

The paleontological results have been framed in the context of a genetic-stratigraphic interpretation of the marine terraces.

Presenter e-mail: carmine.damico@unimol.it

Key terms: *Upper Esino River Basin; Late Pleistocene; Land molluscs; Paleoclimate*

A detailed chronological scheme based on ¹⁴C and U/Th dating of Upper Pleistocene slope and alluvial deposits, containing archaeological remains, pollens and land molluscs in the Upper Esino River Basin (Marches, central Italy), constrains the time-range deposition of stratified slope-waste deposits of cold climatic conditions (Middle and Late Pleniglacial) and coeval alluvial deposits between the Middle Pleniglacial (U/Th 48,000±2,400y BP) and Late Glacial (Coltorti and Dramis 1995).

Near Matelica (Camerino) Upper Pleistocene stratigraphical sections of alternating gravelly and sandy sediments of fluvial environment yielded well preserved non-marine molluscan assemblages of pulmonate gastropods, such as *Succinella oblonga*, *Chondrula tridens*, *Vallonia costata*, *Pupilla muscorum*, *P. triplicata*, *P. sterri*, typical of cold/cool climate and variable humidity. At present, *P. sterri* is Alpine species of very dry exposed calcareous places, characterising loess deposits during the Quaternary in Europe. Quantitative analysis of the molluscan assemblages highlights the palaeocommunity dynamics through the sections due to alternate cool-cold climatic conditions, which is consistent with the sedimentation feature of the study successions: braid plain channel gravelly sediments of middle and upper glacial phases yielded particularly poor in species (oligotypic) assemblages characterizing very dry exposed places (steppe-like), whilst sandy-silty sediments of interglacial phases ("Denekamp-Arcy, Kesselt, Tursac") recorded diversified molluscan fauna with steppe-prairie species accompanied by species of more or less damp conditions (*S. oblonga*), suggesting more humid environment. Dominance or decrease in specimens number of one species or variation in the assemblage composition was strongly influenced by palaeoclimatic changes, that recorded in a stratigraphic succession highlights detailed climatic and palaeoenvironmental variations through time.

PALAEOENVIRONMENTAL RECONSTRUCTION OF THE COSTE SAN GIACOMO CORE (EARLY PLEISTOCENE, CENTRAL ITALY) THROUGH OSTRACOD ANALYSES

MAZZINI Ilaria¹

1 - IGAG-CNR, Via Salaria Km 29.3, CP 10, Monterotondo Staz., I-00016 Roma, Italy

Presenter e-mail: ilaria.mazzini@igag.cnr.it

Key terms: *Ostracod; Temperature; Villafranchian; Italy*

This research deals with the investigation of the 40m deep drill core (CSG1) taken from the sedimentary succession of the Coste San Giacomo locality (Anagni, Central Italy). The site is well known for the abundant fossil mammal remains discovered there since 1978 forming a Villafranchian faunal assemblage. The sedimentary succession underlying the palaeontological level is largely unknown. Only recently, Bellucci et al. (2011) revised the faunal list of the site adding *Hippopotamus* sp. and providing sedimentological and micropaleontological data for the sediment core. Ostracod analyses have been performed on 180 samples. Only in 19 samples, ostracods have been recovered. Many samples were barren and this may be due to chemical dissolution of calcium carbonate related to organic matter decay in an environment where the organic matter flux reaching the bottom was high.

According to the ecological requirements of the 14 recognised taxa (all extant), two main assemblages could be distinguished. The first one (A) typifies a permanent water body with muddy bottom, clear and running shallow waters whereas the second assemblage (B) represents a temporary water body influenced by interstitial and spring waters. The sedimentological characteristics of the sediment core support a floodplain facies for assemblage A and a near-shore facies for assemblage B. The integrate analyses of facies and ostracod assemblage characteristics point to temporary waters linked, most likely, to changes in precipitation regime.

Moreover, the MOTR (Mutual Ostracod Temperature Range, Horne 2007) method has been applied to the most common species (*Candona candida*, *Candonopsis kingslei*, *Herpetocypris reptans*, *Pseudocandona eremita*, *Pseudocandona rostrata* and *Cyclocypris ovum*). The MOTR is a method applied to European species, mostly with Holarctic distribution and refers to a GIS based dataset of distribution in relation to air temperature ranges. Through its application it is possible to calculate mean July (mJu) and January (mJa) temperature ranges. The average temperatures of assemblage A are within the range of the actual average temperatures (mJu= 26°C, mJa= 7°C). Instead, the average temperatures calculated for assemblage B are constantly below the actual means, giving further evidence of the influence of spring waters.

The ostracod assemblages suggest the occurrence of mild climatic conditions in an alluvial environment with clear, running waters, sensitive to the precipitation regime. The aquatic environment was rich in aquatic vegetation (abundance of phytophilic species) and algae (occurrence of characeae) where the herbivorous hippo could thrive.

SEQUENCE STRATIGRAPHIC, EVOLUTIONARY AND ECOLOGICAL IMPLICATIONS OF TREMATODE PARASITISM OF HOLOCENE NORTHERN ADRIATIC BIVALVES

HUNTLEY John Warren¹, SCARPONI Daniele²

1 - GeoZentrum Nordbayern, Friedrich-Alexander-Universität -Erlangen

2 - Dipartimento di Scienze della Terra Bologna

Presenter e-mail: daniele.scarponi@unibo.it

Key terms: *Trematodes; Bivalves; Fossil; Holocene; Po Plain*

The role of antagonistic organismal interactions in the production of long-term macroevolutionary trends has been debated for decades. Some evidence seems to suggest that temporal trends in predation frequency share a common causative mechanism with genus level diversity.

Whereas studies on the role of parasites in "shaping" the evolutionary process are rare indeed. Digenean trematodes (Phylum Platyhelminthes) infest molluscs in at least one stage of their complex life cycle.

Trematodes leave characteristic oval-shaped pits with raised-rims on the interior of their bivalve hosts, and these pits are preserved in the fossil record. Here we survey 11,785 valves from the Pleistocene - Holocene deposits of the Po Plain and from nearby modern coastal environments on the northeast Adriatic coast of Italy. 205 valves exhibited trematode-induced pits. Trematodes were selective parasites in terms of host taxonomy and host body size. Infestation was restricted to lower shore face/transition to platform paleoenvironments. During the Holocene, individuals from transgressive systems tracts were significantly more likely to be infested than those from highstand systems tracts. Temporal trends in infestation frequency cannot be explained as an ecological/evolutionary phenomenon (e.g., the hypothesis of escalation); instead the trend seems controlled by environmental variation induced by climate-driven sea-level changes and inadequate sampling. Since this interaction appears to be ephemeral, both temporally and spatially, it is not likely that any selective pressure would be continuous over geologic time in this region. Furthermore, these results support the hypothesis that antagonistic interactions are lower in the northern Adriatic Sea in comparison to other mid-latitude shallow marine settings.

WHY IS 'RED MARBLE' RED : COULD FE-ISOTOPES SHED LIGHT ON THIS QUESTION THROUGH THE STUDY OF THE ITALIAN AMMONITICO ROSSO AND RECENT ORGANISMS?

PREAT Alain¹, DE JONG Jeroen¹, DE RIDDER Chantal², GILLAN David³, MARTIRE Luca⁴

- 1 - Free University of Brussels, Belgium
- 2 - Free University of Brussels,
- 3 - University of Mons-Hainaut, Belgium
- 4 - University of Torino, Italy

Presenter e-mail: apreat@ulb.ac.be

Key terms: Iron isotopes; Microbial mediation; Italian Jurassic Rosso Ammonitico; Recent sea urchins and bivalves; Red pigmentation of 'marble'

Eight iron (Fe) isotopic compositions of iron deposits in biofilms and granules found in two Recent burrowing marine invertebrates (the sea urchin *Echinocardium cordatum* and the bivalve *Montacuta ferruginosa*), were obtained by Multiple-Collector Inductively Coupled Plasma Mass

Spectrometry (MC-ICP-MS). $\Delta^{56}\text{Fe}$ values ranged between -1.78 and

-0.74 ‰. The lightest $\delta^{56}\text{Fe}$ is associated with the iron granules in the intestinal wall of *E. cordatum* and may be due to the abiotic oxidation of source Fe(II) with an isotopic composition reflecting that of light reduced Fe in sediment porewater. This lightest value could represent the best value for the pristine value. Fe in the biofilms was typically heavier by up

to +1.7‰, mean \sim +0.7‰. These results are compared with Fe isotopic composition of 17 Jurassic limestones from the Rosso Ammonitico Veronese (Italy) containing red and grey hemipelagic facies. The red facies show clear evidence of iron bacteria and fungi, which are interpreted as a possible equivalent of the iron microbial communities associated with the Recent organisms. Pronounced Fe isotope fractionation was observed in the Jurassic red hardground levels and in the more condensed red facies where bacteria and fungi lived and have

accumulated, with values typically lighter by -1‰ than the grey facies where micro-organisms were absent. This fractionation probably involved the passive accumulation of originally light porewater Fe in the EPS (exopolymeric substances) produced by filamentous bacteria, thereby favouring heavier Fe isotopes. Alternating stages of oxidation Fe(II)/Fe(III) occurred near the sediment/water interfaces as a consequence of microenvironmental changes in the marine porewaters and caused the red/grey facies interlayering. The comparison of the Fe isotopic compositions of the 'biominerals' in the Recent organisms and in the iron minerals of the red and grey Jurassic facies suggests an isotopic

biofractionation of at least \sim +0.7‰. Both studied organisms (the sea urchin and the bivalve) thrive in similar microenvironmental conditions as the micro-organisms of the condensed red facies. Their Fe isotope compositions are the same, as is the range of the probable biofractionation.

The microbial (iron-bacteria and fungi) hypothesis has the merit to be compatible with most observed pigmentation pattern. The pigmentation is due to the dispersion of submicronic (hydro)oxides in various studied Phanerozoic microaerophilic environments at dysoxic-anoxic interfaces or amorphous iron oxyhydroxide gel with phosphates formed by bacterial mediation during early diagenesis in the Recent organisms. The main limiting factor is the oxygen content which is always low in these very quiet microenvironments. Red pigmentation is therefore not linked to alteration or contamination of the studied Phanerozoic limestones. Iron-bacteria were present between the initial micritic components and thrived in the superficial part of the unconsolidated sediment. Omnipresent micritic regular filaments with Fe-rich sheaths and different types of ferruginous morphs are observed. There is no bathymetric influence on the process.

JUDGING BY COLOR IN THE EARLY HISTORY OF STRATIGRAPHY

VACCARI Ezio¹

- 1 - Università dell'Insubria, Varese

Presenter e-mail: ezio.vaccari@uninsubria.it

Key terms: history of geology; stratigraphy; color; 18th century

The aim of this paper is to evaluate some significant case studies, particularly during the 18th century, in order to understand how color was used as one of the 'external' features for identifying rock formations, also including fossils, regarded as formed in different times by different causes or events. The reference to color was often considered the main feature used for lithostratigraphical purposes within the so called 'classification' of mountains in the second half of the 18th century, as in the case of the research-work by Giovanni Arduino (1714-1795) in the 1760s and 1770s or Lazzaro Spallanzani's (1729-1799) geological studies in the 1780s and 1790s. Later geologists and mineralogists involved in the early history of stratigraphy, such as Abraham Gottlob Werner (1749-1817), referred to color when a rock formation or specimen appeared to be less defined by other main characters (for example chemical and morphological features).

CRETACEOUS-PALEOGENE ROCK COLOUR CHANGES IN THE UMBRIA-MARCHE BASIN: WHAT DO WE KNOW?

COCCIONI Rodolfo¹

- 1 - Dipartimento di Scienze della Terra, della Vita e dell'Ambiente, Università di Urbino, 61029 Urbino, Italy

Presenter e-mail: rodolfo.coccioni@uniurb.it

Key terms: colour changes; Cretaceous-Paleogene succession; Umbria-Marche Basin; Italy

The Cretaceous-Paleogene succession of the Umbria-Marche Basin (Italy) exhibits several rock colour changes from white gray to green-gray and from pink and red (Oceanic Red Beds, ORBs) to gray-black and black, with the dark colours indicating the presence of high contents of organic matter there preserved (Oceanic Anoxic Events, OAEs).

These changes were on a scale of some hundred thousand years to several million years and their occurrence is not a completely random process, in particular with ORBs and OAEs mostly reoccurring alternately. Are these rock colour changes proxy signals for paleoenvironmental conditions? Are these changing scenarios a result of interacting changes in ocean dynamics, tectonics and climate? Are these rock colour changes isochronous and linked to any biotic event and crises in the marine ecosystems? Are these rock colour changes expressions of local or global (geo)events?

In recent years, a range of multidisciplinary studies has been carried out in the Cretaceous-Paleogene succession of the Umbria-Marche Basin so that a comprehensive data set with regard to document oxygen and carbon isotope excursions and paleoenvironmental settings using pelagic and benthic microfossils is now available within a stratigraphically and chronologically well constrained framework mainly based on calcareous nannofossils and planktonic foraminifera.

This succession represents, therefore, an exceptional laboratory to shed light on these issues.

Key terms: Silurian; Carnic Alps; Valentintörl Section; conodont biozonation; ferruginous laminated structures

The Paleozoic of the Carnic Alps is represented by almost complete sequences (Middle Ordovician - Late Permian in age) which crop out along the Italian-Austrian border with an east-west orientation. The significance of the Silurian of the Carnic Alps lies in the remarkable variety of facies exposed there and in the abundance of fossils that has enabled a precise biostratigraphic assignment of the sequences. In the area of Lake Wolayer (Carinthia, southern Austria) the Silurian crops out in four stratigraphic sections: Seekopf Base, Rauchkofel Boden, Base of Seewarte and Valentintörl. Whereas data available for the first three sections may provide a general overview of the sequences, information for the latter locality are limited to a preliminary dating carried out during the geological mapping of the area in the 1970s by Schönlaub (1970).

At the Valentintörl locality the successions occur on steep cliff faces and are not easily accessible. However, two sampling campaigns carried out in 2008 and 2009 along four different traverses have allowed a good general overview to be obtained. The section bears at the base a 17 m-thick white massive limestone rich in cystoids and bryozoans dated to the Late Ordovician Katian Stage (Amorphognathus ordovicicus conodont Zone). The extremely condensed Silurian succession is represented by 6 m of reddish cephalopod limestones intercalated with biodebris levels and grey to pink micritic limestones. Detailed conodont sampling has allowed six conodont biozones to be identified: Kockella crassa, Wurmiella hamata, Ancoradella ploekensis, Polygnathoides siluricus, Ozarkodina crispata and Auroradella detortus, thus assigning a biostratigraphic range spanning from the base of the Ludlow (Gorstian) to the Pridoli Series. At the top of the succession 4 m of light grey limestones document the earliest Lower Devonian (Icriodus woschmidti woschmidti conodont Zone). The basal part of the Silurian succession is assigned to the Kok Formation. Furthermore, the Cardiola Formation (Polygnathoides siluricus conodont Zone) has been documented for the first time at this locality, as a discontinuous, thinly developed centimetric layer of dark cephalopod limestone. The upper part of the Silurian succession is assigned to the Altilcola Formation (Oulodus elegans detortus Conodont Zone).

The biostratigraphy of the Valentintörl Section has been studied in great detail. The colour of the limestones exposed here is particularly remarkable, varying from grey to pink to red and even rusty-brown. This colour variation derives from the presence of micro-laminated ferruginous coatings around skeletal fragments (mostly trilobites, some cephalopods and echinoderms) as well as planar laminated structures along discontinuity surfaces such as at the Ordovician/Silurian boundary. These laminations are observed as pink to red and green signatures consisting of different iron phases (chamosite, goethite, magnetite, hematite and subordinate apatite) and have been interpreted as evidence of microbial activity (Ferretti et al., in press).

UNRAVELLING THE ENIGMA OF LOWER PALEOZOIC NAUUTOID CEPHALOPOD CONCENTRATIONS: INTERPRETING COLOURS AND EVENTS ACROSS SPACE AND TIME

HISTON Kathleen¹

- 1 - Dipartimento di Scienze della Terra, Università degli Studi di Modena e Reggio Emilia, Largo S. Eufemia 19, I-41100 Modena, Italy.

Presenter e-mail: catherine.histon@unimore.it

Key terms: Nautiloid cephalopods; bioevents; sediment colour; Lower Paleozoic; Paleobiogeography

Enigmatic concentrations of orthoconic nautiloid cephalopods form distinctive colourful strata which are often singled out for use as

ornamental stone in building facades, floors or indeed as pavement slabs in some cities. The most common occurrences are known from the Ordovician, Silurian and Devonian but tend to become rare from the Carboniferous onwards. They display a variety of colours ranging from dark to light red, brown, black and various shades of grey. Most appear to represent shallow water facies with the orthoconic shells often being oriented either by current or wave action on the bedding plane. Studies focused on unravelling the nature of their formation tend to be restricted both spatially and temporally to localized investigations of either the faunas themselves or the successions within which they occur. Various studies have been carried out with regard to their depositional environments, their taphonomy, their use as current indicators and many theories and models have been proposed for their peculiar formation (Holland et al. 1994).

An innovative approach to determining common factors among these particular fossil rich beds by comparing the available lithological evidence and taphonomic features with the color of their enclosing sediments for selected occurrences has highlighted certain recurring features across a broad stratigraphic range and within diverse paleogeographical settings. Those with a predominantly black to gray color generally represent event beds, often mono-specific in nature, while those ranging from red-brown-beige are prevalently time-rich accumulations, often associated with discontinuity surfaces and condensed sequences (Histon, in press). A variety of studies related to the nautiloid faunal composition and the particular taphonomic features presented of the various nautiloid-bearing levels from the Cellon section (Llandoverly-Pridoli) in the Carnic Alps of Austria have been done in recent years and comparative studies with co-eval nautiloid faunas described from other palaeobiogeographical settings have highlighted exchange of these faunas along the North Gondwana margin. However, to date the aspect of the peculiar variety of colors presented by these nautiloid-bearing deposits at this famous Silurian section has not been examined with regard to identification of nautiloid events as outlined above for this middle latitude temperate paleogeographical setting. The findings from this study at a local and regional scale with regard to nautiloid events may be correlated with results from chemostratigraphic studies as was recently done by Manda & Fryda (2010) with regard to climatic events and nautiloid assemblages in the Prague Basin. As the Lower Palaeozoic sequences of the Carnic Alps are stratigraphically well dated by both conodonts, graptolites and chitinozoa and K-bentonite levels have been identified there from various sections the results of this innovative colour comparison approach may be used for regional correlation of these pelagic faunas and nautiloid cephalopod bioevents between the various Peri-Gondwanan Terranes, for palaeobiogeographical reconstruction and paleoenvironmental settings and for timing of significant geodynamic events related to opening and closing of migrational seaways.

10.1474/Epitome.04.0875.Geoitalia2011

IN THE SEARCH FOR A "GOLDEN" EVENT TO DEFINE THE GSSP OF THE NORIAN STAGE (UPPER TRIASSIC): BIVALVE EVENTS AND THEIR AMMONOID CALIBRATION

LEVERA Marco¹, BALINI Marco¹

¹ - Dipartimento di Scienze della Terra "Ardito Desio", Università di Milano. Via Mangiagalli 34, Milano, Italy 20133

Presenter e-mail: marco.levera@yahoo.it

Key terms: Bivalves; Ammonoids; Upper Triassic; Norian GSSP; calibration

Three out of seven GSSPs of the Triassic have been so far defined, namely those for the Induan, Ladinian and Carnian. Two of them, Ladinian and Carnian, are defined on ammonoids, the group on which by tradition the chronostratigraphy of the Triassic system is based since the XIX century. Ammonoids show during the Triassic very high evolutionary rates, combined with wide paleogeographic distributions. Thus, ammonoids could be considered the "golden" group when a primary marker event has to be selected to mark a "golden spike" for a Triassic unit.

Unfortunately this is not always true. Ammonoids are not very common in the sedimentary record, at least in comparison with conodonts. This group of microfossils became popular in the 1960s, because it is undoubtedly more common than ammonoids in limestone facies and because sometimes it shows interesting evolutionary rates. The quality of conodonts as tool for the definition of a GSSP is documented by the definition of the Induan, based on the FAD of *Hindeodus parvus*.

In recent years, however, conodonts have revealed some weaknesses, mostly due to difficulty in the delimitation of the species and in the reconstruction of the ontogeny and evolutionary trends. Thus, sometimes the FOs are rather diachronous or seems to be influenced by the interpretation of variability of the species. Such problems are strongly influencing the discussions within the Induan/Olenekian and Olenekian/Anisian working groups of the STS.

The discussion over the definition of the Norian stage in part reflects these difficulties, but with one difference. If there are not many paleontologic alternatives to ammonoids and conodonts for the Olenekian and Anisian, for the Norian the pelagic bivalves of the genus *Halobia* seem to be a good solution.

The number of species known from the Late Carnian to Early Norian is relatively low, and of these *Halobia radiata*, *H. austriaca*, *H. styriaca* and *H. beyrichi* are the most useful markers.

The systematic is much more stable and well established than that of conodonts, being mostly based on the same characters taken into account by Bronn in his first description of the species in 1830. As in all mollusca, the ontogeny is directly visible on the surface of the shell and it is often used as a discriminating character in their classification, together with the radial ornamentation and the characters of the auricle.

The stratigraphic range of the species can be compared with that of ammonoids, as they show high evolutionary rates. Furthermore, the duration of the zones is close to that of ammonoids' sub-zones around the Carnian/Norian boundary interval.

The paleogeographic distribution is widespread, as a number of species

occur through the whole Tethys as well as Panthalassa.

The main point to be solved in order to select a primary marker event for the GSSP is the correlatability of the most interesting events recorded in the best sections. This test would require an independent tool, and for the Carnian/Norian boundary the best is to use the ammonoids.

At present some new ammonoid bio-chronostratigraphic data are available from the GSSP candidate section Pizzo Mondello (Sicani Mountains, Sicily), while the work on ammonoids from the second candidate section Black Bear Ridge (BC, Canada) is not over. *Halobia radiata* is typical of the Late Carnian, ranging through the upper part of Tuvalian 3, as its FO closely corresponds to the base of the *Gonoionotites italicus* subzone. *H. austriaca* is now regarded as the best non-ammonoid marker for the lower part of the Lacin 1 (lower *Stikinoceras kerri* zone in North America; lower *Guembelites jandianus* zone in the Tethys), and it is closely followed by *H. styriaca* and *H. beyrichi* (upper *Guembelites jandianus* zone). Some refinement is still necessary but the FO of *H. austriaca* seems to be the most suitable "golden" event around the Carnian/Norian boundary.

EARLY APTIAN BLACK-SHALES IN THE BOREAL REALM: CALCAREOUS NANNOFOSSIL AND STABLE ISOTOPE EVIDENCE FOR REGIONAL AND GLOBAL PROCESSES

BOTTINI Cinzia¹, ERBA Elisabetta², MUTTERLOSE Joerg¹

¹ - Institut für Geologie, Mineralogie und Geophysik, Ruhr-Universität Bochum, Germany.

² - Dipartimento di Scienze della Terra "Ardito Desio", Università degli Studi di Milano", Italia.

Presenter e-mail: cinzia.bottini@unimi.it

Key terms: Oceanic Anoxic Event 1a; Black-shales; Calcareous nannofossil; Stable isotope; Boreal Realm

The early Aptian is marked by a global phenomenon of widespread deposition of organic carbon-rich sediments under oxygen-poor conditions known as Oceanic Anoxic Event 1a (OAE 1a: ~120 Ma). Triggering mechanisms for the OAE 1a are thought to have been the emplacement of the Ontong Java Plateau, associated with global warming and enhanced primary productivity.

In northern Germany the OAE 1a has its sedimentary expression in the "Fischschiefer" characterized by finely laminated black shales rich in organic matter. In the Early Cretaceous northern Germany was part of the Lower Saxony Basin being a marginal epicontinental sea forming the southern extension of the Boreal-Arctic Sea, thus located between the Boreal Realm in the north and the Tethys in the south. The relatively restricted palaeogeographic settings probably exerted a regional control on the deposition of the Fischschiefer.

We investigated the Upper Barremian-Lower Aptian interval in three sites from northern Germany (Alstätte, Rethmar, Hoheneggelsen KB 9) applying a multidisciplinary approach, bringing together the biotic and ocean chemistry responses across OAE 1a. Specifically, we performed calcareous nannofossil (abundance and assemblage composition) and carbon and oxygen stable-isotope analyses.

Calcareous nannoplankton is sensitive to changes in temperature, fertility and chemistry of surface-waters, therefore it is the ideal tracer for reconstructing palaeoclimatic and palaeoceanographic fluctuations. The direct calibration of the nannofossil and geochemical data is fundamental to provide a coherent reconstruction of the perturbations across OAE 1a. The main objective of this study is to reconstruct palaeoclimatic, palaeoecological and palaeoceanographic factors that controlled the deposition of the Fischschiefer in the Lower Saxony Basin.

The results obtained for the Boreal Realm are compared and integrated with biotic and geochemical proxies collected across the OAE 1a from the Tethys (Cismon, N. Italy), with the main purpose of understating the interaction between globally driven changes in the ocean-atmosphere system and regional phenomena related to local palaeoceanographic settings.

10.1474/Epitome.04.0877.Geoitalia2011

MODELING THE ANTARCTIC ICE SHEET AND ICE SHELVES IN THE LAST 200,000 YEARS

CASTELLANI Giulia¹, CASSENA Chiara¹, BARATELLI Fulvia², GIUDICI Mauro¹

¹ - Università degli Studi di Milano, Dipartimento di Scienze della Terra

² - Università degli Studi di Milano, Dipartimento di Fisica e Dipartimento di Scienze della Terra

Presenter e-mail: mauro.giudici@unimi.it

Key terms: thermomechanical modeling; antarctic ice sheet; ice shelf

Evolution of the cryosphere is of paramount importance to control climate variations at several different scales, in particular for accurate predictions of global change. Therefore accurate modeling of the thermal and mechanical behavior of glaciers, ice sheets and ice shelves is required for proper assessment of past, present and future trends of the Earth's climate.

Here some results of a model of the evolution of the Antarctic ice sheet in the last 200,000 years are shown. The model is based on the classical Shallow Ice Approximation (SIA), which assumes that the aspect ratio between the vertical and horizontal scale lengths which characterize velocity variation is small: actually, this ratio is approximated as the ratio between the vertical and horizontal lengths of the ice sheet. The SIA and the cryostatic approximation permit to simplify the momentum equation, which is nevertheless coupled with the energy equation, since ice rheology is described by a power-law relationship between deviatoric stress and strain rate (Glen's law) whose phenomenological parameters depend on the temperature field. Moreover, the energy equation includes convection and heating produced by ice straining, so that it requires the determination of the velocity and stress fields. The Antarctic ice sheet is connected to the ocean through the ice shelf, where the ice cap can float over the sea, the velocity field is assumed to be horizontal and the Shallow Shelf Approximation (SSA), similar to the SIA, is introduced.

A finite difference model has been developed to solve the set of basic equations of continuum physics (continuity, momentum and energy equations) for this non-linear thermomechanical coupled system and it has been applied to simulate the evolution of the Antarctic ice sheet over the last 200,000 years. At the surface of the ice sheet, temperature and accumulation rate have been assigned following Ritz et al. (2001) by assuming a relationship between these fields at time t with the present day temperature and accumulation rate and the temperature trend recorded in the Vostok log (Petit et al., 1999). Other input data for the model (e.g., geothermal heat flow, bottom elevation, sea level, etc.) have been taken from public-domain data sets (http://websrvr.cs.umt.edu/isis/index.php/Present_Day_Antarctica). The domain is discretized as a staggered grid with spacing of 100 km and the model runs with a time step of 10 years (5 years for some tests when required by numerical stability issues). The results (e.g., the thickness of the ice sheet) are in good agreement with present day observations and permit to assess some properties of the thermo-mechanical behavior of the Antarctic ice sheet, for instance the ice discharge toward the ocean follows the forcing given by variation of accumulation rate with a time delay of about 1,000 years.

THE LAKES OF TIERRA DEL FUEGO AND SOUTHERN PATAGONIA: ARCHIVES OF THE PAST CLIMATE

LODOLO Emanuele¹, GROSSI Maurizio¹

¹ - Istituto Nazionale di Oceanografia e Geofisica Sperimentale (OGS) - Trieste

Presenter e-mail: elodolo@ogs.trieste.it

Key terms: Holocene lake sediments; Climatic changes; Southern South America

Research on the variability of past climate are an essential requirement in understanding the future evolution of our planet's climate system and its impact on global environmental changes.

The geographic location of the lakes of Tierra del Fuego and southern Patagonia is ideal for reconstructing the environmental conditions of the past. They are in fact within the system of westerly winds from the Pacific Ocean and just north of the Antarctic polar front. In this region have followed glacial phases, with advancing of glaciers that covered much of Patagonia, and interglacial phases, with glacial retreat, which left large sedimentary deposits. The sediments deposited in these lakes represent an irreplaceable archive to reconstruct the history of the dynamics of glaciers, which reflects the climatic changes of the past, particularly those of the last 18,000 years, when some of glacier fronts reached the Atlantic coast.

A group of researchers from the Istituto Nazionale di Oceanografia e Geofisica Sperimentale (OGS) of Trieste, in collaboration with the Instituto de Geofisica "D. Valencio" of the Universidad de Buenos Aires, has carried out on November 2009 and March 2010 a series of data acquisition campaigns, funded by the Italian Ministry of Foreign Affairs. These studies have been focused in the Lago Roca, Lago Yehuin, Lago Chepelmut and Lago Fagnano (the southernmost ice-free reservoir), all located in Tierra del Fuego, and in the Lago Argentino (located in southern Patagonia), which hosts the famous glacier Perito Moreno.

In the course of their research, bathymetric and high-resolution seismic surveys, sediment sampling, and geomorphological studies have been carried out. These are essential information to reconstruct the history of the progress and retreat of glaciers that deposited these sediments in the geological past.

A short video that summarizes the activities carried out during these campaigns will be presented.

10.1474/Epitome.04.0879.Geoitalia2011

VARIABILITY OF THE AIR TEMPERATURE AND PRECIPITATION FROM 1884 TO 1960 IN THE HISTORICAL TIME SERIES OF MONTEVERGINE (AVELLINO) - PRELIMINARY RESULTS

BUDILLON Giorgio¹, CAPOZZI Vincenzo¹

¹ - Università degli Studi di Napoli "Parthenope" - Dipartimento di Scienze per l'Ambiente

Presenter e-mail: giorgio.budillon@uniparthenope.it

Key terms: climate change; variability; trends; air temperature; precipitation

Italy has a long tradition in climate observations and also provides valuable historical time series that have recently been examined as part of National and International projects (eg. Brunetti et al., 2006; Simolo et al., 2010) providing a detailed reconstruction of climate changes in the last 100/150 years, at least with respect to the temperature and precipitation.

The distribution of these observations is not uniform, the center and south of Italy show a lower concentration compared to the northern regions; the Campania region has, for example, only one historical series (Naples), with several gaps, started on 1821. In this context, it was decided to restore and enhance the acquired observations from the meteorological observatory "Montevergine" (AV), located at 1280 asl (40° 56'N, 14° 43'E). This climatological series is one of the oldest of Apennines Mountains and it's very meaningful for high-altitude regions climate's study. The original data set, as often happens in this type of data, is recorded on paper archive and, consequently, required an huge man time to digitalize it. From 2007 up to date the meteorological parameters are, instead, recorded by an AWS.

For this work we analyzed a sub data-set (1884:1960) which includes three daily observations (at 8.00 AM, 2.00 PM and 7.00 PM) of atmospheric pressure, wet bulb temperature, dry bulb temperature, vapor pressure, relative humidity, cloud cover and precipitations (rainy and snowy); moreover, there are also daily observations of minimum and maximum temperature, evaporation and solar radiation, although the records concerning these last two parameters are characterized by several gaps.

In this work we show the preliminary results obtained focusing the attention on the seasonal and yearly anomalies and trends. The analysis of temperature and precipitation series was performed using LOWESS method to detect notable patterns in data and a polynomial model (of first degree) to define trends. The results highlight a slight positive trend for the yearly mean temperature (computed by regards only three daily observations), of about 0.2 K per 50 years. Positive trends are

found also in seasonal analysis, even if they are appreciable only on summer (JJA), 0.5 K/50 years, spring (MAM), 0.2 K/50 years, and winter (DJF), 0.1 K/50 years, while no trend is evident on autumn (SON). As regards the precipitation, the analysis shows a low negative tendency for annual amount, of about -50 mm per 50 years; seasonal examination highlights positive trends on winter, +70 mm/50 years, and autumn +38 mm/50 years, negative trends on spring, -103 mm/50 years, and summer, -45 mm/50 years.

Yearly and seasonal mean temperature trends found in the "Montevergine" time series are less steep than those found in the analysis performed for Italian Peninsula (Brunetti et al., 2006), whose results show an increase of 1 K per century for 1865-2003 period; the different slope is mainly due to the prominent increase of temperature observed in 1980-2003 period, which is not considered in our analysis for the moment. As regard the precipitation trends, they are in good agreement with those found in Brunetti et al. (2006), which observed, for 1865-2003 period, a decrease of 5% per century in the annual precipitation amount, mainly due to the spring season (-9% per century).

EC-EARTH: AN EARTH-SYSTEM MODEL FOR CLIMATE STUDIES

VON HARDENBERG Jost¹, PROVENZALE Antonello¹, VOZELLA Lara¹

¹ - ISAC-CNR, Corso Fiume 4, Torino, Italy
Presenter e-mail: j.vonhardenberg@isac.cnr.it

Key terms: Earth-system models; Climate modeling; Climate impacts

The study of the complex processes at work in the climate system and the creation of future scenarios for evaluating the impact of future climate change, require the development of reliable and innovative tools and models. To this end, EC-Earth (<http://ecearth.knmi.nl>) is a recent earth-system model developed by a consortium of European research institutions and researchers, based on some of the currently most advanced models for the atmosphere, the ocean, sea ice and the biosphere. In particular the model is based on the concept of 'seamless predictions': numerical weather prediction (NWP) models are sophisticated state-of-the-art models which, being based on the same physical principles, may provide advanced atmospheric components for climate models. EC-Earth combines the NWP model by ECMWF with the ocean model NEMO. ISAC-CNR has recently entered the EC-Earth consortium, will contribute to the development of this tool and will apply it for climate studies, with particular interest for climate impact studies in the Alps, the Arctic and the Himalayas. We will present some of these developments and applications in this talk.

THE MED-CORDEX EXPERIMENT: NEW COUPLED REGIONAL PROJECTIONS AND TAILORED IMPACT ANALYSIS.

RUTI Paolo Michele¹, DELL'AQUILA Alessandro¹, CARILLO Adriana¹, SANNINO Gianmaria¹, STRUGLIA Mariavittoria¹, PISACANE Giovanna¹, CALMANTI Sandro¹

¹ - ENEA

Presenter e-mail: paolo.ruti@enea.it

Key terms: Regional Modeling; Climate Change; Climate Services

Since early '90s, many research projects analyzed and focused on downscaling of global climate simulations over the Euro-Mediterranean region. Euro-Mediterranean region is considered as particularly vulnerable to climate variability and change, in particular, by its vulnerability to changes in the water cycle and natural ecosystems. The Mediterranean basin has quite a unique character that results both from orographic conditions and demographic trend. The region features an enclosed sea, which is connected to the Atlantic ocean only by Gibraltar strait, surrounded by very urbanized littorals and a complex topography from which numerous rivers feed the Mediterranean sea. This results in many interactions and feedback between ocean-atmosphere-land processes that play a prominent role in climate and, in turn, determine the impact on human activities.

Based on previous stimulating initiatives and on new regional downscaling tools (Regional Coupled Systems), developed for the CIRCE-EU project, the Mediterranean climate research community proposed the Med-CORDEX initiative. MED-CORDEX is a coordinated action between CORDEX and HyMeX international programs. MED-CORDEX is a unique framework where research community will make use of both regional atmospheric and oceanic climate models and regional coupled systems for increasing the reliability of regional climate information.

Here, we provide some examples of the Med-CORDEX initiative and relevance, presenting a quantitative analysis of the changes in the average seasonal cycle of key environmental parameters over the Euro-Mediterranean area, using a A1B scenario simulation performed with a coupled ocean-atmosphere regional climate model driven by the ECHAM5-MPIOM global simulation included in the IPCC-AR4. The analysis is focussed on surface temperature and on the hydrological cycle output from different simulations performed with a coupled regional system. The impacts of climate change is analysed and evaluated in key parameters related to the hydrological cycle.

LOW FREQUENCY VARIABILITY OF PLANETARY WAVES

RUTI Paolo Michele¹, DELL'AQUILA Alessandro¹, CALMANTI Sandro¹

¹ - ENEA

Presenter e-mail: paolo.ruti@enea.it

Key terms: planetary waves; climate; resonance

Understanding the atmospheric low-frequency variability is of crucial importance in fields such as climate studies, climate change detection, and extended-range weather forecast. The Northern Hemisphere climate features the planetary waves as a relevant ingredient of the atmospheric variability. Several observations and theoretical arguments seem to support the idea that winter planetary waves indicator obey a non-gaussian statistics and may present

a multimodal probability density function, thus characterizing the low-frequency portion of the climate system. We show that the upper tropospheric jet strength is a critical parameter in determining whether the planetary waves indicator exhibits a uni- or bimodal behavior, and we determine the relevant threshold value of the jet. These results are obtained by considering the data of the NCEP-NCAR and ECMWF reanalyses for the overlapping period. Our results agree with the non-linear orographic theory, which explains the statistical non-normality of the low-frequency variability of the atmosphere and its possible bimodality. Analysis of C20C simulations allows us to evaluate the impact of natural and anthropogenic forcing.

SPATIAL AND TEMPORAL VARIABILITY OF GREENHOUSE GASES EMISSIONS FROM TEMPERATE WETLANDS: THE CASE OF LAKE MASSACIUCCOLI (TUSCANY)

LONI Tiziana¹, GUIDI Massimo², NORELLI Francesco²

1 - University of Pisa, Italy

2 - IGG-CNR of Pisa, Italy

Presenter e-mail: tilo@interfree.it

Key terms: greenhouse gases; emissions; wetlands; Massaciucoli

Determining of greenhouse gases (e.g. CH₄ and CO₂) emissions from aquatic systems is of great concern to estimate the influence on climate change. Wetlands can be source and/or sink of these gases, produced mainly by biotic processes (degradation, respiration and photosynthesis). The fluxes of carbon dioxide are driven by the respiration and photosynthesis phenomena, while methane emissions should attributed to the prevailing anaerobic bacterial degradation, as occurring predominantly at the interface with the sediment. This points out the existing relationship between the biosphere and greenhouse gases emissions. However, methane fluxes in wetland are insufficiently investigated, especially in terms of temporal and spatial variability. To study these variations monitoring work has been carried out in a coastal wetland area in North-West of Tuscany, where Massaciucoli lake (mean depth of 2.5 m) is located. The project aims to estimate the greenhouse gases fluxes of CH₄ and CO₂ at air-water interface from the lake. The fluxes have been measured by accumulation floating chamber, manageable (200 mm diameter, 100 mm height, 1.25 kg weight) and provided by a portable CH₄ and CO₂ analyzer. A handheld computer connected to the detectors allowed to compute the flux of gas directly on-site.

To improve the measurement accuracy, floating accumulation chamber was calibrated in laboratory. Monitoring has been carried out during three seasonal periods: autumn (2010 October), winter (2011 February) and spring (2011 April). Fluxes measurements (about 110 points) were performed with a grid 250 m x 250 m, in order to have an adequate number of measurements to represent the spatial variability and to accurately determine the values of total flux.

The methane (Φ_{CH_4}) and CO₂ (Φ_{CO_2}) fluxes measured during autumn ranges between -0.245 and 1.133 mol/m²/day and from -0.046 to 0.386 mol/m²/day, respectively. In winter Φ_{CH_4} varies between -0.931 and

0.392 mol/m²/day and Φ_{CO_2} from -0.037 to 0.220 mol/m²/day. During

spring period Φ_{CH_4} varies between -0.334 and 0.277 mol/m²/day and Φ_{CO_2} between -0.185 and 0.114 mol/m²/day.

Overall, in all of three monitoring periods, there are both positives and negative fluxes for both gases. Methane fluxes are mostly positive, while for CO₂ several negative fluxes are measured in several points around the lake.

Collected data confirm the great spatial and temporal variability of fluxes of CH₄ and CO₂. While the system as a whole emits CH₄, the lake can be sink and source of CO₂ during the three investigated seasons. These first results highlight that pluriannual seasonal monitoring would be necessary to have a reliable estimation of the average annual flux of greenhouse gases from the shallow lake.

Key terms: PM10; Calpuff; PCA

The aim of this study is to identify different sources and to evaluate their contribution to PM10 air quality. The study area is a small town located in Lombardia Region, in the middle of Po Valley, a critical zone especially for PM10 pollution. The local industrial scenario is characterized by the presence of a leader group of particleboard industry.

In order to recognize seasonal differences in PM10 concentration, two seven-day surveys were carried out, one in winter (December 2008) and the other in summer (July 2009). Sampling activity involved five sites: a station inside the factory, a traffic station (located in a high traffic position), two urban stations suitably selected base on meteorology and the distance from sensible receptors (school, park, etc.) and a blank station.

At each monitoring site quartz fiber filters were collected by a Low Volume Sampler (LVS). To single out industrial contribution from other possible sources, filters were collected every 12 hours (at 7 AM and 7 PM), assuming there was no PM10 traffic emission during the night.

Chemical and isotopic analyses were carried out on filters and data were processed by Principal Components Analysis (PCA), a receptor model based on multivariate statistical analysis. Sources affecting the composition of PM10 were identified by Varimax rotated principal components analysis.

In addition, the deterministic model Calpuff was used to calculate the

concentration of PM10 expected at monitoring sites based on the emission from the industrial plant only. The input data to Calpuff consisted in a detailed emission inventory derived from the analysis of the production cycle. This inventory quantifies the diffuse dust emissions caused by wood unloading operations, conveyed emissions from chimney, and traffic emissions of PM10 from trucks for transport of materials (i.e., induced traffic).

The comparison of the results obtained by the PCA receptor model and the Calpuff deterministic model allowed to quantify the contribution of the industrial plant to PM10 pollution in order to improve the knowledge on local source emissions and to adopt strategies for ameliorating air quality.

NONLINEAR DYNAMICS OF THE HADLEY CELL IN SHALLOW WATER MODELS

DALU Giovanni¹, BALDI Marina¹

1 - Institute of Biometeorology- CNR, Rome, Italy

Presenter e-mail: g.dalu@ibimet.cnr.it

Key terms: Tropics; Hadley cell; Jetstream

The dynamics of the Hadley circulation is studied by producing the solutions to a hierarchy of nonlinear models in the equatorial beta-plane and in the shallow water approximation with one, two, and three layers. The solutions to these models are used for determining, within an ample range of values of the environmental parameters, the width and the intensity of the Hadley circulation, and the position of the intertropical convergence zone (ITCZ). The validity of the weak temperature gradient approximation (WTG) and the validity of the lid assumption as an upper boundary are also discussed.

Results show that the latitudinal width of the Hadley circulation is underestimated by the WTG approximation, and it is overestimated by the adoption of a lid as an upper boundary. The width of the circulation increases as the thermal relaxation time increases and as the frictional losses in the lower layer increase; shallow lower frictional layers produce narrower circulations. In a multi-layer model, this width is narrow when the top layer is almost frictionless. Frictionless flows are centered about the equator, even when the center of the forcing is off the equator. In the presence of friction and with the forcing asymmetric about the equator, the center of the Hadley circulation is on the equatorial side of the center of the forcing, and the ITCZ is on the polar side of it. The distance of the ITCZ from the center of the forcing is larger when the width of the forcing is a large fraction of the width of the Hadley circulation.

MIGRATIONS AND ADAPTATION OF THE ESKIMO/INUIT OF EASTERN NORTH AMERICA TO LATEST QUATERNARY ARCTIC SETTINGS - REVIEW HIGHLIGHTS

MARTINI I. Peter¹

1 - University of Guelph, Guelph, ON, Canada

Presenter e-mail: pmartini@uoguelph.ca

Key terms: Eskimo; Inuit; Arctic; North America; late Quaternary

Numerous climatic changes have occurred during the late Quaternary and they led to drastic environmental changes. Living organisms have three main choices to react to such changes: adapt, modify, or migrate. We can readily adapt and since antiquity technology has allowed modifications to the environment at times beneficial to human life, others worsening the natural conditions. When natural or anthropogenic conditions become unbearable migration occurs. Notable examples are those of the Maya of Mexico, Vikings of Greenland, and Americans during the dread Midwest "dust bowl". Early inhabitants of extreme hot or cold settings readily could not sustainably mould the environment to their needs so they had to adapt and migrate. This is the case of the Eskimo/Inuit of North America that live in a frozen-coast landscape. In the High Arctic sunlight, temperature, and land and sea ice-distribution change seasonally totally modifying the landscape and the availability of meagre natural resources. Greater climatic variations occurred associated with glacial and interglacial as well as stadial and interstadial periods. These modified the availability of land, such as in Foxe Basin (NE Canada), submerging it either by large glaciers or by early postglacial inundation of glacial seas, and later reopening it by postglacial isostatic rebound. Even smaller climatic variations such as those occurring during the interglacial Holocene, have affected the thickness and distribution of sea ice and the opening and closing of Arctic icy passageways. This has affected the migration and distribution of marine fauna and of large sea mammals such as whales in particular. The Eskimo/Inuit have successfully colonized those extreme, frigid regions. Evidence exists that starting about 6000 years ago Eskimo people migrated eastward from Asia across North America following the marine mammal prey that could move through open icy passageways during warmer periods (~postglacial Temperature Optimum). As frigid conditions returned they adapted in the new lands by changing habits and technology to capture new marine and land preys. Archaeological information, consisting of remnants of habitations and tools, records a first Small Tool tradition that by 4000 yrs BP spread from Alaska across North America as a Paleo-Eskimo culture with microblades, harpoons tipped with small end blades. In Canada these evolved into the Pre-Dorset culture (~4000-2800 yrs BP) with toggling harpoons. They were followed by the Dorset (~2800-1200 yrs BP) culture characterized by sod houses, typical harpoon heads, point, oil lamps, and shaman's artefacts. The Dorset culture faded away, probably due to warming climatic conditions and reduced sea ice cover, and it was replaced by people of the Thule culture (~1000-600 Yrs BP) that migrated from Alaska during the Medieval Warm period. They hunted large sea mammals including bowhead whales utilizing new tools like large boats, new types of harpoons, drag floats. This large prey could provide sufficient food for relatively large

communities living in semi-permanent sub-subterranean sod houses. Subsequent cooling during the Little Ice Age increased the Arctic ice cover, reduced whale hunting and the modern Inuit culture had to re-adapt to hunting land prey, and seals and walrus from sea-ice platforms modifying their customs and technology accordingly. The smaller food supply reduced drastically the size of the nomadic communities. They lived for part of the year in snowhouses, utilized sled dogs, small boats (kayaks), and used different, more appropriate tools. Famine occurred, frequently wiping out entire families. To help those populations and to be able to control them, in the 1960s, the Government of Canada forced them into permanent villages where they were provided with things like housing, health care, southern-style education and subsidies. This has provided advantages, but also many practical and sociological difficulties.

Key terms: Mesolithic; Sicily; coastal palaeoeconomy

The Mediterranean basin preserves among the oldest evidence of dietary use of coastal resources in prehistoric time, with a robust body of data associated to Mesolithic cultures of the Early Holocene. However, coastal areas of the Mediterranean are scarcely productive, thus it is generally accepted that intertidal and subtidal organisms (e.g. fish, crustaceans, echinoderms, molluscs) probably played only an opportunistic role in the diet of local hunter-gatherer, compared with terrestrial counterparts. In this sense Mesolithic records from NW Sicily (Italy) provide the opportunity to evaluate this economic scenario with a different perspective. On overall archaeological sites testify a variable proportion of both marine and land resources, which is suggestive of an articulated use of coastal environments. Regional records provide compelling evidence that Mesolithic subsistence system in central Mediterranean region may have had different degree of reliance on coastal resources. Small mammals and terrestrial molluscs remains also provide valuable insights into palaeoclimatic and palaeoenvironmental conditions in the Central Mediterranean basin at the time of sites formation.

URBAN TOPOGRAPHY AND ANCIENT LANDSCAPES AT ALTINUM (LAGOON OF VENICE)

MOZZI Paolo¹, FONTANA Alessandro¹, NINFO Andrea¹, FERRARESE Francesco¹, ABBA Tiziano², MIOLA Antonella¹, MARITAN Michele¹, GAUDIOSO Barbara¹

- 1 - Universit  di Padova
- 2 - Geologist, free-lance

Presenter e-mail: paolo.mozzi@unipd.it

Key terms: geoarchaeology; lagoon; alluvial plain; palynology; Venice

Altinum was one of the most important Iron Age and Roman cities in the northern Adriatic, with a harbor located at the inner margin of the Lagoon of Venice. One of the aims of the research is to sort out the possible influence of late Holocene climatic changes and relative sea level fluctuations in allowing human settlement in this fragile, amphibious environment. The city was abandoned in the 5th-7th century AD, as inhabitants moved to the nearby islands of Torcello, Burano, and others; these first stable settlements in the lagoon pre-date the foundation of Venice around the 9th century AD. This migration is generally believed to be due to political problems related to the arrival of Barbarians but climatic instability may have played some role in changing the local river and tidal channel network. The reconstruction of the urban topography and ancient landscapes of Altinum is being carried out through geoarchaeological techniques, with the collaboration of the Archaeological Superintendency and the support of ARCUS s.p.a. and Regione Veneto. Remote sensing has allowed for a detailed mapping of the city walls, street network, dwellings, public and religious buildings of Roman Altinum. The city stood on a 3.5 m high, 1 km² wide mound, surrounded by a complex network of rivers and canals. Two large canals, detected with LiDAR, used to cross the urban center, providing direct connection to the lagoon. The harbor was located at the eastern outskirts of the city. Twenty-five corings were carried out in the city and in the harbour to maximum depth of 8 m. The mound consists of superimposed archaeological layers from Protohistory to late Antiquity. The city canals and the harbor are filled by 2-5 m of organic-rich clayey silt with abundant plant macro remains and lagoonal shells. Pollen indicates phases of deforestation; the great diversity of herbaceous plants suggests a variety of human activities in the area (agriculture, farming, gardening) since the beginning of the common era. The biological proxies of salt/brackish water vary in the core, suggesting fluctuations in the hydrological conditions.

REMOTE SENSING IN ARCHAEOLOGY: A GEOARCHAEOLOGICAL APPROACH TO THE SARDINIAN BRONZE AGE CONTEXT

CADEDU Francesca¹, BALVIS Teresa¹, MUNTONI Francesco¹, DERUDAS Alessandro¹, TEDDE Mauro¹, LOJ Michele¹, MARINI Alberto¹

- 1 - Department of Earth Science - Laboratorio TeleGis - University of Cagliari

Presenter e-mail: fran.cadeddu@gmail.com

Key terms: geoarchaeology; remote sensing; settlement strategies; architectural energetics

Considering the quick evolution of landscape and the resulting changes and destructions, a deep knowledge of archaeological areas is called for to organize interventions and territorial planning. The Earth Observation (EO) methodologies in the last year have been widely used for studying and preserving the archaeological heritage and it's been a long time that geoarchaeology is considered an independent discipline and offers methods and results for a better understanding of the past. On the basis of a multidisciplinary perspective, this paper will provide a methodological approach and new data about the settlement strategies and the economic, political and social organization of the Nuragic civilization, taking into account the EO methodologies and its potential contributions. The approach will be test in a sample area in the North Eastern part of Sardinia (Gallura). This area, well defined by the Limbara mountains, is of particular interest due both to its archaeological and geological features. In addition it has been yet analyzed with some spatial analysis in a GIS environment and the results show a clear definition of its main characteristics.

By evaluating archaeological and geological data through aerial photographs and remote sensing imagery, a territorial characterization will be outlined for identifying hidden structures, as well as for mapping the archaeological monuments already known and discovered. This first phase will allow to plan a survey to verify the results of this first step. The preliminary upshots of this research will be focused on the purpose to define the likely extractive zones used since the Nuragic period and determine the anthropic impact on the environment. From an archaeological point of view, these are among those key to reconstructing settlement strategies and social, politic and economic organization of the Nuragic civilization. These issues are well known, especially in the field of Architectural Energetics and paleo demography, because they allow to gain an insight into the exploitation of natural resources (namely construction materials) and, consequently, the organization of workforce and social structures; in addition it could offer ideas for reconstructing commercial and exchange routes. Even though the discussion is meant to be preliminary, this research can furnish a new integrated methodology that put to use remote sensing, geology and geomorphology applied to archaeological studies. In this paper we show how the knowledge of physical landscape in its different traits can be used for a better understanding of the past and how territorial planning and management can be enhanced through the use of such a multidisciplinary approach. Furthermore the development of standardized research methods allows the use of non-invasive techniques for territorial research and the reconstruction of the landscape and its resources, considering the past in a present perception. In this way is possible to gain a more comprehensive vision of the environment for a new perspective in preserving the natural and anthropized landscape.

Presenter e-mail: paolo.mozzi@unipd.it

Key terms: geoarchaeology; urban geology; alluvial plain; palynology

With origins tracing back to the late Bronze Age, ancient Padua experienced a major development in the Iron Age between the 9th-6th century BC, when it became an important urban center. Since the 2nd century BC it was one of the main Roman cities in NE Italy. The stacked layering of archaeological deposits until the Middle Ages resulted in the upbuilding of a 7 m thick and 1 km² wide anthropogenic mound, which occupies the whole city centre. A research project funded by Fondazione Cariparo has allowed the integrated analysis of the alluvial and archaeological record in and around the urban area, as well as palaeobotanical investigations at selected sites. Methods span from remote sensing and LiDAR to GIS processing of archaeological data, geological field survey and corings, palynology and analysis of plant remains. Alluvial chronostratigraphy indicates that the Brenta River was crossing Padua in the 2nd millennium BC. 3D modelling of the archaeological record and the overall geomorphological evolution of the alluvial plain suggest that during the Iron Age and in Roman times the Bacchiglione River was following its present course through the area, occupying an abandoned meandering bed of the Brenta River. The microscopic plant remains such as pollen grains and seeds/fruits were analyzed in a core in the present city centre (Palazzo Roccabonella, via S. Francesco), on the point-bar of a large meander. The record from the infilling of a probable Iron Age ditch evidence the dominance of herb vegetation. The hygrophilous plants (herbs, trees and shrubs) are quite rare, therefore the soils should have been well drained and suitable for cultivation and dwelling. This is consistent with the high percentage of cereals' pollen and the co-occurrence of seeds and of their weeds (pollen and seeds), as well as ruderal plants. The river changes which occurred at the end of the 2nd millennium BC, possibly related to coeval climatic instability, allowed for the development of Iron Age urban settlements on the stable banks of the underfit Bacchiglione River.

ADAPTING IRRIGATION STRATEGIES TO MID-LATE HOLOCENE CLIMATE CHANGES IN THE SALUT OASIS (SULTANATE OF OMAN)

CREMASCHI Mauro¹, ZERBONI Andrea¹

- 1 - Universit  degli Studi di Milano, Dipartimento di Scienze della Terra "A. Desio"

Presenter e-mail: mauro.cremaschi@unimi.it

Key terms: Oman; irrigation; calcareous-tufa; stable-isotopes; U/Th

The Salut oasis at its apogee, during the Iron age (late 1 millennium BC), may have reached the size of 75 Km² of cultivated land, sustained by irrigation facilities; today its extension is reduced to 6 Km². This suggests

the inactivation of the irrigation system as consequence of late Holocene aridification. The archaeological context indicates that in the area agricultural exploitation begun during the Bronze age, enjoying a mid-Holocene larger water availability confirmed by independent palaeoclimatic data. However, most of the irrigation features were still in use at the beginning of the Islamic era, but they may be referred to the Iron age. U/Th dating on carbonatic tufa (infilling the irrigation canals and falaj) provide evidence for an high standing of the water-table in the Salut plain between the IV millennium BC and the beginning of the Islamic period. Geochemical investigation (O and C isotopes) will clarify changes in water availability in a crucial phase of the late Holocene, marked by incoming aridity. Moreover, the analysis of thin sections of the soils buried in the area surrounding the citadel of Salut permits to elucidate the dynamic of the exploitation of the oasis.

Key terms: geoarchaeology; Ethiopia; landscape erosion

Many recent paleoclimate studies highlighted that repeated climatic changes took place during Holocene both at decadal and multi-century scale. Although these climatic variations have a demonstrated control on vegetational, faunal and geomorphological changes, the role of human activities in favouring or hindering climate-triggered landscape modification is still a matter of investigation.

The town of Aksum is located in Tigray (northern Ethiopia), a region where Holocene climatic changes are well-documented. Between the 3rd and 6th century AD, Aksum was the capital of a kingdom stretching its control as far as the Red Sea coast, the western Sudanese lowlands, and the regions to the west of the Takazza River. The kingdom flourished constantly until the 7th century, when a dramatic decline started.

During Holocene time span, a 6 m thick alluvio-colluvial succession was accumulated in the Abak Creek valley, which is located few kilometers SW of the modern Axum town and cut into tertiary basalts. The Abak succession has been divided into six main units (Abak1-6) bounded by erosive surfaces. The basal unit (Abak1) consists of weakly cemented cross-stratified sandy gravels pointing to a well-developed alluvial drainage. No radiocarbon ages have been obtained from these deposits, which probably accumulated during the Late Pleistocene - early Holocene. Unit Abak2 is made of muddy colluvial deposits containing channelized, gravelly bodies. Radiocarbon datings from charcoals provided a radiocarbon age of 5470-5220 BC and 5540-5370 BC. Unit Abak3 is made of plant-rich, palustrine/floodplain silty sand capped by a vertic soil. Samples from the basal part of the unit provided a radiocarbon ages of 170-40 BC. Radiocarbon datings from charcoals picked about 0.5 m below the vertisol gave an age of 230-350 AD. Unit Abak4 is consists of sand and gravel accumulated in a relatively to high-sinuuous fluvial channels. Subordinate colluvial deposits can occur close to the valley flanks. Unit Abak4 deposits contains abundant axumite pottery fragments, and provided nine coherent radiocarbon ages comprised between 1400 and 1650 AD. Unit Abak5 is deeply cut into the underlying units, and is made of relatively well-sorted fluvial sand. Radiocarbon datings from charcoal fragments point to a modern age (younger the 250 yBP). Unit Abak6 consists of two sub-units (Abak6a and Abak6b) continuously exposed along the creek flanks, and representing two different order of fluvial terraces of modern age.

The present study highlights that after a phase of marked landscape stability, associated with development of vertic soils around 300 - 400 AD. The marked erosive surfaces at the base of units Abak4 and Abak5 testify two major phases of landscape degradation (i.e. soil erosion) followed by aggradation (i.e. valley filling), which occurred around 1400 - 1650 AD (i.e. aggradation of unit Abak4) and modern age (i.e. aggradation of unit Abak5). The present study highlights that the marked antropic pressure acted during the maximum development of the Aksumite Kingdom didn't trigger any landscape degradation, which, on the contrary, started at about 1400 - 1650 AD, when a marked increase in rainfall, punctuated by three main droughts, affected the East Africa.

ENVIRONMENTAL VARIATIONS AND CULTURAL CHANGES: THE CASE OF THE PALMYRA MOUNTAIN REGION DURING THE LATE PREHISTORY AND THE EARLY HISTORIC PERIODS

MORANDI BONACOSSI Daniele¹, IAMONI Marco¹

- 1 - Dipartimento di Storia e Tutela dei Beni Culturali, Università degli Studi di Udine

Presenter e-mail: daniele.morandi@uniud.it

Key terms: Palmyra; desert-kites; climate-change; economic-strategies; oasis

Notwithstanding the importance of the desert region surrounding Palmyra for the economic development of the oasis and the Bronze Age settlement and especially of the great caravan city of the classical period, the Palmyra hinterland has not been the object of systematic and intensive archaeological research. Since 2008 a joint Syrian-Italian mission has been conducting geoarchaeological survey work in the Palmyra oasis and the desert areas to the south and west of it. Palaeoenvironmental proxies from the Palmyrena and the Levant indicate a discontinuity between a wet Late Glacial/Early Holocene and a later dry period, which is presumed to have started at the end of the seventh millennium BC and resulted in the progressive nucleation of the Palmyra oasis on one hand and in a major change in settlement patterns and the exploitation of natural resources on a regional scale on the other. Permanent settlement and agriculture were concentrated within the oasis, where water resources had survived despite reduced precipitation, whereas the surrounding dry steppe was exploited by mobile pastoral and specialized seasonal hunter communities. The paper will explore this major shift in settlement patterns and economic strategies in the region, which is marked by the emergence of

an archaeological landscape characterized by isolated cairns or clusters of cairns, in some cases associated with small groups of huts, and desert-kites.

ENVIRONMENTAL CHANGES AND CULTURAL DYNAMICS BETWEEN THE LATE PLEISTOCENE AND THE EARLY HOLOCENE IN THE PALMYRENA (TADMOR REGION, CENTRAL SYRIA)

CREMASCHI Mauro¹, ZERBONI Andrea¹

- 1 - Università degli Studi di Milano, Dipartimento di Scienze della Terra "A. Desio"

Presenter e-mail: mauro.cremaschi@unimi.it

Key terms: Palmyra; Lake level changes; Early Holocene; Geometric Kebaran; PPN/A/PPNB

Evidence of late Pleistocene to early Holocene occupation of the region surrounding the oasis of Palmyra/Tadmor (central Syria) consists of geometric Kebaran, Natufian and early Neolithic archaeological sites. These are distributed along the margin of the Sabkhat al Mouh and in the Abu Fawares area, in connection with lacustrine deposits, suggesting a period with a humid climate dated to the Upper Pleistocene. To the same phase a high stand of the level of the lake in Palmyra basin is dated, followed by arid conditions and the onset of evaporitic environmental conditions during the last Pleniglacial. Erosive surfaces and gypsum aeolian dunes are further geomorphological indicators for enhanced aridity in the Upper Pleistocene. A subsequent high stand of the lake level is indicated by organic lacustrine sediments found in the range of the Palmyra oasis and dated between the late Pleistocene and the early Holocene. The density of open-air sites, located close to the present day oasis and dating from the Late Epipalaeolithic to the Early Neolithic, confirms environmental conditions suitable for human and animal life. Finally, wet environmental conditions turned toward aridity during the early Holocene (IX millennium BP), in correspondence with the early Neolithic exploitation of the region. As a consequence, later archaeological sites were concentrated in the area of the present-day oasis and marginally within the Abu Fawares basin. Possibly, as documented elsewhere in the Near East, an early Holocene arid event favoured a main shift in subsistence strategies and a population relocation; archaeological sites distributed within the limits of the oasis, especially the sequence at site 288 encompassing a span of time from the PPN/A to the Chalcolithic, recorded this phase.

Presenter e-mail: andrea.zerboni@unimi.it

Key terms: oases-system; Garamantian-kingdom; climate-change; water-availability; Sahara

Throughout the Holocene, climatic changes have been recurrently claimed as one of the major causes for the collapse or flourishing of ancient civilizations; moreover, in arid lands water availability has been recognized as the main factor promoting and accelerating cultural and social dynamics already acting. Concerning the Sahara, the most representative climatic event dated to the late Holocene is the failure of the monsoon system and the consequent progressive decrease in precipitation culminated with the onset of the present hyperaridity. In the central Sahara the response of the environment was rather quick: springs and lakes desiccated and the mountain were almost abandoned, but few ecological niches survived the change. As consequence of geomorphological processes, since 4000 years BP water resources contracted to isolated units of landscape within the mosaic of the desert physiographic features: the oases. A typical example is given by the wadi Tanezzuft that was a large river during the wet Holocene and contracted into an oasis soon after the interruption of the monsoonal circulation. The oasis in the Tanezzuft valley was almost stable in the 4th and 3rd millennia BP, but after several centuries of enhancing aridity its size was reduced. In the course of the 3rd millennium BP the SW corner of the Fezzan region became the southern border of the Garamantian kingdom, and oases were important centers of the caravan routes, connecting the Mediterranean coast to inner Africa. In this framework, Garamantes succeeded in developing a rich agricultural exploitation of the oases environment, introducing large scale irrigation technologies also in the attempt to react against increasing aridity. The Garamantes experienced, thus, the emergence of a complex state formation in the middle of the desert; in the wadi Tanezzuft Garamantian settlements mainly consisted of fortified villages and compounds, located as a protection of the fringes of the oasis, together with fortified citadels strategically located along the main caravan routes. Several minor sites of this age have been found buried inside the alluvial deposits and confirm the exploitation of a wide territory. Sites distribution suggests that the oasis was larger than the present one, and the main rivers were the source of water for the cultivated land. During the 2nd millennium BP the Tanezzuft oasis contracted significantly, possibly also in consequence of several arid spells, evident in the dendroclimatological record of the Cupressus dupreziana. The Garamantian society was well adapted to harsh environmental conditions and possibly resistant to severe dry spells; nevertheless the decline of the Garamantian kingdom occurred in the IV-V century AD. This period corresponded to the decline of the Roman empire and to the consequent almost complete stop of the caravan trade. Political and economic factors have been surely relevant but it is also meaningful to note that this phase also corresponds, in the palaeohydrological record of the SW Fezzan, to a strong decrease of water availability, as consequence of recurrent droughts and climatic instability. Possibly the Garamantian could not halt the encroaching aridification, combined with the collapse of the trans-Saharan trade, and their society underwent a crisis attested both in archaeological and literary sources, which describe a shift from an oasis-based territorial state to the hegemony of the pastoral

tribes of camel herders. The trajectory of the Garamantian kingdom is a paradigmatic case-study illustrating the time and steps of human exploitation of a marginal and fragile environment. The growth of permanent settlements within the oasis, which developed towards a complex chiefdom system, facing a changing landscape, well represents the interconnection between historical socio-economic and climatic factors.

RADIOGENIC ISOTOPE, COSMOGENIC RADIONUCLIDES AND RADIATION DAMAGE METHODS APPLIED TO THE DATING OF CONTINENTAL CARBONATES

SOLIGO Michele¹, TUCCIMEI Paola¹
1 - Università "Roma Tre"

Presenter e-mail: soligo@uniroma3.it

Key terms: uranium-series; radiocarbon; luminescence; Electron Spin Resonance; carbonates

Speleothems, fresh-water tufa and travertines are generally dated using methods based on uranium-series disequilibria, but also on cosmogenic radionuclides and radiation damage. The basic theory of these methods is introduced and related applications in the study of continental carbonates are shown with examples derived from recent research.

U-Th is the most popular method and is based on the measurement of ²³⁰Th formed in situ by radioactive decay of uranium (²³⁴U and ²³⁸U) co-precipitated with CaCO₃. In the absence of detrital minerals (see for example pure speleothems) the extent to which the ²³⁰Th/²³⁴U activity ratio has returned towards unity is a function of time, taking into account also the state of disequilibrium between ²³⁴U and ²³⁸U. Tufa and travertines, however, are impure mixtures of calcium carbonate and incorporated detrital minerals and deserve the recourse to specific correction schemes to determine the authigenic radionuclide component and thus a fitting age. The method extends back to at least 350 ka. The disequilibria between other parent-daughter pairs in ²³⁸U and ²³⁵U decay chains (namely, ²³⁴U/²³⁸U, ²³¹Pa/²³⁵U, ²²⁶Ra/²³⁰Th) are also used in carbonate dating. ²³⁴U/²³⁸U method can be applied to dating carbonates as old as 1.25 Ma, assuming that the uranium activity ratio in the parent fluids has remained constant over time. ²²⁶Ra/²³⁰Th method is used to date continental carbonates younger than 8 ka, presupposing that ²²⁶Ra/²³⁰Th initial activity ratio can be determined on present-day deposition. Recently, the use of the classic U-Pb method has been extended to speleothems dating, opening new perspectives on the study of older speleothems, not datable using standard U-series methods. The use of radiocarbon dating in carbonate chronology is considered problematic, principally because of potential variability in the contribution of "dead carbon" from the host limestone. Actually, precipitating waters may contain a proportion of carbon inherited from the dissolution of a ¹⁴C-free carbonate component in the bedrock. Another problem could arise from the contamination of the material with younger carbon from soil organic matter that might be deposited in the original structure of porous carbonate. In addition to that, bomb-¹⁴C may affect modern precipitation, leading to an inconsistent young age. Because of these problems, relatively few speleothem chronologies are based on ¹⁴C ages. Finally, radiation damage dating methods (electron spin resonance, thermoluminescence, optical stimulated luminescence) are based on the time-dependent accumulation of electrons trapped in the crystal defects of certain crystalline nonconducting minerals, when exposed to ionizing radiation. The trapped electrons cannot return to the ground state, unless a sufficient amount of energy is provided, in the form of heat or electromagnetic radiation (light). Unfortunately, not all the samples are suited for radiation damage dating: indeed, the presence of cationic impurities such as Mn²⁺, Fe²⁺, or Fe³⁺, humic acids (organic matter), can mask the signal of interest, or interfere with it. These methods can be applied to date materials ranging in age from a few hundreds years to about a million year.

ON STABLE ISOTOPES AND TRAVERTINE: OLD AND NEW TECHNIQUES

BRILLI Mauro¹, GIUSTINI Francesca¹
1 - Istituto di Geologia Ambientale e Geingegneria - CNR

Presenter e-mail: mauro.brilli@cnr.it

Key terms: Travertine; Stable isotope; Paleoclimatology; CO₂; Clumped isotopes

Carbon and oxygen stable isotopes were used to characterize the genesis of travertine for the first time by Craig in 1953. To our knowledge, it was Craig who performed the first analysis of the most widely known travertine formations, such as those from Tivoli and Yellowstone. Since then, the study of the stable isotope composition of travertines (and carbonates, in general) has been one of the most active areas of research in carbonate geochemistry.

Carbon and oxygen isotopes in travertine yield two main types of information regarding (i) CO₂ geochemistry and (ii) paleoclimatology. The former is related to the possibility of determining the origin of carbon species in travertine-depositing solutions from the carbon isotope composition. The origin of the carbon species in solution is attributable to several sources: organic or atmospheric CO₂, CO₂ produced by decarbonation reactions from carbonate rocks, magmatic CO₂. The latter is related to the fact that travertine, like all other non-marine carbonates, preserves a valuable record of paleoclimatic conditions.

This applies above all to formations deposited from cold water since the fluid in such cases may have been "ambient" water, the stable isotope compositions of which are determined by local climate conditions. In particular, oxygen isotopes are dominantly indicative of paleoclimatic conditions since the oxygen isotopes of a carbonate in theory directly depends on two factors: temperature and oxygen isotope composition of the water where the carbonate precipitates. Crucial assumptions regarding

the isotopic equilibrium and isotopic composition of water have to be made in order to estimate the temperature of the carbonate formation; these assumptions are often not valid. Nevertheless, reliable high resolution paleoclimatic isotope curves based on travertine sequences have been reported by numerous studies.

The new frontier of isotopes applied to paleoclimate consists of a new carbon and oxygen isotope paleothermometry technique, referred to as clumped isotope thermometry because it measures the temperature-dependent clumping of ¹³C and ¹⁸O (the rare isotopes in the isotope complex of carbon and oxygen) into bonds with each other in the carbonate mineral lattice (Eiler, 2007). The outstanding advantage of this innovative isotope method consists in eliminating the dependence on the isotopic composition of water, as well as most of the common complexities to conventional stable isotope thermometry, such as disequilibrium due to vital effects. Few studies based on this approach have been conducted on different types of carbonates: synthetic inorganic calcite, natural inorganic calcite from a soil, aragonitic otoliths, aragonitic corals, aragonitic mollusks and calcitic brachiopods, and, very recently, speleothems. The application of this technique to travertines is only a matter of time.

A further characteristic of the carbonate clumped isotope thermometry is that it provides a means of rigorously constraining the δ¹⁸O of ancient waters, which can be determined by combining the temperature

estimation with the δ¹⁸O of the carbonate; clumped isotopes are likely to yield a considerable amount of new information that will result in the need to review both early and more recent studies on carbonate isotope geochemistry.

TRAVERTINE AND CALCAREOUS TUFFA: LITHO- AND MICRO-FACIES AND RELATED DEPOSITIONAL ENVIRONMENTS

GANDIN Anna¹

1 - Dip. Scienze della Terra, Università di Siena

Presenter e-mail: gandin@unisi.it

Key terms: travertine; calcareous tufa; litho- and microfacies; petrogenesis; depositional conditions

The depositional facies that characterize old epigeal carbonate bodies can all be recognized in present day fluvial and thermal systems and observed throughout their formation. Both deposits derive from flowing Ca/CO₂-rich waters rising from cool/ambient temperature karstic sources (Calcareous tufa) or warm to hot/thermal spring systems (Travertine).

Their depositional features are quite different:

- in the fluvial environment they reflect the biological activity of a varied micro- and macro-flora and a lower concentration of Ca²⁺.
- Bio/phytohermal constructions related to rapid turbulent flows and muddy palustrine facies prevail in the Calcareous tufa deposition;
- in the thermal system peculiar litho- and micro-facies appear to be mostly controlled by physico-chemical factors. High concentrations of the solution and related cooling and degassing processes associated with the morphology of the substrate and the mechanical properties of the water flow, define the textural characteristics of the Travertine deposits that drastically varies from crystalline crusts connected with rapid laminar or turbulent flows to laminated microbially mediated fabrics such as microbial rafts and mats connected with wetland conditions.

THE MONTIRONE TRAVERTINE MOUND: A MULTIDISCIPLINARY APPROACH. IMPLICATIONS FOR THE EUGANEAN GEOTHERMAL FIELD (NE ITALY)

POLA Marco¹, ZAMPIERI Dario¹, FABBRI Paolo¹, GANDIN Anna², SOLIGO Michele³, TUCCIMEI Paola³, DEIANA Rita¹

1 - Università degli Studi di Padova

2 - Università degli Studi di Siena

3 - Università degli Studi Roma 3

Presenter e-mail: marco.pola@unipd.it

Key terms: travertine mound; extensional relay zone; Euganean geothermal field; deep geothermal system

The Montirone is a travertine-made hill (max. height 15.75 m a.s.l.) located in the Abano Terme area of the Euganean Geothermal Field (EGF), that extends on a plain band of 36 Km² south of Padova (Veneto-Italy).

The existence of an extensional relay zone, buried hundred meters beneath the alluvial cover, between segments of the Schio-Vicenza fault system (SVFS) has been proposed. This structure accommodates a local extensional regime that keeps open fractures in the subsurface of EGF and enhances the uprising of hot waters. The temperature of thermal waters, used mainly for spa, ranges from 60°C to 86°C. 3H and 14C measurements suggest a residence time greater than 60 years, probably a few thousand years. At present, about 250 wells are active and the total average flow rate of exploited thermal fluids is 15 Mm³/Y.

Until the 1960, the only natural occurrence of thermal waters in Abano was located on the Montirone hill; hot waters fed several pools located on the flat top and at the base of the hill and were partially channeled to move a mill-wheel. The intense exploitation of thermal waters, linked to the increasing number of thermal wells, lowered the potentiometric level from more than 16 m a.s.l. to -15 m a.s.l. (year 1982; at present is 5 m a.s.l.) and dried up the hot springs. The hill has a sub-circular shape, covers an area of 10000 m² and can be classified as a regular shaped travertine mound.

The mound is affected by a network of fractures mainly composed of two sets (WNW-ESE and NNE-SSW) that can be interpreted as a fracture mesh developed in a dilational stepover between strike-slip or transtensional fault segments of the SVFS. The trend of fissures parallels the trend of the main regional structural elements (e.g. SVFS; mainly oriented NW-SE) and is consistent with the direction of the anisotropy depicted in the variogram analysis of transmissivity calculated in the bedrock of EGF (N110°E).

Two drillings (about 1m deep) were made to study the depositional facies of the travertine because of the absence of relevant cross sections. Thin

sections of the core samples show the dominance of layered travertine made of lime-mudstone with paper-thin rafts and laminae of bacterial shrub, locally covered by crystalline crusts made of feather-like calcite. Moreover, soft sediment syndepositional deformations and repeated phases of karstic dissolution and redeposition have been observed. Isotopic analyses on uranium-series, carried out on crystalline crusts sampled during the drillings, have given ages from 30 ± 4 ky to 25 ± 5 ky. Moreover, the low content of U (from 3 to 12 ppb) and the high activity ratio of $^{234}\text{U}/^{238}\text{U}$ (>2) clarify the high interaction between rock and water, typical of a deep geothermal system with high residence time of waters.

Geophysical methods, and particularly Electromagnetic survey (EM) and Electrical Resistivity Tomography (ERT) were used to determine the mound geometry. The map of EM measurements (depth of investigation around 1.5m) shows the presence of two resistive areas along the slope and a more conductive region on the top of the mound. The latter can be interpreted as indicative of the uprising of thermal waters through a more fractured zone. ERT surveys confirm the vertical extent of the conductive and resistive anomalies, and support the interpretation above. The presence of the Montione travertine deposit strongly supports the existence of a releasing structure in the subsurface, which controls the development of the EGF, and an ongoing activity of the SVFS, which is generally considered inactive. The analysis on U-series isotopes gives another important constraint on the deep circulation and a long residence time of thermal waters.

FIRST EXAMPLE OF BANDED TRAVERTINE FROM ITALY: THE FISSURE RIDGE OF SEMPRONIANO (GROSSETO - ITALY).

CAPEZZUOLI Enrico¹, BROGI Andrea¹

¹ - Dipartimento di Scienze della Terra - Università di Siena

Presenter e-mail: capezzuoli@unisi.it

Key terms: Travertine; neotectonics; Banded travertine; fissure ridge

Travertine fissure-ridges are common morphotectonic features characterizing the travertine deposits from thermal waters rising along fractures in the bedrock.

A typical travertine ridge consists of a central fissure along its long axis, and bedded travertine dipping away from the central fissure. The crestal fissure, often filled by vertical laminated crusts (banded travertine), exactly follows the fractures affecting the bedrock, hidden below the bedded travertines. Consequently, the travertine-fissure ridges are the most significant travertine masses for tectonic investigations. Several examples of banded travertine related to fissure-ridges were described in different geological contexts around the world. Nevertheless, although some fissure ridges were identified from different localities of Central Italy (e.g. Rapolano Terme, Bagni S. Filippo, Canino) they seem not to have banded travertine along their central fissure.

Recent studies on the travertine units in the Albegna Valley (Grosseto - Southern Tuscany) allow the investigation of the travertine cropping out Semproniano, at a quote of 600 a.s.l., where a 400m long and 70m wide continental carbonate deposit was mapped. We refer such a deposit to a wide, vertical banded travertine body precipitated within the central fissure, whereas only in its southern portion, part of the related bedded travertine is still preserved.

In this view, the Semproniano travertine can be interpreted as a partially dismantled fissure ridge where it is possible to characterize in detail the inner, filled in portion along which overpressured hydrothermal fluids can rise upwards.

Presumed age of this structure is surely younger than the fissured Middle Pliocene deposits.

Structural studies on the tectonic context, in which the Semproniano fissure ridge formed, are still in progress and could contribute to the better understanding of the tectonic framework acting in this region during the Quaternary.

ANCIENT STRUCTURES ON THE MARTIAN SURFACE SUPPORT MODELS OF AN EARLY NOACHIAN ROTATING LITHOSPHERE.

CAPRARELLI Graziella¹

¹ - University of Technology Sydney

Presenter e-mail: Graziella.Caprarelli@uts.edu.au

Key terms: Mars; Tharsis; dichotomy; structures; volcanism

Two of the most striking geological features of Mars are the crustal dichotomy, marked by a roughly east-west 2.5-6 km deep scarp bounding the elevated and ancient crust of the southern hemisphere and the smooth northern hemisphere plains; and the Tharsis Rise, host to the Tharsis volcanoes: Arsia, Pavonis and Ascraeus. Tharsis volcanism is characterized by younging of the volcanoes from south to north. To explain the younging of the Tharsis volcanoes and their alignment, approximately perpendicular to the crustal dichotomy, Zhong [2009; 1] proposed that in the Early Noachian single plume convection and lithospheric thickness variations initiated differential rotation of the lithosphere relative to the mantle. The lithosphere would have then rested in its present position when the dichotomy came to lie on the plume. The Martian equatorial bulge generated by the rotation of the planet around its axis should cause faulting of a lithospheric shell rotating on it [2]. Melosh [1980; 3] calculated that the fracture patterns resulting from the stresses induced in a rotating lithosphere by the equatorial bulge are oriented according to NW compression and NE extension in the eastern hemisphere, between Tharsis and the Hellas basin.

Recent work provided evidence consistent with Melosh's [1980; 3] calculations. A detailed examination of a small equatorial area centered at

longitude 111°E (north Tyrrhena Terra), using Mars Express HRSC imagery and altimetry, led Caprarelli et al. [2007; 4] to conclude that the observed dominant NW-SE fabric was associated to 308° azimuth normal faults. At mid-latitudes in the western hemisphere Caprarelli and Leitch [2009; 5], using Mars Global Surveyor and Mars Odyssey data, mapped the volcanic rocks and structures in Pickering Crater, approximately 130 km in diameter, located 131°W-134°W and 32°S-35°S. These authors interpreted the fretted character of the rim of the crater (and of other nearby features) as due to an episode of deformation under a strike-slip tectonic regime with a principal compressive stress oriented either N-S or E-W, pre-dating the emplacement of all observable lava flows and the formation of NE-SW trending grabens. These observations are also consistent with Melosh's [1980; 3] predictions.

Further studies must be undertaken to search other regions of the Martian crust for evidence of structures consistent with a lithosphere rotation model. The main difficulty associated to these investigations relates to the fact that the ancient crust has undergone extensive erosion, resurfacing and more recent episodes of tectonism. Future investigations will focus on the Martian subsurface, where traces of ancient structures may have been preserved.

Key terms: Mars; Volcano; Modelling; Finite Element; Ascraeus Mons

Ascraeus Mons was one of the first of the Martian volcanoes to be imaged by the High Resolution Stereo Camera (HRSC) experiment onboard the ESA Mars Express spacecraft. The volcano is entirely covered by high resolution images (12 m/pixel) where details of lava flows, sinuous rilles, flank vents and tectonic features are clearly recognizable. Concentric fractures systems (pit chains, grabens) around the volcano changing transitionally into radial structures systems were cartographed upon a HRSC mosaic. These structures were dated by crater counts on coeval lava flows using a mosaic obtained by Context Camera images (CTX, Mars Reconnaissance Orbiter mission) with a spatial resolution of 6 m/pixel. The resulting ages range from 60 to 100 Ma.

The observed structures on Ascraeus flanks show strong analogies with concentric dykes (cone sheets) and fractures on many terrestrial volcanoes such as Isla Fernandina (Galapagos), Tejeda Complex (Canary Islands) and Cuillins Complex (Isle of Skye, Scotland). This last terrestrial analogue was studied in detail and the shape and depth of the inflating magma chamber that originated the cone sheets was determined by the use of a Finite Element Method (FEM) modeling. In particular, the shape of the magma chamber was discovered to be oblate in shape. By analogy, we tested the presence of an oblate magma chamber below Ascraeus Mons. The diameter of the transition zone between concentric and radial structures on Ascraeus Mons flanks is strongly related to the diameter of the magma chamber itself. In addition, with a FEM model built for the Ascraeus Mons we find the average depth of the oblate magma chamber, which could have originated the concentric structures. The presence of a plume instead of the magma chamber was also tested.

Presenter e-mail: dvbgeo@uniurb.it

Key terms: COPRATES CHASMA; KARST; EVAPORITE

Coprates chasma is part of the large Valles Marineris canyon system. It forms part of the backbone of the Valles Marineris canyon system, extending approximately east-west for roughly 966 kilometers (600 miles). Coprates Chasma is the longest and deepest of the Valles Marineris troughs system. In the westernmost part of Coprates chasma, next to the borderline with Melas Chasma an embayment on the northern wall can be observed. In the central part of the embayment, a mound of layered material rises from the chasma floor displaying a characteristic dome-shaped morphology.

The mineralogical characteristic of the dome has been previously determined by analysis of the CRISM image HRL00003752. The dome appears to be constituted by magnesium sulphate materials, showing mainly clear signatures of kieserite (MgSO₄ H₂O) an evaporitic mineral also found on the Earth. Further studies carried out on the characteristics and the genesis of Kieserite both on Mars and on the Earth showed that the dome cannot be constituted entirely by kieserite alone but probably it might be constituted also by the same salts that on the Earth alter to kieserite.

In this work we investigated in great detail the surface features of the dome located in the eastern part of TC, with the aim to try to determine

the processes involved in their formation and shaping. The morphological features of the dome have been investigated through the integrate analysis of HiRISE, HRSC, MOC and THEMIS data, while the morphometric characteristics have been measured on a topographic map (100 m contours lines) built using HRSC and MOLA data.

The observation of the dome surface highlights features created by fluvio-erosional and solutional processes. The solutional surface is characterized by landforms typical of the karst morphology such as karren and dolines that strongly resemble the evaporitic karst morphologies found on the Earth. In some part of the dome characterized by lower inclines of the slope, such as, the down slope area in the south-eastern part, we observed that dolines totally pock some parts of the surface and occupy almost all the space, displaying polygonal karst landscapes. Several eolian features are recognizable in the dome surface. They mainly consist of transverse dark sand dunes and dark sand deposits. Depositional forms such as multiple fan-system deposits can be seen at the foot of the slopes, while they seem to be lacking along the dome flanks.

These landforms indicate the presence of liquid water, probably caused by the melting of ice in a periglacial environment, or permafrost rich soil, suggesting that either the material is ice-rich or was so at one time. The landforms might be consistent with responses to climatological change and the presence of liquid water. During the dome history, there was probably only one episode with available water, a geologically short "cool-wet episode" after which there was no water.

A NEW APPROACH TO IMPACT CRATER DATING OF MARTIAN SURFACES.

MAHENDRAN Rathini¹, CAPRARELLI Graziella¹

1 - University of Technology Sydney

Presenter e-mail: Graziella.Caprarelli@uts.edu.au

Key terms: Mars; impact craters; depth; diameter; ages

Meteorites impact the surface of all planets. Planetary bodies with thin or no atmosphere, and with ancient surfaces not extensively reworked by processes such as plate tectonics, are ideal laboratories to study the effect of impacts on their surfaces. Impact craters are broadly classified into three categories: simple, complex and large. The shape of simple craters is that of a simple bowl bounded by a rim gently sloping outward in an apron formed by the material ejected during impact. Complex craters are larger and display a central peak. Large craters, often termed basins when they are extremely large, are extensive crustal depressions, displaying multiple rings and sometimes multiple peaks. When the impact craters are undeformed by subsequent impacts or other geological events, mathematical relations among their morphological features exist.

On Mars the transition between simple and complex craters occurs at a diameter value = 7 km. That between complex and large craters is generally set at ~ 100 km diameter [1]. Using Mars Orbiter Laser Altimeter data to measure the dimensions of thousands of Martian impact craters, Garvin and co-workers [1-3] defined a series of power laws describing the dimensional relations between Martian crater diameters, rim heights, floor depths and crater profiles for simple and complex craters. These power laws represent the theoretical Martian relations between these morphometric parameters, and as such they have been broadly used to draw inferences on the composition of Martian surfaces: an impact crater found to have a larger floor depth than that predicted by Garvin et al.'s [2003; 1] depth - diameter power law must sit in very hard material, such as fresh volcanic rocks. If an impact crater is shallower than predicted, the surface on which the impact occurred should be made of soft material. This conclusion is however valid only if the examined craters are pristine.

Caprarelli et al. [2007; 4] used the depth-diameter power law [3] to subdivide the surfaces in which simple craters were located in their study area in north Tyrrhena Terra into three categories: (1) hard surface / basaltic rocks; (2) soft surface; (3) aged surface (no longer pristine). The work we present here builds on these findings.

We hypothesized that depth-diameter power law calculations for the third category could be used to draw consistent inferences about the age of Martian surfaces. We carried out measurements of thousands of impact craters in three Martian regions characterised by broadly different ages and geological histories: Daedalia Planum (younger), Isidis Planitia, Arabia Terra (older). Our preliminary results suggest that impact crater morphometric relations provide a record of the relative ages of the Martian surfaces we investigated, thus supporting our working hypothesis. Further work is under way to model our results into a set of equations of general applicability.

SERS INVESTIGATION OF EXTRATERRESTRIAL LIFE TRACES: ADENINE ADSORBED ON A MARTIAN METEORITE

MOGGI CECCHI Vanni¹, CAPORALI Stefano², PAGLIAI Marco², PRATESI

Giovanni², SCHETTINO Vincenzo²

1 - Museo di Scienze Planetarie

2 - Università di Firenze

Presenter e-mail: v.moggi@pratoricerche.it

Key terms: Raman spectroscopy; Martian meteorite; SERS; Adenine; Dar al Gani 670

Introduction: Surface Enhanced Raman Scattering (SERS) is a powerful technique for the chemical and structural analysis of minerals and organic molecules. This technique provides a huge enhancement of the Raman

signal by means of the interaction with silver, gold or copper nanoparticles [1]. In recent years, owing to its high sensitivity, this technique has gained an increased attention especially for the study of trace biological molecules.

Since microbial life, if extinct or extant on Mars, would give rise to the formation of biomolecules that could be adsorbed on rocks and sediments, the SERS investigation of nucleic acids is important to understand if and how primitive life originated in extraterrestrial environments. Two main limitations usually impair the employment of the conventional Raman technique for this purpose, the low sensitivity and the occurrence of fluorescence, which could interfere with the observation of vibrational bands. Even if SERS spectroscopy allows overcoming these issues [2,3] its suitability to be used as "in situ" technique for direct investigation on Mars surface still remains to be assessed.

In this contribution we report the results of a SERS investigation on DAG 670 meteorite [4] (Martian shergottite) where adenine, a nucleobase detected in several meteorites [5,6], has been deposited.

Experimental: A thick slide of the meteorite was polished with diamond slurry down to 0.25µm, ultrasonically cleaned with water, rinsed with bidistilled water and air dried. Then, a drop of dilute (~ 10⁻² mol.dm⁻³) water solution of adenine was deposited on the surface. Once the solvent was evaporated a drop of silver colloidal nanoparticles were added.

Results: Aiming to find the optimal experimental conditions for the detection of adenine in a real Martian rock we carried out SERS investigation on three mineralogical phases constituting the main part of the meteorite (olivine, orthopyroxene and ilmenite) by means of three different excitation laser lines; two in the red light region (632.8 nm and 785 nm) and one in the green light region (514.5 nm). In such a way we collect an accurate overview of the Raman signal as function of the substrate as well as the excitation laser wavelength. The results show adenine can be unambiguously identified by detecting the intense SERS band located at ~735 cm⁻¹, which frequency results practically unaffected by the nature of the substrate. However, silicate substrates (olivine and orthopyroxene) result more prone to give intense and sharp peaks respect to the oxides (ilmenite) and therefore they should be preferred for analytical purposes. On the other side, fluorescence phenomena were greatly enhanced when short excitation wavelength were employed turning in a much lower analytical performance for the green light region excitation laser respect to the red ones.

Conclusions: Experimental evidence of the capability of SERS technique to detect traces of adenine on Martian-type rock (Martian shergottite, DAG 670) were provided allowing a clear identification of this nucleobase as small trace (about 10⁻¹g). We also demonstrated the use of red-light laser excitation helps to limit the fluorescence phenomena, while the use of LiCl-stabilised silver nanoparticle does not infer in the technique analytical performance allowing the use of this more stable Ag hydrosol.

Key terms: bloedite; equation of state; icy satellite brine; synchrotron radiation; hydrogen bond

Bloedite Na₂Mg (SO₄)₂·4H₂O is a common mineral in evaporitic marine sediments. Being one of the phases in the system H₂O-MgSO₄-NaSO₄, it has a large planetological interest. In fact, the density variations in the Mg-Na-H₂O system involve many aspects of the petrogenesis and physical volcanology of icy planets. Namely structural models of icy satellites are controversial since the crust-mantle differentiation are based on buoyancy forces not well known especially at different depth.

The bloedite structure consists of parallel layers of MgO₂(H₂O)₄ and NaO₄(H₂O)₂ octahedra, interconnected through SO₄ tetrahedra and hydrogen bonds. The Fundamental Building Block of the structure is the [Mg(H₂O)SO₄-] with finite hetero-polyhedral clusters linked by low-valence cations. The open sheets of these clusters form a structure module that is also common to 4-types structures (bloedite, leonite, anapaite, schertelite).

This paper intends to investigate the HP behavior of bloedite in order to determine the equation of state (EoS), the density evolution and the water storage capability with P as well the evolution of H-bond in comparison with other sulphates.

The HP single-crystal diffraction was carried out on a bloedite gem quality crystal at ID-09 beamline of ESRF (Grenoble). A diamond anvill cell with 600 micron diamond culets, He as P medium and ruby chip as P calibrant was used. A flat panel detector, Mar555 (with a 555mm diagonal active area) allowed a very high quality of collected data. Lattice parameters and reflection intensity was obtained by CrysAlis software and SHEXLX software was used to refine the structure at different P up to 10 GPa. EoS was determined with data collected up to 12 GPa and EOS-Fit programme (Angel, 2000). The second order Birch-Murnaghan EoS fit yields V₀ = 495.6(9) Å³ with a K₀ = 40.5(7) GPa, whereas a third order Birch-Murnaghan EoS fit yields V₀ = 497.6(4) Å³, K₀ = 34(1) GPa and K'

= 5.8 (4) GPa-1. The lattice parameters compressibility are $\bar{\beta}_a = -0.0074$

(4) GPa-1; $\bar{\beta}_b = -0.0069$ (4) GPa-1; $\bar{\beta}_c = -0.0054$ (2) GPa-1 with an anisotropic ratio of 1: 1.07:1.37. The bloedite structure resulted most incompressible along [001], the direction perpendicular to open sheet. The crystal structure refinements showed that the SO₄ tetrahedra are incompressible whereas the bulk modulus of MgO₆ octahedra is 90 GPa and that of NaO₆ octahedra is 42 GPa.

Due to the difficulty to determine the H-position under HP condition by using X-ray diffraction, the H-bond evolution were followed through the measurements of Odonor-Oacceptor distances. The longer distances

O6-O1 and O6-O4 (2.854 and 2.955 Å at 0.001 GPa), have a compressibility ranging from 2.8(9) to 4.4 (7)10⁻⁴ GPa⁻¹, whereas the shortest ones, O5-O1 and O5-O4 (2.715 and 2.742 Å) have a compressibility of 7.7(6) and 9.2(7) 10⁻⁴ GPa⁻¹ respectively. The arrangements of O5-O1 and O5-O4 are along y axis whereas O6-O1 and O6-O4 are along x axis with a strong component along z axis. This configuration explains the large compressibility of a and b parameters with respect to c lattice parameter.

The comparison of structural evolution of bloedite with Ca-sulphate (Comodi et al. 2008), shows similarities and differences. In fact, the bulk moduli of bloedite and gypsum are quite similar, as well as the compressibility of hydrogen bonds. No phase transition was observed up to 12 GPa in bloedite which remains stable at very HP at room condition, whereas gypsum undergo to a phase transition at 4 GPa. The lack of a strong structural rearrangement, essential to compensate the dehydration process, would suggest that water remains in the structure of bloedite in the investigated P range, while the density increase of about 20 per cent over 10 GPa.

Key terms: Mercury; temperature; crystal structure; X-Ray Diffraction; TIR spectroscopy

It is well known that the surface of Mercury shows temperature variations extremely large at specific locations (Strom, 1987). The temperature can range in 44 earth days between 70 and 725 K at different latitudes and such variations affect significantly the crystal structure and density of the minerals present on the surface of the planet. As a consequence, several kinds of remote information linked to mineral structures, including relative spectral signatures, are strictly dependent on the environmental conditions and vary according to the surface temperature. By "looking at the planet" in remote sensing, Mercury may change its outer face through time and from place to place as a function of solar irradiation. This could drive to important misinterpretations and limit our capability of inferring compositions and rheological properties of materials from remote sensing acquisition. Thus, we need to investigate the behavior of planetary geological materials in situ, or under extreme temperature environments, and improve the geological interpretation and compositional inferences by applying the knowledge acquired to the analysis of available remote sensing data. Here we present a new in situ multi-methodological laboratory approach comprehensive of X-ray diffraction (single-crystal and powder materials) and spectroscopy. In particular, we used Thermal Infrared (TIR) spectroscopy, in the range 7 to 14 µm on olivines and clinopyroxenes in order to evaluate if temperature variation may cause the same density variation due to a cation substitution. In such wavelength range the spectra can be used very effectively to identify the fine-scale structural properties of minerals (Hamilton, 2010).

We performed laboratory measurements at the Planetary Emissivity Laboratory (PEL) at the German Aerospace Center (Deutsches Zentrum fuer Luft- und Raumfahrt in Berlin), where is available a high-temperature and vacuum spectrometer, to acquire emissivity spectra of several single mineral phase with the aim to monitor how their specific spectral features changes as a function of temperature, reproducing the most likely environmental conditions of the hermean surface. In fact, although a significant number of minerals have been well-characterized by means of TIR spectroscopy (Christensen et al. 2002) in our knowledge no TIR data acquired at high-temperature have been published so far with the exception of those by Herbert and Maturilli (2009) on a labradorite plagioclase. The PEL has been build up over the last 5 years to study systematically the effect of temperature on TIR spectral signature and build up a new spectral library taking these effects into account. This is of special significance, since the Bepi Colombo mission, scheduled for launch in 2014, will carry the first thermal infrared imaging spectrometer (Mercury Radiometer and Thermal Infrared Spectrometer, MERTIS) to map the surface of Mercury from orbit, acting in the wavelength region from 7 to 14 µm. The instrument is under construction at Deutsches Zentrum fuer Luft- und Raumfahrt and at the same time the spectrometer of the Planetary Emissivity Laboratory is working for real measurements on minerals. The produced data allows to build up a new TIR mineral database that will be extremely useful in interpreting the future data acquisitions by remote sensing.

Key terms: Mercury; VNIR Reflectance; MidIR Emissivity; Basalts

One of the primary objectives of the MESSENGER (NASA) mission, presently orbiting Mercury, and the following BepiColombo mission (ESA and JAXA joint project) is the determination of the surface mineralogy of the hermean planet. To this aim MASCS (Mercury Atmospheric and Surface Composition Spectrometer, on MESSENGER; McClintock & Lankton, 2007), will analyze the reflectance in the 0.2 to 1.4 µm wavelength range, whereas the BepiColombo spectrometers VIHI

(Visible-near Infrared Hyperspectral Imager) will operate in a wider range from 0.4 to 2.0 µm and MERTIS (Mercury Radiometer and Thermal Infrared Imaging Spectrometer) will measure emissivity spectra from 7 to 14 µm (Helbert et al., 2005; Sgavetti et al., 2007; Flamini et al., 2010). Mercury has the largest range in diurnal temperature in the solar system, varying from -173 to 430°C. This extreme temperature excursion is expected to affect the physical processes responsible for the spectral features of minerals and rocks. Recently Helbert & Maturilli (2009) highlighted that the spectra of a labradorite sample show significant changes in spectral features in the mid-infrared with changing temperature. This result suggests that the surface temperature and the thermal history of an observed area must be taken into account in the interpretation of the spectra from an extreme planet such as Mercury. The new MESSENGER's observations have documented that volcanism was important in shaping the surface of Mercury (Head et al., 2009). These new data have shown numerous volcanic vents, in particular around the interior of the edge of the Caloris basin, interpreted as expression of effusive volcanism. A possible shield volcano (100 km in diameter) was suggested, as well as pyroclastic eruptions represented by bright haloes around the vents, particularly distinctive in color data (Head et al., 2009). Moreover the MDIS (Multispectral Dual Imaging System) multispectral images revealed differences in color and thus, possibly, composition of Mercury's crust indicative of lateral and vertical heterogeneities (Denevi et al., 2009).

Here we describe the integrated approach aimed at the spectral characterization of basalts in VNIR reflectance and in the MidIR emissivity, through accurately inter-calibrated data from different laboratories.

We report the preliminary results of a study focused on two basaltic samples from an Etna lava flow collected in different vertical positions within the flow. These samples present similar bulk-rock compositions and mineral phases associations, but different textures, with different degrees of crystallinity, due to the different conditions of crystallization from the inner portion of the lava flow (that has a slower cooling) to the surface (faster cooling, with the formation of a glassy-microcrystall groundmass). Mineral composition has been analyzed by microprobe to relate the compositional characteristics to the absorption band parameters. The samples were spectrally characterized at different grain-sizes and the emissivity measured at three "hot" temperatures.

The VNIR spectra of fine powders reveal a clear absorption band at 1 µm compatible with the presence of pyroxene and olivine (Burns, 1993) for the holocrystalline sample, on the contrary the hyalopilitic sample show a lower albedo and almost featureless spectra. The MidIR emissivity of fine powders show always a CF position at 7.7 µm, and a similar absorption structure between the CF and 12 µm can be observed for both samples.

These preliminary results indicate that an integrated approach can provide a better quantitative determination of the minerals and of their abundances, and will be extremely beneficial to the interpretation of our remote sensing data. The two instruments provide complementary information on composition and texture, which will allow, for instance, to separate different portions of a volcanic lava field with different rock texture and also to improve the interpretation of the surface composition.

Key terms: plagioclase; MGM; EGO; mixtures; Hermean planet

Low contrast reflectance spectra are often observed at the surface of different terrestrial planets. Among other causes we outline the interference of adjacent absorptions bands due to different minerals. While the combined effects of Fe²⁺ absorptions in various clinopyroxene (Cpx), orthopyroxene (Opx) and olivine (Ol) mixtures have been widely studied, the spectroscopic effects of plagioclase have been considered only for <0,26% FeO bearing compositions. Here we show the effects that different modal abundances and chemistry of plagioclase can produce on

the absorption bands of Fe, Mg mineral mixture spectra in the 0.8-1.2 µm spectral region.

We analyzed mixtures with various abundance of multimineral grains and pure plagioclase, separated from cumulate rock of a layered intrusion belonging to the anorthosite kindred. Multimineral grain assemblages with two different compositions represent the Fe, Mg components in the mixtures. One consists of orthopyroxene En82 (28.2%), clinopyroxene En45-Wo46 (3.4%), olivine Fo84 (68.4%). The second one includes clinopyroxene En45-Wo46 (43.9%) and orthopyroxene En77 (56.1%). Three distinct plagioclase compositions were systematically mixed to each starting assemblage, having FeO% concentration of 0.1, 0.36, 0.5. The amount of plagioclase in the mixtures ranges between 20% and 90%.

Mixtures with grain sizes of 63-125 µm and 125-250 µm were prepared,

for a total of 64 samples. Absorption features in the 0.35-2.5 µm wavelength interval were analyzed via decomposition with Modified Gaussian Model- MGM (Sunshine et al., 1990) and Exponential Gaussian Model-EGO (Pompilio et al., 2010) algorithms, to determine band spectral parameters such as center position, band intensity, width and asymmetry. Mossbauer spectroscopy has been used to determine the relative concentration of Fe²⁺ and Fe³⁺ in mafic minerals.

The most relevant results regard the absorption centered at about 1.2 µm in both the olivine bearing and olivine free series. In the olivine bearing

mixtures, the 1.2 µm feature results from the combination of olivine band 3 and plagioclase band. The relationship between the spectral parameters

of 1.2 µm band and the FeO volumetric concentrations shows: 1) for a given Mg/Fe ratio in the Fe, Mg silicates and FeO content in plagioclase, the asymmetry increases positively with increasing plagioclase modal abundance; this trend is superimposed on the expected minimum shift toward longer wavelengths and the band intensity attenuation; 2) for the same Mg/Fe ratio in silicate and different FeO content of plagioclase, the band 1 and 3 intensity ratio increases and minimum moves toward longer

wavelength with increasing FeO content in plagioclase. In the olivine free mixtures, the 1 μm feature can be decomposed using 2 Modified Gaussians assigned to Fe²⁺/M2 sites in orthopyroxene (0.9 μm) and clinopyroxene (1.05 μm). One of the effects of increasing plagioclase volumetric FeO concentration in mixtures is the shift of band center toward shorter wavelength, with the 1.05 μm clinopyroxene center moving more than the orthopyroxene center. In parallel, the 1.25 μm band assigned to Fe²⁺ in plagioclase shifts to longer wavelength and both intensity and FWHM increase. Ongoing work is focused on the analysis of very fine samples of the same mixtures. Both the correlations and discrepancies between spectral and compositional parameters contribute to a better understanding of spectra such as those interpreted as ferroan anorthosites on the Moon, featureless spectra characterizing the Hermean surface, and perhaps other spectra observed on different small bodies.

Key terms: ROSETTA-OSIRIS; LUTETIA; STRATIGRAPHY; GEOLOGICAL MAP; ASTEROID 21

The OSIRIS images acquired during the recent Rosetta fly-by of Lutetia (10th of July 2010), enabled us to unravel the long geological history of the asteroid. This is recorded on its highly varied surface which displays geological units of disparate ages. In particular, using images of the closest approach, five main regions (in turn subdivided into minor units) have been discriminated on the basis of crater density, overlapping and cross-cutting relationships and presence of linear features (i.e. fractures, faults, grooves, troughs). Other regions, with still unclear stratigraphic position, were also recognized on images of lower resolution on the bases of geomorphological properties such as crater density, relationship with scarp and ridges and sharp morphological boundaries. In this work the geological evolution of Lutetia surface is reconstructed through the description of its main units and related contacts.

The oldest regions imaged during the closest approach (Achaia and Noricum) are pervasively affected by fractures and grooves and display surfaces so heavily cratered to be dated back to a period not far from the Late Heavy Bombardment (yielding Achaia a crater retention age of 3.5 Ga). A crater of 60 km of diameter, named Massilia and corresponding to the Narbonensis region, cuts both Achaia and Noricum regions and probably represents the most prominent event of the Lutetia history. Nonetheless it looks quite old as testified by the high crater density on its floor and walls, the absence of discernable deposits related to the impact event, and the intense deformation of its floor. What appears really young (less than 1 Ga) is the North Poles crater cluster (Baetica Region) associated to smooth ejecta broadly mantling the surrounding units and displaying few craters and no linear features. The North Pole cluster is the product of superimposed impacts; the last one of 21 km of diameter excavated the pre-existing ejecta up to the bedrock which locally outcrops at the crater rim. The ejecta of this last impact were involved in several gravitational phenomena testified by the great variety of deposits made up of mega-boulders diamictons, fine materials, gravitational taluses and landslide accumulations. A part from the big cratering events generating Massilia and the North crater cluster, the Lutetia geological history is also punctuated by minor events still recorded by its stratigraphic record well imaged by the closest approach data.

GEOLOGICAL MAPPING OF THE DAEDALIA PLANUM LAVA FIELD THROUGH MORPHOLOGICAL AND SPECTRAL ANALYSIS

GIACOMINI Lorenza¹, CARLI Cristian², SGAVETTI Maria³, MASSIRONI Matteo¹

- 1 - Università degli Studi di Padova
- 2 - INAF-IASF, Roma
- 3 - Università degli Studi di Parma

Presenter e-mail: lorenza.giacomini@unipd.it

Key terms: Volcanism; Lava flow morphologies; Spectral analysis

Daedalia Planum is a plain located south west of the Arsia Mons where more than 1500 km-long lava flows were emplaced, over an almost flat terrain (<0.5° and commonly <0.1°). We have analyzed the area from different points of view, beginning with a stratigraphic study and a deep investigation of the flow surface morphologies and concluding with a spectral analysis of the region. By analyzing the higher resolution images of Mars Odyssey THEMIS VIS and IR, Mars Global Surveyor's MOC and MRO/HIRISE images several different morphologies among the lava flows were distinguished. The oldest ones include the most widespread flows of the area showing the typical pahoehoe and platy-ridged surfaces textures whereas the youngest units are represented by numerous narrow lava flows with central channels or with brecciated surface. The high ground-resolution of MOC and HIRISE allowed us to detect in some lava flows several morphological features recalling inflation fingerprints, like tumuli, lava rises and lava ridges. On the base of these morphological differences and stratigraphic relationships among the flows different geological units were distinguished on the Daedalia Planum lava field.

The great variety of morphologies observed on the Daedalia Planum lava flows encouraged a detailed study of their spectral characteristics, in order to obtain some information about lava composition and detect possible differences in the flows spectra. The OMEGA spectra collected in the lava field appear rather similar, with absorptions between 0.8 and 1.4 μm and

1.8 and 2.5 μm , suggesting the presence of mafic minerals, which are typical primary mineral phases of volcanic rocks. Moreover, after the continuum removal, we highlighted the presence of two classes of spectra both compatible with tholeiitic basalts but with different content of Ca in the pyroxene. Above the similar absorption bands, however, Daedalia spectra show also some differences in albedo and spectral slope. By employing the average spectra of the different flow units as endmembers, a SAM classification was performed. The resulting spectral map reveals a good relation between spectral behavior and surface textures of the flows. By integrating the morphologic and spectral units a new geologic map of the area was obtained allowing us to demonstrate the great potential for improving Martian geological maps by integrating morphological and spectral characteristics of the surface.

Presenter e-mail: matteo.massironi@unipd.it

Key terms: Crater Chronology; Mercury; Basins; Layering; Physical properties

Raditladi and Rachmaninoff basins are peak-ring basins of about 250 km in diameter discovered during the first and third MESSENGER flybys of Mercury. Both basins have a relatively fresh appearance with continuous smooth plains within a peak ring structure. A crater age determination has been performed using the Model Production Function (MPF) on several terrains associated with these basins. Our analysis constrains the formation age of Rachmaninoff and Raditladi basins to about 3.6 Ga and 1.1 Ga, respectively. In addition, the age of the smooth plains within the Rachmaninoff basin's floor suggests a volcanic activity until very recent time (possibly to about 1 Ga or less), whereas the plains related to Raditladi appear coeval with the basin itself and most probably of impact origin. MPF enable us to retrieve some useful insights also on the target layering beneath the surface. Therefore, with this work we address the importance of considering terrain parameters, as geo-mechanical properties and layering, into the process of age determination.

STATE OF THE ART OF GROUND AND AERIAL LASER SCANNING TECHNOLOGIES FOR HIGH-RESOLUTION TOPOGRAPHY OF THE EARTH SURFACE

PIROTTI Francesco¹

- 1 - CIRGEO - Interdepartmental Research Center for Cartography, Photogrammetry, Remote Sensing and GIS

Presenter e-mail: francesco.pirotti@unipd.it

Key terms: Terrestrial Laser Scanner; Airborne Laser Scanner; Digital Terrain Models (DTM); Point cloud accuracy

Airborne and terrestrial laser scanning (respectively ALS and TLS) have become, in the past years, well established technologies for measuring spatial characteristics of objects on the earth surface and the geometry of the earth surface itself. Research and development have created the technology for providing a market with a wide choice of instruments. The distinctive data produced by laser scanners is a 3D point cloud with high-quality positional and return-related information (3D coordinates, reflectance, return echo ordinal number etc...). Partially obstructed impulses give multiple returns, thus important added value to the dataset, by penetrating gaps which are present in certain elements (e.g. vegetation) and reflecting the ground surface as last return. In the last years sensors have been developed which provide the digitization of full return waveform. This capability provides significant data for sophisticated classification and reflectance calibration of the targets and a practically infinite number of return targets per emitted pulse (Briese et al., 2008). Terrestrial and airborne laser scanning share many features related to scanning mechanisms and processing methods whereas they also differ in terms of accuracy, range, data-capture modes and project size (Vosselman and Maas, 2010). In this presentation a comprehensive overview of airborne and terrestrial laser scanning technology and processing is presented focusing on aspects related to high resolution topography of the earth surface. Accuracies, error budgets, and processing methods to improve and assess quality of the scan are reported to give an outline of the potential of current laser scanner sensors for providing high resolution models of the earth surface.

2 - Dipartimento Interateneo di Fisica, Politecnico di Bari
3 - CNR-ISSIA

Presenter e-mail: raffaele.nutricato@gapsrl.eu

Key terms: COSMO/SkyMed; DEM; Interferometry; High resolution

DEM products for Earth observation space-borne applications are being to play a role of increasing importance due to the new generation of high resolution sensors (both optical and SAR). These new sensors demand elevation data for processing and, on the other hand, they provide new possibilities for DEM generation.

Till now, for what concerns interferometric DEM, the Shuttle Radar Topography Mission (SRTM) has been the reference product for scientific applications all over the world. SRTM mission [1] had the challenging goal to meet the requirements for a homogeneous and reliable DEM fulfilling the DTED-2 specifications.

However, new generation of high resolution sensors (including SAR) pose new requirements for elevation data in terms of vertical precision and spatial resolution. DEM are usually used as ancillary input in different processing steps as for instance geocoding and Differential SAR Interferometry.

In this context, the recent SAR missions of DLR (TerraSAR-X and TanDEM-X) and ASI (COSMO-SkyMed) can play a promising role thanks to their high resolution both in space and time. In particular, the present work investigates the potentialities of the COSMO/SkyMed (CSK) constellation for ground elevation measurement with particular attention devoted to the impact of the improved spatial resolution wrt the previous SAR sensors. The recent scientific works, [2] and [3], have shown the advantages of using CSK in the monitoring of terrain deformations caused by landslides, earthquakes, etc. On the other hand, thanks to the high spatial resolution, CSK appears to be very promising in monitoring man-made structures, such as buildings, bridges, railways and highways, thus enabling new potential applications (urban applications, precise DEM, etc.).

Both SPOTLIGHT and STRIPMAP acquisition modes are analyzed through standard SAR Interferometry as well as multi-pass interferometry [4].

Acknowledgments

3D SURVEYING AND MODELING VERTICAL CLIFFS FOR GEOLOGICAL AND MAPPING PURPOSES

REMONDINO Fabio¹, ZUCCA Francesco², PELOSO Christian³, AGUGIARO Giorgio¹, RIZZI Alessandro¹

1 - FBK Trento
2 - University of Pavia
3 - Helica

Presenter e-mail: remondino@fbk.eu

Key terms: vertical cliff; oblique scanning; LIDAR; Dolomites; reflectance

The article describes the challenging work of 3D surveying and accurately modeling of the vertical cliffs of the "Tre Cime di Lavaredo" (Dolomites mountains). The Tre Cime di Lavaredo are often considered the "true" icon of the Dolomites, because they fully represent, with their shapes and colors, the concept itself of the UNESCO's site and are a typical example of landforms linked to morpho-selection. More specifically the vertical cliffs in Lavaredo show a morpho-tectostatics shape determined by the trends of important displacement and fracture lines and related belts of cataclastic rocks, which facilitate differential weathering and erosional processes. The vertical dimension of these and similar mountain complexes are usually unmapped and poorly resolved in cartographies which are typically produced using nadir acquisitions and surveying. The goal of the project called "Peaks-3D" is the highly detailed 3D surveying of the "Tre Cime di Lavaredo", especially their vertical cliffs, nearly 600 meter high, for digital documentation and conservation, geological and geomorphological analysis, tourism and communication purposes, 3D mapping of the ascent routes, etc. The digital recording of the current situation and the monitoring of ongoing processes are fundamental prerequisites for analyses and establishment of sustainable measures of protection.

The 3D recording is based on a fusion of oblique airborne and terrestrial 3D laser scanning, in order to survey all the relief complex, focusing especially on the vertical cliffs. The aerial acquisitions were performed with the patented Helica system composed of an Optech sensor coupled with a GNSS/INS unit, a Rollei digital camera and a NEC infrared digital camera. The oblique mounting of the laser scanner allows the detailed surveying of complex sites where a traditional nadir acquisition would not be sufficient. To overcome some recording gaps of the airborne surveying, primarily due to occlusions and hidden rock features, two terrestrial field campaigns were necessary. The aerial and terrestrial range data were afterwards co-registered and merged into a unique and seamless 3D point cloud, considering the multi-resolution data and the 3D geometry (not 2.5D). Then, in order to produce photo-realistic 3D results, digital images were mapped onto the 3D geometric data. The availability of accurate and detailed 3D model over such complex cliffs offers the opportunity to systematically study relationships between relief shapes (e.g. rock faces) and the network of planar discontinuity (e.g. faults, fracture, joint and bedding) that can be extracted from the unstructured 3D point clouds or polygonal mesh. The acquired geometric data provided fundamental information to study slopes, stratigraphy and produce accurate and detailed mapping products. The range data delivered also information

regarding the intensity of the surveyed scene that is, in principle, proportional to the surface's reflectance and depends on the physical and chemical properties of the surface. Experiments on reflectance series obtained from TLS data show intensity variations along a stratigraphic section and give an estimate of the rock content variations during the geological time, highlighting cyclicities that can represent the clue of sedimentary cycles. The analyses of the acquired thermal images showed also interesting temperature changes. Results of the geometric modeling and geological analyses will be presented and discussed.

CREST AND TOE AUTOMATIC EXTRACTION IN TLS SURVEY IN CAVE AND MINING SITES

SGRENZAROLI Matteo¹, CAMPANELLA Marco¹, FIOCCO Marco¹, VASSENA Giorgio Paolo Maria²

1 - Gexcel srl
2 - University of Brescia - Gexcel srl

Presenter e-mail: giorgio.vassena@unibs.it

Key terms: crest and toe; volume extraction; TLS

The paper deals with an innovative approach to the crest and toe automatic extraction from TLS cave and mines sites. The software to manage data coming from Terrestrial laser scanning acquisitions, are often limited to the countour lines extraction. On the other side few software solutions provide the crest and toe automatic extraction that is often an important request from the geologist working on the field. The paper deals with a new software approach able to easily manage the 3D scanned data, to evaluate volumes, countours line and the automatic extraction of the crest and toe informations. The paper describes also the approach for ICP scans alignment and how to manage data coming from different sensors.

Presenter e-mail: andrea.lingua@polito.it

Key terms: data recording; geological survey; Solid True OrthoPhoto; Quaternary; Germanasca Valley

In the modern geological mapping activities, geomatics technologies can facilitate data collection during the field survey and avoid practical problems related to the data transfer to the topographic map.

These improvements appear particularly important in the geological survey aimed at the production of geological maps which can present many types of information at different levels of detail; a basic map records the rock and landform distribution in a given area and may be a key for the evaluation of the geological history.

Printed geological map can be produced with a GIS layout. Several practical problems can arise during a field survey, particularly during the survey data transfer to a topographic map. The geological bodies, landforms and structures (e.g., outcrops, geological boundaries, scarps, trenches, faults, tectonic contacts) can be incorrectly plotted, especially where the available map is outdated or insufficiently detailed. Structural measures or sampling points can also be erroneously plotted where the surveyor position is not precisely determined. Portable instruments such as GPS and laser distance meters can reduce such errors, but the Solid True Orthophoto (STOP) can minimize the difficulties and sources of inaccuracy encountered during the field survey.

The STOP is a new product that integrates an orthophoto (2D photographic map) with the height values derived from the Dense Digital Surface Model (DDSM) generating georeferenced 3D information. In fact, STOP can be view using an experimental software tool, developed by the authors in Visual Fortran that includes simple query functions, a 3D coordinate viewer, some measurement commands (e.g., angles, 3D distances, areas, planes, volumes), georeferenced note and comment record utilities.

This viewer can be used on a simple netbook or tablet PC permitting the surveyor to acquire, directly on the field, the 3D geological information in a rapid, comprehensive and accurate way. In fact, the GSTOP (GNSS STOP) viewer can manage, in real time, a direct connection with navigation sensors as a low cost GPS/GNSS receiver to define the current location and a low cost IMU sensor to measure attitude angles (heading, pitch and roll) of PC: inside the STOP, the user can view his position (a red circle) and the azimuth of line of vision (a red arrow) and generate a 3D solid image in order to be compared the effective scene.

The application was used to produce a detailed geologic map and the reconstruction of Quaternary evolution of the area. The STOP viewer was tested by producing a digital map of the Quaternary sediments and landforms in a 3-km² area of the Rodoretto Basin, a minor tributary of the Germanasca Valley, shaped in the greenstone and schist of the Piemontese zone (Northwestern Italy).

The Quaternary sediments and landforms in this area was essentially the result of the alpine glacial expansions and gravitative deformations. The previous geological literature did not refer any glacial and gravitative evidence. The production of a new geological map thus focused on the relationships among the landforms and sedimentary bodies that developed during the Quaternary evolution.

In detail, a wide, deep-seated gravitational slope deformation was defined, with evidence of many trenches of various sizes, doubled ridges, and slide scarps. Some glacial evidence, such cirques, lateral and frontal morainic ridges and outwash incisions, was also pointed out, connected to small local Pleistocene glaciers.

APPLICATION OF MODERN TECHNIQUES FOR THE CREATION OF QUATERNARY GEOLOGIC MAP OF MENDRISIO (1373-MENDRISIO SHEET, SOUTHERN SWITZERLAND)

SOMA Linda¹, AMBROSI Christian¹, BERNOULLI Daniel²

1 - SUPSI, Istituto Scienze della Terra

2 - Institute of Geology and Paleontology, Basel University, Basel, Switzerland

Presenter e-mail: linda.soma@supsi.ch

Key terms: landslide; Southern Switzerland; ArcGDS

The Swiss Federal Office of Topography (swisstopo) tasked SUPSI with the creation of the geologic map of quaternary deposits for Mendrisio (1373 - Mendrisio Sheet), part of the Geological Atlas of Switzerland (swisstopo, 2003). The referenced area is located in the Southern part of Switzerland, between Lake Lugano to the North and Lake Como to the East.

The research team has already completed the data integration of quaternary deposits into the 1:25.000 scale geologic map sheet. The map, made using ArcGIS 9.3 software, contains data collected and processed during geological surveys with maps in scale 1:10.000 and integrated with previous GESPOS (IST-SUPSI database) drilling and bibliographic data (Bini et al., 2001).

Modern techniques were used during the data acquisition phase, such as landslide photointerpretation and 2-meter Digital Elevation Model (DEM) analysis to recognize and characterize shapes present in the Mendrisio area. Applying a 2-meter DEM gave the team the advantage to derive additional spatial data, which through ArcGIS tools can help develop hill shades, slopes, landforms and topographic profiles, recreating the territorial complexity. With this new data, the system is able to display different hill shades, orthophoto information, various slope categories, and additional isohypses.

In order to define landslide boundaries, the team used ArcGDS, a new extension of ArcGIS that permits collection, editing and update of 3D features using a stereoscopic 3D interface. This innovative approach may replace traditional stereographic methods in the future as it results in more detailed features. In addition to 2D (X-Y plane) data, ArcGDS captures altitude data (Z) by continuously connecting points in superposed images.

A lithostratigraphic method was applied to distinguish deposit types. Glacial and fluvioglacial deposits were also characterized using the Late Glacial Maximum (LGM) (Ivy-Ochs et al., 2008). To distinguish deposits older than LGM or contemporary to LGM, the team used alteration of granitoid clasts, depth of decarbonation profile, and pedogenic development as categorization criteria.

The followed approach has resulted in the creation of Mendrisio's digital geologic map with a greater level of homogeneity (2-meter DEM) than traditional methods and allows to recognize easier big landslides. The overall process may become the standard for future map development and open the door for the advancement of future technologies.

HR-DTMS, GEOMORPHOMETRY AND LANDSCAPE MANAGEMENT: THE PRICE AND THE VALUE OF HIGH RESOLUTION.

TREVISANI Sebastiano¹

1 - UNIVERSITY IUAV OF VENICE

Presenter e-mail: strevisani@iuav.it

Key terms: engineering geology; high resolution DTM; geomorphometry; surface texture

The last decade has shown a growing interest toward the characterization of the landscape and the related hydro-geological processes. A main step in this direction is the quantitative and detailed characterization of solid earth surface topography. From this perspective the new technology based on airborne LIDAR plays a pivotal role, making possible the derivation of high resolution digital terrain models (HR-DTM) of regional coverage. For example, the "Autonomous Province of Trento" (area 6500 km²) is completely covered by a HR-DTM with cell size of 2 m (1 m for the urban areas).

The availability of HR-DTMs opens new prospects in many aspects of the applied earth sciences: from the geological/geomorphological mapping to the quantitative characterization and modeling of hydro-geological processes. However, the added value of high resolution has a price: advanced geo-computational methodologies are needed to fully exploit the high informative content of the HR-DTMs. In this context the geomorphometry, the discipline of quantitative analysis of solid earth surface, plays and will play a key role in the next future. Another relevant point, relies on the fact that the high resolution available poses special challenges from the side of field validation of the elaborations performed. This presentation is aimed to outline some of the most relevant potentialities and issues related to HR-DTMs information retrieval in the context of hydro-geological issues.

THEORETICAL AND PRACTICAL ASPECTS IN LANDSLIDE MONITORING USING TERRESTRIAL LASER SCANNING TECHNIQUE

BARBARELLA Maurizio¹, FIANI Margherita²

1 - DICAM - Università di Bologna

2 - DICIV - Università di Salerno

Presenter e-mail: m.fiani@unisa.it

Key terms: LiDAR; Monitoring; Landslide; DTM; Reliability

The Pisciotta landslide (Sa) causes extensive damage to both an important state road and two railway sections of the Tyrrhenian line connecting North and South Italy. Because of the effectiveness of the LiDAR technique in surveying large areas in a fast, low-cost and quick way, it could be a viable alternative to the traditional surveying methods. We carried out a LiDAR "zero" measurement and about three months later a repetition measurement using a long-range terrestrial laser scanner. In order to survey the top of the landslide area the laser stations can be located in a few points on the stable side facing the landslide at several hundred meters away from the area. During each survey two GPS antennas are mounted on two pillars in order to connect them to both the external stable frame, to the laser stations and to a number of targets which are located in the landslide area.

These two points are not sufficient to establish a stable frame. Some other points located ahead of the landslide have therefore been chosen and linked by means of static GPS measurements to four permanent GNSS regional stations and to other points on the landslide surface. These locations must be visible from multiple laser stations. On each of them a spherical calibrated target must be mounted and it must be recognizable

in the laser strips. The target positions are then measured by GPS and these points are thus the "double points" needed to frame all the laser measurements in a single reference one.

Once these steps are done a number of DTMs of the landslide body are available. Once all surveys have been framed it is possible to compare DTMs at different times, by interpolating the point clouds on a grid in order to identify and analyze over time the areas of greatest deformation and the directions of landslide movement. We also made a number of "local" analysis in the lower part of the landslide. For these analysis we assumed that both upstream and downstream railways tunnels, clearly visible on the scans, may not have moved significantly in the time elapsed between the two surveys, and hence they can be considered as a stable reference. The alignment of the two laser scans gives us satisfactory results in terms of precision and we have been able to measure ground motion of even 50 cm in absolute value.

The former two laser surveys brought to light a strong dynamic of the slope but also highlighted some difficulties mostly due the limited precision of the laser scanner. Other difficulties are related to the targets measurement and above all to the presence of canopy. This is why a further measurement campaign was carried out in the spring of 2011. In the latest survey we also used a laser instrument able to analyze the calibrated relative reflectance in the attempt to filter the effect of the obstacles and thus to generate easier a DTM starting from the DSM acquired. In the third campaign we used a Riegl VZ-400 instrument for surveying the upper part of the landslide, the most troubled due to the presence of canopy, and a Leica C10 in the lower part where natural ground motion and man-made actions have bared the soil making easier the shape reconstruction.

The latest generation of TLS systems, similar to airborne sensors, records the sampled waveform of the echoes of the emitted laser pulse (full-waveform TLS). Thus, extracting multiple echoes and deriving several reflecting surfaces becomes possible.

Using two different kinds of laser scanners (full waveform and traditional mono-eco) on the same portion of landslide allow us to make interesting comparisons between the two methodologies for landslide monitoring in a real-world context, where the presence of the vegetation can cause a loss of reliability.

LANDSLIDES AND MOUNTAINS 3D ANALYSIS AND SURVEY, OBTAINED MERGING TERRESTRIAL, AIRBORNE AND CAR-MOBILE LIDAR DATA

VASSENA Giorgio Paolo Maria¹

1 - University of Brescia

Presenter e-mail: giorgio.vassena@unibs.it

Key terms: volume extraction; LIDAR; multiplatform; LANDSLIDE; VIRTUAL SCAN

The paper deals with a study where lidar data coming from Terrestrial Laser scanners, airborne lidar sensors and mobile systems (Lidar sensors mounted on a car) are combined to obtain one single 3D model. The data are managed using the software developed by the University of Brescia and its Spin Off Company, and uses the innovative "virtual scan" approach, where the data coming from different platforms, are resampled at a regular grid as taken from one single global "Virtual Scan". The Terrestrial data comes from different sensors. The project is georeferenced using GNSS data and managed directly in Cartographic UTM system. The paper also describes how the data can be fully transmitted and measured by internet, in full resolution so to be shared and by different technicians and experts.

The paper describes the method applied to a real dataset of lidar data. The papers ends describing the approach used to extract countour and break lines and to evaluate the volumes of the material interested in the slide.

INTEGRATED HIGH RESOLUTION DTMS TO DEFINE GEOMORPHOLOGICAL FEATURES OF ROCK SLIDES

BERTACCHINI Eleonora¹, CAPRA Alessandro¹, CASTAGNETTI Cristina¹,

RIVOLA Riccardo¹

1 - DIMeC - University of Modena and Reggio Emilia

Presenter e-mail: cristina.castagnetti@unimore.it

Key terms: High resolution DTM; Geomorphology; Rock slide; LiDAR; TLS

The Digital Terrain Model (DTM) is a very important tool for a good and reliable description of the geomorphology of a landslide to study and analyze the phenomenon itself along with the way it changes during time, the volumes transportation, the boundaries evolution and further interesting information by means of the comparison of a number of them. The fastest way to have a large amount of information is using a laser scanner which allows the measurement of millions points to carefully describe a large area. However, landslides often present a complex morphology and a wide extension so that it is not easy at all to perform the survey by means of a single technique: the integration between airborne LiDAR and terrestrial laser scanner (TLS) allows to extract high resolution DTMs. The power of LiDAR methodology is highlighted when a large area is involved and/or when a lot of vegetation covers the area, anyway some problems exist, such as the bad resulting DTM when vertical walls of rock need to be surveyed. In this case, few points can be detected by the flying airborne, as a consequence a not reliable description of the wall and a not complete DTM result. Rather than this, the long-range TLS technique can generally acquire point clouds with higher resolution and accuracy if compared to the airborne laser scanner, especially when the observed objects are perpendicular with respect to the laser beam direction such as vertical wall of rocks. One of the main features of airborne LiDAR is that the laser beam can easily reach the ground due to its vertical position of measurement and this allows a more reliable result for dense vegetated areas. The integration between the mentioned technologies appears to be the best choice to provide a high resolution DTM.

The case study, which will be fully presented, is the Collagna Landslide that is located in the North Appennines (Reggio Emilia, Emilia Romagna - Italy). This large scale composite landslide area is made by both a wide rock slide sector affecting more than 2 million cubic meters of calcareous rocks and a more limited earth slide sector that, that, after high precipitation rates, disrupted the National Road 63 in proximity of

Piagneto, Collagna (RE, Italy) in December 2008. According to the previous description, this is the perfect example for testing the integration of the two technologies: LIDAR will survey all the area, carefully describing the ground hidden by vegetation thanks to its vertical view, while TLS will provide a detailed description of the vertical walls of rock thanks to its frontal view. A detailed comparison among several DTMs, each one resulting from different dataset collected over time, will be presented. Such analysis will allow to carefully identify changes in terms of morphology. It will also be helpful to compute the volume transportation and make hypothesis about future processes or at worst for the collapse of rock blocks. Comparing surfaces is not easy at all, thus a discussion about the encountered problems will be taken into account.

MULTIPLE CHANGE DETECTION TECHNIQUE FOR EVENT SHALLOW LANDSLIDE RECOGNITION AND MAPPING.

MONDINI Alessandro¹, CHANG Kang-Tsung², GUZZETTI Fausto¹

1 - CNR IRPI (Italy)

2 - Kainan University (Taiwan)

Presenter e-mail: alessandro.mondini@irpi.cnr.it

Key terms: remote sensing; change detection; landslides; classification; semi-automatic

An important part of the modern landslide research is the semi-automatic recognition and delineation of landslides at the catchment scale, which has increasingly been based on high and very high-resolution (HR and VHR) satellite images in recent years. This study presents a new method that exploits VHR panchromatic and HR multispectral satellite images and combines change detection techniques for mapping shallow landslides. Combination is carried out through unsupervised methods or multivariate models supervised by ancillary information or expert actions. The models classify each image element (pixel) in stable or unstable areas or assign the probability that the pixel contains (or does not contain) a new landslide. Results are further filtered through morphometric constraints, sieving, and clumping processes. We applied the multiple change detection (MCD) technique to map landslides triggered by two typhoons of vastly different magnitudes in Taiwan (2008 and 2009) and to map landslides triggered by strong rainfall in Messina (2009). Results are compared to pre-existing inventory maps and performances of the models are evaluated using four-fold plots and receiver operating characteristic curves. Further developments plan the exploitation of a priori knowledge of morphometric parameters obtained from very high resolution Digital Terrain Models, in a Bayesian framework. The proposed method is fast and it facilitates the rapid production of accurate landslide event-inventory maps over large areas, when event landslides leave features on the land cover, and the land cover changes are impressed faithfully in the post-event images. Application of the method advances our ability to evaluate landslide hazards, and fosters our understanding of the evolution of landscapes shaped by mass-wasting processes.

UNCERTAINTY ESTIMATION IN DIFFERENCE OF DEM ACHIEVED USING GNSS AND PHOTOGRAMMETRY SURVEY. APPLICATION ON CECINA RIVER (TUSCANY, ITALY)

AUDISIO Chiara¹, DUCI Gabriele², SCOZZAFAVA Rosaria³, TERUGGI Liliana⁴, ZILIANI Luca⁴

1 - University "G. D'Annunzio" - Chieti and Pescara (Italy)

2 - University of Pavia

3 - University of Florence

4 - University of Padua

Presenter e-mail: chiaraudisio@gmail.com

Key terms: Difference of DEM (DoD); fuzzy logic; Cecina River; Italy

The study of rivers has assumed growing importance over the last twenty years with an implementation over the last decade, mainly due to legislative awareness on river environment enhancement and fluvial geomorphology knowledge. Recently studies focused on morphological fluvial changes and processes has emphasized the need to evaluate the uncertainty associated to fluvial morphometry firstly using maps and aerial photo but also with Digital Elevation Models (DEM). Concerning topographical river measurements, instruments and methods available (total stations, photogrammetry, GNSS, LIDAR, TLS) imply different time consuming, number of operators, skills and budget, but also different levels of precision. All these provide a three-dimensional representation of the field by DEM achieved using suitable software. The questions to be asked are: how could we consider different uncertainty associated to digital models obtained by measurements done with different instruments? If we want to analyze morphological and volumetric variations along a river, or rather the Difference Of DEM (DoD) obtained with different instruments and surveys, what is the mistake that we are making? How good is our morphological changes estimation and sediment budget at reach scale too?

These questions have been tempted to write a response from a method developed by Joe Wheaton through the use of fuzzy logic system. As a matter of facts, the author proposed a method for the estimation of morphological changes using a fuzzy interference system in order to quantify the spatial variability of elevation uncertainty in individual DEM and DoD as well.

The application of the method was carried out on a stretch of about 2 km along the Cecina River. The Cecina River drains a 905 km² basin in Tuscany (central Italy) and its channel is about 53 km long. In the selected reach, the channel is incised in gravel deposits and shows a single-channel thread along two bends of meander. The basin is characterized by calcareous and clayey rocks in the upper part and pelitic in the medium part.

The decision to apply this method on this river reach is due to the availability of three DEM obtained by three different surveys (2007, 2009 and 2010) with two distinct methods. The 2007 and 2010 surveys were carried out with two GNSS measurements, while the 2009 DEM derived a photogrammetric survey. In addition, the river was affected by two floods in March 2009 and January 2010 which have significantly changed the morphology of the site. The work shows the results of the method and discusses the goodness of the DEM used for evaluating the hydromorphological changes along the river.

The determination of elevation uncertainty could be useful to define error

committed in geomorphological measures and, as a consequence, can improve morphological changes and sediment budget evaluations related to short period of time and single flood event. The contributions of the authors to this work can be considered equal.

3 - Geomatica & Ambiente s.r.l. - viale dell'Università 16, 35020 Legnaro (PD) - Italy

Presenter e-mail: giulia.sofia@unipd.it

Key terms: LIDAR; Drainage Network; High-resolution DTM; Feature extraction; Agrarian landscape

Drainage networks in agrarian landscape within floodplains constitute man-made surfaces discontinuities, and they are expected to affect hydrological response during flood events. Drainage network recognition and quantification of water storage capacity within drainage channels, becomes therefore crucial for watershed planning and management. These evaluations require accurate spatial information for the area of interest and in most cases, when studying large catchments, broad datasets of ditches locations and descriptions are not available. In order to characterize drainage networks for large areas, the availability of high resolution topography (DTMs) derived by airborne laser scanner (LiDAR) represents a new tool for drainage systems recognition. LiDAR derived DTMs have been proven to be reliable and accurate for hydrological applications in steep mountain landscape in several recent researches (Sofia et al. 2011, Tarolli and Dalla Fontana, 2009), where the topographic information has been considered at different resolution scales. Only a few studies have been conducted to take into account the specific characteristics of agrarian landscapes, and drainage network identification for agrarian/urbanized areas actually represent the next challenge when using high-resolution topography. The accuracy with which a DTM is able to detect and correctly represent the hydrological asset of a catchment is determined by the strength of the landscape gradient (i.e. flatness and/or slope changes). Alluvial plains are therefore more challenging even when high-resolution DTMs are available: for these environments, network extraction through GRID-derived flow-direction matrices is not applicable due to the low relief of the landscapes. The goals of this research were to propose a method able to (1) identify drainage networks in agrarian/floodplain context, and (2) to estimate some of the network summary statistics (i.e. network length, width, drainage density and storage capacity). A morphometric and semi-automatic methodology is proposed, that relies on consideration of having to extract local small-scale, low-relief features (ditches and channels) and to eliminate as far as possible the large-scale landscape forms from the data. The procedure is applied in two typical alluvial plains areas in the North East of Italy, and tested comparing automatically derived network information with field surveyed ones. The results underline the capability of high resolution topography for drainage network extraction and characterization in the context of agrarian landscapes within floodplains, opening at the same time a new challenge to evaluate hydrological processes in these areas.

TOPOGRAPHICAL DIFFERENCES BETWEEN STATIC AND MOBILE ARMOUR LAYERS

MAO Luca¹, COOPER James²

1 - Faculty of Science and Technology, Free University of Bozen-Bolzano (ITALY)

2 - Department of Geography, University of Sheffield (UK)

Presenter e-mail: luca.mao@unibz.it

Key terms: laser scanner; laboratory; armouring; gravel-bed rivers

Gravel-bed rivers typically exhibit an armoured surfaces covering a finer subsurface mix of sediments. The coarser surface has implications for hyporheic flow exchange, fish habitats, and bedload transport estimation. The armour is called static when it is created by a flow that selectively entrains only the finer elements from a non-uniform bed material. Static armour is typical in limited sediment-supply systems, and can be created in laboratory exposing a non-uniform mixture to a constant flow rate with no sediment input. Conversely, a mobile armour layer can coexist with the transport of all available grain sizes, including the coarsest, and its development has been explained using the concept of equal mobility of all grain sizes of a heterogeneous gravel bed. Mobile armours have been developed in sediment recirculating flumes, and the bed surface coarsening is mainly caused by a kinematic sorting process.

A series of laboratory flume experiments under conditions of sediment starvation (zero sediment feeding) and recirculation were conducted in order to identify the temporal evolution and surface properties of static and mobile armour layers. The experiments were carried out in an 8m long flume using a bimodal grain-size mixture (D50 = 6.2 mm) and a range of shear stresses ranging from 4.0 to 8.6N m⁻². The results confirm that a static armour layer is coarser than a mobile one, and that the grain size of a mobile armour layer is rather insensitive to changes in the imposed flow strength.

An analysis of laser scan bed surveys revealed the highly structured and imbricated nature of the static armour layer. Under these conditions the vertical roughness length scale of the bed diminished and it became

topographically less complex at higher forming discharges. The topography of mobile armour layers created by rising discharges differed. They exhibited a greater roughness length scale and were less organized, despite the fact that the grain size of the surface material maintained an approximately constant value during recirculation. Also, the mobile armour tended to create larger cluster structures than static armour layers when formed by higher discharges. These differences were mainly due to the transport of the coarser fraction of bed sediments, which diminished to zero over the static armour because of being hidden within the bed, whereas in the mobile armour the coarser particles protruded into the flow and were actively transported, increasing the vertical roughness length scale. Overall, the results show that an examination of the grain size characteristics of armour layers cannot be used to infer sediment mobility and bed roughness. Detailed elevation models of exposed surfaces of gravel-bed rivers are required to provide critical insight on the sediment availability and sedimentation processes.

ACCURACY EVALUATION IN DIGITAL TERRAIN MODELS INTERPOLATION

GODONE Danilo¹, GARNERO Gabriele¹
1 - Turin University, DEIAFA

Presenter e-mail: danilo.godone@unito.it

Key terms: Laser Scanner; Classification Analysis and Regression Tree; Validation; GIS

Digital terrain models are key tools in land analysis and management as they are directly employable in GIS systems and other specific applications like hydraulic modeling, geotechnical analyses, road planning...

The diffusion of survey methodologies, like Laser Scanner, giving as a result a point cloud describing survey's target has highlighted the importance of interpolation techniques in order to reconstruct the surveyed object.

In the present study different algorithms, stochastic and geostatistic, will be analyzed in order to spot an optimal interpolation methodology, and particularly: Inverse Distance Weighing, Kriging, Spline and Natural Neighbors. The tested estimators are those usually available in GIS environment like ESRI ArcMap. Computations will be carried out on point clouds obtained either by airborne or by terrestrial, Laser Scanners. Two first data set will be investigated: survey carried out by helicopter-borne sensor for hydraulic modeling purposes and a terrestrial survey performed in order to analyze a mountain slope morphology and its proneness to avalanches.

According to the terrain characteristics the whole dataset will be subdivided into thematic datasets representing different land covers, e.g. a riverbed and its banks, an urban area, an hillside... Datasets will be split into two subsets in order to perform interpolation techniques with a percentage of the entire set of data and then, with the remaining data, to evaluate the interpolation accuracy.

Moreover, a statistic analysis will be carried out, by classification techniques, with the purpose of highlighting critical input data that influences, in the interpolation phase, the quality reduction of the final output. The residuals obtained from the evaluation procedure, from differences between the "test dataset" and the interpolated surfaces will be analyzed in comparison with different morphological variables that may influence the interpolation. The employed analysis methodology is the Classification Analysis and Regression Tree, a robust technique, which allows multiple testing on independent variables and give their importance as functions of dependent variable fluctuations (Breiman et al., 1984; Kittler and Devijver, 1982; Urban, 2002). The final result is a tree diagrams that splits every independent variable according to a split value that defines its range of influence on the dependent one.

Variables, computed in GIS environment by surface and raster analysis are the intensity of reflected beams, pulse density per square meters, terrain slope, curvature and morphological complexity - expressed as elevation's standard deviation computed from a 3x3 moving window (Gloersen et al., 2004).

The analysis, carried out on a helicopter-borne survey, has highlighted, among the tested interpolators, the Inverse Distance Weighing as the best one, with the lower residuals. The CART test performed on the same dataset has drawn the attention to the beam intensity and to the morphological complexity as the main factors affecting interpolation accuracy and thus, causing highest residual values.

High resolution digital terrain models (DTMs) created from interpolation of 3D point clouds from airborne laser scanners can suffer from "noise" attributable to different causes. Noise is usually defined as a random error (white noise), thus with no bias (zero mean) and finite standard deviation. In this presentation we assume a broader sense for noise, including any other causes whose effect is the deviation from a correct representation of the ground surface. It is known that DTMs which are derived from filtered and interpolated laser scanning data have low geo-morphological quality (Kraus and Pfeifer, 2001), with spurious pits in valleys which decrease the

quality of hydrological analysis. LiDAR surveys with high pulse frequencies (used to obtain high point densities) sometimes do not have an homogenous distribution of the point density, thus resulting in lower quality interpolation.

In the following presentation a comparison is carried out of methods which increase the geo-morphological quality of DTMs in mountainous areas. Results show that post-processing with a despeckling method which uses the best orientation of normals (Sun et al., 2007; Stevenson et al., 2010) has the significant characteristic of preserving significant features while virtually eliminating most of the noise. The study compares also the effect of threshold over the method, concluding that a threshold of 0.4 gives best results for obtaining high-resolution DTMs with high geo-morphological quality in mountainous areas. This study can be helpful to document how to process DTMs which have a lower quality due to noise factors.

PRODUCTION OF CHECKED DTM BY TERRESTRIAL LASER SCANNER (TLS)

ANGELINI Maria Giuseppa¹, COSTANTINO Domenica¹
1 - Department of Environmental Engineering and Sustainable Development, Technical University of Bari

Presenter e-mail: mg.angelini@poliba.it

Key terms: Digital Elevation Model; Laser scanner; Gridded data; Numerical algorithm

Has been implemented a procedure of calculation and experimentation addressed to the extraction of DTM and validated elevation values with a distribution pseudo regular by TLS data.

The calculation procedure was developed in MATLAB environment and is able to generate digital terrain models, through two-dimensional functions with assigned structure, from data collected using laser scanning supplemented with data collected by topographical techniques and GPS. The third dimension (height of the points) has been calculated by least squares estimation from some points with surveyed height topographically. Has been made, at first, a field test on which were conducted survey integrated methodologies. In particular, has been surveyed points at a distance minor of two meters, with classical topographic technique, using a total station of good accuracy. On the same points has been conducted simultaneously a kinematic GPS survey mode. Finally, has been made a TLS survey using a TOF instrument, setting the grid acquisition with range and density maximum which corresponded to a mesh of points equal to a 0.05x0,05 m. The results obtained allowed the assessment of the appropriate procedure and simplified for determination of the DTM using laser technology and the possibility of improve and verify the accuracy attainable of the altitude plane. This led to the definition of the relevant procedure simplified and integrated (depending on the required precision with classical topographical and/or kinematic GPS survey) and a calculation method that allows by the creation of gratings digital terrain models altimetrically compensated from TLS data. In the future will be implemented a software for the morphological characterization procedures that will consider also filtering and classification of laser data in order to apply to any type of surface.

Key terms: terrestrial laser scanning; digital elevation model; Solfatara; vegetation filtering

The mapping of the topography and landforms characterizing a certain portion of the earth surface allows to determine the morphology and the changes of a site. Correlations can be defined between the terrain morphology, its lithological features and the environmental shaping factors. The earth surface, composed by rocks, is continuously modified through the action of natural and anthropic processes. Among them, climatic changes (like frost and thaw, rain and wind), tectonic and volcanic phenomena, and deforestation are the most important factors. The study and analysis of the surface processes occurring in areas affected by particular and dangerous natural phenomena, such as in the volcanic areas, require a reliable knowledge of the geomorphological characteristics of the sites. In this context, Digital Terrain Models (DTMs) play undoubtedly a major role for the understanding of earth surface processes. However these modern digital terrain representations depends strongly on the quality of the topographic data. In the last decade, a range of new remote sensing techniques has led to a dramatic increase in terrain information. Both Terrestrial Laser Scanner (TLS) and Airborne Laser Scanner (ALS), using LiDAR (Light Detection And Ranging) technology, now provide high resolution topographic data with notable advantages over traditional surveying techniques. A valuable characteristic of these technologies is their capability to produce sub-meter resolution Digital Terrain Models (DTMs), and high-quality land cover information (Digital Surface Models, DSMs).

This work describes the generation of a detailed DTM of a volcanic area derived from a TLS survey. The study site, called Solfatara, is a shallow volcanic crater located at Pozzuoli, in the Campi Flegrei volcanic area, near Naples (South Italy). It is an ancient dormant volcano, which since about

2000 years still emits jets of steam with sulphurous fumes. The crater floor is a popular tourist attraction, as it has many fumaroles and high temperature mud pools. The survey was performed using the long-range (max. 2000 m) RIEGL LMS-2620 laser scanner. Measurements were acquired from 4 different positions, two located inside the crater and two located along the north-east side of the ridge, which partly surrounds the Solfatara. The average resolution step was set to 10 cm at 300 m standoff distance from the laser scanner. For each laser station a set of GPS measurements were also collected through a rapid-static survey for the georeferencing of the whole 3D model of the crater in the WGS84 reference frame. Post-processing of GPS data was carried out by using three GPS permanent stations (ACAE, IPPO and SOLO) as fixed stations. Laser data processing was instead performed with RIEGL proprietary software, RiscanPro. Here a two-steps procedure was adopted to obtain a unique 3D model from the single point clouds. Firstly, laser scans have been roughly pre-aligned through the so-called Backsighting orientation and the post-processed GPS data. Then the initial alignment of the point clouds has been refined by means of the Multi Station Adjustment (MSA), a Riegl global registration method based on a variant of the Iterative Closest Point (ICP) algorithm. At the end of this step a Digital Surface Model (DSM) of the Solfatara was obtained with a residual registration error of 1.2 cm (1 σ). Finally, vegetation was filtered out from the DSM through an iterative procedure based on the method developed by Axelsson for the filtering of ALS data. The resulting point cloud was then triangulated and a set of contour lines were extracted with 1m interval.

A DISCUSSION AROUND LOMBARDY AIR BASINS

MUSSIO Luigi¹, DANTE Valentina¹, POZZOLI Alice¹

1 - Politecnico di Milano - DIAR

Presenter e-mail: luigi.mussio@polimi.it

Key terms: Air basins; 3D dynamic scenarios; Topology and symmetry; Integrated geodesy approach; Geomatics and human sciences

Topographical information increased in quality and detail with diffusion of new techniques for data acquisition (laser sensors, performing terrestrial surveys as TLS, or installed on airplanes as LiDAR, maybe equipped with synthetic diaphragm on mobile platforms, as SAR). Using all these technologies, a new generation of digital terrain models was born, with a far more high spatial resolution respect to traditional procedures. Availability of data base gives new perspectives to recognizing morphologies of slides and landscapes: final result would be acquiring a very high detail for 3D information - comparable in accuracy to a direct relief on site. Describing topographical surfaces with very high resolution and accuracy can also improve hydro-morphologic processes analyses: terrain morphologic characteristics have strong impact on hydro-geological and geomorphologic processes, due to erosion and defluxion phenomena. In this context, Lombardy air basins constitute a significant example of 3D dynamic scenario modeling, even if design happened some years ago. Indeed, due to region topography, a cartographic representation of basins would not fit basin description at all. In order to achieve the best possible result, elevation was split in three levels (river canyons, central geographic zones and tops of mountains), fitting different regions and their peculiar characteristics. A global archive provided the base for a small scale digital elevation model (DEM) that required some refining with new information: therefore, a remote sensing image was acquired, geo-referenced and suitably displayed on the DEM. Then, texture mapping of the geo-referenced image on the small scale DEM further improved quality of data base, providing 3D dynamic scenarios of Lombardy air basins displayed in 3D regions. Then, in order to study their dynamic behavior and geographical distribution, an integrated approach to spatial-temporal modelling was applied, performing a treatment mixing deterministic and stochastic methodologies and procedures. Polynomial and spline interpolation were performed, in order to remove general trends and local variations, then collocation method was applied, using covariance estimation, in order to refine phenomena description. There is now a chance to evaluate results, thinking about fundamentals of applied methodologies and procedures. Therefore, a description of general mechanisms for abstraction of 3D reality and its conceptual modelling has to be pointed out. In this case, topology has the strongest part about conceptual model definition. As a consequence, linear approximation was used before performing graph theory algorithms, whilst only a limited case selection was effective in recognizing analogous numbers between topological relations and groups of symmetry. Spatial - temporal modelling follows basically a three-level procedure:

- firstly, low level polynomial interpolation removes the general trend;
- then finite element method catches and matches local variations;
- finally, assuming topography as the realization of a continuous, normal, stationary and isotropic stochastic process, it is possible to apply a filtering technique, based on covariance estimation and collocation method.

Therefore, the three levels can be computed together: indeed, integrated geodesy approach states a simultaneous solution of a unique global single adjustment. Furthermore, an interesting approach comes from taking into account boundary problems regarding linguistics and its contributions to pattern recognition (where geomatics meets human sciences). Indeed, regarding pattern recognition techniques, parsing shows some ambiguities, i.e. different rewriting rules of a grammar or language may be involved in the derivation of strings. Thus, stochastic languages can be used for pattern description, considering formal grammar ambiguity as for natural languages.

APPLICATIONS OF HIGH-RESOLUTION DEMS FOR GEOMORPHOLOGICAL MAPPING AND ANALYSIS OF HIGH-ALTITUDE MOUNTAIN AREAS (AOSTA VALLEY) AND PLAINS (PIEDMONT, ITALY).

LUCCHESI Stefania¹, GIARDINO Marco¹, PEROTTI Luigi¹

1 - Università degli Studi di Torino

Presenter e-mail: srstefania.lucchesi@libero.it

Key terms: Geomorphology; Geomatics; Geomorphological mapping; Quaternary; North-Western Italy

During geomorphological studies conducted in the Aosta Valley and in Piedmont (NW-Italy), high spatial resolution Digital Elevation Models

(DEMs) have been tested as support elements for collecting and analyzing data. In particular, detailed analysis of DEMs have been fundamental for: 1) creating geomorphological hazard maps of high-altitude mountains areas (Aosta Valley), and 2) supporting the reconstruction of Quaternary evolutionary stages of river network in the central Piedmont (Asti and Turin Provinces).

In the first case, geomorphological mapping of high-altitude mountain areas (Gran Paradiso and Gran San Bernardo massifs) has been performed, by integrating photogrammetry and remote sensing. Different kinds of images and digital products have been overlapped and compared in a GIS environment: aerial photographs, digital orthophotos and high-resolution DEMs. Detailed stereoscopic aerial photointerpretation (approximately 1:3000 to 1:5000 in scale) has been coupled with airborne DEM LiDAR analysis (resolution 2m). Integration allowed single landforms individualization; then, comparison with other geo-environmental features allowed genetic interpretation of geomorphological processes (fluvial, glacial, gravitational dynamics, etc.); finally, the interpreted landforms have been used to define the areal distribution of related deposits, in order to estimate extent and distribution of unstable debris and other hazard-prone areas.

Integrated DEM LiDAR methodology demonstrated very useful for geomorphological analysis and mapping, because it allows to:

- describe in details high-altitude, often inaccessible areas;
- identify landforms masked by vegetation or others not easily distinguishable in the field;
- quickly change scale factor of digital images, from overview of the total area to details of a single landform;
- easily map the areal, linear and punctual elements in a GIS system, obtaining detailed cartographic documents associated to geodatabase.

In the second case, the geomatics enhancing in the topographical analysis of the middle River Tanaro basin (Central Piedmont) allowed to collect new elements for the interpretation of Quaternary evolutionary stages of the hydrographic network.

DEM sections derived from orto-photogrammetrical data of the Regional Technical Map have been elaborated into properly-defined altitudinal belts. The process highlighted flat surfaces at equal elevations, scarps and alignments at the top of reliefs, as well as topographic anomalies (slope breaks, isolated reliefs, abrupt changes in the fluvial incisions). Among fluvial landforms it has also been possible to identify those related to the present-day drainage network and those relics of ancient ones, being uplifted and/or deformed. All these elements were recorded, analyzed and then compared with data of different nature, as to reconstruct the ancient drainage network.

In conclusion, besides the already mentioned enhancements of geomorphological results by application of high-resolution DEMs, we emphasize the relative rapidity of their use and the reduced costs of data acquisition. These advantages should not obscure that the lack of a direct comparison requires field verification of the hypotheses arising from the interpretation of digital models; as an example, field data are still essential for interpreting composition of the deposits whose morphological expression have been individualized; moreover, dating elements (alteration rate of sediments, presence of soils, etc.) are needed for chronological reconstructions of evolutionary stages of landforms. As a consequence, from our case-studies, it can be asserted that high-resolution DEMs are important and complementary working tools, and that the indications coming from their analysis is useful for enhancing direct field surveys, optimizing research times and the dedicated resources.

A LIDAR BASED ANALYSIS OF HYDRAULIC HAZARD MAPPING

CAZORZI Federico¹, DE LUCA Alberto², CHECCHINATO Antonio², SEGNA Francesca², DALLA FONTANA Giancarlo³

1 - University of Udine

2 - Geomatica e Ambiente srl, Legnaro, Italy

3 - University of Padova

Presenter e-mail: alberto.deluca@unipd.it

Key terms: LiDAR; topography; hazard mapping

Mapping hydraulic hazard is a ticklish procedure as it involves technical and socio-economic aspects. On the one hand no dangerous areas should be excluded, on the other hand it is important not to exceed, beyond the necessary, with the surface assigned to some use limitations-. The availability of a high resolution topographic survey allows nowadays to face this task with innovative procedures, both in the planning (mapping) and in the map validation phases. The latter is the object of the present work.

It should be stressed that the described procedure is proposed purely as a preliminary analysis based on topography only, and therefore does not intend in any way to replace more sophisticated analysis methods requiring based on hydraulic modelling.

The reference elevation model is a combination of the digital terrain model and the digital building model (DTM+DBM). The option of using the standard surface model (DSM) is not viable, as the DSM represents the vegetation canopy as a solid volume. This has the consequence of unrealistically considering the vegetation as a geometric obstacle to water flow. In some cases the topographic model construction requires the identification and digitization of the principal breaklines, such as river banks, ditches and similar natural or artificial structures.

The geometrical and topological procedure for the validation of the hydraulic hazard maps is made of two steps. In the first step the whole area is subdivided into fluvial segments, with length chosen as a reasonable trade-off between the need to keep the hydrographical unit as complete as possible, and the need to separate sections of the river bed with significantly different morphology. Each of these segments is made of a single elongated polygon, whose shape can be quite complex, especially for meandering river sections, where the flow direction (i.e. the potential energy gradient associated to the talweg) is often inverted.

In the second step the segments are analysed one by one. Therefore, each segment was split into many reaches, so that within any of them the slope of the piezometric line can be approximated to zero. As a consequence, the hydraulic profile (open channel flow) in every reach is assumed horizontal both downslope and on the cross-section. Each reach can be seen as a polygon, delimited laterally by the hazard mapping boundaries and longitudinally by two successive cross sections, usually orthogonal to the talweg line. Simulating the progressive increase of the river stage, with a horizontal piezometric line, allow the definition of the stage-area and stage-volume relationships. Such relationships are obtained exclusively by the geometric information as provided by the high resolution elevation model.

The maximum flooded area resulting from the simulation is finally compared to the potentially floodable area described by the hazard maps, to give a flooding index for every reach. Index values lower than 100% show that the mapped hazard area exceeds the maximum floodable area. Very low index values identify spots where there is a significant incongruity between the hazard map and the topography, and where a specific verification is probably needed. The procedure was successfully used for the validation of many hazard maps across Italy.

A SEMI-AUTOMATIC DERIVATION OF CHANNEL NETWORK FROM HIGH-RESOLUTION DTMS: THE EXAMPLE OF AN ITALIAN ALPINE REGION.

MION Elena¹, GOLDIN Beatrice¹, CREMA Stefano¹, CAVALLI Marco¹
1 - CNR IRPI - Research Institute for Geohydrological Protection, Padova, Italy

Presenter e-mail: elena.mion@irpi.cnr.it

Key terms: hydrographic network; LiDAR; HR-DTM; geomorphometric indexes

High-resolution digital terrain models (HR-DTMs) of regional coverage open interesting scenarios for the analysis of landscape, including derivation and analysis of channel network.

In this study, we present our experience in the derivation of the channel network from a HR-DTM of the Autonomous Province of Trento. This region (about 6200 km²) has a complex orography, with a high variety of lithotypes and different types of land use (forests, bare ground at the highest elevation, rocky outcrops and debris, mountain grasslands and agricultural areas mostly located in valley floors).

A preliminary automatic extraction of the raw channel network was conducted using a curvature-based morphological algorithm (Tarboton and Ames, 2001) applied to a 2 m resolution DTM derived from an airborne LiDAR survey carried out in 2006.

This algorithm shows a good performance in terms of drainage density and channel heads location when preliminarily compared to available cartography.

The raw channel network automatically extracted from the HR-DTM needs a supervised control to check the spatial pattern of the channels and to classify every reach of the hydrographic network.

This analysis was carried out by means of different informative layers grouped into three main classes: i) geomorphometric indexes derived from HR-DTM encompassing 2 m resolution shaded relief map, openness (Yokoyama *et al.*, 2002), local anomalies, and plan curvature; ii) high-resolution orthophoto imagery (panchromatic and near-infrared); iii) technical cartography (1:10000, 1:25000 scale).

The result is an accurate and scale independent channel network definition of the study area that therefore needs to be complemented and corrected via field surveys and expert supervision, especially in urban areas. Summary statistics are presented to relate the drainage density to different topological and geomorphological parameters.

LiDAR AND FIELD SURVEYS FOR CHANNEL NETWORK MORPHOLOGICAL ANALYSIS

VIANELLO Alessandro¹, CAVALLI Marco²

1 - ARPAV
2 - CNR-IRPI

Presenter e-mail: vianhuber@libero.it

Key terms: channel width; local slope; LiDAR; DTM

The study analyses the variation of headwater channel geometry under bankfull conditions, and the relations between morpho-geometric variables of the channel network in two headwater basins of the Eastern Italian Alps. The two study basins cover areas of 5 and 7 km², and are characterized by a network of ephemeral colluvial incisions; the main alluvial channels are dominated by rapids and step-pool morphologies. Field surveys were carried out on channel heads and on selected colluvial incisions, as well as along the alluvial channels, with the aim to quantify geometric and morphometric parameters. Airborne LiDAR data, with a vertical accuracy of 0.2 m, made it possible to obtain a high resolution DTM (1 m grid size) of the two basins and to derive, through the use of GIS techniques, morphometric indicators suitable for the characterisation of channel morphologies. A comparison between field and DTM derived morphological data permitted to verify their overlapping degree. The research focuses on the relationships between channel width at bankfull stage, local slope and contributing area. The hydrological variables were derived from high resolution DTM. The relationships between the considered variables were investigated both for the whole hydrographic network, and considering separately the various channel bed morphologies (colluvial channels, step-pools and rapid reaches of the main alluvial stream). The relationships have been firstly investigated in the channel reaches surveyed in the field, and then extended to the whole channel network on the basis of field and DTM derived data comparison. The integration of field surveys carried out on the channel network with the analysis of high resolution LiDAR-derived DTMs is a promising approach for improving the knowledge of morphodynamic relationships in mountainous basins. In particular, LiDAR surveys give the possibility of deriving DTMs with grid size close to the width of the narrowest elements of the channel network and smaller than the width of the main alluvial channels, thus opening new prospects for the analysis of slope-area and width-area relations in headwater basins, as well as for the recognition of channel-bed morphologies.

Key terms: Upslope Position Index; Digital Elevation Model; geothematic data

In this paper we present a topographic index (Upslope Position Index - UPI) as a tool for quantitative analysis of Digital Elevation Model (DEM) and identification of relationships with spatial distribution of geological-geotechnical parameters.

The study areas are selected catchments in Tuscany (Italy) where a DEM with a cell size of 10 m is used as input datum.

We first implement the flow length GIS function in order to calculate the downstream and upstream weighted distances along a flow path from each cell to, respectively, either the valley bottom or the watershed divide. By normalizing the upstream flow length in respect to the flow path, we then obtain the UPI.

The UPI allows us to make spatial comparisons among catchments with both different size and geographic locations. In this study area we obtain "normalized" watershed profiles which highlight different shapes of catchments, as well as sub-catchments pertaining to the same first-order catchment.

Based on the above results we search for correlation among normalized profiles and geological-geotechnical parameters, like substratum-superficial geological units, lithological units, and landslides spatial distribution. We extract these geothematic datasets from the so-called "continuum geologico", the new geothematic cartographic dataset at the scale of 1:10,000 of the Regione Toscana.

Finally, we search for correlation among the above normalised profiles and spot geotechnical data obtained by sampling and analyzing the superficial formations of selected second-order catchments.

Key terms: landslide; DTM; GIS

The northeastern part of Pakistan is known to be a region of extremes, where the highest reliefs of the world are and where the geology can be considered young from an orogeny point of view. In this environment, a big multidisciplinary project, named SEED (Social, Economic and Environmental Development in the CKNP Region Project), is taken by Ev-K2-CNR project. SEED is made by several different projects, each one focused on a different theme (e.g. glaciology, meteorology, land cover) that permit to characterize, from different points of view, the new Central Karakorum National Park. One of it is focused on a better knowledge of the territory through the analysis of the hazardous areas, important instrument for a future rational planning. The geostatic evidences, better known as landslides, will be firstly identified using a new generation of high quality DTM (Digital Terrain Model) at a spatial resolution better than the one obtained through traditional techniques. These high quality data permit to individuate different slope morphologies and to recognize possible geostatic phenomena. The methodology will permit to identify the geostatic phenomena that will be secondarily identified on the field, only in sample areas in order to validate the tool. This permit to create the first, upgradable in real time, landslide inventory for the area of the Central Karakorum National Park.

Presenter e-mail: valerio.lancianese2@unibo.it

Key terms: geochemistry MAPS; stream sediment sampling; catchment basin; landscape patch; open source GIS applications

The environmental geochemical mapping is a valid tool for land monitoring. The knowledge of the distribution, diffusion and concentration of chemical elements provides important information about economic and/or environmental problems concerning agriculture, discovery of mineral resources and their exploitation, waste disposal, water supply, irrigation, animal health, soil utilization, epidemiological surveys, industrial pollution. Geochemical maps regarding the distribution of chemical elements, background values and anomalous signature are produced by means of statistic methods (i. e. Multifractal IDW, Kriging) that sometimes can lead to significant inaccuracies because of data are obtained by irregular sampling grid. The construction of a geochemical mapping therefore requires new criteria in the sampling site selection. Regarding the sampling of Tuscan-Emilian Apennines, this analysis employs catchment basin extraction of landscape patches using open source GIS applications. The best sampling is represented by stream sediment and may be performed on rivers into each catchment basin. A background geochemical map integrated with catchment basin map allows both an immediate interpretation of geochemical data and a more certain estimation of the elements concentration regarding the areas for which sampling data were not available. In this way the distribution of chemical elements depends on soil, geological and physical characteristics of the patches. This study compares deterministic approaches to probabilistic analysis, showing the higher reliability of the first methodology in order to produce maps based on more certain techniques.

QUATERNARY ARCTIC COASTAL LANDSCAPE, SEDIMENTS AND LANDUSE OF FOXE BASIN, CANADA - HIGHLIGHTS

MARTINI I. Peter¹

1 - UNIVERSITY OF GUELPH, GUELPH, ON CANADA

Presenter e-mail: pmartini@uoguelph.ca

Key terms: *Foxe Basin; Arctic coasts; Periglacial features; Landuse*

Foxe Basin is a downfaulted Arctic basin in northeastern Canada floored by Paleozoic carbonates and mostly surrounded by crystalline Precambrian terrains. During the Pleistocene the area was covered by a thick glacier dome, and then inundated by an early sea as the glacier melted. Exposed Quaternary deposits record the events of the last glaciation and subsequent sea cover and the emergence. The deposits consist of a surficial veneer of glacial drift and frost-shattered clasts, locally reworked by sea waves during isostatic emergence (approximately 70 cm/century at present). This paper deals mainly with three major types of coasts of Foxe Basin: (1) 'Low hilly coasts' developed on metamorphic/igneous terrains: they are jagged, steep and rocky, with pebbly pocket beaches and some bouldery ice-push ridges in coves; (2) 'Lowland gravelly coasts' formed over a carbonate substrate, characterized by well developed beach ridges; and (3) 'Lowland muddy coasts' developed on relatively wide low-energy carbonate platforms (coastal plains) and/or in sheltered tidal embayments. Although strong storms develop during ice-free times, the shallow mesotidal sea is covered by ice for 10 months of the year and this ensures that the overall energy of the coasts is low. Cold climate processes active since postglacial emersion of the land have led to frost heaving of bedrock blocks, solifluction lobes on slopes, frost boils in sedimentary deposits of flatter areas, frost shattering and solution of surficial carbonate pebbles, and formation of shallow soils best developed in the top 1 m thick 'active layer' above the permafrost table. Foxe Basin is a remote region. Its coastal areas are used as breeding grounds by numerous species of migratory birds. A very large colony of migratory geese exists in the southeastern coastal Koukdjuak Plain (Dewey Soper Migratory Bird Sanctuary). Caribou herds and other land mammals visit the mainland coasts each year. The sea, particularly to the northwest, is very productive, including fish and migratory sea mammals. Because of this, the coasts have been inhabited by Inuit since antiquity. Two small permanent Inuit villages (Hall Beach and Igloolik) are now thriving with people still following some of the old customs, but increasingly becoming accustomed to modern facilities such as communications, transport, hunting tools, foodstuff, health care, education and work practices. An incipient tourist industry is emerging as well. The people there are very protective of the environment and this has led recently to a moratorium for hunting-tourism to avoid depletion of the decreasing sea-mammal stocks. Similarly, concerns have been expressed about the proposed shipping of iron ore from a Baffin mine through a nearby inlet because the use of freighters may affect the floating ice used by sea mammals, hence interfere with their population that is vital for the Inuit sustenance-hunting.

RELATIVE SEA LEVEL CHANGES DURING THE HOLOCENE IN THE ATLANTIC PATAGONIAN COAST: NEW DATA

ZANCHETTA Giovanni¹; BINI Monica³; CONSOLONI Ilaria¹; PAPPALARDO Marta¹; RAGAINI Luca¹; RIBOLINI Adriano¹; BORETTO Gabriella²; Fucks Enrique³; TERRASI Filippo⁴

1 - University of Pisa

2 - CICTERRA, Cordoba Argentina

3 - Universidad nacional de La Plata Argentina

4 - Second University of Naples

Presenter e-mail: zanchetta@dst.unipi.it

Key terms: *relative sea level; Holocene; Patagonia; Radiocarbon dating*

Despite the Atlantic coast of south America has supplied a significant number of information for the variation of the relative sea level during the Holocene, the Patagonian coast was considered an area with data not particularly accurate (e.g. Milne et al., 2005). Recently, Schellmann and Radtke (e.g. 2010) have significantly reduced this gap of knowledge, but the accuracy of the data proposed is strongly affected by the difficulties to use depositional sea level markers in an area characterised by stormy and macrotidal conditions. In the last two years, careful field work on selected coastal areas between Cabo Raso and Puerto Deseado has improved the reconstruction of the relative sea level for this area, but has also highlighted the main limits of the current sea level markers used for the area (e.g. Ribolini et al., 2011). Indeed, new data seem to suggest that, locally, Middle Holocene highstand was ca 2-3 m above high tide level, lower than previously reported (Ribolini et al., 2011; Zanchetta et al., 2011a). Therefore, it is not still clear if there are significant differences on sea level curve in different sector of coastal Patagonia, or a comparable pattern exist. It is worth of note that the updated radiocarbon age dataset for the area points to a discontinuous depositional records, claiming for strong erosion phases affecting the coast and/or a short relative sea level low stand between ca 5000 and 4000 yr BP (e.g. Zanchetta et al., 2011ab).

THE BOSCO PANTANO DI POLICORO BEACH (BASILICATA, SOUTHERN ITALY): AN EXAMPLE OF A SYSTEM QUICKLY ADAPTED TO THE PRESENT-DAY SEA LEVEL RISE

LONGHITANO Sergio¹, SABATO Luisa¹, CILUMBRIELLO A.¹, GIOIA D.¹, SPALLUTO L.¹

1 - University of Basilicata

Presenter e-mail: sergio.longhitano@unibas.it

Key terms: *Coastal systems; sea-level changes; Basilicata; anthropogenic activities*

Coastal systems are very sensitive in recording quick sea-level changes and many are the ancient analogues that recorded such important variations in their depositional architectures or facies tracts. The present-day sea-level rise is seriously damaging shorelines in many coastal areas of the world, generally producing severe problems of beach erosion, destruction of coastal environments and consequent shoreline retreating.

The Bosco Pantano di Policoro represents the southernmost segment of a wider shoreline facing the Ionian Sea in Basilicata, southern Italy. The Ionian coastline is a microtidal, wave-dominated 40 km long shoreline, which was intensely characterized by anthropogenic activities and a heavy touristic development during the last 30 years. The studied coastal segment represents an exception along this human-influenced coastline, because the total absence of social activities and the presence of primary coastal environments. Such a rare circumstance allowed us to evaluate the 'natural' response of a coastal system to the pressure induced from the recent sea level rise.

The results of the ProviDune Euro-project carried out along the Bosco Pantano di Policoro beach document a strong coastal retreating during in the last 15 years, that has recently increased through the back-stepped migration of the foreshore which has replaced the backshore facies developed during the previous stage of shore accretion.

This important change has been revealed by specific sedimentary facies occurring in the back area of a natural/artificial dunefield. These facies consist of sparse accumulations of detrital matter admixed to coarse-grained sediments deriving from the suspended load of repeated storm waves.

This process is producing substantial modifications in the dynamic equilibrium of the studied beach system which can be considered as a good case study to observe how a beach system does react to the effects of a rapid sea-level rise.

Presenter e-mail: speleokikers@tiscali.it

Key terms: *Cave sediment; Gypsum karst; Palaeoclimate; Palaeoenvironment; Cueva C3 (Sorbas, Spain)*

The arid zone of Sorbas (Almería, SE Spain) is one of the most important evaporitic karsts of the world. Karst develops in Messinian gypsum plateau that comprises continuous strata of very pure selenite overlying upper Tortonian marl units and covered by Mio-Pliocene-Quaternary siliciclastic sands and conglomerates.

In the last decades the well-exposed sedimentary strata of the Neogene intramontane basin of Sorbas have been exhaustively studied from genetic and chronologic points of view on the basis of their stratigraphic position in the overall formation. Most researches have focused on the recent alluvial fan conglomerate and braided fluvial systems deposits and have tried to define the palaeoenvironments associated with changes in the base level of the basin over the past 200k years.

However, no research has taken into account the Quaternary sediments deposited within the caves of Sorbas and their palaeoclimate implications. These clastic sediments consist of fluvio-karstic deposits, dominated by a poorly organized fluvial system possibly related to intense rainfall patterns extremely different from today's. In many cases they have been covered by subsequent carbonate flowstones.

The detailed analysis of this kind of karstic infill may allow to define, with high resolution, the sedimentary phases that occurred within underground galleries of the Sorbas karst. The mechanisms leading to the deposition of detrital materials within the cavities are strictly dependent on climatic processes. However, each type of sediment should be considered individually, because associated with a single different phase. For better understanding the no linear palaeoclimatic behaviour, field works, lab experiments, petrographic, isotopic and radiometric analyses are indispensable. They permit to determine the specific constraints controlling sedimentation in different environments.

With the aim to provide a past climate record referred to the present one, the clastic sediments of the gypsum caves of Sorbas have been examined. Samples were taken from various sedimentary environments in different stratigraphic positions. The preliminary results involve a sampling of three different levels of medium-fine sandy materials, alternate with pebbles-bearing debris flow lens and pelitic levels, in the Cueva C3 cave, a part of the Covadura karst system. After a first speleogenetic stage that led at the cave conduits formation, the sediments were carried into the system in fluvial conditions, filling entirely the cave passages, as testified by sediments stucked on the wall and ceiling of the cave. During a further phase, these deposits were partially eroded due to the lowering of the water table. Future OSL analysis will give rise to the chronology of these

previous humid periods and will allow the reconstruction of the palaeoenvironment conditions occurred before the establishment of the current arid climate condition.

FUTURE SEA LEVEL RISE AS POTENTIAL THREAT FOR THE MEDITERRANEAN POSIDONIA OCEANICA MEADOWS. CONSIDERATIONS FROM THE HYDRODYNAMIC POINT OF VIEW.

VACCHI Matteo¹, SCHIAFFINO Chiara Francesca¹, MONTEFALCONE Monica¹, BIANCHI Carlo Nike¹, FERRARI Marco¹

¹ - University of Genova-DipTeRis

Presenter e-mail: ferrari@dipteris.unige.it

Key terms: Posidonia oceanica; sea level rise; Mediterranean sea; morphodynamic profile; Brunn role

In the face of a global rise in sea level, understanding the response of the nearshore zone to changes in sea level is a critical scientific goal. Seagrasses represent key ecosystem influencing the nearshore zone in many seas all over the world and their loss results both from direct human impacts and natural causes. Among the latter, effects of climate change represent a crucial topic. The possible effects of a changing global climate on natural and agricultural terrestrial plant communities have already received attention. On the contrary, relatively little importance has been given to the possible effects of global climate change on aquatic plant ecosystems, including seagrasses. The characteristics of sea level rise include both elevation in the mean level of the ocean surface and increase in the tidal variation around that mean. The consequent effects on available light, local hydrodynamics, current velocities, depth, and salinity distribution, are all factors that control the distribution and development of seagrasses. Therefore, sea level rise has important implications for seagrass populations and the habitats they create.

Aim of this contribution is to consider if the future sea level changes could represent a major threat for the Posidonia oceanica meadows, the most important seagrass of the Mediterranean sea. Starting point of these considerations is represented by some recent studies which individuated significant hydrodynamic influence of both upper (landward) and lower (seaward) limits of the P. oceanica meadows. In particular, upper limit of the meadow is controlled by the breaking depth (i.e. the depth where the wave breaks whereas the lower limit is controlled both by near shore zone extent and light availability).

Several data from tectonic and non-tectonic areas are consistent with a global eustatic near stability of the Mediterranean Sea during the last 6000 years, challenging the assertions recently proposed by isostatic modellers of a significant additional melting of the Antarctic ice sheet after 6000 years BP. However recent studies, based on satellite and tidal gauge data, reported a mean sea level rise of approximately 7 mm/year in the Mediterranean Sea. Its spatial distribution is not uniform and, for instance, while the Levantine basin is rising at a rate of 25-30 mm/year, the Ionian Sea is falling by 15-20 mm/year.

In tectonically stable areas, elevation of the mean sea level will cause a landward shifting of the shoreline and so an adaptation of the hydrodynamic zones along the beach profile. This will modify the location of the meadows limits until reaching a new hydrodynamic equilibrium. In this study the P. oceanica meadows response in relation to hydrodynamic characteristics variations due to the sea level rise was analyzed. In particular three Liguria beaches with different morphodynamic conditions (dissipative, intermediate, reflective profiles) were studied.

Obtained results showed a different response to sea level rise in relation to beach morphodynamic characteristics most of all on the meadow higher limit that is more affected by the new hydrodynamic conditions.

MONITORING OF THE LITTORAL STRETCH BETWEEN THE HARBOR OF GIULIANOVA AND TRONTO RIVER (NORTHERN ABRUZZO REGION).

ACCIARRI Alessio¹, BISCI Carlo¹, CANTALAMESSA Gino¹, DI PANCRAZIO Giorgio¹

¹ - Università degli Studi di Camerino

Presenter e-mail: gino.cantalamessa@unicam.it

Key terms: littoral monitoring; Gavrilovic model; river sediment transport; sedimentological and morphological analysis; northern Abruzzo

Italy is the European country with the longest shoreline; approximately 40% of it presently is under erosion because of the reduced contribution of fluvial sediments caused by extraction of gravels from river beds, construction of dams and hydraulic works, stabilization of hillslopes, widespread cementification, abandonment of agriculture, destruction of coastal dunes etc.

In many physiographic units, the progradational trend of shores, which since the end of the Roman Empire has been remarkable and brought to the creation of extended coastal plains, starting from the end of the XIX century reversed, generating permanent alarm for many activities and facilities which have been built up there.

Surveying and analysis of historical, cartographic, geomorphologic and geologic data have been carried out along the coast stretching between the Tronto river and the harbor of Giulianova (ca. 15 km long) in order to improve knowledge of the marine dynamic and to highlight anthropic and natural modifications which happened during the last century.

In this physiographic unit, limited marine trasgressions took place from the beginning of the XX century due to the end of the small glacial era. This, in addition to the above-mentioned causes, assumed particularly severe rates at the Tronto river mouth (the biggest sediment tank of the area, estimated in over 1'000'000 cubic m and since a long time absolutely exhausted); there, in fact, from the half of XIX century up to today the retreat has been evaluated to be about 600 m.

At the north end of the area, at the the southern side of the Tronto river mouth a long groin has been build around 1930, stretching in the sea for hundreds of metres thus blocking the (few) sediments within the physiographic unit. To the south, the harbor of Giulianova with its long breakwaters, whose construction began in 1913, prevents the natural sediment feeding coming from Tordino river (once more reduced, due to excavation along the river bed and hydraulic protection works). The potential sedimentary contributions useful for the nourishment of the shores, coming from the inner torrents of the unit (Salinello and Vibrata) have been quantified using the Gavrilovic's model, suited for torrential

river basins. They turned out to be approximately 50.000 cubic m per year, while the esteem of the sediment losses toward the sea and caused by wind has been evaluated to be more than 70.000 cubic m per year. The average annual deficit therefore exceeds 20'000 cubic m of sediments. Neglecting local effects due to the building of cross-sectional and longitudinal structures for the control of waves, this shortage of debris has produced in the first stretch of the shore (Alba Adriatica, still lacking artificial protection works) a recession of about 90 m in the 1970-2004 timespan. Taking into consideration the protection works to the north too (cross-sectional and longitudinal breakwaters), the recession is exceeds 100 m.

Sedimentologic and morphologic analyses carried out on several transects uniformly distributed along the whole physiographic unit evidenced that the stretches in erosion are characterized by larger average grain size of the beach sediments, steeper slopes and deeper sea bottom. On both sides of the protection works, finer debris and remarkable advances of the shoreline have been recorded, in contrast with huge recessions at distances ranging from a few hundred metres and about 1 Km. These latter testify both the remarkable influence of artificial barriers on the sediment circulation along the shore and a typical bidirectionality of waves in this area.

10.1474/Epitome.04.0945.Geoitalia2011

EVOLUTIONARY ANALYSIS OF THE MARCHE COAST BETWEEN THE CONERO MOUNT AND THE TRONTO RIVER MOUTH FROM THE ROMAN AGE UNTIL TODAY

ACCIARRI Alessio¹, BISCI Carlo¹, CANTALAMESSA Gino¹, DI PANCRAZIO Giorgio¹

¹ - Università degli Studi di Camerino

Presenter e-mail: gino.cantalamessa@unicam.it

Key terms: littoral evolution; DSAS; spatial analysis of shoreline; southern Marche; evolution of coastal defense work

An analysis of the southern portion of the Marche coast has been carried out taking into account both natural and anthropic effect intervening from the Roman Age until today.

The study area, stretching between the harbor of Numana and the Tronto River mouth, faces the central Adriatic Sea and has a length of ca. 74 km. It is characterized by gravelly-sandy beaches, fading without breaks into alluvial plains; locally, narrow beaches are backed by fossil wave cut cliffs running in parallel with the present shoreline. The Sirocco (from SE) is the prevailing wave direction, while the Bora (from NE) and the Levant (from E) play a secondary even though relevant role in the evolution of the shoreline.

The study took advantage of modern techniques of acquisition, treatment and elaboration of data and aimed to quantitatively estimate the mobility of the shoreline. It has been based on the finding, co-georeferencing and analysis of maps, both raster and vectorial, surveyed during a long timespan. Using ESRI ArcGis 9.2 software, different cartographic bases have been imported and co-georeferenced in order to digitise rivers and shorelines. Processing carried out using techniques of spatial analysis, allowed to evaluate changes in shoreline position for each time interval (1835-1874, 1874-1894, 1894-1944/45, 1944/45-1953/55, 1953/55-1978, 1978-1984, 1984-1988, 1988-2000, 2000-2006). Variations and relative rates (meters/year) of the shoreline for each time interval have been calculated following regularly spaced (100 m) transects perpendicular to the shoreline.

Basing on the results of the above analyses, a study has been carried out to determine the climatic, natural and anthropic factors which have influenced the evolution of the area.

The decrease of river solid load is considered the primary cause of the regressions of Italian beaches together with the building of coastal defence works. Data reveal that the shoreline in the Roman age was much more inland than today (1200 m at the Tronto mouth, 700 m at the Tesino mouth, 650 meters at the Chienti mouth and 300 metres at the Potenza mouth); successively, from the Middle Age to the XIX century, various factors generated an increase of the river solid load which allowed the development and the advancement (up to some hundred metres) of the shoreline. In this period, evolved the deltas of the biggest Marche rivers. The first regressions started at the end of the XIX century along fluvial mouths and then in the nearby shores. After the Second World War, an enormous urban development of the coastal areas and of related infrastructures brought to widespread extraction of debris from river beds that has been paralleled by a dramatic decrease of the river solid load which induced severe regression of shorelines.

The request of wider beaches due to the increase of touristic demands induced local administrations to start to build coastal defence works. Therefore, during the last fifty years the evolution to the Marche coast has been essentially regulated by many different anthropic works lacking planning and forecasts of local alteration of coastal dynamics. Erosive phenomena concentrated downstream to the structures while huge advancements affected the upstream side; above all, anyhow, it has been underlined that lacks of sediment balance generated by protection works have been generally solved building up other structures, with a domino effect that brought to a nearly uninterrupted line of defence artifacts along the whole investigated coast.

Q3-8 Orale Corradi, Nicola

10.1474/Epitome.04.0946.Geoitalia2011

LIGURIA POCKET BEACHES: BONASSOLA CASE STUDY (LA SPEZIA, ITALY)

BALDUZZI Ileana¹, CAVALLO Carlo², CORRADI Nicola¹, FERRARI Marco¹, SCHIAFFINO Chiara Francesca¹

¹ - University of Genoa, Italy

² - Regione Liguria, Italy

Presenter e-mail: corradi@dipteris.unige.it

Key terms: Pocket Beach; Morphodynamics; Sedimentology; Liguria

Physiographic features of Liguria coasts are mostly ascribed to Neogene - Quaternary geodynamic processes impacting on Liguria and North-Tyrrhenian margins, that substantially determined the region's geologic and geomorphologic evolution. 2/3 of the coast length (around 320 km) are in fact made of cliffs with jutting headlands, broken up by variously sized beaches. Therefore, apart from a few interdeltic beaches (Roja, Centa, Entella Magra), most Liguria beaches are pocket beaches, even if they can be very different, and their size must be interrelated more to structural influences than to progradational sedimentation

processes.

Liguria pocket beaches can be divided into two main categories:
 ° small pocket beaches, often with a high embayment rate, nourished by rocky cliffs instability, mainly composed of gravel sediments;
 ° beaches nourished by rivers, whose drainage basins may vary in relevance and slope, and whose size depends on the seafloor of small coastal plains. In this case, sediments are a mixture of gravel and sand, according to sediment loads characteristics and to wave motion exposure. Bonassola beach (SP), in its homonym bay, lies to the West of the Cinque Terre Park, in an area worldily renowned for its nature and its landscape. The beach is located between two headlands, Punta Levante (to the East) and Punta della Madonna (to the West), marking off the small stride, around 410 m wide, with no defense works around it. The beach, as well as the small plain of the Bonassola village, is nourished by S. Giorgio and Rossola streams, draining basins which are respectively 3.3 and 1.7 km² wide. At the beginning of 1960s it was fundamentally made of pebbly sediments. With time, the beach underwent obvious changes in its size as well as in its grain size characteristics. This was a consequence of the pouring of material coming from tunnel excavations for the laying of a second track (during the 1960s). Wave motion exposure conditions suggest that sediment transport processes on emerged beach and mobile seafloor are more forceful cross-shore. Seafloors are mainly made of sand; in the rocky parts of the headlands there are small meadows of *Posidonia Oceanica*. According to the analysis of aerial photographs provided by Liguria Region (1973, 1983, 1993, 2003) and to the regional geodatabase "SICoast", the beach is relatively stable, characterized by little advance and in particular by shoreline rotation. In 2006, after erosion had taken place (1999, 2000), the Bonassola municipality carried out a nourishment including about 13,000 m³ of local quarry material. Following this operation, single and multi-beam bathymetric surveys were carried out (2007, 2009, 2010), together with a campaign for seafloor samples collection which aimed at highlighting seafloor evolution trends. The first results show that, on the whole, seafloors remained substantially stable. Bathymetric data chiefly underline the accretion of a longitudinal bar, at a depth between 6 and 7 meters, and the effects on the seafloor of rip currents triggered by the predominant cross-shore transport.

10.1474/Epitome.04.0947.Geoitalia2011

BEACH NOURISHMENT ON MIXED SAND AND GRAVEL BEACHES USING BIMODAL STREAM SEDIMENTS. THE CASE OF OSPEDALETTI (LIGURIA, MEDITERRANEAN SEA).

SCHIAFFINO Chiara Francesca¹, CECCHIN Alessio¹, FERRARI Marco¹
 1 - Dipartimento per lo Studio del Territorio e delle sue Risorse, Università degli Studi di Genova

Presenter e-mail: chiara.schiaffino@unige.it

Key terms: mixed beach; beach nourishment; stream sediment; bimodal sediment; Liguria

Nowadays erosive phenomena are one of the most important problems affecting beach areas due both to natural causes like storm events or sea level rise, and anthropic causes as indiscriminate exploitation of beaches. One of the methods put to use to curb this tendency and to defend coastal environment is nourishment. During the last decades replenishment has become the most common practice for beach maintenance due to its low environmental impact. In fact, in comparison with other methods, it produces faster results, it allows to maintain or increase beach width for storm protection, it is carried out without disturbing recreational activities and it is less expensive than structural defences.

Beach nourishment projects involve the placement of predefined quantities of fill material (sand or gravel) into the nearshore system. Clearly the fill material modifies the beach profile causing a perturbation in the natural shore system and the as-built beach profile is equilibrated throughout its natural dispersion and diffusion both in cross-shore and longshore directions. There is a correlation between as-built profiles and fill grain size. Coarse sediments create a strong beach steepness, thus obtaining a greater increase of the nourished area for equivalent volume of discharged material and therefore a drier beach per cubic metre of placed fill. Finer sediments move across-shore more than coarser ones, therefore offshore loss increases as size decreases.

In this study the performance of a recharge scheme using overbank stream sediment (bimodal mixed sediment) was analysed together with its efficacy on the creation of cross-shore morphodynamic equilibrium for the beach profile.

The study area is Ospedaletti Beach, located in the western Liguria region. The beach is 250 m long. This is a typical mixed sand and gravel beach: in fact it is characterized by gravel on submerged and emerged beach until the breaking zone and by medium and fine sand on the submerged beach beyond the breaking zone. During the nourishment carried out in 2008-2009, 65000 m³ of overbank stream sediment coming from the Argentina stream were filled. The borrow sediment was made up of almost 80% of gravel and 20 % of sand, with mean grain size varying between a

minimum of 0.5 ϕ for the sand fraction and a maximum of -5 ϕ for gravel. The nourishment analysis was performed comparing pre- and post-recharge beach behaviour from a morpho-sedimentologic point of view.

In Dean and Van der Meer profiles, calculated for the finest and coarsest fractions of the grain size curve, it is highlighted that while the coarsest fraction stays on the dry beach, the finest fraction is dispersed on the submerged zone beyond the breaking zone maintaining the distinctive slope break noticed here before the nourishment. Survey data confirm the creation of a slope break on the cross-shore profile.

In the present study it can be noticed that the use of bimodal stream sediments leads to the creation of two different slope break of beach cross-shore profile, related to the two main grain sizes of the fill sediment. Up until the breaking zone, the beach is made up of gravel sediments, and its intermediate morphodynamic profile (0.93), even if leading to plunging breaks, is able to counter and absorb wave energy within a short distance, due to increased clast size. On the other hand, beach nourishment on the submerged beach part between breaking zone and closing depth was performed with sand fraction, thus improving its morphodynamic profile. Therefore, the use of bimodal sediments essentially allowed the recreation of a morphodynamic profile similar to the pre-existing profile before beach nourishment.

10.1474/Epitome.04.0948.Geoitalia2011

HOW STRONG IS THE HUMAN IMPACT ON MODERN BEACHES? COMPARISON WITH LAST INTERGLACIAL AND MODERN BEACHES

PASCUCCI Vincenzo¹, ANDREUCCI Stefano¹
 1 - Dipartimento di Scienze Botaniche, Ecologiche e Geologiche, Università di Sassari, Via Piandanna 4, Sassari, Italy
 Presenter e-mail: pascucci@uniss.it

Key terms: Beaches; Late Quaternary; MIS5; Climate Change; Human impact

Most of the modern beaches present around the Mediterranean Sea are suffering severe erosion. Main causes are indeed the strong human pressure on them and their high exploitation during touristic season. However, some natural effects cannot be ruled out and in some cases these can accelerate (or slow down) the human induced processes. Climate changes are seen as the principal trigger of coastal erosion, although the high urbanisation of Mediterranean coasts can amplify a lot this natural phenomenon.

It is widely accepted that the Holocene is an interglacial time and that since 6 ka years sea level did not changed much. However, it is not clear if we are at the apex of an interglacial high stand or if we are moving toward higher sea levels.

According to the record of the last 400 ka, after a glacial time sea level rises continuously without major still stands. Once the sea water has reached a maximum high, it stands for about 10 ka before to fall toward a relative low stand.

The last interglacial (MIS 5, 130-75 ka) may be considered the best analogue to be compared with the present one. Several studies have indicated that it could be split in five intervals (a, b, c, d, e) where a-c-e are the relative sea-level highs and b-d the lows. A general agreement exists considering that during MIS5e sea level was at about 5-6 meters above the present and that Mediterranean climate was about 5 °C warmer and tropical fauna developed in this warm sea. Less agreement occurs, instead, on the sea-level high during MIS5c and MIS5a. Recently, studies on MIS5 have been conducted in Sardinia. This because the island has been and can, thus, provide valuable information about sea-level variation in relation to climatic changes of the late Quaternary. Systematic studies conducted in north-west Sardinia on late Quaternary deposits have indicated that during MIS5c sea level was at about 1 m above the present and climate comparable to the present one. The objective of this presentation is to compare the main features of the MIS5c beaches with modern equivalents to unravel the question: how strong is the human impact on modern beaches.

MIS5c beaches were mainly sandy with a well developed coastal dune system in their backshore. In few places mixed sandy-gravelly beaches have been found as well. Sand is composed of siliciclastic and bioclastic grains. These last are normally up 40% of the grain population. Bioclastic grains derived from organisms living in the *Posidonia oceanica* seagrass meadows, well developed just few meters offshore. Similar modern beaches composed by 60 to 90 % bioclastic grains occur in protected areas where human influence is negligible (Maddalena and Asinara National Parks). They show an equilibrium profile and are not interested by erosive processes. On the contrary most of other heavily used (mainly for tourism) beaches of north-west Sardinia, such as Alghero, Stintino and Palatamona, suffer considerable erosion. Most of them are slanted for artificial nourishment to be able to sustain touristic activities.

This example indicates that uncontrolled, intense human activity leads to deterioration of the coastal environment. The obliteration of the coastal dunes, for example, that are the temporary storage of sand during storms, disrupts the natural cycle of the natural re-nourishment of the beach during fair-weather conditions. Beside depleting of the quality of the environments and of the natural vegetation and fauna, this will entail a considerable increase in expenditures to maintain the setting acceptable for the activity intended.

FORESEEING THE GEOLOGICAL CARTOGRAPHY OF SUBMERGED AREAS FROM THE EXPERIENCE OF THE CARG PROJECT

FIORENTINO Andrea¹, D'ANGELO Silvana¹
 1 - ISPRA - Geological Survey of Italy

Presenter e-mail: andrea.fiorentino@isprambiente.it

Key terms: geological map; marine geology; geodatabase

Geological cartography of submerged areas so far produced within the CARG Project has allowed to establish direct connections between marine and land deposits. Criteria of representation evolved from basic texture of sediments to different categories of deposits subdivided according to their depositional environment and in the frame of unconformity bounded stratigraphic units, applying sequence stratigraphy methods.

The great diversity of geo-morphological settings of Italian Seas requested to take into account several parameters in order to be able to represent every attribute of each environment. All features have subsequently been represented according to standards homogeneous over the entire national territory.

The characteristics of the areas surveyed vary from a high rate of sedimentation to starvation, from carbonate sedimentation to volcanic deposits, from tectonically active shelves to lagoons. Such variety highlighted specific aspects of the seafloor which entangle other issues as the reconstruction of past climatic cycles, changes of coastline, assessment of risk levels in submerged areas, identification of areas of environmental interest, spread of pollution, marine resources. It has become clear that a multidisciplinary approach is needed in carrying on any kind of research in marine environments. The Geological Map of Italy (including submerged areas) could profitably be integrated with other data. The geodatabase, which constitutes a fundamental achievement of its realization, may well work as the connecting tool to interface with different disciplines.

In the future it might be desirable that, while planning a survey for any specific task, every aspects would be taken into account in order to collect in one shot all relevant data. This would lead to a better understanding of the environments surveyed and to a more detailed characterization of the issues to be studied, since there are no parameters which are not

connected to others. Sediment texture does not depend only on geological and morphological factors, but also relies on the biogenic component produced by organisms; biocoenoses do not depend only on temperature and nutrients, but also on the geological composition of the substrate; physical parameters are also influenced by living assemblages.

- Presenter e-mail: m.putignano@alice.it

Key terms: Campania Region; Cartography; sea level change

The Campania Region has participated in the National Project CARG confirming its institutional and financial presence with the aim of improve the geological knowledge in the region.

In particular, the CARG project of the Campania Region aims to make available a new national geological mapping at scale 1:50,000 and 1:25,000. At the same time, this project provides to local and regional communities a series of maps at 1:10,000 scale, produced following the CARG criteria specific for coastal areas. For this reason, the Campania Region has fully funded the implementation of geological mapping of the emerged and submarine coastal zones.

The regional CARG project has planned the geological survey of the submarine areas, from the coastline down to -200 m depth; the geological surveys have been carried out at 1:10,000 scale in order to make a significant contribution to knowledge, so allowing to define the evolutionary trends, which are very useful for the planning and managing processes of the coastal zones.

The selected scale corresponds to that required by ISPRA for the emerged landscape.

Three specific geological environments have been analysed:

- 1) the emerged area;
- 2) the submarine coastal zone (from 0 down to -30 m depth);
- 3) the marine zone (from -30 m down to -200 m depth),

and the results were summarized in a single final map. Of particular importance as well as innovative was the underwater geological survey of the submarine coastal zone (from 0 down to -30 m depth). The peri-coastal sea-bottoms were investigated at scale of 1:10,000 through underwater surveys with scuba diving techniques, by geologists with proven expertise in underwater CARG Project. These surveys have enabled the production of thematic and basic geological maps which were produced using the same standard criteria established for the maps of the contiguous emerged areas.

The cartography of the submerged coastal zone obtained by direct observations (divers) was also based on other types of geophysical seabed investigations (Multibeam, Side Scan Sonar, Sub-Bottom Profiler). These geophysical surveys are an useful support for the complete mapping of the outcropping geological units as well as for the spatial distribution and depiction of the geomorphological and biocenotic aspects.

The reconstruction of the seabed physiography through precise bathymetric surveys highlighted the geomorphological elements (i.e., erosion and deposition marine terraces, paleo-cliffs, etc.) which represent indicators of ancient sea-level stands and changes. At the same time, dives have identified further evidences of paleo sea-levels (i.e., sea-notches, sea caves, small abrasion platforms, bands of littoral deposits, beachrocks, etc.) which, because of their small size, can not be identified with geophysical methods, particularly when they are located along steep underwater cliffs or buried by limited marine vegetation covers.

The results have been reported in official maps at 1:25,000 scale according to the ISPRA standards, after a suitable generalization for the adopted reference scale, while are widely expressed in the regional geological maps at 1:10,000 scale. In particular, all the islands of the Gulf of Naples (islands of Ischia, Procida and Capri, and Isle of Vivara), characterized by numerous witnesses due to sea level changes, show a rather complex evolutionary scenario especially during the Quaternary.

SEDIMENTARY DYNAMICS OF THE MARETTIMO CONTINENTAL SHELF AND MARETTIMO CHANNEL (EGADI ISLANDS - WESTERN MEDITERRANEAN): ANALYSIS OF DEPOSITIONAL AND EROSIONAL FEATURES.

POLIZZI Sabrina¹, LO IACONO Claudio², AGATE Mauro¹, SULLI Attilio¹

- 1 - Department of Earth and Marine Science of the University of Palermo.
- 2 - Unidad de Tecnología Marina - CSIC (Barcelona, Spain).

Presenter e-mail: sabrina.polizzi@unipa.it

Key terms: Sedimentary dynamics; Marine geomorphology; Marine bedforms; Egadi Islands

Sedimentary dynamics of the Marettimo continental shelf and Marettimo Channel (Egadi Island - Western Mediterranean), have been unveiled based on the erosive and depositional features observed at the seafloor. Different morphologic features were recognized through side scan sonar, multibeam and high-resolution seismics, acquired in the framework of national Research Projects (CARG, GebecSud, MaGIC) carried out by the Department of Earth and Marine Science (former Department of Geology and Geodesy) of the University of Palermo. Sediment samples have been also collected and analyzed.

The Egadi Islands are part of the NW Sicilian offshore, and belong to the mountain chain that connects the Sicilian chain to the Maghrebides one. The Marettimo Island represents an isolated portion of the Egadi continental shelf and is separated from the rest of the archipelago by the Marettimo Channel.

Previous studies allowed to recognize different kind of sedimentary

structures along the seafloor. Lo Iacono and Guillén (2008) described extensive field of subaqueous dunes (Ashley, 1990) along the Marettimo inner shelf, forming on gravelly and pebbly sediments and related to strong storm events (H:5.5 m, T: 12 s). Larger dunes have been observed in the north-western sector of the inner shelf with wavelengths ranging from 1 to 2.5 m, heights between 15 cm and 30 cm and extending laterally for hundreds of meters. Moreover in the north-eastern sector of the inner shelf, sorted bedforms have been detected at a depth of 40 m: they are characterized by a width varying between 15 m and 50 m and a length that reaches hundreds of meters.

In the south-eastern sector of the Marettimo outer shelf, Colantoni et al. (1993) map two groups of sedimentary structures. In the same area, Lo Iacono (2004) recognized two-dimensional and three-dimensional subaqueous dunes. 2D dunes are found at depths between 60 and 90 m and show a wavelength variable between 15 and 50 m. 3D dunes, which are found at a depth of 80 m, are characterized by a wavelength of 30 m and a lateral extent of 50 m.

Morphological evidences of a strong hydrodynamic regime come also from the morphobathymetric analysis of the Marettimo Channel, that is a 24 km long submarine valley oriented NNW-SSE, with a depth ranging from a minimum of 180 m to a maximum of 370 m and a width from 2 km to 14 km. Inside the channel, south of its narrowest point, a 180 m deep bathymetric threshold separates two areas, which deepens towards opposite directions: north-west and south. The flanks of the sector that deepens towards the NW are affected by mass-wasting features (Lo Iacono et al., 2007). The western flank of the channel, which delimits the Marettimo continental shelf, is carved by gullies, making the shelf-edge very uneven. Gullies develop to a maximum depth of 280 m and have a length of 250 m and a width of 50 m. At the bottom of the channel a linear incision 20 m deep, 400 m wide and almost 3 km long, is probably generated by erosive bottom currents.

On the whole, the morpho-sedimentary structures here described reveal a strong hydrodynamic regime. The morphological and textural features of the bedforms observed on the Marettimo inner continental shelf suggest the occurrence of sporadic medium to strong storm events coming from western sectors. The morphological characteristics of the Marettimo Channel reveal the occurrence of strong bottom currents probably related to the severe interchange of water masses between the Tyrrhenian Sea and the Sicily Channel.

MARINE LANDSCAPES AND HABITATS OFF THE CAMPANIA REGION (EASTERN TYRRHENIAN SEA)

VIOLANTE Crescenzo¹, D'ANGELO Silvana², MONTI Lucilla³, PUTIGNANO Marisa³

- 1 - Istituto per l'Ambiente Marino Costiero - CNR
- 2 - ISPRA Geological Survey of Italy
- 3 - Campania Region - Settore Difesa Suolo

Presenter e-mail: crescenzo.violante@iamc.cnr.it

Key terms: Marine Landscape; Habitat; Campania; Geodiversity; Geosite

Marine landscapes off Campania region are dominated by geologically young structures and by sedimentary processes. This mid-latitude sea area is composed of three main basins namely Voltorno Bay, Naples Bay and Salerno Bay and by a number of minor basins. It develops along the eastern margin of the Tyrrhenian sea across the boundary between the Apennine chain and the Tyrrhenian extensional area where Quaternary tectonics deeply controlled the physiographic setting. Sedimentary processes related to dynamics of Voltorno and Sele rivers contributed to shape the seascape off the Voltorno and Sele plains respectively. In the Naples Bay the occurrence of some of the most active volcanoes, namely Phlegrean Fields and Somma-Vesuvius, significantly influenced marine and coastal habitats and landscapes.

The Marine Landscape concept aims to describe the marine environment with respect to its main geophysical features, in terms of both the seabed and water column. It focuses also on the formation and consequences of spatial heterogeneity and dynamics in natural and human dominated environments and how spatial pattern controls ecological processes. Moreover, the strong ecological relationship between the physical environment and the character of biological communities allows the use of Marine Landscapes as surrogates for marine communities.

Whilst the habitat mapping approach is most suited to detailed (fine-scale) classification of the seabed, marine landscapes allow classification of the marine environment at an ecological relevant scale. The two approaches are hierarchical related to each other even if many habitat types can occur in several landscape types.

Currently the Marine Landscape concept is applied for management purposes both in Europe and USA. The general deterioration of the marine environment have resulted in the wide recognition that an ecosystem based approach to the management of marine environment is necessary for promoting a future sustainable development. There are various initiatives and legal requirements, such as the implementation of EU directives (EC Habitats Directive, EU Water Framework Directive, EU INSPIRE Directive and the EU Marine Strategy Directive), the identification of marine protected areas (MPAs) and the assessment of the ecological coherence and representativity of existing MPA networks, e.g. the Natura 2000, that endorse the current needs for broad-scale information. In particular the Regione Campania (Southern Italy) has issued "Standards and strategic directions for the protection, management and development of the regional geodiversity and places of special geological interest (GEOSITES)". Such legislation apply to marine environment with the identification of submerged geosites and recognizes the need to protect the various geologic and physiographic attributes as important entities shaping marine landscapes.

Based on such regional directive we started to classify seabed off the Campania Region using available bathymetric, backscatter and sedimentologic data that allowed to identify topography and bedform features. The interpretative process led to a first individuation of submerged Geosites occurring on the continental shelf area.

APPLICATION OF ACOUSTIC METHODS FOR MARINE HABITAT MAPPING AND CLASSIFICATION IN THE MARATEA COAST (BASILICATA, ITALY)

INNANGI Sara¹, BARRA Marco¹, DE FALCO Gianni², DI MARTINO Gabriella¹, TONIELLI Renato¹

1 - IAMC Sede - CNR
2 - IAMC UOS Oristano - CNR

Presenter e-mail: sara.innangi@iamc.cnr.it

Key terms: Multibeam; Backscatter; Acoustic facies; GIS; Habitat mapping

Habitat mapping and classification is recognised as a central topic in the definition of the quality of marine environment in the framework of the EU Marine Strategy. Acoustic methods for seafloor mapping have been widely developed over the last decades. In particular, the development of swath bathymetry has enabled the creation of detailed maps of seabed topography and acoustic backscatter data; these data have been used to predict sediment and habitat types.

The Institute for Coastal Marine Environment (Istituto per l'Ambiente Marino Costiero - IAMC) of CNR of Naples carried out a multidisciplinary study focused on the construction of subsurface sedimentological and bionomic maps along the Maratea coast (Basilicata region, south Tyrrhenian sea) which represent the raw data for the definition of marine protect area. For this purpose acoustic swath bathymetric data were collected, together with sediment sampling and direct scuba investigation on benthic communities.

In September 2007 the whole margin of the Basilicata Tyrrhenian coast was mapped using the Multibeam Seabat 8125 which, thus producing very high resolution digital terrain models. Furthermore backscatter data by Multibeam were acquired in order to distinguish the different habitat types based on their acoustic response. The backscatter is based on the acoustic signal detected by the Multibeam's receivers, and it works as the receivers of standard sidescan sonar by recording the acoustic response of the seabed, in relation to the morphology, composition and fine scale roughness of the beds. The main difference between standard sidescan and the "multibeam backscatter" is that the first may be brought to the towing vessel to the wanted depth, while the "multibeam backscatter" is mounted to the pole and its resolution decreases with increasing depth. Nevertheless the high-resolution data of acoustic swath mapping with Seabat 8125 allowed creating a 20 cm per pixel backscatter mosaic until to ~50 m depth. Furthermore the differences between the acoustic signals derived from different facies, in terms of pixel intensity of the sidescan image, have been tested using statistical methods.

The boundaries of the recognized acoustic facies were subsequently digitalized with software GIS Geomedia Professional to obtain a first habitat mapping. On the basis of acoustic facies recognized, forty-five sediment samples along the coast (~10 to ~30 meters) were collected by grab Van Veen and analyzed for sediment grain size. Ground truth data were also collected with scuba diving investigation in order to attribute the different acoustic facies to a specific habitat. Finally bionomic and sedimentological maps were obtained and used to characterize the marine environment of Maratea coast.

Key terms: Deep-water corals; Otranto Channel; acoustic methods; gravity cores

Deep-water coral communities were imaged and sampled in the Otranto Channel (southern Adriatic Sea) during the BIOS submarine fibre optic cable system survey performed by the R/V OGS Explora in February 2011. The presence of coral bodies have been observed by both Side Scan Sonar and Sub-bottom profiler on the top part of carbonate mounds and confirmed by corings.

The evidence of these coral colonies were previously supposed by geophysical analysis of a vintage MS multichannel seismic line and a more recent high resolution acoustic dataset (Sub-bottom profiler and Multibeam echosounder) by Geletti (2008) and Del Ben et al. (2008). This discovery of "white coral" communities adds to findings made in surrounding areas on the Apulian Plateau in the Ionian Sea (Tursi et al., 2004; Taviani et al., 2005a; Fusi et al., 2006; Taviani, 2008) and on the Gondola Slide, Bari Canyon, Jabuka Trough in the Adriatic (Zupanovic, 1969; Bombace e Frogliola, 1972; Trincardi et al., 2007; Freiwald et al., 2009).

Acknowledgements

We wish to express our sincere thanks to the Bezeq International telecommunications group for permission to publish the gravity cores data.

Key terms: Mediterranean; sea level; archeology; geodesy; geophysics

Coastal settlements and maritime installations built in antiquity along the coasts of the Mediterranean sea provide important insights into relative sea-level changes and vertical motion of the land during past millennia.

We present and discuss field data from more than 150 sites of valid coastal archaeological sites dated back to 1.6-2.5 ka BP. Particular attention was given to the elevation of the significant architectural features related with the sea level and we introduced the concept of "functional elevation". Field measurements were performed by invar rod, optical or electronic methods, during calm sea with null wave action. Elevations are related to the sea-level position at that moment. Data accuracy with their uncertainties for age and elevation at each site, are estimated on the basis of the type of indicator used and of the historical literature, based on the artifacts or on the architectural features. Observations of geomorphological indicators, such as beachrocks and solution notches, are used to integrate and reinforce the archaeological interpretations as in Antonioli et al. (2007).

The analysis was performed during four different steps: 1) the elevation of the valid sites were measured with respect to the sea level at the time of surveys; 2) measurements were reduced to mean sea level of the site itself, applying tidal corrections at the surveyed sites, using the data of the nearby tide gauges (www.idromare.it; www.pmsl.ac.uk). 3) finally, we examined the predicted and observed sea levels, by comparing the current elevations of the markers with the sea-level elevation predicted by the proposed glacio-hydro-isostatic model for each location. We hypothesize tectonic stability at the sites where the elevations of the markers are in agreement with the predicted sea-level curve. Conversely, we hypothesize that the area has experienced tectonic or volcanic subsidence or uplift when the elevations of the markers are below or above that of the predicted sea-level curve, respectively. We use the calibrated model results to separate out the tectonic contribution, widely diffused in the Mediterranean, from the vertical movements related to the glacio-hydro-isostatic changes. Our analysis are consistent with model predictions as well as trends inferred from seismic strain analysis of earthquakes occurred during the last 30-40 years and tide gauge data for the last ~100 yr. This indicates that besides the glacio-hydro-isostatic effect, also the tectonic contribution can affect the relative sea level changes along the coastlines of the Mediterranean, since the last ~2.5 ka.

Presenter e-mail: sbiolchi@units.it

Key terms: Sea level change; geoarchaeology; Malta

Until now, few archaeological or geomorphological data have been considered to evaluate late Holocene sea level changes along the Maltese coast, although both the geomorphological evolution and the development of coastal settlements could provide useful information on the active tectonics.

We aim at providing new data on coastal archaeological remains collected along the southern coast of Malta and at discussing the relative late Holocene sea level changes.

Malta lies in the Sicily Channel, about 200 km south of the convergent segment of the Europe-Africa plate boundary. The Sicily Channel has been

affected, during Neogene-Quaternary, by continental rifting which produced extensive structures, controlled by NW-directed sub-vertical normal faults. The Maltese graben system is characterized by two intersecting fault trends.

The studied sites are located on lower Miocene limestones, belonging to the Globigerina Limestone Formation. We studied three archaeological structures, the first at St. George's Bay, at Birzebugia, the second at Marsaxlokk and the latter next to Manoel Island, at the Valletta Harbour. The Birzebugia archaeological site provides remains of activities related to the coastal zone, during the Bronze Age. It provides two types of archaeological remains. The first type are Bronze Age pits (3500-2900 BP), located close to the shoreline on a Globigerina Limestone platform, which are partially submerged. They were dated using pottery discovered in an archaeological site close to the coast. The altitude of the lowest pits is -0.9 m and it represents the upper limit of sea level in the studied period, considering that they had to stay surely always above the sea. The altitude of the lowest pit is -0.9 m. The second type are prehistoric cart tracks, completely submerged.

At Marsaxlokk two Roman age piers have been found out and measured: they are slightly inclined off-shore, are about 12 m long and their top ranges from -0.6 and -0.9 m m.s.l. The bottom of the sea is at about -1.15 m. Considering the functionality of the structure, they could be used as very small docking structures.

At Manoel Island, submerged tanks, maybe Roman in age have been surveyed: their altitude ranges between -1.20 m at the bottom and -0.7 m at the top of the walls. They could be used to produce garum or purpura.

On the island, archeological structures directly carved on rocky outcrops are very common, because of their high rock erodibility. The soft Globigerina Limestones outcrop along the Southern and Eastern sector of the island. Archeological remains have been surveyed just along these coasts. Anyway, observations carried out along the Maltese coast recorded the presence of a number of nineteenth-century (Victorian-age) swimming pools, usually architecturally well-defined. Their position and their relative bad conservation can easily cause misunderstandings, inasmuch as they can be confused with coastal archaeological remains.

Considering the submerged tanks at Manoel Island, despite their complex attribution, concerning both the age and the function, they seem to suggest that sea level was some tens of centimeters lower than the structure, that is about -1.0 m lower than nowadays. Even Roman age piers at Marsaxlokk seem to indicate the same relative sea level change. On the contrary, the altitude of the lowest Bronze Age pit represents the upper limit of sea level in the studied period, considering that they had to stay surely always above the sea.

No presence of MIS 5.5 deposits have been surveyed due to the exposition of the island, that prevents the conservation of rocks and deposits, or to the slightly submerged position of the Tyrrhenian deposits which deleted them.

Even if, at the moment, few data are available and better interpretations are required, the comparison of surveyed data and Lambeck predicted curve, slight late-Holocene vertical displacement seem to be occurred.

Key terms: Coastal geomorphology; Tectonic uplift; North-eastern Sicily; Marine geology

Vertical position of sea-level, pointed out by related deposits and morphologies, provide useful markers to estimate tectonic uplift rates. For the Holocene very high uplift rates are measured in the northeast Sicily coast (Antonoli et al., 2009). This study compare vertical tectonic movements and marine geology data in the coastal sector between Capo d'Orlando and Brolo (NE Sicily); tectonic lineaments show different trends both onland (Nigro & Sulli, 1995) and offshore (Nicolich et al., 1982) and also the morphological response follow closely this difference. The geomorphologic survey provided data on Holocene uplift rates. We studied an archaeological ancient quarry of grinding wheels for oil that has been found in the Capo d'Orlando inshore (Scicchitano et al., 2011). They present semi submerged circular holes in Stilo-Capo d'Orlando deposits (Carbone et al., 1998). The tectonic uplift was evaluated as the difference between the observed local paleo-sea level position and the predicted sea-level curve for the same locality (Lambeck et al., 2011). The resulting uplift rates is 0.36 mm/yr (Scicchitano et al., 2011). In this area we studied also the Brolo stack. It is a metamorphic rocks emerging at 450 m from the coastline. The study led to discovery a fossils-bearing conglomerate in protected trays at 3.5 m a.s.l.. Radiocarbon analysis on a gastropod, gave us an age of 4965 years \pm 70 cal BP. If we compare this data with the predicted local sea level curves (Lambeck et al., 2011), we obtain an uplift rate about 1.5 mm/yr (Lo Presti et al., 2010), which is higher than that calculated in the study of archaeological rest. A detailed study of Brolo sector show us different morphological coastline position of Brolo plain. A picture of the year 1847 shows the coastline about 200 m landward. In Brolo coastal plain we have also found a Spondylus at -6 m b.s.l. We wait for the radiocarbon dating which allows us to have a new uplift rate data.

The analysis of marine geology data (Multibeam) evidenced structures connected to different faults systems, such as the submarine canyons that are the continuation of river beds. Multibeam data evidenced also tilted NE-ward submerged surfaces, indicating existing structural movements, interesting only restricted areas. So, very different uplift rates in the Holocene in very close areas distant only about 10 kilometers: both 0.36 mm/yr (Scicchitano et al. 2011) and 1.5 mm/yr (Lo Presti et al. 2010), and morphobathymetric data (tilted surfaces), evidence the important role of active tectonic lineaments. Seismic reflection profiles support this assumption, showing the metamorphic basement strongly dissected by high-angle faults, which at place determines the occurrence of emergent rock bodies (e.g. the Brolo stack). All this suggesting the occurrence of "restricted regions" in the coastal-marine sector with different geological behavior as response to prominent tectonic releasing bands, determining their horizontal and vertical movements.

Key terms: Mediterranean; sea level; archaeology

Coastal settlements and maritime installations built in antiquity provide important insights into sea-level changes during past millennia, and reconstructions of historical sea-level change using archaeological coastal sites are particularly effective in the Mediterranean sea, whose coastlines still preserve remnants of human activity since the last glacial maximum. The first pioneering results on sea level changes from archaeological indicators in the Mediterranean were published during the '70s, but new and more detailed results arise for the Mediterranean during the last decade.

Unfortunately, despite the large number of archaeological remains in the Mediterranean, only a part of them can be used to obtain reliable information on their former relationship to sea level. Limitations arise as a result of their uncertain use, poor preservation, or because they were built in geologically unstable areas which produce local disturbances. Particularly valuable are the roman age coastal sites. Fish tanks, piers and harbors constructions, generally dated between the 1st century BC and the 1st century AD, are very precise indicators. Quarries carved along the coastlines and located nearby fish tanks and harbors or villas of similar age, can provide additional data on past water level, as well as information on their elevation above sea level, although these alone are less precise indicators.

In this work we indicate the guidelines on how the coastal archaeological sites can be used to measure the intervening relative sea level changes since their construction. Particular attention was given to the elevation of the significant architectural features related with the sea level. We defined the "functional elevation" as the elevation of specific architectural parts of an archaeological structure with respect to the local mean sea level at that location and at the time of its construction. It depends on the type of structure, its use and the local tide amplitudes. The minimum elevation of particular structures above the local highest tides can also be defined. Finally, structures from different ages can provide a relative sea level curve for that specific site.

IODP-ITALIA: PRESENT AND FUTURE.

ERBA Elisabetta¹

1 - Università degli Studi di Milano, Dip. Scienze della Terra

Presenter e-mail: elisabetta.erba@unimi.it

Key terms: IODP; Italian participation; state of the art; perspective

Italian Earth scientists have been involved in DSDP, ODP and IODP, writing proposals, participating as co-chiefs, shipboard and shorebased scientists, serving in the science advisory structure, (co)organizing and participating to conferences, workshops and summer schools. Italy also hosts one of the International Micropaleontological Reference Centers in Parma, where DSDP, ODP and IODP material has been used for research and training.

The talk is intended as an update of the financial and organizational situation of IODP-Italia as well as a report of IODP-related activities organized and/or performed by Italian researchers during FY 2010 and FY2011.

Information about possible post-2011 scenarios will be presented in order to increase interests of the Italian Earth Science community and consciousness about the role that individual researchers can play.

ON-AXIS VS OFF-AXIS ACCRETION OF SUPERFAST SPREAD CRUST IN THE PACIFIC OCEAN (EAST PACIFIC RISE, 6°44.2' N)

TARTAROTTI Paola¹, CRISPINI Laura², PANSERI Matteo¹, FONTANA Emanuele¹

1 - UNIVERSITA' DEGLI STUDI DI MILANO

2 - UNIVERSITA' DI GENOVA

Presenter e-mail: paola.tartarotti@unimi.it

Key terms: oceanic crust; crustal accretion; fast spreading ridge; Pacific Ocean; lava flow

Crustal accretion at mid-ocean ridges occurs by a combination of magmatic and tectonic processes. Along fast and superfast-spreading ridges magmatic activity is the dominant process. Fast spread ocean crust is believed to be less variable than crust formed at slower spreading rates and closer to the ideal "Penrose" pseudostratigraphy developed from ophiolites (Anonymous, 1972). For this reason, ocean crust created at superfast East Pacific Rise was selected by Integrated Ocean Drilling Program with the main purpose of sampling a complete in situ section of ocean crust far from transform faults. IODP Hole 1256 (6°44N, 91°56W) lies in 3635 m of water in the Guatemala Basin on Cocos plate crust formed ca. 15 my ago on the eastern flank of the East Pacific Rise. Three IODP Expeditions (ODP Leg 206, IODP Exp. 309 and 312) have been devoted to drill Hole 1256D, and in these days (April-June 2011) a fourth cruise, IODP Expedition 335, is in progress for deepening the hole. The uppermost crust at Site 1256 comprises a ca. 100 m thick sequence of lava dominated by a single massive lava flow up to 75 m thick. The lavas immediately below include sheet and mas-sive flows, along with minor pillow flows. The extrusive section occurs down to 1004 mbsf before a lithologic transition marked by subvertical intrusive contacts and mineralized breccias. Below 1061 mbsf, subvertical intrusive contacts are numerous, indicating the beginning of a ca. 350 m thick sheeted dike complex dominated by massive basalts. The contact with underlying gabbros at 1407 mbsf is not sharp but characterized by cm-sized gabbroic and trondhjemite intrusions within recrystallized granoblastic dikes, marking the top of the plutonic complex. Two major bodies of gabbro were penetrated beneath this contact, with the 52 m thick upper gabbro separated from the 24 m thick lower gabbro by a 24 m screen of granoblastic dikes. The stratigraphy of the superfast spread ocean crust at IODP Site 1256 differs from that of other drilled fast and intermediate spread crust (e.g., ODP Hole 504B) for the relatively thin sheeted dike complex and occurrence of a thick lava flow (lava field) on the top. The lava field is of probable off-axis origin, although it may have originated at the ridge axis before flowing onto the ridge flanks, as is observed for very large lava flows on the modern ocean floor. However, structural investigations on cores and thin sections, integrated by geophysical log data confirm the inference of an off-axis origin for the lava field. It is much less fractured than the deeper lavas and shows higher values of electrical resistivity and compressional wave velocity. The frequent occurrence of channelized lava flows in fast spreading ridges have been documented by high-resolution side-scan sonar surveys. Spreading rate is an important parameter controlling crustal accretion. In fast spreading ridges, however, volcanic material is not only added at centrally located ridge axis, but it is also delivered off-axis. The resulting stratigraphy is thus affected by accretion modality referable to both on-axis and off-axis settings.

Key terms: Oceanic Anoxic Event 1a; Osmium isotope; Volcanism; Weathering

In the early Aptian, the ocean experienced a global phenomenon of widespread deposition of organic carbon-rich sediments under oxygen-poor conditions: the Oceanic Anoxic Event 1a (OAE 1a or Selli Event: ~120 Ma). Triggering mechanisms for OAE 1a are thought to be an exceptional episode of submarine volcanism, namely the emplacement of the Ontong Java Plateau (OJP), associated with global warming and enhanced primary productivity. Osmium- isotope ratios are used as a high-resolution geochemical proxy because they potentially offer information on the timing, duration and proportion of globally significant volcanic/hydrothermal activity versus continental weathering. Here, we consider new Os-isotope and Carbon stable-isotope analyses produced from two sections: DSDP Site 463 (Mid-Pacific Mountains, situated relatively close to the Ontong-Java province at the time of its emplacement; and the Cison core (Southern Alps, N. Italy) that accumulated in the margins of the Tethyan Ocean. Both sections are well dated through bio-, magneto-, chemo-, and cyclostratigraphy, providing high-resolution time control and correlation; moreover, micropaleontological and geochemical proxies contribute to the characterization of the OAE 1a.

Variations in the 187Os/188Os ratios are suggestive of both massive magmatic pulses and accelerated continental weathering. The Ontong Java emplacement started before and then persisted very intensely for most of OAE 1a (as conventionally defined). The dominant feature is a ~880 kyr-long unradiogenic Os-isotope interval, requiring a large contribution from a mantle source, and implying a homogenous Os-isotope composition of seawater. A short-lived (~100 kyrs) radiogenic Os-isotope spike has been detected in the early phase of OAE 1a. These high-resolution records also show how volcanism and the associated marine anoxia were related to changes in marine biota that took place before and during the interval of global anoxia.

Key terms: Planktic foraminifera; Paleogene; Biostratigraphy; Phylogeny; Ocean Drilling Program

The evolution of planktonic foraminifera in the Paleocene-Eocene time interval is characterized by a high rate of diversification after the major extinction event observed at the Cretaceous/Paleogene boundary. The accelerated speciation rate resulted in the appearance of several new genera (i.e., Igorina and Acarinina among others) each of them identified on the basis of distinctive wall texture of the shell. Phylogenetic relationships within many genera are still poor understood including the origin and phylogeny of the genus Igorina. This group, characterized by a thick, nonpinose and incrustated wall, appears in Subzone P3a (early late Paleocene) and disappears in Zone E9 (middle Eocene). To date, nine species have been assigned to the genus Igorina (I. pusilla, I. trichotrocha, I. tadjikistanensis, I. convexa, I. albeari, I. laevigata, I. lodoensis, I. broedermanni and I. anapetes) based on both wall texture and morphologic similarities.

This study is aimed to reconstruct the phylogeny and evolution of the igorinid species with cladistic analysis by applying the method of parsimony. To perform the study, two hundred samples have been analysed from Ocean Drilling Program (ODP) Leg 198 Hole 1209B (Shatsky Rise, Central Pacific Ocean), Leg 143 Hole 865B (Allison Guyot, Central Pacific Ocean), Leg 15 Sites 151 and 152 (Caribbean Sea) and Leg 113 Hole 690B. The biostratigraphic analysis of sub-tropical localities revealed some problems in applying the previous biostratigraphic scheme (Berggren and Pearson, 2005) mainly because some marker species 1) have been misinterpreted and/or misidentified several times in previous studies, 2) show a delayed appearance with respect to what reported from other localities, and 3) are very rare or absent in the studied samples. Species identification was mainly performed through comparison with the original descriptions and illustrations and partially follows Subbotina (1953), Blow (1979), Olsson and others (1999), Pearson and others (2006). Phylogenetic relationships of the species assigned to Igorina are determined through stratocladistic analysis by using a data matrix of 23 taxa (including key species of Acarinina), 31 morphological characters (unordered), and a stratigraphic character (ordered) mapping the first occurrence of the taxa under investigation. The morphological characters included in this analysis are based on morphometric measurements such as the angle of chambers, maximum diameter of the inner whorls, angle of peripheral margin, among others.

Some morphotypes of uncertain taxonomic identification but showing consistent morphological and wall texture features have been coded and analysed separately as morphotypes A, B, C, D, E and F to determine their ancestor-descendant relationships and evaluate their validity as discrete species. The software PAUP* (Swofford 2002) has been used to process the data and to obtain a numerical matrix with codified the selected characters, then the matrix has been processed using the heuristic search option to discover the most parsimonious trees.

Results suggest that Igorina pusilla is the first representatives of the Igorina lineage and is subsequently followed by I. laevigata, I. albeari, and I. tadjikistanensis in agreement with their stratigraphic distribution. Morphotypes (C, E, F) have been included in Igorina parapsiralis (Soldan and others, 2011) while Igorina morphotype A represents a single species (Igorina praecarinata Soldan and others, 2011). Morphotypes B and D fall in the variability of well-know species. Moreover, the analysis provides evidence that I. lodoensis, I. broedermanni and I. anapetes are more closely related to genus Acarinina than Igorina and clearly belong to a different lineage. A preliminary analysis of the wall texture architectures of the broedermanni group has been performed to assess their ancestor-descendant relationships and to evaluate the possibility to place them in a discrete new genus.

CARBONATE PRESERVATION AND PRIMARY PRODUCTIVITY INFERRED BY CALCAREOUS NANNOFOSSILS: AN EXAMPLE FROM THE MIDDLE-LATE PLEISTOCENE SEDIMENTS OF THE NORTH WEST PACIFIC OCEAN (ODP198-1209B, SHATSKY RISE)BORDIGA Manuela¹, LUPI Claudia¹, COBIANCHI Miriam¹¹ - Pavia University, Department of Earth Sciences and Environment

Presenter e-mail: manuela.bordiga@dst.unipv.it

Key terms: Calcareous nannofossil; Primary productivity; Preservation; Middle-Late Pleistocene; ODP198-1209B

Calcareous nannoplankton is one of the major producers of pelagic carbonates and contributes significantly to the primary productivity influencing the global climate. To better understand the complex interactions between phytoplankton and climate system, the relationship among preservation of fossil assemblages, paleoproductivity and glacial-interglacial cycles is intensively studied. This work, based on a quantitative micropaleontological approach, aims to evaluate the calcareous nannofossil preservation and the primary productivity in the North West Pacific Ocean during the Middle-Late Pleistocene. The studied material was recovered from the site ODP198-1209B located in the southern margin of the Shatsky Rise, an oceanic plateau east to Japan. The Pleistocene calcareous nannofossil content is here studied in detail for the first time. A total of 109 samples were collected from the top of the core to 11 mbsf (meter below sea floor) with a sampling rate of 10 cm and analysed in their nannofossil content under a polarized light microscope at 1000X magnification. The studied interval records the last 0.785 Ma, inferred from magneto-biostratigraphic data, with an estimated time averaging of about 7 kyr. Additional Scanning Electron Microscope (SEM) analyses were carried out on random samples in order to check the absolute abundance of some proxy species (like Emiliaia huxleyi and Florisphaera profunda). The nannofossil associations are abundant, well preserved and diversified. The nannofossil dissolution is evaluated using several indices proposed in literature that take into account the ratio between dissolution-resistant and more delicate taxa. These indices are: the dissolution curve of Calcidiscus leptoporus (Matsuoka 1990), the NDI index (Marino et al 2009), the CEX index (Dittert et al 1999) and the CEX' index (Boeckel and Baumann 2004). The Fragmentation Index (FI) from planktic foraminifera, is also evaluated only for 4 meters of the record. The C. leptoporus curve, the NDI and the FI suggest good preservation throughout the succession, confirming the qualitative observations made during the counting and their usefulness for the dissolution evaluation. The C. leptoporus curve and the NDI show a correlation value of 0.97 and both, in turn, correlate for a value of about -0.68 the FI. The CEX and CEX' show low correlation values with the other indices maybe for an underestimation of the small specimens of E. huxleyi to the light microscope, suggesting a probable major usefulness for SEM collected data-base. The primary productivity, evaluated through the N' (Lopez-Otalvaro et al 2008) and the PP (Beaufort et al 1997) indices both

based on the relative abundance of *F. profunda*, records several fluctuations throughout the core also remaining rather high. The PP index appears to be fairly positive correlated with the absolute abundance curve of calcareous nannofossils and negatively with the abundance curve of *F. profunda*, which proliferates during low nutrient intervals. Calcareous nannofossils appear, therefore, to be a major component of the primary producers. Comparing these data with the benthic oxygen isotope curve for the Middle-Late Pleistocene and therefore to the glacial-interglacial cycles, it is possible to observe carbonate dissolution maxima mainly during deglaciations, whereas the maximum efficiency of the biological pump and the nannofossil abundance maxima are recorded in the glacial phases. In conclusion, during the glacial phases the CO₂ sink is driven mostly by the shallow biological pump, partly buffered by the CO₂-producing carbonate pump. On the contrary, during deglaciations the main mechanism of CO₂ sink is the carbonate dissolution in the deep waters. It must be noted, however, that the oceans' capacity to absorb atmospheric CO₂ is further complicated by other parameters such as temperature, water dynamics, deep ocean carbonate chemistry and climate.

CARBONATE EXPORT PRODUCTIVITY OF CALCAREOUS NANNOFOSSIL ASSEMBLAGES DURING THE PALEOCENE - EOCENE TRANSITION

AGNINI Claudia¹, DE BERNARDI Bianca²
1 - Dipartimento di Geoscienze - Università degli Studi di Padova
2 - Dipartimento di Scienze della Terra - Università degli Studi di Milano
Presenter e-mail: claudia.agnini@unipd.it

Key terms: IODP; Calcareous nannofossils; paleoceanography

The extraordinary high abundance of calcareous nannoplankton in the sea-surface marine waters makes them the main primary producers at the base of the marine food-chain. They are a fundamental part of the global biogeochemical carbon cycle, because of the role they play both in producing organic carbon and carbonate. Their first geological appearance in marine sediments has been recorded at about 230 Ma, so that they are thought to be a useful tool for Mesozoic and Cenozoic paleoceanographic reconstructions. From the 80ies till today, volume calculation of extant calcareous nannoplankton has been performed in order to convert coccolith fluxes data into carbonate export productivity. Here, we present volume evaluations of the most abundant Paleocene calcareous nannofossils, our data are eventually used first of all to make a quantitative estimation of the calcareous nannofossil carbonate production but also with the aim to calculate the ratio between the carbonate secreted by calcareous nannofossils and the total carbonate production. To obtain a more global perspective, our dataset comes from several DSDP/ODP Sites located at different latitudes both in the Atlantic (DSDP 401 and ODP 690, 1051, 1260, 1263 Sites) and Pacific (ODP Site 1209). The volume calculation of the most common early Paleocene calcareous nannofossil taxa were applied to a specific case history, the Paleocene Eocene Thermal Maximum, in order to investigate the absolute abundance of coccolith, the coccolith carbonate mass per species and the total calcareous nannofossil contribution to carbonate production before, during and after this prominent episode of global warming. Preliminary data show that a dramatic decrease both in the number of specimens/mm² and

carbonate production starts well before the onset of $\delta^{13}C$ negative shift suggesting a modification of pre-event conditions and a very perturbed paleo-environment during the main phase of the event.

5 - School of Earth Sciences, The University of Queensland, Australia
Presenter e-mail: balestrabb@gmail.com

Key terms: calcareous nannofossils; benthic foraminifera; early Eocene X-Event (ETM3); biotic response

The early Eocene Greenhouse World was punctuated by multiple transient global warming events, or hyperthermals, the most prominent of which was the Paleocene-Eocene Thermal Maximum (PETM). Additional Eocene Thermal Maxima (ETMs) exhibit a negative carbon isotope excursion (CIE), carbonate dissolution and biotic perturbations, and include the Elmo horizon (ETM-2, ~1.8 Myr after the PETM) and 'X' event (ETM-3, ~3.1 Myr after the PETM). We document the marine biotic response to the climatic and carbon cycle changes during the latter event (planktic foraminifer Zone P7, calcareous nannofossil Zone CP10; CIE ~0.9‰; warming ~2.5°C) through a study of stable isotopes combined with coccolith and benthic foraminiferal abundances at ODP sites drilled on Walvis Ridge (SE Atlantic), with paleodepths of ~1500m (Site1263) and ~3600 m (Site 1262). We analyzed samples spaced at 1-2 cm across the prominent clay layer. It is difficult to deconvolve effects of dissolution and changes in trophic state because the oligotrophic indicator species detected, also tend to be solution-resistant. We observed an increase in relative abundance of such species (*Discoaster* spp., *Sphenolithus* spp) during the CIE at Site 1263, while *Toweius* spp., (mesotrophic) decreased slightly, but species in the 'HS group' (eutrophic indicators) increased sharply. At the deeper Site 1262 assemblage changes were similar but more muted than at the shallower site, and the HS group doesn't vary significantly. Benthic foraminiferal assemblages decreased in diversity during the CIE at both sites, relative abundance of cylindrical species decreased, that of abyssaminids increased. At Site 1262 *Quadriformina profunda* increased in abundance, but it had its uppermost occurrence at shallower Site 1263. Benthic foraminiferal accumulation rates (BFAR), an indicator of food supply to the sea floor, remained even at Site 1262, while declining sharply at Site 1263, where *Nuttallides truempyi*, a low-food indicator, increased in abundance at both sites but more sharply at 1263.

We do not yet fully understand the environmental effects of the X-event but overall our records suggest that surface primary productivity may have increased at the shallower Site 1263 which was also closer to the coast (possibly due to increased nutrient inputs), while increased stratification due to warming caused increased remineralization of organic matter and declining food supply to the sea floor. The records were affected by increased dissolution, but the more extreme changes at the shallower site suggest that dissolution does not explain the records by itself. The biotic response to the X-event was less intense than that to the more severe Elmo and PETM hyperthermals at the same location, suggesting that the intensity of the biotic response reflects the severity of the environmental disturbance.

Key terms: Nannofossils; Biostratigraphy; Eocene; Oligocene; Southern Ocean

ODP pioneer drilling projects in the Southern Ocean (ODP Legs 113, 119, 120) have provided excellent stratigraphic sections for high-resolution biostratigraphic and paleoceanographic studies and are still relevant today as source of further information. However, it was evident that the widely used Eocene-Oligocene zonations of Martini (1971) and of Okada and Bukry (1980) were not applicable in high southern latitudes where some warm and temperate-water markers were rare or absent. Edwards (1971) first established a nannofossil zonation for the sub-antarctic Paleogene of New Zealand and later Wise (1983) proposed a Cenozoic zonation for the Falkland Plateau. The first detailed nannofossil zonal scheme for the Eocene and the Oligocene for the Southern Ocean (SO) was developed by Wei and Wise (1990) using well-preserved nannofossil assemblages from ODP Leg 113. These studies provided a large database on species stratigraphic distribution and revealed the importance of nannofossil assemblage studies in the SO for high-latitude biostratigraphic correlations.

However, despite the most recent SO Paleogene coring (e.g. ODP Leg 183), some significant problems regarding biostratigraphy have remained unresolved and recent updates on the Eocene-Oligocene biostratigraphy at SO sites have pointed out the need for revision of the existing zonations. This revision is also based on the refinement of nannofossil taxonomy and the recognition of several stratigraphic discrepancies in taxa distribution at southern latitudes. The biostratigraphic data discussed here are derived from the analysis of species distribution and from their correlation between ODP Sites 738, 748, and 744 (Kerguelen Plateau), ODP Sites 689 and 690 (Maud Rise), ODP Site 1172 (Tasman Plateau), and ODP Site 702 (Islas Orcadas Rise).

Eleven zones and six subzones are described, together with a number of additional biohorizons, intended to provide a high-resolution subdivision for the Eocene-Oligocene of the SO. Our approach was to follow as much as possible the Wei and Wise (1990) Zonation, tending to not altering the name of the zones. Nevertheless, ten zone and subzone boundaries are redefined, and six additional bioevents are introduced.

We propose 21 bioevents for the time interval from ~43 to 25 Ma. The proposed zonal scheme offers an average biostratigraphic resolution of ~800 ky over a ~18 Ma time interval, which significantly improves previous subdivisions.

The nannofossil bioevents were calibrated by using available magnetostratigraphic records, providing an improved biochronologic framework. Some of the Paleogene biostratigraphic datums used here show more restricted or expanded stratigraphic ranges at high latitudes compared to low and middle latitudes. In particular, the ranges of *Chiasmolithus solitus* and *Chiasmolithus oamaruensis* are more extended at high latitudes, and those of *Discoaster* spp. and *Ericsonia formosa* appear reduced, in response to different paleoclimatic conditions. Thus, the long cooling trend following the Middle Eocene Climatic Optimum event (~40Ma) is considered responsible for the early exclusion of warm-water taxa (*Discoaster* and *Ericsonia formosa*) from the southern high latitudes as well as for their time-transgressive behaviour between low and high latitudes.

The proposed scheme clarifies some long discussed enigmas (e.g., the *D. saipanensis* Zone), improving the correlation between high and low-mid latitude nannofossil biostratigraphy. Furthermore the new biostratigraphic scheme will allow more reliable paleoecological interpretations of nannofossil Eocene and Oligocene assemblages, which in turn are used for paleoceanographic and paleoclimatic reconstructions of this crucial time interval. The new zonal scheme is intended to better constrain in time the paleogeographic changes and to add contributions to the debate about the timing of the opening of ocean gateways surrounding Antarctica.

THE RECORD OF MURICATE SYMBIOT-BEARING PLANKTONIC FORAMINIFERA FROM THE SUBTROPICAL ODP SITE 1051 A (ATLANTIC OCEAN) ACROSS THE EARLY EOCENE CLIMATIC OPTIMUM (EEO)

LUCIANI Valeria¹
1 - UNIVERSITY OF FERRARA

Presenter e-mail: valeria.luciani@unife.it

Key terms: PLANKTONIC FORAMINIFERA; EARLY EOCENE CLIMATIC OPTIMUM; MOROZOVELLIDS

Within an extended interval of greenhouse-climate regime punctuated by at least two major transient hyperthermal events (< 200 kyr), the Earth reached the peak of Cenozoic warmth during longer lasting warming of the Early Eocene Climatic Optimum (EEO, ca 50-52 Ma) subsequently followed by a general long-term cooling trend culminating in the Eocene-Oligocene glaciation (e.g., Zachos et al. 2001 Science; 2008 Nature). This long term cooling has been mostly attributed to decrease in atmospheric carbon-dioxide pressure and its feedbacks within the climate system (e.g., Pagani et al. 2005 Science). A number of critical issues concerning the EEO event still need to be addressed albeit several data

has been recently acquired from both land and ODP (Ocean Drilling Program) Legs dedicated to Early Paleogene climate evolution. One of the most fascinating aspects of the investigation on early Paleogene climate is to evaluate the potential role of climate on the biotic evolution. On land, dramatic plant and mammal faunal turnover appears related to the EECO, thus supporting a direct primary climatic evolutionary control (e. g., Woodbourne et al. 2009 PNAS). In the marine realm, new evolutionary trends linked to the EECO give course to modern structure in calcareous nannofossil communities (Agnini et al. EPSL 2006). Recent studies on the planktonic foraminiferal response to the EECO event have been carried out on the classical early Paleogene section of Possagno (Venetians Pre-Alps, NE Italy). Results show that the EECO produced a permanent impact on the planktonic foraminiferal assemblages beside the transient modification related to the climatically-induced environmental perturbations. Specifically, the specialized muricate, symbiont-bearing surface-water morozovellids, that dominated together with the acarininids the low-latitude early Paleogene oceans, markedly decline in abundance just following the EECO and never recover. This reduction is coupled with the gradual disappearances of a number of morozovellid species, giving only in part reason for the decrease in abundance. During the EECO the Eocene pelagic ecosystems reached its maximum warmth and afterwards it passes from the greenhouse to the doubt-house/icehouse regime. The consequent modification in the water column structure and the reduced carbon-dioxide pressure might have negatively affected the ecological niches of the highly specialized muricate forms and biased the complicated mechanism of the morozovellid symbiosis processes. The short-term or permanent loss or inhibition of photosymbionts (bleaching) has recently been reported in many modern organisms including corals and benthic foraminifera in response to environmental stress. Bleaching events in the planktonic foraminiferal fossil record are still relatively unknown. They have been associated both to transient marked increase of SSTs, response to surface-water pH decrease (Middle Eocene Climatic Optimum, Edgar et al 2011 CBEP Abstr.) or to an extreme though detrimental reaction to an unfavourable environment (latest middle Eocene Morozovelloides extinction, Wade et al. 2008 Evol. Ecol.). It is therefore crucial to extend the analyses to diverse paleoceanographic settings and different time-slices. The superb documentation across the EECO of the pelagic calcareous plankton record archived in the deep-sea sediments of the subtropical ODP Site 1051A (Black Nose, Atlantic Ocean), provides the exceptional opportunity to evaluating the potential transient/permanent modifications within the planktonic foraminiferal muricate forms. Preliminary data reveal that a significant decrease in abundance of the muricate forms follows the EECO at the ODP 1051A site as observed for the Tethyan Possagno section although the initial proportions are different due to the diverse paleogeographic settings. A close interaction between global climate and biological evolution appears therefore supported by the ODP Site 1051A record.

CALCAREOUS NANNOFOSSIL RESPONSE TO THE MIDDLE EOCENE CLIMATIC OPTIMUM: CLUES FROM DIFFERENT DEPOSITIONAL SETTINGS.

TOFFANIN Federica¹, AGNINI Claudia¹, FORNACIARI Eliana¹, RIO Domenico 1 - Università degli Studi di Padova

Presenter e-mail: federica.toffanin@unipd.it

Key terms: calcareous nannofossils; Middle Eocene Climatic Optimum; paleoecology; paleoclimate

Calcareous nannofossil assemblages show specific paleoecological affinities and thus can be utilized for palenviromental reconstructions. We investigated the response of calcareous nannofossil assemblages to the Middle Eocene Climatic Optimum (MECO) a significant temporary reversal in the middle-late Eocene long-term cooling trend. This warming event is characterized by a prominent perturbation both in oxygen and carbon stable isotopes occurred at Chron C18r-C18n transition (ca. 40 Ma) and lasting ca. 500-600 kyr (Bohaty et al., 2009). Our main aim is to point out if biotic response to the MECO is global and unique over wide areas and depositional settings or is more related to local conditions. To this purpose we are currently comparing calcareous nannofossils modifications at three sites. At Alano, a bathial section (NE Italy), our data indicate that the MECO interval seems to coincide with significant changes in calcareous nannofossil assemblages. Eutrophic/cold taxa and reworked specimens show an overall increase in abundance during the warming event. Conversely, oligotrophic/warm taxa are characterized by a peculiar anticovariant trend with respect to meso-eutrophic taxa, decreasing significantly during the MECO and post-MECO intervals. These results are interpreted as a transient enrichment in dissolved nutrients in warmer sea surface waters and suggests that the enhanced availability of nutrient in the water column overrides other environmental factors in the make-up of calcareous nannofossil assemblage. Moreover, the increase in reworking is consistent with an augment in terrigenous input, likely due to accelerated chemical weathering triggered by the enhanced hydrological cycle. Our results from ODP Exp. 320-321 (U1333C) in the Pacific Equatorial Ocean, show dramatic changes in preservation state, with the number of specimens counted on a specific area (1 mm²) virtually collapsing during the event. We observed changes in calcareous nannofossil assemblages that are consistent with strong dissolution, corresponding to the MECO. A strong decrease of specimens/mm² is clear, but if we considered the relative abundance (%) of the most resistant genus, Discoaster, there is a remarkable increase, as it is expected if the pristine assemblages were altered/biased by preferential dissolution. The last site we are considering is ODP Site 1051, in NW Atlantic Ocean, our preliminary results seem to show changes in calcareous nannofora assemblage during this transient episode of global warming, but a more detailed analysis of relative and semiquantitative data is needed, in order to obtain a more global perspective on nanoplankton response to the MECO.

IODP EXP. 334 CRISP A: THE FIRST STEP TOWARD DRILLING THE SEISMOGENIC ZONE IN CENTRAL AMERICA

VANNUCCHI Paola¹, IODP EXP. 334 Shipboard Scientific Party²

1 - Università di Firenze
2 - Various Institution

Presenter e-mail: paola.vannucchi@unifi.it

Key terms: IODP; Subduction; Seismogenesis

The Costa Rica Seismogenesis Project (CRISP) is designed to understand the processes that control nucleation and seismic rupture of large earthquakes at erosional subduction zones.

CRISP targets the only known erosional end-member of convergent margins within reach of scientific drilling. With a relatively thin sediment cover, fast convergence rate, abundant seismicity, subduction erosion, and change in subducting plate relief along strike, the Costa Rica margin in the CRISP area offers excellent opportunities to learn the causes of earthquake nucleation and rupture propagation.

This project complements other deep-fault drilling (San Andreas Fault Observatory at Depth and Nankai Trough Seismogenic Zone Experiment) and investigates the first-order seismogenic processes common to most faults and those unique to erosional margins.

Integrated Ocean Drilling Program Expedition 334 was the first of several planned expeditions to reach the seismogenic zone. The primary goals of Expedition 334 were:

1. Characterization of lithological, physical, and frictional properties of upper plate material;
2. Estimation of subduction channel thickness and the rate of subsidence caused by subduction erosion;
3. Characterization of the fluid flow system and thermal structure of the erosive margin;
4. Determination of the change in the stress field across the updip limit of the seismogenic zone
5. Explore the Cocos Ridge-volcanic arc gap-Cordillera de Talamanca relationship.

In order to accomplish these objectives, coring was conducted at three slope sites (Sites U1378 and U1380 on the middle slope and Site U1379 on the upper slope) and at one site on the Cocos plate (Site U1381). Both slope sites might serve as pilot holes for a potential future riser drilling project. Sites U1378 and U1379 were first characterized by logging while drilling (LWD) to document in situ physical properties, stratigraphic and structural features, and stress state, in addition to continuous core sampling to the target depth. Cores at both sites were taken to examine slope sediments and the underlying upper plate basement. The coupling of LWD data with data from sediment and basement samples provides important information about tectonic, hydrologic, and seismic features along this erosive convergent margin.

3 - SHIPBOARD SCIENTISTS IODP EXPEDITION 317

Presenter e-mail: GIULIANA.VILLA@UNIPR.IT

Key terms: IODP Expedition 317; CALCAREOUS NANNOFOSSIL; SEA LEVEL

Expedition 317 aimed to understand the relative importance of eustatic variations, local tectonic and sedimentary processes in determining depositional cyclicity on continental margins (Fulthorpe et al., 2011).

The goals of this Expedition were: 1) date clinoform sequence boundaries and study the facies variations associated to them; 2) date the Marshall Paraconformity; 3) understand the erosion history of the Southern Alps; 4) determine sediment drift depositional history and paleoceanographic record.

Three shelf sites (U1351, U1353 and U1354) and one slope site (U1352) were drilled along a transect perpendicular to the margin. Nineteen regional middle Miocene to Pleistocene sequence-bounding unconformities were identified from sequence stratigraphy on the prism of the Canterbury Basin.

For the age-control of the drilled sequences, all core-catcher samples were analyzed onboard using calcareous nannofossil, planktonic and benthic foraminifera biostratigraphy. During Exp. 317 Holocene to Eocene sediments were recovered. Calcareous nannofossil assemblages showed strong variations in abundance, preservation and composition associated with different lithologies.

Here we present calcareous nannofossil preliminary records for the Eocene-Miocene part of the drilled sediments. The calcareous nannofossil zonal scheme of Martini (1971) was used, together with the marker species of Okada & Bukry (1980) and de Kaenel and Villa (1996). Calcareous nannofossil assemblage analysis provided a good age control of the successions and the dating of the sequence boundaries.

The Miocene/Pliocene boundary was drilled at shelf Sites U1351 and U1353 and at slope Site U1352. Reworked calcareous nannofossils are abundant in Miocene assemblages. Abundance and composition analysis of reworked material will be one of the foci of post-cruise research.

A major hiatus (~12 m.y.), associated with the Marshall Paraconformity (MP), separates the early Miocene (18-19 Ma) from the early Oligocene (30.1-32 Ma). The MP likely represents intensified current erosion related to the inception of the Protoantarctic Circumpolar Current. At Site U1352 Oligocene and Eocene sediments were also drilled. The Eocene/Oligocene boundary falls within a hiatus lasting from the late Eocene (35.2-36.0 Ma) to the early Oligocene (32.5-32.9 Ma). The deepest sample taken during Exp. 317 was dated at 35.2-36.0 Ma (late Eocene).

MAPPING GEOLOGY OF A SECTOR OF UPPER MARECCHIA VALLEY (ROMAGNAN APENNINES) FROM REAL FIELD TO 3D MODELLING.

DE DONATIS Mauro¹, SUSINI Sara², REGNICOLI Stefano²

1 - University of Urbino

2 - Laboratory of Information technology for Earth and Environment

Presenter e-mail: mauro.dedonatis@uniurb.it

Key terms: Val Marecchia; Northern Apennines; digital field mapping; GIS; 3D modelling

Field digital mapping, GIS, multidimensional modelling are in the last years one of the new way of producing an innovative geological cartography (Bonham -Carter, 1994; McCaffrey et al., 2005; Wawrzyniec et al., 2007). Since the use of portable hardware in the field (Tablet PC, PDA and now also smartphone and iPad) allows to more accurately georeference (GPS receivers) and digitally store (database) data, informations, hypotheses and interpretations. The disponibility of these ones in digital format has led to new way of analysis and final map elaboration. Moreover this usage of information technology helps quite a lot private companies and public agencies to lower time and money consuming and more, to get uncertainties reduction (Jones et al., 2004) and a better knowledges management (Bond et al., 2007). Therefore many research groups worked on finding their own ways from field work to map elaboration (Briner et al., 1999; Walker & Black, 2000; Akciz et al., 2002; Howard, 2002; Brodaric, 2004; De Donatis et al., 2005). The academic research could be much more free to explore new methods and tools, from out-of-the-shelf products (ex. ArcPad) to home-made systems (ex. BeeGIS).

phase

1st

Starting in the lab, planning the field project development, base cartography, forms and data base were designed in the way we thought was the best for collecting and store data in order of producing a digital n-dimensional map. Bedding attitudes, outcrops sketches and description, stratigraphic logs, structural features and other informations were collected and organised in a structured database using rugged tablet PC, GPS receiver, digital cameras and later also an Android smatphone with some survey apps in-house developed.

A

new mobile GIS (BeeGIS) was developed starting from an open source GIS (uDig): a number of tools like GPS connection, pen drawing annotations, geonotes, fieldbook, photo synchronization and geotagging were originally designed.

phase

2nd

After some month of digital field work, all the informations were elaborated for drawing a geologic map in GIS environment. For that we use both commercial (ArcGIS) and open source (gvSig, QGIS, uDig) without big technical problems.

phase

3rd

When we get to the step of building a 3D model (using 3D Move), passing through the assisted drawing of cross-sections (2D Move), we discovered a number of problems in the interpretation of geological structures (thrusts, normal faults) and more in the interpretation of stratigraphic thicknesses and boundaries and their relationships with topography.

phase

4th

Before an "on-armchair" redrawing of map, we decide to go back to the field and check directly what was wrong. Two main vantages came from this: (1) the mistakes we found could be reinterpreted and corrected directly in the field having all digital tools we need; (2) previous interpretations could be stored in GIS layers keeping memory of the previous work (also mistakes).

phase

5th

A 3D model built with 3D Move is already almost self-consistent in showing the structural features of the study area. The work was not so strightforward, but the result is more then satisfying, even if some limitations were not solved (i.e. visualisation of bedding attitudes). Geological maps are fundamental for knowledge transfer among experts but, if combined with the innovative digital methods from survey to 3D model, this knowledges could reach a much larger number of people, allowing a cultural growth and the establishment of a larger awareness of the Earth and Environment.

SURFACE TEXTURE ANALYSIS OF AN ALPINE BASIN WITH

COMPLEX MORPHOLOGY AND POTENTIALITIES FOR GEO-ENGINEERING

TREVISANI Sebastiano¹, CAVALLI Marco², MARCHI Lorenzo²

1 - UNIVERSITY IUAV OF VENICE

2 - CNR-IRPI (PADOVA)

Presenter e-mail: strevisani@iuav.it

Key terms: engineering geology; high resolution DTM; geomorphometry; geostatistics; surface texture

In this presentation the results of a geomorphometric analysis of an alpine basin are presented with a special focus on their relevance in the applicative context. The complex morphology of the studied basin makes challenging the geomorphometric analysis of fine-scale topography. Moreover, the studied basin is representative of the geological, geomorphological and vegetation conditions frequently found in the Dolomites. The analysis of the surface morphology was performed on a high-resolution digital elevation model (cell size 2 m), derived from an airborne LiDAR survey. A set of spatial-statistical indexes were calculated locally and used as signature of the local surface morphology. Subsequently, these indexes were used in a fuzzy k-means classification that permitted to segment the basin into different spatial subdomains characterized by a specific surface texture. The results of the classification are compared with the actual surface morphology using high-resolution orthophotos, aerial photos and by conducting field surveys. The surveys were carried out with the aid of a GIS system mounted on a tablet rugged PC with GPS capabilities. This procedure permitted to pair the geomorphometric analysis results and other thematic layers with field evidences.

The analysis performed proved to offer a valuable interpretative tool of the complex surface morphology of the studied alpine basin. This kind of analysis seems exploitable in different contexts, among which: 1) speed up of field surveys; 2) comparative studies; 3) landslide susceptibility mapping; 4) ecological modeling.

3 - Dipartimento di Scienze della Terra, Università di Napoli Federico II

Presenter e-mail: rosa.nappi@ov.ingv.it

Key terms: G.I.S.; seismotectonics; Campanian plain

This paper deals with an interdisciplinary research that has been carried out for investigating the neotectonic activity of the Campanian plain and surrounding carbonate massifs (Southern Apennines). The analysis of the available seismic, tectonic and gravimetric data of the area has been carried out through the Geographic Information System (GIS) which has provided the capability for storing and managing large amount of spatial data from different sources.

The implementation of the GIS system (software ArcGIS 9.3) has been affected by both completeness of information, and quality of geographic data; for this reason special attention has been dedicated in our system to collect all the existing relevant data together with the updated territorial information about the Campanian area.

Three thematic Datasets have been generated for this area, the fault, earthquake and gravimetric datasets. In particular, the database creation has consisted of these main steps: (a) collection and acquisition of digitalized aerial photos, numeric cartography, Digital Terrain Model data (DTM), geophysical data; (b) generation of the vector cartographic database and alpha-numerical data; (c) image processing and features classification; (d) cartographic restitution and multi-layers representation. The UTM-WGS84 reference system has been used for geocoding the whole dataset.

The fault Dataset has been compiled by examining the available structural maps, and many recent geological and geophysical papers of literature, since the active fault systems of the Campanian area are not completely known and not comprehensively reported in up-to-date and reliable neotectonic maps.

The earthquake Dataset has been implemented collecting seismic data by various available historical and instrumental Catalogues; new precise earthquake locations have been carried out for some clusters of events, for better constraining existence and activity of some outcropping and buried tectonic structures. Seismic data have been standardized in the same format into the GIS and merged in a final catalogue.

For the gravimetric Dataset, the Multiscale Derivative Analysis (MDA) of the gravity field of the area has been performed, relying on the good resolution properties of the Enhanced Horizontal Derivative (EHD). MDA of gravity data has allowed localization of several linear and close trends, identifying anomaly sources whose presence was not previously detected. The main results of our integrated analysis show a strong correlation among the new hypocentral location of seismic clusters matching some fault systems bordering the Campanian Plain, and MDA lineaments from gravity data relative to the same tectonic structures.

THE GEOLOGICAL DATA AND WEB SERVICES OF THE GEOLOGICAL SURVEY OF ITALY

DELOGU Daniela¹, CAMPO Valentina¹, CIPOLLONI Carlo¹, CONGI Maria Pia¹, ROMA Mauro¹, VENTURA Renato¹, BATTAGLINI Loredana¹, ZONETTI Claudio¹

1 - Servizio Geologico d'Italia - ISPRA

Presenter e-mail: carlo.cipolloni@isprambiente.it

Key terms: geologic; standard; metadata; geoportale; web service

The geoportal of the Geological Survey of Italy, which is available at the URL (<http://sgi.isprambiente.it/geoportal>), is been re-designed to allow easy access to the digital informations contents of all the database and projects. This system is built as integrated architecture composed by an OGC/INSPIRE standard Metadata catalogue service (CSW 2.0.2.). According to the national law and to the INSPIRE European Directive we use a multi-profile standard. In the metadata catalogue all the services associated to web map services are archived as ISO-Core and as INSPIRE metadata, while the dataset metadata are directly archived in a special

profile that satisfies both the Italian standard RNDT (National Inventory of the Territorial Data - DigitPA) and the INSPIRE Implementing Rule. Therefore specific test are performed using the validation tool (i.e. INSPIRE Geoportal website and RNDT website) on the XML format export files.

The web services are publishing with ArcGIS Server technologies in several format to be available to the users a suite of web services that are in the same time interoperable with the OGC Standard (WMS/WFS/WCS/KML) and able to fulfil an high cartographic standard in the geological symbols representation (i.e. ArcGIS). The portal, at the moment, allows the consultation in the same framework of a set of standard vocabulary using standard ontology (OWL and/or SKOS) for implementing in the next future the terms definition in the same content of the data visualization.

Specific section related to the projects or to the standard are been created, and a direct access is available in the left side menu. Thanks to the new available technologies (flex and JavaScript) allow us to produce a gallery of the viewer application, where different user's typology could be access easily to the geological contents and to the natural hazard events. In particular we maintain daily updating, a list of javascript viewer using google-map images as base-map with landslide and geological bedrock information drape on, are been created to common user and presented as highlights object on the home-page. The Geoportal presents moreover an OGC/INSPIRE section that gives to the user a direct access to standard web services.

The real use of the Geoportal is as Geological search engine for the metadata, data and view services. This tool is realised to integrate in both direction viewer and metadata catalogue for discovering in the catalogues, add and view directly the available web services and, when it adopted the rule in this regard, to download data too. The Portal of the Geological Survey of Italy would be a focal point to search and fund the geological data at national and international level, in fact is also possible make query on the international standard metadata catalogue relate to the geological data (i.e. OneGeology, USGS, etc.).

ONEGEOLOGY-EUROPE: A HARMONIZED GEOLOGICAL SPATIAL DATA INFRASTRUCTURE IN EU

PANTALONI Marco¹

1 - Servizio Geologico d'Italia - ISPRA

Presenter e-mail: marco.pantaloni@isprambiente.it

Key terms: OneGeology; Europe; geological map; spatial data infrastructure; harmonization

OneGeology-Europe is an ambitious project, started in September 2008 and finished in September 2010, aimed to make basic geological data, held by the Geological Surveys of 24 European countries, most popular and accessible, developing an integrated data system.

The project's aim was to create dynamic digital geological map data for Europe at 1:1M scale, working to allows different types of data and formats to be made available and accessible by anyone using the web. This objective has been reached through the implementation of a web mapping portal (<http://onegeology-europe.brgm.fr/GeoPortal/viewer.jsp>), realized using the latest computing technology, GeoSciML.

During the two years of the OneGeology-Europe project has been addressed issues relating to data licensing, multilingual aspects, sharing of geological knowledge, geological data harmonization and demonstration of best practices in provide and use of spatial geological data in the public and private sectors.

The project idea was born from the awareness of the presence of a wealth of spatial geological data often accessible only to specialists; this amount of data, unfortunately, is often hard to find and poorly accessible, almost never shared or, when shared, decipherable only through adequate knowledge and appropriate reading keys. These data, mostly owned by the Geological Surveys of different countries, are sometimes "locally" standardized and then absolutely not homogeneous between them.

The project has been divided into 10 Work Packages (WP), composed of experts and professionals from various Organizations with considerable experience in their field. Many of the Organizations work together in existing multi-national groups and projects and have achieved excellent results.

Work Package 3 (WP3) worked on essential basis for the OneGeology-Europe project: a specification for geological spatial data and an interoperable 1:1M scale dataset for the whole of Europe. This includes vocabularies to describe lithology, age and genesis of the rocks, tectonic structures, term definitions and relations. Based on the specification it identified the generic and specific geometric and semantic harmonisation issues.

Afterward WP3 "amended" existing national datasets to make significant "progress towards harmonization", a crucial step on the way to INSPIRE objectives. The standards, architecture and framework developed in OneGeology-Europe project can be "reorganized" to more detailed levels and deployed for higher resolution geological data. This work of the OneGeology-Europe Data Specification WP provide a solid base for the description of geology of each European Union country in the future. The architecture developed in the project is service oriented and OGC standards-based; the pan-European geological map produced is not stored in a centralized database but it is composed through various web services, each supported by the Geological Survey of the country involved in the project. Map data served to the Internet as part of OneGeology will remain in the ownership of the originating Geological Survey, and ideally be available at no cost. The format of the "web mapping and feature services" allow registry and technical references.

These procedure and architecture constitute a significant contribution to the development of INSPIRE, by developing systems and protocols for sharing, finding, viewing and downloading of geological European spatial data.

OneGeology-Europe consisted of a consortium of Geological Surveys of many European countries and representatives of user communities; therefore it was absolutely a multilateral and multinational programme. The project allows Europe to play a leading role into the OneGeology-global initiative, that follows the indications given by United Nations General Assembly in 1997 (the so called "Agenda 21") that asks nations to reduce the gap in the availability, quality, standardization and accessibility of data between world countries.

10.1474/Epitome.04.0976.Geoitalia2011

SHARING DATA AND INTERPRETATION OF GEOLOGICAL MAPS ON THE WEB

BALESTRO Gianni¹, BINI Sara², CADOPPI Paola¹, FIORASO Gianfranco³, PERRONE Gianluigi¹, PIANA Fabrizio³, TALLONE Sergio³

1 - Università di Torino - Dipartimento di Scienze della Terra

2 - CNR-Istituto di Geoscienze e Georisorse

3 - CNR - Istituto di Geoscienze e Georisorse

Presenter e-mail: gianni.balestro@unito.it

Key terms: metadata; GIS databases; geological mapping

Web sharing of geological data is ever-increasing and geoscientists are now involved in the development and in the maintenance of IT (Information Technology) applications (Spatial Data Infrastructures, Geoportals, Web-GIS,...). Spreading of geo-referenced information is driven by different organizations (e.g. the Open Geospatial Consortium) and initiatives (e.g. the INSPIRE European Directive) that give useful standards and suggest common methods for storing actually sharable data. The Web Map Service (WMS) protocol for map images and the ISO19115 for geospatial metadata, are two examples of standards that increasingly characterize the management of geo-scientific information on the web. The aim is both supporting the interoperability of services and meeting different needs related to clearness and quality of web disseminated knowledge.

In the frame of the realization and sharing of geological maps, a better understanding of information is particularly needed. Maps and related geological datasets are stored in large and complex databases that suffer from incompleteness that is the lack of knowledge about interpretations that lie behind data. The datasets of geological maps do not always correspond to prompt information for data-users and are actually usable if they contain information about the knowledge-paths followed by data makers, with their generalizations and uncertainties. IT allows facing these problems through homogeneous meta-description of the digital processing of data (from the field to the map to the web), and by user-friendly tools that allow querying of maps gathered by different expertise, in different context and with different methods.

An example of an easy infrastructure (the CNR-IGG-TO Geoportal) for spreading on the web datasets of geological maps is given. In this geoportal maps are retrieved by the WMS protocol and managed through a catalog service of metadata, compiled according to the ISO19115 standard. The metadata descriptive classes (e.g. the "Identification" class or the "Data-quality" class), besides giving different information about where, when and how data were captured, allow bringing out in an explicit format the processing steps (e.g. "Lineage" class) performed from original field data to map generalization.

The Torino operative unit of the Institute of Geosciences and Earth Resources - CNR IGG Torino - (<http://www.csg.to.cnr.it/>) recently set up a geoportal, where geological information are described referring to GeoSciML semantics, ISO19115 MetaData standard and shared through WebMapService technology.

(<http://server21.to.cnr.it/geonetwerk/srv/en/main.home>). The CNR IGG TO Server contains field data and related geological maps mainly in the frame of the CARG project (1:50000 Geological Map of Italy) and other field geological research programs such as the Geological Map of Piemonte region at 1:250.000 scale, the map of the Ligurian-Maritime Alps boundary and many others. Not only geological maps are stored, but all several kinds of geo-referenced geological data set are intended to be represented and shared through the geoportal.

The CNR IGG purpose is to get this information conceptually described, using the Geographic MD international standard for the geological context, in order to give geological interpretations in an explicit format. These "geological metadata" have been compiled mainly as regard the

"Identification" and the "Data Quality" classes. The Abstract element (Identification class) explains the criteria on which data are interpreted and the meaning of them, giving the peculiarities of interpreted features.

The Resource Locator element (Identification class) allows to link datasets with conceptual supplemental information (conceptual schemas), where concepts and methods adopted in the acquisition of knowledge are given. The Lineage element (Data Quality class) gives the different process steps performed on data, specifying the provenance of interpreted features and making them traceable.

The development of the CNR IGGTO geoportal was also carried out in the frame of the EU MEDOCC IDE-Univers project (<http://www.geoportal-idec.net/ideunivers/>) and the CNR GIIDA (<http://www.dta.cnr.it/content/view/2735/2735/lang, it/>) project (an initiative to implement the Spatial Information Infrastructure of CNR for Environmental and Earth Observation data).

EXPERIMENTAL METHOD FOR AUTOMATED APPLYING OF STANDARD STYLES TO DATABASE OF THE CARG PROJECT IN ARCMAP GIS ENVIRONMENT

BATTAGLINI Loredana¹, CARTA Roberta¹, PORFIDIA Benedetto¹

1 - ISPRA

Presenter e-mail: loredana.battaglini@isprambiente.it

Key terms: CARG PROJECT; GEOLOGICAL DATABASE; GIS STYLES

This work describes an experimental method for the automation assigning colors and symbols in a GIS software client to vector data from CARG Project Geological database, using official standards defined in the Guideline - "Linee guida per l'allestimento e per l'alimentazione per la stampa dalla banca dati (Quaderno Serie III Volumi 6-12 Carta Geologica d'Italia - scala 1:50,000)".

The process of revision and correction of CARG Geological Database, which involves also the field "COLORE" containing color codes assigned to each geological map on the basis of codes published on SGI's Chromatic

Handbook, carried out the possibility to use these codes to obtain a better visualization of geological CARG Database elements, similar to the printed map, and in the future also through web services. For this purpose, official CMYK color codes used for printed geological maps, has been converted into RGB triplets and assigned to corresponding features through a VBA script.

The work has been done using ESRI software but can be simply ported on other platforms, web included.

OPTIMIZATION AND STANDARDIZATION PROCEEDINGS OF THE CARG GEOLOGICAL DATABASES TO PERFORMS THE USABILITY THROUGH THE PORTAL OF THE GEOLOGICAL SURVEY OF ITALY

BATTAGLINI Loredana¹, CARTA Roberta¹, CONGI Maria Pia¹, LETTIERI Maria¹

1 - ISPRA

Presenter e-mail: roberta.cart@isprambiente.it

Key terms: GEOLOGICAL DATABASE; CARG PROJECT; PORTAL OF GEOLOGICAL SURVEY OF ITALY

The aims of CARG Project, funded since 1988, is to realize the new Geological Map of Italy at 1:50,000 scale: the first phase is almost concluded with the production of the 255 geological sheets (corresponding to 40% of the entire Italian territory).

The Project is carried out through the continuous collaboration between the Geological Survey of Italy (SGI) and Regions, Autonomous Provinces, CNR, University Departments and Institutes. The SGI coordinate the achievement of geological sheets and, by the expertise of its technical staff and the "Coordinating Committees for homogeneous geological areas" support, guarantees the quality of geological sheets with technical and scientific testing.

In order to attain a homogeneous and organized project, the SGI, with the effective collaboration of experts, published the Guidelines which define the content and the standards for survey, data storage, print process and "Explanatory Notes" of the official geological and geothematic maps at scale 1:50,000. In particular the Guideline - "Linee guida per l'informatizzazione e per l'allestimento per la stampa dalla banca dati (Quaderno Serie III Volumi 6-12 Carta Geologica d'Italia - scala 1:50,000)" - were established to define database geological model and ensure uniformity of data supply.

The database of the single sheet, compliant with legislation through technical tests, are now 130 of which 117 have been published on the website of SGI.

The loading phase of the database of individual sheets in the general Geodatabase is a further test of conformity with the requirements of standardized dataset, since only during this operation emerge the unevenness between adjacent sheets and sometimes within the same. Detailed analysis of information content of databases, both for individual sheets and for wider geographical areas, it was necessary to establish the criteria and the procedure to be followed in order to standardize the information stored in general Geodatabase.

Therefore the correction process must relate to the content referable substantially to geological units present in sheet that sometimes in adjacent sheets may include information not homogeneous.

On the basis of this analysis, the abbreviations of geological units contained in the field related to the code of the litho-stratigraphic units have been aligned.

A second phase involves the work of cleaning and standardization and in some cases the integration of tabular data for compliance and completeness of the information as stated in the Guidelines referred to above.

For this purpose it was decided to work in particular on:

- the correction of codes present in the tables relating to geological units sometimes incorrectly completed or imprecise
- the integration and review of the content of field 'LEGENDA'
- the inclusion of the missing information in some required fields
- the revision and integration of the data in the field "COLORE" on the basis of codes published on SGI's Chromatic Handbook
- the inclusion of new fields necessary to clarify the meaning of some coded information.

The process of revision and correction, which involves a considerable amount of data, aims to improve the current archive with more correct and homogeneous information and provides, as most immediate result, a better representation of the information contained in it, through the publication on the Portal of the Geological Survey of Italy.

Key terms: GIS; vector-based drawing software; geological map; high-quality cartography

We are carrying on a geological map project, financed by Regione Liguria, that covers an area of about 160 km² straddling the Savona and Genova provinces in central Liguria. We perform the field mapping at 1:10,000 scale, for a final rendering at 1:25,000 and 1:50,000 scale.

The aim of the project is twofold: to produce a high cartographic-quality map and to create a geological database. The only way to link these two elements is to use a vector drawing software with GIS capabilities. During fieldwork we collect different kind of information and to manage these data we have to use 4 types of GIS features:

- georeferenced raster images (Coordinate System: Monte Mario - Italy, Zone 1),
- polygons,
- straight lines,
- points.

Polygons represent the outcrops of different lithologies, and they have a specific graphic style (reported in the legend), defined by fill (colors and textures) and stroke (weight, color, dash pattern).

Lines represent faults and are characterized by a specific stroke and color. We show as points two different kinds of information: sampling locations that are represented as a non-oriented symbol and attitude data that are

represented on the map as oriented symbols (e.g. arrows) in order to express the real orientation of planes (e.g. schistosity, bedding, faults, fractures) and lines (e.g. fold axes, lineations).

To each vector datum we associate a database made of both numerical, alphanumeric and boolean attributes.

To handle this map project, we need:

- high-resolution raster images to display topography,
- advanced graphic tools (able) to draw smooth curved lines,
- layer-based graphic project to control the overlapping order of different items.

Both high-resolution raster images and smooth lines are necessary to draw a high-quality geological map; the possibility of changing the layers overlapping order is useful to correctly display the superposition of different geological objects (e.g. bedrock - sedimentary covers - geomorphological elements). We moreover need to link the geological database to graphical objects (either polygons or lines or points), to make queries (both spatial or attribute-based) and eventually analyse the selected data in external applications, and to link external objects (e.g. photographs, graphics, etc.) to graphical objects.

To exchange and integrate data with other research groups, we have to read files from other graphical (such as Macromedia Freehand®, Bentley Microstation® and Autodesk AutoCad®) and GIS software (e.g. ESRI ArcGIS®) and to export our project both as shape files and text files. Finally, since we use a GPS device during fieldwork to precisely locate outcrops, the software we use must be able to download gps data.

In order to manage this map project we chose Avenza MAPublisher® 8.3.3 for Adobe Illustrator® CS4. Developed as a suite of plug-ins for Adobe Illustrator, MAPublisher is the bridge between the graphics capabilities of this vector-based drawing software and the GIS potentiality, to produce high-quality maps. This software is able to manage simultaneously both georeferenced data and simple graphical and text elements, and, unlike the most part of GIS programs, it can manage text data as a feature instead of a mere object label: this means that MAPublisher allows you to create an attribute schema linked to a text object.

Future development could be the use of a portable device, with an integrated GPS device and display adequate for use in the field.

Here we show the preliminary output of this graphical-GIS map, compared to a simple GIS project, and the potential of spatial and attribute-based queries on the databases associated to different features.

Key terms: GIS; Pocket PC; Planning; Cartography; GNSS

Analysis and country-planning procedures need precision and quickness, not only during field survey operation, but also in post processing data. With the digital systems spreading there's a necessity of testing innovative instruments for field data collection. The purpose is to collect "digital" data directly suitable for database and subsequently analysis.

In the last years several projects have been set up involving Regional Administration, National parks, Italian and foreign Universities and the Geosilab, Dipartimento di Scienze della Terra Università degli Studi di Torino. The result of a pre feasibility study directs our choice on a methodology that use a pocket pc for data collection, possibly with a GNSS capabilities and integrated camera. The use of a pocket pc as an instrument of survey represents the innovative side of this test, as an alternative to this, many other organizations of research and control of the environment suggest the use of a tablet pc. The instrumentation put on trial during several tests is thus composed by a pocket pc, to gather data through a GNSS connection, to collect and filing information, to access georeferenced maps, take pictures and associate them to the observed data.

The choice done for data collection was a Portable GIS devoted software (in this case ArcPad of the American ESRI) which allows to carry on the field whatever kind of georeferenced image used as base map (from Technical Map at 1:10.000 passing through geological map at 1:50.000, to thematic map and to digital orthophotos).

To this base equipment has been added the possibility to record the observations in a fast and reliable way, using a standardized format that can improve the precision of collected information and lower the possibility of errors and data omission. In this sense, specific forms have been developed for gathering different thematic data (geologic/geomorphologic, faunal and floristic, path system...etc.) For what concerning the path system, beside information about physical and morphological characteristics, the hiking difficulty and practicability could be collected points of interest, signs and degradation factors. The cartography obtained from the field work allowed to arrange maps useful for many purposes from country-planning to promulgation

Key terms: geological heritage; geomatics; inventory; evaluation; Piemonte

The multidisciplinary research project "PROGEOPIEMONTE" aims to achieve a new conceptual and operational discipline in the management of the geological heritage of the Piemonte Region. The goal is to develop

techniques for recognizing and managing its rich geodiversity at the local and regional scale. After a systematic review of inventoried geosites, 9 strategic geothematic areas will be investigated to represent the geodiversity of Piemonte. Each one characterized by high potential for scientific studies, enhancement of public understanding of science and recreation activities and for economic support to local communities. Geological history, climate and environmental changes, natural hazards, soil processes and georesources will be popularized not only with geosites but also with museum collections, evidences of mining activity and quarrying, science exhibits and nature trails. The recognition of the economic value of geodiversity will lead to the production of regional guidelines for Geoconservation integrated quality management system, suitable for tourism and sustainable development strategies. In order to collect scattered information concerning the geological heritage of the Piemonte region, cooperation between the University of Torino (Earth Science Department) and the Natural Science Museum of Torino was performed. The aim of this cooperation is to identify possible ways of acquiring knowledge and allowing enjoyment of the Region's geological heritage. This can be achieved not only by means of inventory and assessment processes of the most important sites of geological interest, but also by programs of usage and popularization. In order to define the state of the art in geosites studies and to identify the geoconservation projects developed by public or private institutions, a bibliographic research joined with field data collection was performed. The information are highly heterogeneous in quality and quantity, hence the need to develop a common methodology to performing the collection and the management of data. From the analysis and comparison of different methods already in use by public institution and research institutes, a new tool was developed for inventorying and evaluating geosites. The PROGEO-Piemonte form takes into account the specific regional needs derived from the state of the art, and follows the guidelines proposed by ISPRA for the project "National Census of Geosites". The form has been structured in two parts: 1) inventory and 2) evaluation.

- In the first part there are several sections requiring mandatory information, in order to get a holistic point of view on a geological site.
- The second part of the form concerns the evaluation process, in order to determine the value of geosites. It is divided into seven sections, where a series of predetermined parameters allow to assign a numerical value to each of the aspects taken into account.

At the end of the evaluation process, every geosite gets a score from each of the considered aspects. Depending on the final purpose of the evaluation process, geosites with higher score will be taken into account. The electronic image of the inventory and evaluation form has been placed into a database, so, the data can be retrieved and visualized from Internet.

In order to facilitate field data collection, the inventory form has been inserted as customized extension into a mobile-GIS software and adapted for use on pocket PC.

The whole information can also be used for the dissemination and promotion of geological heritage, so a map interface has been developed to make it accessible on Internet. The web-mapping tool used (Google Maps API with extension GoogleEarth) allows to enhance an interface of intuitive navigation for various additional features offered by advanced Internet Mapping.

GOOGLE MAPS MASH-UP FOR PETROGRAPHY, MINERALOGY AND PALAEONTOLOGY

SCIUTO Pier Francesco¹, MARTINELLI Giovanni²
 1 - Via Michelangelo 8- Grosseto
 2 - ARPA Emilia Romagna, Sez. Reggio Emilia

Presenter e-mail: giovannimartinelli@arpa.emr.it

Key terms: mash-up; GIS; geographic data; image management; javascript

Google maps is a very popular WEB 2.0 application for mapping geographic data. Mash-up is a javascript-html programming language for the customization and data integration of the Google maps frameset. Google maps mash-ups, developed initially only for G.I.S. (Geographic Information Systems) applications have since been utilized for scientific image management. The need to superimpose geo-referenced raster images on Google Maps has prompted some developers to produce specific free applications to generate tiled image pyramids for these pictures e.g. Maptiler, GMap Image Cutter and Mapcruncher. This made it possible to give each image two new features: the option to zoom to max. resolution of the picture and to associate each pixel with a pair of coordinates as in a geographic map. Initially these packages were used only for G.I.S purposes but they have recently been applied to different images such as photos of paintings (The Kremer Collection of art/) and big photo collages and panoramas (see webworks of Marcus Dressen, Kalle Hagman, Blaubo Design) with the possibility of sharing over the web. Recently Google realized the potential of this approach, promoting the Art project: a virtual tour of some of the world's most important museums (but only from an artistic viewpoint and without explicit use of coordinates) and new dedicated packages are soon to be distributed to web users (e.g. Iipimage) for the new Google map V3 standard. These functions were previously available with a technology named Zoomify which permitted pyramid tiling of images but not coordinate attribution (at least in the free software version). Like the art images, scientific ones too such as T.E.M., S.E.M. images, microfossil photos and pictures of petrographic thin sections can be shared on the web in G.I.S modality with a Google Mash-up adopting the above-mentioned procedure. Results appear interesting both for didactic and scientific purposes in the field of Earth Sciences. In particular, image data, previously not really accessible, and now complete with detailed and localized information, can be made visible over the WEB. This can represent a new resource for the scientific community and a new cultural platform for sharing scientific information. Some examples developed with Google Map V2 scripts can be downloaded at the web address http://sciuto.yolasite.com/dwnld_4_v2.php

PROPOSAL FOR A GEOREFERENCED DATABASE OF MINING AND MINERALOGICAL SITES IN THE TRENTO PROVINCE

FERRETTI Paolo¹, CASAGRANDE Lara¹, CONCI Francesca¹, ZANDONATI Michele¹

1 - Museo Tridentino di Scienze Naturali

Presenter e-mail: ferretti@mts.n.tn.it

Key terms: mining sites; mineralogical sites; Trento Province; georeferenced database; cultural heritage

The Provincia Autonoma di Trento owns an important heritage both of mining sites (that can be traced back to the prehistoric period) and of mineralogical sites (hanged out by scholars and mineral searchers since the end of 18th century).

Geodiversity is documented by over 200 mineralogical species, 5 of which have their type locality in the Province: pectolite, dachiardite-Na, chabazite-Ca, gehlenite and celadonite.

The mining activity in Trentino can be studied both by means of documentary and archaeological sources.

The first European mining law, the Liber de postis Montis Arzentarie, was drawn up by the Prince-Bishop Federico Wanga in his Codex Wangianus: it governed the extraction of the argentiferous galena in the Monte Calisio plateau, north-east of Trento, in the early XIII century.

Some evidences of metallurgical activities of the Copper Age, indirectly testify that the mineralogical deposits of the Province were exploited since the prehistoric period; the material traces of the mining activities performed during medieval times are also impressed in the landscape, where drifts and pits can be studied also by remote sensing (e.g., LIDAR survey).

More recent exploitations are clearly evident and well documented, for example in the archives of the mining societies that operated in the region until the 60s-70s and in some cases even beyond (the last mine was definitely closed in 2009 - in Darzo, Valle del Chiese).

The end of the modern extractive activity, the security measures implemented in open galleries and pits and the vegetation recapture of the working sites, produced a rapid loss of the material traces and of the historical memory of this important chapter in the socio-economic history of the Trento province.

This progressive disappearance of the mining activities and the reduced presence of mineral searchers in these particular sites, makes the creation of a dedicated archive relevant.

For this reason the Museo Tridentino di Scienze Naturali have launched a specific project with the aim of collecting all the disposable data concerning mineralogical and mining sites in the Province, focusing on geology, historical and technical aspects, and to the private and public collections of objects pertaining the extractive activity. The latter (from minerals to mining tools) in particular deserve great attention because of the increasing rarity of this kind of data.

The plan is to create a specific 3D georeferenced database taking into account both mining and mineralogical sites but also ore processing sites, museums and private collections and archaeological or architectural evidences that can be linked to the mining sites both geographically or chronologically. To each record a bibliographic, cartographic (maps and historical reliefs) and photographic documentation will be attached, both newly acquired or found in existing archives (museum collections, bibliographic catalogues, websites, public archives).

During this early stage the database is employed only for researches focused on single localities or on specific geological and historical subjects. Afterwards it will be part of the Museo delle Scienze del Trentino (MUSE - Science Museum of Trentino) public activities and, in the online version, will be accessible by external users.

The database might also be relevant in touristic and cultural valorization, providing a new tool to evaluate the scientific, historical and ethnoanthropological relevance of the sites.

SINGLE FREQUENCY GPS MONITORING OF GLACIAL DISPLACEMENTS: THE CASE OF GRANDES JORASSES GLACIER

ROGGERO Marco¹, LUCIANAZ Claudio², DIOTRI Fabrizio²

1 - Politecnico di Torino

2 - Fondazione Montagna Sicura

Presenter e-mail: marco.roggero@polito.it

Key terms: GNSS; deformation monitoring; glacier

Short baseline single frequency GPS positioning has been successfully applied in deformation monitoring networks. The reason to use L1 observables instead of L1+L2, it is the lower noise when the differential effect of ionospheric refraction can be neglected, that is the case of very short baselines (few kilometers length). For monitoring purposes also low cost receivers can be used in a dangerous environment, and the proposed technique has been applied since 2008 by Fondazione Montagna Sicura in the monitoring system of the Grandes Jorasses's serac. It is an unbalanced hanging glacier standing above Ferret Valley. The glacier is subject to periodic icefalls which (especially in winter) can trigger snow and ice avalanches.

The current monitoring system consists of poles with prisms placed on the surface of the serac and an automatic total station sited on the valley floor. The major drawback of this system is that fog or bad weather could impair its operation, thus causing loss of information about the serac movement.

For this reason low cost GPS receivers have been installed on the serac, transmitting data with a wireless network and gain high accuracy exploiting permanent GNSS stations. The system is characterized by low

cost (throwaway sensors due to the environment), high precision (mean velocity is about 5 cm/day) self recovery and stand-alone electric supply. The developed network is composed by three slave nodes (GNSS receiver plus PCB) one relay station and one receiving station. The receiving station logs the data in RINEX format closing one hourly file for each GNSS station. The high accuracy is than obtained by means of differential computation using local permanent GNSS stations and Bernese 5.0 software. The slave nodes have been installed on a pole with a prism on its top, in order to compare the GNSS log with the total station measurements.

TERRESTRIAL LASER SCANNING IN THE APUAN ALPS MARBLE DISTRICT (ITALY): MULTITEMPORAL MORPHOMETRIC ANALYSIS OF A QUARRY

RICCUCCI Silvia¹, SALVINI Riccardo¹, FRANCONI Mirko¹, SCOGNETTI Antonio¹

1 - University of Siena - Earth Sciences Department and Centre of Geotechnologies

Presenter e-mail: salvini@unisi.it

Key terms: Terrestrial Laser Scanning; Digital Terrestrial Photogrammetry; Multitemporal Analysis; GIS; Map Algebra

The paper describes the results obtained from the processing of multitemporal topographical data acquired by Laser Scanner, Total Station, DGPS, and photogrammetric surveys, useful for the identification of rock fall phenomena inside a marble quarry in the Apuan Alps (Italy). The assessment of the stability in mining rocky slopes is essential both to ensure safety in the workplace and to evaluate the feasibility of cultivation plan in accordance with regulations.

The study area is characterized by 100 meters high quarry wall dominated by a natural slope and historical dump deposits, locally called "ravanetti". Two underground tunnel portals are present; boundaries among dry-stone wall, marble outcrops and reinforced concrete, which stabilize the portals, represent areas where differential failures could be generated.

Laser scanning permits to get accurate information about the slopes also in inaccessible areas; multitemporal surveys allow to point out zones characterized by rocks and debris accumulation or by fall.

During fieldwork some optical targets were positioned to represent benchmarks needed in the registration process of multitemporal laser scanner points clouds and, together with some evident morphological elements of both anthropic and natural origin, in the orientation of digital images captured for photogrammetric processing. The coordinates of benchmarks and ground control points, relative and absolute, were acquired by Laser Total Station and differential GPS measurements. Five multitemporal laser scanner surveys were done with a time interval of about 2 months one from the other. Laboratory activities concerned multitemporal points clouds processing: the first phase of the work was the editing of the five points clouds in order to eliminate data representing areas out of interest (i.e. anthropic features) and to build the DDSM (Digital Dense Surface Model).

GIS analyses and Map Algebra techniques were applied to compute the spatial difference among the multitemporal DDSM and to evaluate the changes occurred in the study area. In order to overcome the unreliability of the interpolation process in the DDSM creation, strictly connected to shadows in the points clouds, the multitemporal comparison was done only for spatial positions corresponding to effective points of laser scanner clouds.

Afterwards, difference values were classified according to their statistic distribution but also considering both the registration error, the instrument accuracy and the topographic error related to the GPS and Total Station surveys.

High difference values achieved in some areas have well highlighted rock falls occurred during the analyzed period. In different zones, where the multitemporal photogrammetric analysis have not shown any variations, the high difference can be connected to high values of front slope and to the misalignment between different points clouds caused by slightly diverse positioning of the instrument during the surveys. Then, the compared analysis between difference rates and slope values was done in order to verify the effective weight of the points misalignment in the difference calculation. Results confirm that the highest difference values correspond to the most dipping areas or zones where the morphology changes suddenly its direction (quite often considering the artificial origin of the marble quarry front).

Zones characterized by low values of slope have presented differences included in the error range while only a reduced number of isolated points, without a outstanding spatial distribution, have shown a multitemporal difference greater than the threshold: they are due, thanks to the interpretation of the produced multitemporal orthophotos, to the spontaneous vegetation growth.

10.1474/Epitome.04.0987.Geoitalia2011

INTEGRATED USE OF ROBOTIZED TOTAL STATION AND LASER SCANNER FOR LANDSLIDE MONITORING

ALLASIA Paolo¹, GIORDAN Daniele¹, BALDO Marco¹, MANCONI Andrea¹, LOLLINO Giorgio¹

1 - CNR IRPI

Presenter e-mail: paolo.allasia@irpi.cnr.it

Key terms: Landslide monitoring; Robotized Total Stations; Laser scanner

In the last decades, Robotized Total Stations (RTS) have been widely considered to monitor the evolution of surface displacements due to landslide phenomena. RTS are frequently preferred to other monitoring methodologies due to their relatively simple installation, straightforward operational use and data processing, as well as their limited costs. One of the main disadvantages in the use of RTS is the need to install a network of artificial targets (prisms) directly on the surface of the monitored site. In many landslide phenomena this operation might be very difficult for different reasons: (i) limited access to the landslide area; (ii) problems in defining the landslide boundaries due to poor a-priori information; (iii) large extensions of the instable area. Moreover, when the morphological variations are relatively fast, the prisms may easily go outside the suitable range of the instrument or even fall down. Thus, the retrieved displacement time series might be often not well representative of the landslide evolution. In these cases, new generation RTS allowing a monitoring in modality "laser scanner" (thus without the installation of

prisms) can be very helpful. In this work, we present a case-study where the RTS Topcon IS has been installed to monitor the headwall sectors of the Montaguto landslide, a large earthflow located in Campania, southern Italy. We used the Topcon IS to monitor continuously a network of prisms with sampling rates of about 2 hours. Moreover, since this instrument can work also in "reflectorless mode", we use periodically its laser scanner facilities to generate multi-temporal DTMs. Our first results show the effectiveness of considering of an integrate analysis of surface displacement data provided at points in zones where their installation is possible and over areas where the installation of targets is difficult and/or even precluded.

BEEGIS: SOME NEW FEATURES FOR FIELD MAPPING DEVELOPED IN RISKINAT PROJECT

LANTERI Luca¹, ANTONELLO Andrea², DE DONATIS Mauro³, FRANCESCHI Silvia², SUSINI Sara¹

1 - Arpa Piemonte

2 - Hydrologis

3 - Università degli Studi di Urbino

4 - LINEE-Laboratory of Information technology for Earth and Environmental Sciences, Urbino.

Presenter e-mail: l.lanteri@arpa.piemonte.it

Key terms: Tablet PC; field survey; digital mapping; open source; GIS

One of the main goals of the Geological Department of Arpa Piemonte (the Regional Agency for Environmental Protection) is to set and to update the framework about the hydrogeological instability in the Piemonte region. In order to constantly maintain an efficient and up-to-date inventory the field survey work is a matter of utmost importance. Particularly, when a heavy-rain event occurs, the surveyors must collect a great amount of data, often scattered in a wide areas, in as short a time as possible. New GIS technology coupled with the improved performance of the next generation of portable hardware allows to have effective tools that aid to simplify and speed-up the field work.

As result of a early testing phase of the different available hardware products (mainly PDA vs tablet PC) rugged tablet PC results as the most efficient tools for this specific work. In this first step also different commercial software was tested. As a consequence of the limitations due to the commercial license, and following the indication of Regional Law n. 9 of 26 march 2009, that recommend to privilege the use of open-source software, ARPA had choose to join the BeeGIS community.

BeeGIS is an open source GIS software for field mapping conceived for pen computer working with any common operating system (Windows XP, Vista and 7, Mac OS, Linux). This software is developed mainly by Hydrologis, an environmental engineering company with extensive experience in Java-based GIS, in collaboration with LINEE (Laboratory of Information Technology for Earth and Environmental Sciences of Urbino University).

BeeGIS is a plugin of Udig, an open source (LGPL) desktop application framework, built with Eclipse Rich Client (RCP) technology. Several new tools were designed ad hoc in order to create an efficient and user friendly tool for professionals who may have a limited knowledge of GIS and who want to minimize the learning time for new technologies.

A particular attention was made to preserve the traditional methods for mapping, while replacing the pencil and the paper (map and field book) with a digital stylus and touch-screen. All conventional GIS features can be used directly during survey, as using different topographic maps and orthophoto and overlapping several different data layers. In addition the surveyors have at their disposal some tools who drastically simplify the field work, such as: a real time GPS positioning, the geonote to catch georeferenced note and sketch, a fieldbook to organize and search the geonotes and the annotation tool who allow to draw over the map as in the paper-based cartography.

Currently the developing of some new features and the improving of the existing ones is included into RISKINAT, a strategic Italian-French Interreg European Project. Particularly a new feature, named form editor, allow anyone with few knowledge of digital work to create and to manage their own survey forms. This tool is particularly useful for project that needs a prearranged forms to store data with standard structure, especially when there are more than a single surveyor. Moreover a new style editor that support SLD (the OpenGIS Styled Layer Descriptor format) has been developed, a complete library of geological and technical symbol is going to be created coupled with an exhaustive user guide. Also a lot of minor improvements and bug fixing are done.

Thanks to the LGPL license, BeeGIS can be distributed without limitation both to all project partners and others users. Therefore one's contribution can be shared to all scientific community.

1 - CNR - Institute of Ecosystem Study

2 - CNR - Institute for Electromagnetic Sensing of the Environment

3 - CNR - Institute of Marine Sciences

Presenter e-mail: a.oggoni@ise.cnr.it

Key terms: Sensor Web Enablement; Spatial Data Infrastructure; sensors

The Sensor Web Enablement has indicated a set of rules that allow the integration of sensors and the observations they detect within a Spatial Data Infrastructure. The SWE services have changed the way of expose and share data collected by distributed sensors, as at the moment they constitute the only actual opportunity for a standardized and interoperable spread of observations. In fact sensors of various types (fixed, mobile, in-situ and not in-situ) can be registered, observations on time series or representatives of bi- and three-dimensional domains can be shared, and finally access selected by either geographical, or time instance or time range, and concerning one or more Properties or Procedures can be performed by getObservation operations.

In this work are presented some experiments concerning the possibility to use the Sensor Web Service in different sectors (meteo-hydrology, biology/ecology, physics, chemistry and remote

sensing), introducing the possibility of using requests like RegisterSensor, InsertObservation and GetObservation, assessing the critical aspects, gaps or points of force, and finally test the interoperability within different clients.

HARMONIZATION AND INTEROPERABILITY OF THE GEOLOGICAL SURVEY OF ITALY DATABASES

CIPOLLONI Carlo¹, PANTALONI Marco¹
1 - Servizio Geologico d'Italia - ISPRA

Presenter e-mail: carlo.cipolloni@isprambiente.it

Key terms: OneGeology; GeoSciML; Standard; Geological Map; CARG

The Geological Survey of Italy has applied the Geoscience standards (GeoSciML 3.0) to some national cases deriving from the experience developed during the realization of the OneGeology-Europe project and in the use of GeoSciML as member of the Interoperability Working Group of IUGS-CGI.

Geological information are achieved from several databases, such as the one derived from the Geological Map of Italy at 1:1,000,000 scale (GeoIMDB, Cipolloni et alii, 2009) based on its explanatory legend, where each feature is related to the geologic units information (i.e. lithology, chronostratigraphy, orogenetic phase, geologic event, tectonic event, tectonic structure, depositional environment, petrography, metamorphic grade, metamorphic phase).

A further database is the deep borehole DB in which the available geological information consists of lithology, formation description, chronostratigraphy, biostratigraphy, etc.

Another specific application of the data model has been pointed out on the Italian Geological Cartography Project (CARG project) database; these data are more detailed and plentiful; we decide their use for testing the detail case model and/or in other part of the GeoSciML model that aren't evaluated in the lower scale data.

Following the semantic structure defined by the "1:1M pan-European Scientific Data Specification, Identification and Sourcing" realized by the specific working package (WP3) of the OneGeology-Europe project, we are working to harmonize the GeoIMDB, particularly on definitions (lithology - chronostratigraphy) and structure of the surface geology.

The data model is mainly developed on the GeoSciML schema version 2.1.1 that represent the geologic schema used into OneGeology-Europe project that, probably, will represent the model for INSPIRE Data Specification - Annex II. In this model each feature require terms and definitions, referred to existing definitions and standards. A major basis for the Data Specification work come from the GeoSciML scheme and the CGI/GeoSciML vocabularies.

In order to match the local terminology versus the harmonised vocabulary we have created some bridge tables where all the local information are reconfigured to international ontology. An important challenge is represented by a new testbed that use the geologic data integration model made by ESRI that easily re-create a compliant model.

The access to geological datasets is settled as web map service (WMS) and web feature service (WFS) using a specific Java-connector, developed by BRGM for the OneGeology-Europe project; this connector allow us to configure a OGC standard WMS (1.3) and WFS (1.1.0) to INSPIRE data sharing service in multiple-language and in GeoSciML response.

At the moment our web map service is available in different format to spread the user's accessibility; the metadata of data and services are stored in multilingual format, according to INSPIRE rules, in two different metadata catalogues, accessible from the OneGeology-Europe portal (<http://www.onegeology-europe.eu>) and the Geological Survey of Italy portal (<http://sgl.isprambiente.it/geoportal>).

Cipolloni C., Pantaloni M., Ventura R., Vitale V. & Tacchia D. (2009) - The GeoIMDB: the database of the 1:1,000,000 scale geological map of Italy. Proceeding of "6th European Congress on Regional Geoscientific Cartography and Information System", 1, 235-237 pp., Munich (Germany).

A 3D MODEL IN GIS FOR THE ANALYSIS OF A KINEMATIC PHENOMENON IN LIGURIA (ITALY)

BOVOLENTA Rossella¹, PASSALACQUA Roberto¹
1 - UNIVERSITA' DEGLI STUDI DI GENOVA

Presenter e-mail: bovolenta@dicat.unige.it

Key terms: LANDSLIDE; GIS; MODELING

The present paper deals with a 3D model in GIS, realised in order to study a diffused and continuous kinematic phenomenon in Santo Stefano d'Aveto (Liguria - Italy).

The extensive area of interest (almost five square kilometers) is sited on a top-valley gentle slope (mean angle 11°), which downgrades directly from the south-side faces of the Northern Apennines summits locally arriving at 1800 meters a.s.l. From the geological and morphological points of view, the entire area was formed by a pliocenic glacial till and its body of widely assorted sediments had been reckoned as a large relict landslide.

The loose-soil thickness spans from few meters up to 90, before of reaching the bedrock formations. The seasonal rain/snow falls on the watershed represent the main trigger actions on the soil body's behavior. In consequence of the widespread and locally differential movements at ground level, many buildings and structures exhibit such damages that most of them are in constant need of repair.

Since the wide landslide is influenced by the interaction between water and soil, the creation of a 3D model, integrating the digital terrain model (DTM), the water table and the bedrock, is particularly effective for the stability analyses. The model has been implemented in GIS, which is an useful tool for the integration and analysis of georeferenced information for the territory monitoring, management and planning, also in support of risk analyses. GRASS (Geographic Resources Analysis Support System) has been chosen. It is a free and open source GIS, whose main feature is to allow the usage of existing algorithms and procedures, as well as the integration of additional features that can be returned to the community with the same characteristics of reusability.

In the work, all of the relevant data, yet available for the site under study, have been collected and examined. They are represented by the geotechnical - geophysical characterizations and monitoring, the topographical - GPS surveys and the results of a satellitar interferometry analysis. A full georeferenced integration of the raster, vector and spot

informations have been obtained, making possible the study of their intercorrelations. More than that, this first phase of implementation has been of great help into choosing the on-site positions where additional investigations have to be carried out, in order to obtain a proper dataset cover on the whole area.

The results attained by this research, which is still in progress, are represented by the 3D modeling of the phreatic surface and the loose soils' thickness for the overall area. This has been obtained by rather simple correlation techniques and interpolation procedures, applied on specific geophysical and hydrological measures collected on-site for these very purposes.

Great advantages are established by such an integrated working platform. In fact, the final objective lies into make possible to easily conduct classical, but widespread, 2D slope stability analyses, or better, apply non-standard 3D simulations on this micro-territorial complexity. A yet planned further development is to simulate the evolutions of the phreatic level by modeling the whole sediments' body as a charging-discharging subsurface reservoir, feeded from selected rainfall histories. To carry out this capacity, a proper description of the site rainfall-runoff response capacity is needed, and this may be attained using an overall Curve Numbers' grid, whose values may be scored, mostly, from the observation of the site's georeferenced satellitar images on the GIS interface.

The presented results are promising, because it seems that a challenging 3D physical modeling is today possible by GIS integration. It shall allow both a more proper land use planning and the correct placement/design of accurate rehabilitation measures.

THE GEOGRAPHIC INFORMATION SYSTEM OF THE PROVINCE OF LA SPEZIA FOR THE MANAGEMENT OF THE PATH NETWORK

BIONDUCCI Riccardo¹, CAVIGLIA Davide², COSSO Tiziano³, SGUERSONO Domenico⁴

1 - Provincia della Spezia

2 - Gis&Web s.r.l.

3 - Gter s.r.l.

4 - Università di Genova

Presenter e-mail: tiziano.cosso@gter.it

Key terms: path network; WebGIS; Open Source

The Province of La Spezia, in the activities of informatization of the PA, has organized the implementation of a provincial information system of footpaths;

object of analysis is therefore complementary and alternative road network for hiking and civil defence.

According to what is already tested in terms of cadastre roads ex Legislative Decree 285/92 and Road Information System, information on the entire system of footpaths provincial ((CAI, REL, other paths mapped etc.) will be usable in the logic of paths information system, that is thematic, yet fully integrated into the provincial DataWarehouse designed to collect and make available all the resources available to the provincial S.I.T.I. Web community.

This helps to make accessible and connectable information to different ownership in an integrated organizational context in which each operator is the supplier of information produced by himself and user of the information generated by others, with the possibility of deriving more, by free combination and intersection.

The system shall be based on G-PASTRO (Gter - Path System Accessibility Outliner Tracks) which is the engine of the GRASS GIS environment and GisClient platform for the management of Web interfaces that can be created ad-hoc to interact and update the system; to store the data will be used PostgreSQL and PostGIS spatial extension.

In particular, GIS is used for proper and efficient planning and management of maintenance activities of mountain environments, besides as a support for any rescue operation.

The implemented features allow you to:

obtain elevation profiles and travel time along any stretch of the path network;

obtain elevation profiles and travel time along a path that is not included in the path network (useful for planning and managing research missing, often in areas not covered by paths);

automatically evaluate how the current trail network covers the territory, being able to identify where and by what route to create new sections of trail by the criterion of minimum energy;

store and update in a single DB all information relating to the conservation status of both trails and shelters, to plan and manage maintenance;

integrate information on the network footpaths with other data related to morphology of the land and the sources of risk (landslide areas, river network,) burned areas to assess when and where specific interventions of maintenance and possibly changes to current network;

integration with access points that can be used by emergency vehicles (jeep, helicopter,....).

The application is developed open source environment and can therefore be adapted to meet specific needs. In particular, it is already designed an interface for manipulating individual parameters to calculate the travel time, so you can easily and quickly adapt to different types of people (young / old man / man / woman,.... ..).

GIS-BASED CALIBRATION OF THE LANDSLIDE MODEL MASSMOV2D

MOLINARI Monia Elisa¹, CANNATA Massimiliano², MEISINA Claudia¹,

AMBROSI Christian², BEGUERIA Santiago³

1 - Università degli Studi di Pavia, Dipartimento di Scienze della Terra

2 - Scuola Universitaria Professionale della Svizzera Italiana, Istituto scienze della Terra

3 - Consejo Superior de Investigaciones Científicas, Estación Experimental de Aula Dei, Zaragoza

Presenter e-mail: moni.molinari@gmail.com

Key terms: landslide; model; calibration; GIS

MassMov2D (Begueria et al., 2009) is a numerical model for simulating run-out and deposition of landslide phenomena over a complex topography; the software, based on Saint-Venant equations (Navier-Stokes equations under shallow water assumption) with the integration of rheological models for the flow behavior control, is implemented within the free GIS PCRaster; currently the porting of the code into GRASS GIS with GPL license is under development.

During this research the model has been applied to the case study of the "C" instability: a complex landslide located on the left slope of the Canaria stream. In case of failure the mass accumulation would probably generate a natural dam that, if collapsing, would consequentially produce a flash flood. This may severely damage the population and the transport infrastructures (highway, main road and railway) of North-South axis of San Gottardo, with consequent high economic losses.

In agreement with the exposed scenario, a partial failure involving a volume of 350000 m³ happened in 2009; fortunately in this case the damages were limited. Thanks to a monitoring program performed with traditional survey techniques and terrestrial laser scanning, high resolution (1m) digital elevation model of the area before and after the collapse was available.

This research improved the MassMov2D code introducing the Nash-Sutcliffe model efficiency coefficient calculation in order to enable the semi-automatic sensitivity analysis and calibration that may replace the inefficient 'trial and error' approach that has been used for this model.

Here the authors want to illustrate (i) the mathematical model foundations, (ii) the sensitivity and calibration process with the obtained results and (iii) the hazard assessment analysis results. Moreover, the porting of the model to the GRASS GIS will be illustrated and presented. It has to be noted that the hazard analysis has been performed by applying the calibrated model to different future expected failures scenarios; all the analyses steps, with exception of the modeling, have been performed taking advantage of the GRASS GIS processing features.

SIMULATION OF DAM BREAK WITHIN THE GIS GRASS

MARZOCCHI Roberto¹, CANNATA Massimiliano¹

1 - IST, Institute of Earth Science, University of Applied Sciences and Arts of Southern Switzerland (SUPSI), Campus Trevano, CH 6952 Canobbio, Switzerland

Presenter e-mail: roberto.marzocchi@supsi.ch

Key terms: dam break; flood hazard delineation; risk assessment; GIS

A Dam failure is a technological disaster of particular concern. In fact it could happen for several causes (overtopping of embankment, faults in construction methods, geological problems of foundations, landslides and earthquakes, etc.) and it has the potential to cause more death and destruction than the failure of any other man-made structure.

One of the main phases of the dam break risk management is constituted by the flood hazard delineation. To this purpose, we have developed a new numerical model for the solution of the two-dimensional dam break. It solves the conservative form of the 2D Shallow Water Equations (SWE) using a Finite Volume Method (FVM); the inter-cell flux is computed by one-side upwind conservative scheme extended to a two-dimensional problem.

We have implemented it in the GRASS GIS as a GIS embedded module (r.damflood), in order to taking advantages of the GIS features for risk assessment and emergency planning.

Aim of this work is to verify the model implemented in GRASS (Marzocchi & Cannata, 2009) and enhance the algorithms by adding controls and auto-calibration procedure able to guarantee numerical stability of the solutions. A new case study has been applied to verify the sensibility of the model to different grid spatial resolutions. Latest enhancements and results regarding the r.damflood model are here presented.

GEOMATIC TECHNIQUES CONTRIBUTING TO UNDERSTANDING GEO-MORPHO-STRUCTURAL ASSESSMENT OF VENEY VALLEY (COURMAYEUR, AO)

PEROTTI Luigi¹, BACENETTI Marco¹, ZAMPARUTTI Paolo¹, GIARDINO Marco¹

1 - Università degli studi di Torino, Dipartimento di Scienze della Terra

Presenter e-mail: marco.bacenetti@gmail.com

Key terms: pocket - PC; LiDAR; Coltop 3D; Close range photogrammetry; Geomorphology

The present work is orientated at the comprehension of the geomorphologic processes of periglacial environment past and on going of Veneý valley (Courmayeur, AO) and their interaction with the morpho-structural setting through geomatic techniques. Previously studied sectors within the project area with large quantities of data were integrated and compared by detailed research within sectors of scarce pre-existing field data.

First, the field data were collected using pocket-PC and integrated GPS in order to create an ESRI-GIS based geodatabase. Considering that the area was setting in an alpine context, stereoscopic models from the '97 and '03 flights with a 4 m precision were built to map geomorphological features in unaccessible area. Contemporaneously, to support these data, LiDAR '08 images were processed to include hillshade, slope, and aspect maps. Two areas of keen geomatic interest were individuated: the potential failure surfaces of the Mont Rouge de Peuterey and the Miage glacial basin. Using the Coltop 3D software, kinematic analysis of the data were performed using the Markland test. The software allowed also, through back-analysis, the determination of main areas of potential gravitational instabilities. MIVIS '99 images analysis allowed to classify the debris cover of Ghiacciaio del Miage and detected the potential rock instability using the Principal Component Analysis (PCA). On the same slopes close range photogrammetry was performed to measure joint sets setting.

Data interpretation yielded to obtain three geomatics layer: a) geomorphologic, within mapped landforms b) morpho-structural, concerning the structural evolution c) debris cover of Miage glacier, for the multitemporal analysis.

The remote sensing technologies, applied in this project, showed to be

more affordable than the usual field-based approaches, in the prespective of a safe analysis of stability conditions in mountainous areas.

2 - CNR - IRPI, Turin

Presenter e-mail: elisa.damiano@irpi.cnr.it

Key terms: Landslide; geomatics; multitemporal analysis

The purpose of this study is to achieve an understanding of the failure mechanism which caused a large landslide in San Martino Sulla Marrucina (SM) municipality (Chieti Province, central Italy).

The gravitative event occurred during the spring 2001 and it quickly affected many buildings and infrastructures of the urban center and is located nearby the main road connecting all villages in the valley. The landslide evolution has been characterized by a continuous activity (from 2001 to 2004), which caused the formation of a main crown 20 meters high and 1.5 km long. After this phase, the surface displacements have been less prominent, and nowadays the landslide is considered almost quiescent.

In this work, we aimed at investigating not only the structure of the landslide but also its potential triggering mechanisms. We considered several techniques, ranging from field surveys to surface displacement monitoring (GPS and airborne LiDAR), traditional stereoscopy and advanced geomatics methods (GIS spatial analysis, Digital cross-correlation techniques). Besides, thanks to Geographic Information System (GIS), a multitemporal approach has been carried out to reconstruct the main geomorphologic and topographical changes, occurred on the slope during the last eighty years.

The results achieved with this integrated study suggest that the SM landslide is actually a local reactivation of a wider quiescent landslide and that doubtless, his morphological evolution is characterized by a retrogressive trend. Furthermore, it has been inferred a preliminary geodynamic model based on a deep kinematic conditioning. This data will allow investigating the landslide susceptibility of the whole municipality territory and will represent the base for future risk evaluations.

TRIDIMENSIONAL DIGITAL MODELING OF THE PESTARENA GOLD MINE (PIEDMONT - NORTH ITALY)

GIULIANI Andrea¹, FORNARO Mauro¹, ROSSETTI Piergiorgio²

1 - Università di Torino - Dipartimento di Scienze della Terra

2 - Università di Torino - Dipartimento di Scienze Mineralogiche e Petrologiche

Presenter e-mail: andrea.giuliani@unito.it

Key terms: Gold mine; 3D modeling method; Reopened dismissed site

Introduction

Among all conventional metals subject to a progressive increase in value in the international market, gold has jumped powerfully into the spotlight during all economic crises, which affect both developed and emerging Countries.

This contingency has led to reconsider the dismissal process for some Italian mining sites, occurred in last decades for many metalliferous mines, among which a very particular situation is the case of the gold mine Pestarena.

This mine site, placed in the north of Piedmont (Macugnaga - VB), is developed on an area of 4 square kilometers through about 40 km of tunnels.

From a mining point of view, the ore-body in Pestarena is characterized by the presence of significant gold-bearing grades in the mineralized rocks, but that is organized in filonian rock structures of small dimensions and complex geometry, not so easy to reconstruct from the surface.

This aspect makes very difficult to assume a profitable method of exploitation without a whole prospection of the ore-body, pursuing the goals of safety and sustainability of the yards.

Working method

In order to better understand the geometric relationships that link the different levels of the Pestarena mine, it was necessary to digitalize the only still existing mining plan, updating at the end of 1960; the operation has proved difficult due to the physical size of the document.

The digitization of the available data has been divided into different steps:

1. Reproduction in electronic form of paper mine plan (three meters long) through a professional scanner and its post-processing elaboration with a computer graphic software in order to zip the achieved files;
2. Ortorectifying and georeferencing on the UTM-WGS84 coordinate system of the cartographic base obtained with a specific software (ArcGIS 9.2 - ArcMAP), in order to place all the mining yards in the correct position in relationship with actual topographic maps;
3. Digitalization point by point of the main excavation voids in Pestarena mine (Morghen, Adit-Acquavite, Calpini, Tredici e research levels) by means of the creation of a point shapefile for each level and each descendency reported on the map (30.000 points in total);
4. Semi-automatic quotation of progressive altitude values for each beated point and realization of TIN for the foot-wall of each mining levels;
5. Plot of all TINs in tridimensional view thanks to a dedicated software (ArcGIS 9.2 - ArcScene), with the visualization of foot-wall, roof and walls for each tunnel.

The whole process led to the creation of a digital map of the Pestarena mine, with its three-dimensional model of all mapped levels. This tool has proven to be necessary for the understanding of spatial relationships between the surface topography above and the mine elements, also thanks to the redefinition of the nomenclature of the 34 levels that in some areas were difficult to detect because of repeated overlapping.

Conclusion

The help furnished to the Company that held the mining concession, allowed to plan the terrain surveys based on new criteria that represent a more deep geo-mining grade of knowledge planning only some technical operations environmental-friendly.

The research work has covered a valency of potential interest for the

manufacturing sector and, in any case, for a type of mineralization widely studied, but not well known from the practical point of view, also because it was possible to find only extraction yards conducted in the past with limited equipments by men guided by instinct instead of science knowledge.

Presenter e-mail: luigi.perotti@unito.it

Key terms: Glaciers; Geomatics; Hazard; Multitemporal

The alpine glacial and periglacial areas are difficult to be studied because they are impervious and they often lack of data. The dynamics of that areas need appropriate techniques for the collection, elaboration and representation of information.

The purpose of this work is the multitemporal analysis (last fifty years) of the evolution of some glaciers of the Western Alps, set in the Orco Valley, using suitable geomatic techniques applied both to remote sensed and to field data. The interest for reconstructing changes in glacial and periglacial areas is the high velocity of change of the geomorphological landforms and glacial mass extent in the valley: as a consequence, critical situations can arise where anthropic activities are located close to glacial and periglacial areas (dams, winter and summer touristic attractions, small towns).

The multitemporal assessment of variations of glaciers area and volume is performed by field work and by the application of digital photogrammetric techniques. The field work is carried out through a pocket pc with integrated GPS: this tool allows a precise contouring of glaciers and a precise positioning of the snout. Longitudinal and vertical profiles of glaciers and proglacial areas are obtained through a GPS campaign.

Using geomatic applications, stereo couples of aerial photographs from different years, have been digitalized and elaborated by mean of a photogrammetric system. A multitemporal aerial triangulation minimizes errors from the model, as photographs of different periods are put all together in one block. Ground control points have been implemented thanks to the GPS campaign in the field. As output, different cartographic products, as Digital Elevation Models, orthophotos and longitudinal and vertical glaciers profiles, are obtained.

The creation of Digital Elevation Models to calculate variations of elevation on glacial surfaces, permitted to notice significant variations of glacial masses and a thickness reduction of several meters from 1954 to 2000, in agreement with field observations reported on annals of the Italian Glaciological Committee. Moreover, graphical elaborations of topographic data, such as slope and hillshade maps, allow to identify factors which are associated to instability prone areas.

The present work is carried out in the framework of CNR-IRPI activities for the Alcotra 2007-2013 project N. 056 "GLARISKALP".

TOPOGRAPHIC AND GEOLOGICAL MAPPING OF USAKLI HOYUK (TURKEY) HITTITE SITE

SALVINI Riccardo¹, SALVI Maria Cristina¹, CARTOCCI Alice¹, MAZZONI Stefania²

1 - University of Siena - Earth Sciences Department and Centre of Geotechnologies

2 - University of Florence - Department of Antiquity Sciences

Presenter e-mail: salvinir@unisi.it

Key terms: High Resolution Remote Sensing; Stereoscopy; Topography; Geology; Spectral Signatures

Usakli Hoyuk, in Central Anatolia, is a Hittite site that was the focus of archaeological surveys by the University of Florence since 2008, after hittitologist O.R. Gurney identified it, in 1995, with the old sacred Hittite city of Zippalanda, cultural centre of the Storm God. The evidence came by epigraphic sources and its importance was based on some considerations obtained during the survey carried out by the Turkish METU University relatively to the close Kerkenes Project.

In order to aid the archaeological researches, a geological survey was carried out with the goal of producing the new geological map at the scale of 1:10,000.

A fieldwork was done to define the chronological development of the region and to recognize the geological and geomorphological structures useful to rebuild the ancient landscape controlling the archaeological settlements. The analysis of the geological setting was also functional to the identification of raw materials exploitation sites and path routes, cited in some ancient sources, which connected the Hittite capital of Hattusha to all the cultural cities of the surrounding areas.

The study area constitutes a perfect area to apply remote sensing techniques: since the region was unoccupied from a longtime, it is still unexcavated and the close connection with other important cultural sites in the vicinity can be well pointed out.

A GeoEye stereopair was properly acquired for the project in a way to have a multispectral image covering an area of about 100 km² with a spatial resolution of 0.5 m. GPS measurement of rock outcrops, morphological features and ancient sites was the core of preliminary fieldwork activities. The acquisition of topographic GCPs (Ground Control Points) and the processing of their tridimensional coordinates allowed, together with Rational Polynomial Coefficients, the external orientation of the stereopair.

Afterwards, digital satellite photogrammetry techniques permitted the stereorestitution of the topographic map at the scale of 1:10,000, the production of the DEM (Digital Elevation Model) and the orthophoto.

The DEM was helpful also for the interpretation of relevant geomorphological data related to the present landscape, to probable ancient scenarios and to site connecting paths.

During fieldwork, more than 100 geological and geomorphologic ground truths were surveyed and almost 100 rock samples collected for petrographic and micropaleontological analyses.

The new topographic map was used as reference cartography. All the geological outcrops surveyed were photographed, described and their

position coordinates recorded by a GPS.

In the southern part of the study area mainly granitic stones, belonging to the Yozgat Batholith, outcrop. The granitoids are overlaid by volcanic, clastic and calcareous Eocene deposits. To the North, the Neogene clastic sediments, mainly constituted by sandstones, marls, conglomerates and breccias, represent, together with limited Quaternary alluvium, the youngest rocks outcropping in the zone.

The archaeological site is located within Eocene rocks near the fluvial deposits of a small stream tributary of one of the main rivers of the area WNW- ESE trending.

On the southern side of the Tell which identify the site, an area of about 800 m² was surveyed using the FieldSpec 3 Full Range[®] Analytical Spectral Device in order to collect spectral signatures of land cover.

Superficial spectral signatures are being compared with results achieved by the automatic extraction of linear features and by the stereointerpretation of the satellite imagery in a way to recognize possible ancient buried remains. The position of the surveyed sites on the Tell was chosen in accordance with results from contemporary and previous geophysics studies.

Moreover, around the Tell area, spectral signatures of stones were recorded with the aim to create a geodatabase to be compared with spectral signatures of rocks coming from surrounding areas source of ancient quarries.

2 - University of Brescia

Presenter e-mail: giorgio.vassena@unibs.it

Key terms: volumes evaluation; laser scanner; reconstructor

The paper deals with an automatic system able to extract volumes from deposits of material. The system is composed by a TLS (Terrestrial Laser Scanner), protected by a climate box and remotely controlled by internet. The system is able to monitor automatically the volumes and the variations of volumes in the time.

The TLS is controlled thanks to the software JRC 3D Reconstructor, and the volumes evaluated thanks to an algorithm that creates from the scans a 2.5 D mesh and DTM.

The system is realised so to manage, in the same time, up to 4-5 TLS. The laser scanners acquisitions are automatically registered, and the 2.5D model is automatically extract. The system presented is one of the first systems, using TLS, where the information needed (the volume of the stockpiles) can be obtain automatically by the end user, without the support of an expert surveyor.

HIGH RESOLUTION SATELLITE IMAGERY AND FIELD SURVEYS TO MONITOR CHESTNUT INK DISEASE

D'ERAMO Luca¹, ADAMO Dario², PEROTTI Luigi¹, GIORDANO Gentile²

1 - DST - GEOSITLAB, UNIV. di TORINO

2 - COMUNITA' MONTANA DELLE ALPI DEL MARE (CN)

Presenter e-mail: luca.deramo@unito.it

Key terms: IKONOS; NDVI; Supervised Classification; Phitophthora cambivora; Castanea sativa Mill

Chestnut ink disease, caused by Phitophthora cambivora, is one of the most dangerous and deadly pathologies afflicting chestnut trees. During the last decade, an outbreak of this phytopathology was recognized in southern Piedmont. This pathology causes considerable economic losses and prevent the development of new chestnut groves (Castanea sativa Mill.).

To monitor the disease extension inside the area of Comunità Montana delle Alpi del Mare (Cuneo province) was adopted a methodology combining high resolution satellite imagery and field works. We used the municipality of Robilante as test site. After a preliminary survey to identify some sample areas within ill/healthy plants, a second field work was done to acquire plant positions using a total station and a double frequency GPS. The global accuracy of data acquired has been estimated around 5 cm. Subsequently, the points collected have been reprojected onto a IKONOS image. Launched in 2000, IKONOS satellite is composed by one panchromatic band and 4 spectral channels (red, green, blue, near infrared), with a geometric resolution of 1 m and 4 m at nadir, respectively.

As known, the photosynthetic activity of plants is better observed within the red and the near infrared bands, using the Normalized Difference Vegetation Index (NDVI). After the radiometric calibration, from digital number to reflectance, an atmospheric correction was applied on image (dark subtraction). The area covered by chestnut groves were extracted from a NDVI mask, using ancillary information coming from the chestnut database realized by the agency cited above. The collected field samples were split into two groups. Using one of these sample, we test the efficiency of three different supervised classifications i.e., minimum-distance, parallelepiped, and maximum likelihood, to evaluate the best method able to highlight the spread of disease. During the first attempt, the sample used was estimated too less representative and meaningful. Thus, more chestnut areas, extrapolated from database, were introduced into classification process. After several tries, maximum likelihood algorithm was estimated as the best classificatory method.

Thus, the maximum likelihood classification has been applied on second sample, using confusion matrices to validate the procedure. The overall accuracy of methodology was confirmed by 85,4 % of properly classified plants (ill/healthy trees). Concluding, we can say that the methodology proposed can be very helpful to monitor the spread of this pathology. The high geometrical resolution of IKONOS images permits to check the health status of each plant over time, if a multitemporal monitoring is carried out. The main disadvantages are related to high acquisition costs of IKONOS imagery, and long time needed in acquiring a representative sample suitable for classification. In the future, it is planned to apply a topographical correction to IKONOS data, in order to reduce classification errors induced by different lighting conditions, and test the capabilities of other satellite such as SPOT or ASTER, which may represent a good compromise between data quality and acquisition costs.

THE MIAGE GLACIER: GEOMORPHOLOGICAL MAP AND STUDY OF THE DEBRIS COVER USING DIGITAL PHOTOGRAMMETRIC TECHNIQUES AND REMOTE SENSING

ZAMPARUTTI Paolo¹, PEROTTI Luigi¹, GIARDINO Marco¹

¹ - Geosilab - GIS and Geomatics Laboratory - Dipartimento Scienze della Terra - Università degli studi di Torino

Presenter e-mail: paolo.zamparutti@gmail.com

Key terms: Miage Glacier; Remote sensing; Photogrammetry; MIVIS; Debris cover

The aim of this work is the geomorphological study of the Miage Glacier (Aosta Valley, NW-Italy) by means of fieldwork, photogrammetric and remote sensing techniques. The fieldwork campaign was done during 2008-2009 summers using a pocket-PC with GPS. Using orthophotos and LIDAR DEM as a support to the cartography, a geomorphological map of the whole Miage basin and a glacier-cover map, both at the scale 1:10000, were created. The photogrammetric analysis was conducted on two flight series: RAVA 1997 and Ghiacciaio 2003, stereoscopic models were built with a 4m precision. The displacements of 18 large rock-blocks were evaluated for years 1997-2003-2006-2008 intervals, data for 2006 and 2008 were taken respectively from orthophotos of Ministero dell'Ambiente and LIDAR DEM. An estimation of the velocities for the glacial mass was performed for the interval '97-'06, giving ~50m/y for the upper part and ~10m/y close to the glacial fronts. The areal size deformation of the debris-cover units due to the ice mass flow has been evaluated. Short and strong climatic-induced variations on bédère and ice-cliff were also noticed. MIVIS images analysis allowed to classify the debris cover of Ghiacciaio del Miage using the Principal Component Analysis (PCA). An interpretative map of the whole basin, comparable with that by Deline (2002), but larger, was then created. Integration of all collected data inside a geographic information system allowed to understand that the origin of the debris cover is localized where glacial dynamic, tectonics, geographical settings and local climate strongly interact each others for producing rock material. While on the glacier surface the material is subjected to extensive translational, longitudinal, lateral and vertical processes due to the ice mass dynamics. The use of new technologies supported the integration of the data collected and their geomorphologic interpretation.

Presenter e-mail: francesca.grendene@unito.it

Key terms: Crystalline silica; Pathogenicity; Silicosis; Surface reactivity; Free radical

Crystalline silica polymorphs are highly pathogenic mineral dusts. Prolonged inhalation of most crystalline silica particles causes lung inflammation and development of the acute and chronic granulomatous and fibrogenic lung disease, known as silicosis. Silica is also associated with the development of lung cancer. The International Agency for Research on Cancer has recently confirmed the carcinogenicity of some crystalline silica polymorphs (IARC 2010) although the carcinogenicity was not observed in all workplace circumstances.

The mechanisms of pathogenicity of crystalline silica are still partially obscure at the molecular level. It is generally accepted that "the variability of quartz hazard" is due to the involvement of several properties at the same time and different steps of the multistage process which occurs when the silica particles gets in contact with cells within the lungs. Several studies have suggested that the variability in surface properties may arise from the origin, the mechanical history of the dusts and from a different level of contaminants, associated with the original mineral or acquired during the industrial processes.

In that regard the Italian agency INAIL (Piedmont division) has funded a Ph. D fellowship in order to evaluate which productive division have higher silica exposure hazard, and which cases of silicosis and cancer compensated by the INAIL agency were associated to the exposure to crystalline silica.

This study was focussed on the identification of physico-chemical properties which may be related to the development of silica related diseases in order to better understand the mechanism of silica pathogenicity.

On the bases of the results discussed by Maria Gullo in "The hazard due to occupational exposure to crystalline silica in Piedmont" the samples chosen are: i) clays from the stones division, ii) diorite from the bricks division, iii) silica sand from the glass division and iv) different firebricks from the metallurgical division.

The samples have been characterized by means of different techniques: X-ray diffractometry (XRD) for identification of silica crystalline polymorphs, X-ray fluorescence spectroscopy (XRF) for elemental analysis, scanning electron microscopy (SEM) to evaluate micromorphology and particle sizes. All samples were tested also by means of the spin trapping technique both for their potential to generate HO[•] radicals, via Fenton-like reaction, and COO radicals, through the cleavage a C-H bond of organic molecules.

The results obtained showed that all samples exhibits the typical XRD spectrum of the quartz overlapped to other crystalline phases, probably due to the impurities of the silica samples, as shown by elemental analysis (XRF spectroscopy).

All samples contain particle with irregular shapes, very sharp edges and acute spikes, a morphology characteristic of quartz obtained by grinding, and have a similar, very heterogeneous, distribution of particle size.

All samples show a remarkable activity in free radicals generation. Metallurgical division samples are the most reactive. These findings, although preliminary, are in agreement with the data reported in INAIL database discussed by Maria Gullo, that show a higher number of silicosis in the metallurgical division a possible role of particle-free radical generation in pathogenicity of crystalline silica. Further cellular studies will be necessary to confirm this hypothesis.

Presenter e-mail: ma.gullo@inail.it

Key terms: Crystalline silica; Silicosis; productive division

Occupational exposure to some crystalline silica polymorphs causes health damage which are well known in the scientific community. In particular silicosis, the most ancient occupational disease, requires a close attention because of their invalidating consequences for a large number of workers and for a great number of benefits paid by the Italian government agency for the insurance against work-related injuries (INAIL). The International Agency for Research on Cancer has recently confirmed the carcinogenicity of some crystalline silica polymorphs (IARC 2010) although the carcinogenicity was not observed in all workplace circumstances. Numerous studies on several quartz specimens derived from different sources, revealed a high variability in quartz hazard. The origin, the mechanical history of the dust and the different levels of contaminants, either associated with the original mineral or acquired during the industrial processes, have been recognized as important factors in determining its harmful effect.

The consequences of the IARC update was a decrease of Threshold Limit Value (TLV) by the American Conference of Governmental Industrial Hygienists (ACGIH) and the necessity of further studies on the silica hazard raised by the Institutions involved in the healthcare and human safety.

In that regard, the Italian agency INAIL (Piedmont division) has funded a Ph. D fellowship in order to evaluate those cases of silicosis and cancer compensated by the agency which were associated to the exposure to crystalline silica. Main results of this project will be discussed by Francesca Grendene in "Chemical basis of the hazard due to occupational exposure to crystalline silica"

This study was focussed to the identification of the most hazardous productive division in order to identify which division have higher silica exposure hazard, type of silica dusts used and the mechanisms of pathogenicity.

837 known cases of silicosis have been recognized between 1980 and 2007. They are representative of a phenomenon which is in strong decrease thanks to the elimination of silica by several industrial cycles and mitigation of exposure hazard for workers. 444 cases have been analyzed in detail.

The results obtained showed that 43% of the cases occurred in metallurgical activities (foundries and steelworks), 26% to mineral processing, 15% to construction and 10% in other activities.

Among each productive division some activities were the most hazardous, e.g. trimmer, founder, shaper and caster for metallurgical division, stone mason, miner and quarryman for mineral processing and bricklayer, cementer, hodman and packer for the construction compartment. Among all cases of silicosis examined 24 are associated with lung cancer in the most hazardous productive divisions (12 in metallurgical division, 7 Bricks division, 4 stones division and 1 electrical division).

Silicosis affects mainly men, indeed only 1.8% of cases analyzed were women, probably because some activities are typically masculine. All data reported highlight on the one hand the most hazardous productive divisions, where further preventive actions are needed, and on the other hand a limited carcinogenic hazard for metallurgical workers where other factors (e.g. asbestos and mineral oils) contribute or exacerbate the carcinogenic hazard.

MICRO/NANOSTRUCTURES, CHEMISTRY, BIOACCESSIBILITY AND TOXIC POTENTIAL OF AEROSOL PARTICLES FROM CAST IRON FOUNDRIES

MORONI Beatrice¹, CAPPELLETTI David¹, VITI Cecilia²

¹ - University of Perugia

² - University of Siena

Presenter e-mail: b.moroni@tiscali.it

Key terms: magnetite; quartz; carbon soot; SEM/TEM; metal solubility

Foundry operations of cast iron production involve numerous sources of potentially harmful particles including metal particles, crystalline silica and carbonaceous compounds. Studies assessing the health risk associated with iron founding tend to consider the risk factors separately with few or no account to possible synergistic effects resulting from concomitant exposure to different types of particles in the same working environment. In this work, we have investigated the airborne dusts from foundry plants by combining single particle and bulk chemical analyses in order to make some inferences on the toxic potential on cellular media.

Fifteen aerosol dust samples from different working stations and three samples of moulding quartz sand raw material were analyzed by scanning and transmission electron microscopy (SEM and TEM, respectively), coupled with image analysis and energy dispersive spectrometry (EDS) microanalysis. Quartz sand raw materials were also analyzed by cathodoluminescence spectroscopy. The concentration and the solubility of Fe and other metals of potential health effect (Mn, Zn, and Pb) in the bulk samples were determined by inductively coupled plasma atomic emission spectrometry (ICP-AES).

Aerosol particles mostly consist of magnetite nanocrystals typically 5 to 50 nm in size. Measured d-hkl spacings of magnetite are slightly larger than those of the reference phase, due to frequent replacement of Fe by other cations such as Si, Mn, Zn, and Pb. The presence of well-known toxic elements (i.e., Mn and Pb) especially in nanoparticles, points to increasing toxic potential of the metal particles as a function of decreasing particle

size. Results from solubility tests reveal Fe and Pb as the most abundant, least soluble elements, while Mn and Zn are the most soluble elements in the aerosols. Due to this fact, and to the small size of particles, direct diffusion into the cell and chemical release of toxic elements into the cytosol may be assumed for moderately soluble particles, while the soluble transition metals may be directly involved in cellular DNA damage. Variable amounts of quartz particles are present in the aerosol samples. Cathodoluminescence analyses on quartz grains evidence significant amounts of defective crystals of possible pathogenic effect even in the raw materials. This fact points to the impact of the inherent physico-chemical characteristics of raw materials in influencing the toxic potential of quartz. A second aspect which is to be taken into account when considering the presence of quartz in the iron foundry aerosols is the evolution of the chemical and physical properties of quartz grains when passing from raw material to the airborne dust. The main points at this stage are size reduction and increasing complexity of morphology. When considering any possible effect of treatment (such as heating and crushing of quartz in the melting and moulding working activities, respectively), and of contamination of quartz grains by metal particles, the impact of coexisting inhalable metal and silica particles on pathogenicity should not be ruled out.

The final question which arises when approaching the risk factor related to iron foundry aerosols is the remarkable presence of inorganic C particles. High-resolution TEM images show that they consist of multiwall graphite nano-onions variable in size from 20 to 100 nm, typically close to 30-50 nm, similar to those observed in carbon soot. Graphite lattice fringes are often overlapped to Fe-rich particles, suggesting the metal particles be embedded in a poorly crystalline graphitic matrix. Considering the cytotoxic mechanisms of carbon soot, and the redox-dependent responses of macrophages in the presence of iron and carbon species, the possible synergistic effects of metal and carbon particles in the airborne dusts should be studied and considered in detail.

Key terms: natural tremolite asbestos; synthetic tremolite asbestos; XRPD, SEM-EDS, TEM-EDS characterization; A549 cells, citotoxicity, immunohistochemistry.

Two different samples of asbestos tremolite have been investigated to improve the comprehension of their toxicity. Natural asbestos tremolite (NAT) from Brachiello (Val d'Ala, Piemonte Region, NW Italy), and synthetic asbestos tremolite (SAT) were mineralogical characterized by X-ray powder diffractometry (XRPD), transmission and scanning electron microscopy (TEM, SEM) with annexed energy dispersive spectrometry (EDS).

NAT fibres are very long and rigid with diameters ranging from 1 µm to 1.5 µm; several thicker crystals range in diameter from 15 µm to 20 µm. They have an high crystallinity and absence of structural defects; at the TEM observation scale thin talc lamellae develop from some fibre border. SAT fibres are highly crystalline too but in general thinner than NAT ones: the width ranges from 0.04 to 0.68 µm. Some structural defects are present and they consist in different distances of the same structural planes. Traces of quartz have been detected. Dimensions for both NAT and SAT fibres are included in the respirability criterion.

The crystallochemical formula of NAT and SAT is respectively: Ca_{1.71}Mg_{5.24}Si_{8.01}O₂₂(OH)₂ and

Ca_{1.66}(Mg_{4.62}Fe₂+0.27Al_{0.18}Mn_{0.02})₅.09Si_{8.00}O₂₂(OH)₂. The SAT was synthesized on purpose iron free.

As pathogenetic mechanisms of asbestos are not entirely understood, we evaluated their morphological, immuno-histochemical, and functional effects in alveolar epithelial A549 cells representing the first target of inhaled micro-environmental contaminants.

Effects at 50 µg/ml resulted in functional and structural damages evidenced by viability, motility, and morphological investigations. Phalloidin labelling showed irregular distribution of cytoskeletal F-actin. Immunohistochemical investigations evidenced abnormal expression of

VEGF, Cdc42 and β-catenin, considered risks indicators for cancer development.

Results at 24 h better reflect the different action of both fibres: NAT effects result in survival of compromised cells highly expressing VEGF while SAT fibres exert a direct cytotoxic effect and can be considered as standard samples in several investigations. The potential health hazard of NAT fibres in vivo corresponds with their iron content and ROS generation capacity providing the opportunity to elucidate the effect of asbestos on cancer induction.

- 2 - Provincia di Torino

Presenter e-mail: m.sacco@arpa.piemonte.it

Key terms: ultrafine; particles; particulate; monitoring; air

Like all large urban areas of Po Valley, Turin metropolitan area is very critical with respect to particulate concentrations in ambient air. The measures which are carried out by Environmental Protection Agencies concerning institutional purposes are focused on mass concentration, which is the indicator provided for by law. In recent years, however, concern for number concentration measures is greatly increased, due to its importance for the evaluation of particulate toxic effects, in particular in respect of ultrafine fraction. The need for a deeper knowledge in this field was explicitly highlighted in the results of European Commission Programme CAFE (Clean Air For Europe).

In this context a research project was promoted in order to collect ultrafine particles data in the Turin metropolitan area through long-term measures carried out both at ground level and at an altitude comparable to winter planetary boundary layer height. A specific instrumentation was acquired (UFP Monitor 3031-TSI Incorporated), specifically designed for routine use within air quality monitoring networks.

This instrument was installed at the beginning of October 2009 in the first monitoring site which is located on the fifteenth floor of Province of Turin headquarters in the city centre at an altitude of about 50 meters.

The UFP operates continuously and provides both the size distribution and the number concentration of particles between 20 and 1000 nm. The set up channels of size resolution are six (20-30 nm, 30-50 nm, 50-70 nm, 70-100 nm, 100-200 nm, 200 -1000 nm).

The average number concentration in the year 2010 is approximately 7200 particles/cm³. The calculation was carried out on the basis of hourly average concentrations of particles whose size is between 20 and 200 nm. About 70% of the particles measured in the range 20-200 nm have a diameter between 20 and 50 nm, and the higher concentrations are recorded in the class 20-30 nm.

The data were correlated with other pollutants monitored at two traffic stations placed at ground level in the city centre (Torino Consolata and Torino-Rivoli) and at the background station of Torino-Lingotto. The comparison shows a good correlation with the concentrations of nitrogen monoxide, PM₁₀ and PM_{2.5}. The lowest correlation coefficients were found for nitrogen dioxide and benzene. The mean variability during the day for classes 20-30 nm and 30-50 nm is relatively high, whereas other classes have a more constant trend.

Monthly averages trend shows a relative maximum in July which does not seem to be explainable just on the basis of the weather situation and will require further investigation.

The analysis of critical events during cold weather shows that the concentration of ultrafine particles is related to the inversion layer height.

Key terms: PM10; electron microscopy; characterization

Samples of summer and winter (2010-2011) atmospheric particulate (PM10) of Milan urban area were collected and characterized for some classes of components with health impact. Moreover, the PM chemical characterization of the main components (i.e. inorganic compounds, organic compounds, and elemental carbon) was performed by XRF and ICP-MS. Toxicity test on pulmonary immortalized cell lines showed different effects produced by summer and winter samples. Indeed, the summer PM10 fraction has a more pronounced inflammatory effect, due to the presence of endotoxins. Nevertheless, their inhibition did not completely vanish the inflammatory effect, which may be related also to both silicic materials of crustal source and transition metals. The quantity of such materials is significantly higher in the summer PM10. The morphology and chemistry of this fraction components were characterized by scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDX). Further SEM and EDX analysis will enable to a better characterization of this particulate. Moreover, the analysis at transmission electron microscopy (TEM) will allow to discriminate the mineralogical phases that contribute to the PM10 silicon and transition elements.

Key terms: Atmospheric particulate matter; multivariate source apportionment (PCA/APCS); SEM/EDS; image analysis; vertical profiles

In this paper combined PCA/APCS factor analysis on bulk chemical analyses and individual particle analyses by SEM/EDS have been applied to the characterization of airborne particulate matter sampled at urban and regional background sites near Terni, Central Italy, in order to discriminate local sources from long range dust intrusions of both natural and anthropogenic particulate pollutants. The distinctive morpho-chemical features of particulate matter of various origins (industrial, anthropogenic, long-range transport) have been characterized by a year long extensive sampling campaign at urban and remote background sites. These data were integrated by a 15-day long wintertime campaign exploiting a

tethered balloon equipped with real time instrumentations, able to continuously sample the lower troposphere from ground up to 600 m height.

Five distinct PM sources were identified, namely crustal/road dust, industrial (steel plant), traffic direct, oil combustion/incineration and secondary aerosol, and the contribution of each source to the particle size ranges modelled accordingly. Results show direct vehicular and industrial metallurgical activities be the main sources for PM in the fine fraction, and soil/road dust as the main contribution to the coarse fraction. Individual particle analyses revealed six different classes of particles in the aerosols, namely silicates, carbonates, carbonaceous and metal particles, sulphates and Ca-phosphates. They were included in the statistical analysis leading to three main clusters of crustal, secondary/transport and direct combustion/industrial sources. Except for silicates and carbonates, the rest of particles are from urban and industrial anthropogenic sources. Metal particles, in particular, result from a mix of sources from ground (car exhaust) to upper level (steel plant smokestacks) in the troposphere. A general tendency towards increasing size and size heterogeneity is observed when passing from atmospheric stability to convective conditions.

Multivariate source apportionment turned out to be a powerful tool in discriminating natural from anthropogenic sources of particle pollutants, but failed to distinguish local from long range transported soil dust. At this point discrimination between local and long range soil sources was focused on the correlation between individual particle analyses and bulk chemical composition of the coarse fraction in the aerosols. Based on the mineral chemistry of the constituent particles, corroborated by back-trajectory calculations and atmospheric vertical profile analyses, it was also possible to estimate the extent of the contribution of local and Saharan dust to the soil source.

The presence of local and mid- to long range anthropogenic sources of particulate pollutants has been put in evidence in this study. With regards to short range anthropogenic particles, those coming from automotive exhausts tend to be confined within the lower level in the atmosphere, whereas those coming from industrial emissions tend to permeate at higher levels in the atmosphere. On the other hand, long range anthropogenic sources of secondary aerosol from NE-Europe have been found to explain the observed increasing amounts of gypsum for increasing altitude upon Terni. Vertical dispersion of particle pollutants appears to be highly influenced by topography (which protects from ventilation), and also by thermal inversion within the mixing layer.

Key terms: Micro-Raman Spectroscopy; VP-SEM/EDS; Malignant Pleural Mesothelioma; Asbestos; Mineral Particles

During the XX century Italy was a big producer and importer of asbestos until 1992 when asbestos was banned: for this reason it results still now affected by a lot of asbestos-related diseases, as proved by the data published by ReNaM (Registro Nazionale dei Mesoteliomi).

The correlation between inhaled fibrous materials and diseases of the respiratory system - asbestosis, mesothelioma, pulmonary carcinoma - is demonstrated by a large scientific literature.

These pathologies are typically characterized by a long latency time, i. e. the time interval between exposure and the disease onset, therefore the effects on the human health of asbestos exposures occurred in the past appear decades later. Scientific studies indicate, despite the ban of these materials, an occurrence peak of asbestos-related diseases in the next decade.

Moreover, not only occupational and/or family exposure, but also the environmental one may today represent a cause of asbestos-related pathologies onset.

Previous works carried out in our laboratories proved that micro-Raman spectroscopy is a technique able to recognize mineral phases on untreated samples. In particular recently micro-Raman spectroscopy, using 632.8 nm laser beam as excitation source, has been coupled with VP-SEM/EDS - Variable Pressure Scanning Electron Microscopy with annexed Energy Dispersive Spectroscopy - to characterize, without digestion of the biological matrix, particles/fibres directly in the histological sections used for the medical diagnoses. In particular a methodology allowing the characterization of the same particle/fibre under the two techniques, on thin sections of lung and pleural tissues from patients affected by Malignant Pleural Mesothelioma, due to past professional exposures, have been studied. All the inorganic phases, fibrous or not, have been characterized on their spectroscopic and chemical aspects. The results obtained on all the analysed sections indicate on the silicate particles/fibres inhaled and detected in the respiratory system an interaction cell-particle/fibre affecting the crystalline structure.

Also the "asbestos bodies", where the inhaled fibre is coated by an iron rich protein material, have been characterized. The laser beam was addressed either on the material coating the fibre either on the portion more free from the coating. By this way identification about the mineral phase corresponding to the fibre in the core can be achieved.

Key terms: Asbestos; Nanofibers; Toxicity; Ultrasonic Treatment

Inhalation of asbestos fibers causes asbestosis, lung cancer and pleural mesothelioma. Fiber length, biopersistence and surface reactivity are involved in the development of the respiratory diseases. The fiber length was the first parameter correlated with asbestos toxicity. In vivo studies on rodents showed that long (> 8 µm) and thin fibers have the highest potential to induce mesothelioma. Nevertheless, a large number of fibers in the mesothelial tissues of exposed workers has diameter < 0.2 µm and length of few µm. Nanofibers (NFs) have also been recovered in subjects only exposed to environmental pollution. NFs could result from the splitting up in the lung of long fibers - mainly of chrysotile asbestos - in sub-micrometric fibrils, or might be inhaled already in nanometric size. In the past NFs, were released from several products, e.g. brake pads, following mechanical stress. They are also detectable in the natural environment, e.g. in turbulent waters from mountain streams that flow through serpentinite outcrops.

The pathogenic potential of the asbestos NFs is still unclear. Therefore the main goal of the present work are a) to develop a size selective procedure for preparation of short (<5 µm) and thin (< 200 nm) chrysotile NFs and b) to compare their potential toxicity by respect to long fibers.

We investigated the effect of ultrasonic treatments on size, shape and structure on a pure sample of chrysotile asbestos from the Italian Central Alps widely characterized in previous investigations, in order to identify the best conditions to produce a homogenous batch of short asbestos fibers. Ultrasonic treatments were carried in water for different time periods (from 3 to 24 h) and the final products were subjected to morphological analysis to verify change in shape and size distribution (Scanning Electron Microscopy) and to crystallographic (XRD, micro-Raman spectroscopy) and elemental analysis (X-Ray Fluorescence) to detect any change in structure/composition. The preparation of asbestos NFs was performed also on a commercial chrysotile sample (from the Balangero mine, Italy) and the potential toxicity of the two samples was compared with the well known toxicity of the original asbestos. First we examined the surface properties considered relevant to pathogenicity then some cellular responses in human epithelial cells.

Among the most relevant surface properties involved in asbestos toxicity we examined the potential to cause oxidative injury within the lung by measuring free radical generation and depletion of antioxidant defenses. The potential of NFs to generate hydroxyl and carboxyl radicals when in contact with biological fluids has been investigated by means of the spin trapping technique. The potential to consume the antioxidant defenses has been evaluated by monitoring the depletion of cysteine and ascorbic acid, during the incubation of the sample over time. The amount of bio-available iron on the sample surface was also evaluated by mobilization of ferric and ferrous ions using specific chelators. In all cases NFs showed a lower reactivity than the long fibers. Cellular responses were measured as leakage of lactate dehydrogenase (LDH) into the extracellular medium, ROS and nitric oxide (NO) production, and lipid peroxidation.

The data of the cell test showed a different toxicity of the fibers correlated to their length. Nanofibers are less toxic than the long fiber of the same asbestos source.

CHARACTERIZATION BY VP-SEM/EDS OF PARTICULATE MATTER IN AREAS WITH DIFFERENT ENVIRONMENTAL IMPACT: RELATIONSHIPS WITH EMISSION SOURCES

MUSA Maya¹, CROCE Alessandro¹, ALLEGRINA Mario¹, RINAUDO Caterina¹

1 - Dipartimento di Scienze dell'Ambiente e della Vita - Università degli Studi del Piemonte Orientale "Amedeo Avogadro", Alessandria, 15121, Italy

Key terms: VP-SEM/EDS; Particulate Matter; Emission Sources; Methodology; Characterization

The increase of air pollution is one of the most important issues due to its effect on the human health and the European laws require a steady monitoring of suspended Particulate Matter (PM)₁₀. Deep investigation of the different components into the PM₁₀ (particles with aerodynamic

diameter less than 10 µm) is essential to obtain information about their chemical/physical properties, including how they interact with other aerosol species and gases in the atmosphere, and their effects on the human health. PM₁₀ is usually monitored by high volume device, collecting the suspended material onto specific membranes, made either in fused silica (commercially "quartz") or in glass fibres and measuring the concentration of the suspended PM₁₀ by the gravimetric method, defined as the total mass of the PM₁₀ per cubic meter of air within 24 hours. This type of analyses provides only the weight of suspended materials without information on their chemical composition. Moreover, the European Community is recently showing an increasing interest in assessing the chemical characterization of the different components occurring in the PM.

By our research group a quickly and not expensive methodology to characterize the PM starting from the filters routinely collected by the environmental protection agencies to determine the air quality - has been elaborated. A procedure for removing the solid components of the PM from the sampling filters and deposit them onto polycarbonate supports, more suitable for the VP-SEM/EDS, instrument used for the characterization study. The developed procedure proves able to:

- distinguish easily particles/fibres of the original support from those composing the PM;
- detect the inorganic/mineral phases on the basis of the EDS analyses;
- propose an apportionment to different sources, natural or anthropogenic, in the different analyzed samples and in each sample to define the percent weight of each of them;
- notice the presence of fibrous phases, in particular those ascribed to the minerals defined "asbestos" by the law.

The results obtained in different environmental situations: urban, rural and outskirts areas, localities characterized by various anthropogenic sources of pollution will be presented.

Key terms: Particulate Matter 2.5; Mineralogical Characterization; Analytical Methods; Environmental and health issue

The characterization of the airborne particulate represents a real issue. Many studies have examined the effects of the particulate matter on human health suggesting that the small particles represent a severe problem.

In the present work chemical and mineralogical investigations on the particulate matter of the city of Rome were carried out. The particulate samples (PM_{2.5}) were collected in Rome since April 2010. Polycarbonate filters were used to trap and recover airborne particles according to a standard procedure, and then utilized for different analytical techniques. Preliminary investigations on PM_{2.5} filters (SEM-EDS, X-ray and DTA) provided information about the inorganic compound. High iron content was highlighted as oxides, hydro-oxides, and sulphates. In particular, the presence of melanterite FeSO₄·7(H₂O)[1] was evidenced. Ca-sulphates and clays were also found. Moreover, innovative methodologies, such as Atomic Force Microscopy (AFM), resulted useful for morphological and dimensional investigations of the micro and nano-particles[2]. Hygroscopic properties of mixed urban aerosol can be monitored by FT-IR. Furthermore a complete functional group characterization of PM_{2.5} phases in the 4000-400 cm⁻¹ spectral range, with a procedure based on diffuse reflectance (DRIFT), is in progress.

The association in the atmospheric dust particles of amorphous phases and heavy metals is known to increase the release of these dangerous chemical elements. To obtain the bulk chemical composition of the particulate material the Regional Protection Agency usually utilize ion mass spectrometry (ICP-MS) on a little amount of particulate matter (2 mg; D.M. 60/2002). In this work ICP-MS analyses were performed on a high content of material (35 mg). The high amount was here used to investigate the presence of heavy metals and their release in biological environment. Data on PM_{2.5} samples was fully comparable with those typically observed by Regional Protection Agencies (ARPA). Test of release were executed in physiological solution (PH 7.4, 37 °C, 30 days). Release evidence were obtained for Fe, V, Pb, As and Cr. These results confirm that the release of heavy metals in the biological environments already occurs from the first hours. In vitro experiments are in progress to assess the relation between the fine and ultrafine particles and the health effects.

Key terms: natural and artificial inorganic fibers; biological samples; Animal Sentinel System; SEM-EDS

It has long been established that occupational exposure (high dose) to certain fibrous minerals is harmful to human health. The effects of environmental exposure (low doses) is still rather difficult to determine.

Recent publications show the advantage in using animal population called Animal Sentinel System (ASS), in alternative to the human ones, as indicator of environmental contaminants.

The aim of this work has been to assess the presence of fibers in general and asbestos in particular (breathable fibrous inorganic fraction: bfrif) airborne in the Regional Park of "La Mandria" (entrance of the Lanzo Valley, Torino) monitoring their presence in samples of lung tissue of ASS lived in that area with a natural environmental exposure (continuative and at low doses).

In the Regional Park of "La Mandria", in fact, some fibrous minerals are present both in the composition of the lithologies naturally present end in the debris come from the ex-mine of Balangero, used in the past to cover the footpaths.

Samples of lung tissue from 15 ungulates were been examined. The investigations were carried out by using the scanning electron microscope (SEM) equipped with an energy dispersive spectrometer (EDS) and have allowed us to obtain qualitative and quantitative data on breathed "bfrif" and in particular on asbestos.

The fibers found in the lung tissue of ungulates are chemically related to 2 main groups: silicate and non-silicate fibers. The different types of the detected silicate fibers are listed in decreasing order of abundance: artificial silicate with Na and possibly Mg, Al, Ca, K, chrysotile/antigorite; illite/smectite/montmorillonite, hornblende, tremolite asbestos, micas, phyllosilicates not better identified, vermiculite, crocidolite, Na-Ca feldspar, chlorite, edenite, pyrophyllite, kaolinite, diopside, zeolite. The two different types of the found out non-silicate fibers are listed below in decreasing abundance order: titanium dioxide, gypsum or anhydrite. Both crocidolite and tremolite asbestos and chrysotile/antigorite fibers were found in 40 % of the samples. Globally, these three groups were present in 47 % of the samples.

The antigorite fibers are released from both outcropping local serpentinitic rocks (natural source) and the debris from the ex-mine of Balangero (natural source), while those of chrysotile can come both from the local rocks (natural source) and the asbestos-containing materials (anthropogenic sources) such as the roofs of buildings.

The tremolite asbestos come from serpentinitic rocks (natural source) and not from the debris of the ex-mine of Balangero because this species has not been detected in the rocks of that area.

Crocidolite come exclusively from the asbestos-containing materials (anthropogenic source, such as the roofs of buildings) because this type of asbestos isn't naturally present in Italian lithologies.

Although it is not possible to establish from which of the two sources (natural and anthropogenic) the chrysotile/antigorite fibers come, as regards tremolite asbestos and crocidolite the ASS represent a good model for assessing environmental exposure in relation to topographic features, geological and human environment in which they lived.

Presenter e-mail: fabrizio.bardelli@gmail.com

Key terms: ferruginous bodies; asbestos; synchrotron radiation; XAS; XRF

It was not until the late 1950s that asbestos was recognized as a human carcinogen and exposure to fibers started to be associated with several different lung injuries, including respiratory diseases, asbestosis, mesotheliomas, and lung cancer. Since that time, the mechanism by which asbestos causes cancer has been intensively studied, but, however, it is still not well-understood. Ferruginous Bodies (FB) consist of a coating of inorganic fibers (usually asbestos fibers, but not only) composed of inorganic and organic material. If the core of these bodies consists of asbestos, FB are known as Asbestos Bodies (AB), and their count is one of the most valuable tools for establishing if a subject underwent professional exposition to asbestos, or to estimate the degree of asbestos exposure among the general population [1]. It was generally accepted that the coating of embedded fibers to form AB is a protective mechanism produced by macrophages trying to segregate the cytotoxic fibers from the organic tissues [2]. However, more recently, other authors suggested that the coating material may enhance the cytotoxic properties of the asbestos fibers by increasing the production of free radicals [3]. Therefore, the exact knowledge of the composition of the AB, and of FB in general, is of fundamental interest. Accordingly, iron on the surface of AB was shown to be catalytically active [4] and capable of inducing the formation of single strand breaks in phiX174 RFI DNA [5]. Earlier studies, exploiting Transmission Electron Microscopy and X-ray diffraction on split AB, showed that the coating contained crystalline particles of the same order of size quoted for the inorganic iron core of the ferritin molecule [6]. More recently, synchrotron radiation soft x-rays imaging and fluorescence microscopy revealed novel properties on the composition of FB [7]. In this work, samples of human lung tissue rich in FB, due to professional exposure, were collected from three subjects died of lung cancer. Tissues were digested using NaClO to produce a suspension of inorganic material that was filtered on porous membranes. The membranes were preliminarily characterized by optical microscopy and Scanning Electron Microscopy, in order to estimate the number of the filtered particles. The samples were brought to the European Synchrotron Radiation Facility in Grenoble (France), a high brilliance x-ray source. Exploiting the high spatial resolution provided by the micro-focused x-ray beam (down to 0.5 microns), 100 x 100 microns² fluorescence maps of selected bodies were acquired. The fluorescence maps revealed that, except for bodies containing the asbestos fibers (which also contain Si, Mg, and Al), the FB are mainly composed of Fe, Cu, Zn, As, and, for certain subjects only, Ge and Ba. X-ray Absorption Spectroscopy at the Fe K-edge was also performed on selected FB in order to unravel the speciation of iron. The near edge part of the absorption spectra (XANES) revealed features that are in excellent agreement with the ferritine standard.

The results obtained will help solving a long time debate and lead to a better understanding of the toxicological mechanism of a large class of air pollutant particles that, nowadays, constitutes a serious risk for human health.

GEOLOGICAL RISKS AND PUBLIC SENTIMENT: HANDLE WITH CARE

VALENSISE Gianluca¹

1 - INGV, Roma

Presenter e-mail: gianluca.valensise@ingv.it

Key terms: Geoethics; Societal implications; Sustainability

Unlike most other professionals, geologists are often confronted with technical issues that also bear significant societal implications, and that for this reason are also the object of public debates and political standings. The geologist's process towards acquiring the necessary knowledge and forming the requested assessment or opinion is often fraught with elements that have nothing to do with the technical merit of the question at hand.

Why is it so? Is it normal for that geologist to be biased by his/her own perception of issues such as the acceptability of a given risk level, the sustainability of natural resource exploitation, the environmental downsides of economic growth? Or should consideration of these issues be part of the good practice of any informed professional? And why does this happen to geologists more than to other professionals? Perhaps because they lie somehow in between exact science and social science?

The recent history of the Italian Earth Science community offers many of such cases and of the associated dilemmas, which together represent a perfect example of what Geoethics is about. We will recount some of them, attempt to find common causes and circumstances, and discuss possible remedies and recommended practice.

U1-3 Orale Nikitina, Nataliya

10.1474/Epitome.04.1017.Geoitalia2011

ETHICAL PRINCIPLES AND THE VALUABLE APPROACH FOR PRESERVATION OF GEODIVERSITY

NIKITINA Nataliya¹

1 - LLC Intergeo

Presenter e-mail: nikitinank@mmcintergeo.ru

Key terms: geodiversity; value; principles; approach

The natural diversity is a fundamental feature, the property of the nature. It reflects the set of the structural functional characteristics of nature organization which have been implemented during the evolution and which provide now sustainable development of a planetary life, bio- and the geospheres, supporting ecological balance, ecological stability and at the sometime allow to develop inherent in the nature potential.

Having been adopted as geological equivalent of the term "biodiversity" the geodiversity is the natural range of geological processes, rocks, minerals, fossils, geomorphological processes and land forms, characteristics of subsoils and organic soil.

While endogenous and exogenous geological processes have a leading role in formation, preservation and destruction of a variety of subsoil, surface and landscapes of the Earth because of their exceeding power and duration, which is non-comparable with the duration of the existence of the human species.

Now human impacts on the Earth as on a geological body mentions only the lithosphere and affects in following basic directions: geological survey, exploration and a mining, construction and operation of underground facilities, formation of lithospheric technical zones under territories of city and industrial development; a dumping of household and industrial wastes, lithospheric (geological) weapon.

There is six types of values of the geodiversity: internal or intrinsic value, cultural (geomythological, archaeological and historical) value; aesthetic value; economic value; functional value; scientific and educational value. Our relation to the lifeless nature should be based on the fact that the Earth, its subsoil, geological objects on a planet surface have the primary right to exist, independently from advantage for the person, and owing to their internal value.

Any processes of degradation and decrease in level of a geodiversity as parts of the natural diversity are caused, first of all, by underestimation of their real economic value. Any offered variants of preservation of geodiversity will constantly lose competition to the mining industry as state budget revenues of this sector of economy are clear and tangible. All arguments about possible own utility of a geodiversity are easily eliminated by cost value of implementing conservation measures.

Value of the geodiversity is defined also by the reason that without its preservation it is impossible to keep a biological diversity of plants, animal, microorganisms, functioning of terrestrial biosphere in which the mankind lives.

RISK MANAGEMENT: A PROPOSAL FOR COMMUNICATION STRATEGIES

FONTANA Michele¹, ROSSETTI Matteo², DE AMICIS Mattia Giovanni¹

1 - Dipartimento di Scienze dell'Ambiente e del Territorio, Università degli Studi di Milano-Bicocca

2 - Studio di Architettura Rossetti, Milano

Presenter e-mail: mattia.deamicis@unimib.it

Key terms: civil protection; risk management; communication strategies

The increment of disasters related to natural hazards observed during the last decades, sometimes associated to the low perceived risk in the population involved, shows the need of non structural risk prevention and mitigation measures that contribute to improve people's safety towards natural hazards. Among the usually most effective non structural measures that serve to improve the preparedness of the population, is the development of locally adapted communication campaigns that actively involve the population. Three different strategies can be developed. A basic educational project addressed mainly to the schools; a collaborative work developed with an alpine institute to improve the scientific quality of the educational material, and a large communication campaign was designed in collaboration with several colleagues.

The content of the communication campaign was defined by combining the indications of the "Direttiva Regionale per la pianificazione di emergenza degli Enti locali" of Lombardy Region with the results of the survey applied in the CM Valtellina di Tirano. In addition, the operative procedure was inspired in advertising strategies. A widespread campaign to try to reach every family was preferred over great events that, even if have greater visibility, at the same time do not have enough long time impact. Therefore, was selected a horizontal communication strategy, that could be carried out by the local authorities (whom are the natural references in case of emergency), and that, at the same time, could become a normal part of everybody daily life.

The choice, of focusing on the daily life, has two reasons: first because is not yet possible to define the precise moment in which a catastrophe can take place. Therefore, the idea is not to generate fear in people with sudden announcements of imminent disasters, but to help the citizens to recognize that, on a particular territory, specific risks exist, and that with risk awareness and a correct territorial management the risk can be soundly reduced. Second, a daily familiar communication has greater penetration and can be more effective in influencing people reaction.

The communication campaign is composed of four phases. First, the dispatch, to all 10.000 resident families, of a brochure with the four symbols previously described. Afterwards, an umbrella with the symbols printed, will be sent to all families. Later, a public posting campaign will be developed in every municipality explaining the specific content of each symbol, the communication strategy in case of an emergency, the emergency routes and the safe meeting places in every municipality, and for every possible scenario. Parallel to the previous phases, a website has been designed, and will be possibly hosted in the website of the Comunità Montana authorities, with the aim of assuring the continuity of the education. The website contain the designed iconic symbols which will serve as links to several types of information and files, including the Emergency Plan, scientific results about risks in the study area, emergency procedures, contact details in case of emergency, etc. Thus, this communication path starts with an institutional communication, pass through a common object that is kept by the people, and conclude with a local institutional communication, but remains thanks to the possibility to constantly access the website.

At the end of the third phase, the public posting campaign, several public meetings will be performed in different public places of the study site. The aim of the meetings is not only to inform and educate about the local hazards and emergency plan, but also to stimulate the participation of the community in risk reduction strategies. By promoting the participation in the meetings is expected to receive feedbacks from the population which may collaborate to improve the quality of decisions made in the process of planning the warning system and all risk management.

ETHICS, SCIENTIFIC RESEARCH AND GOALS OF PUBLIC USEFULNESS

DI CAPUA Giuseppe¹, PEPOLONI Silvia¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: giuseppe.dicapua@ingv.it

Key terms: geoethics; scientific research; society; popularization; natural hazards

In the research activity, often the necessary fulfillment of administrative and bureaucratic practices can lead to neglecting the transfer of scientific results to the community, with the effect of a loss in terms of cultural growth for society itself, which has indirectly financed the products of that research and at the end risks not to have advantage by using them.

In a research project, it is necessary to find the right balance between the scientific-technical work and the financial and administrative management, and to assess time needed to develop the project in all its components, including the space for the dissemination and popularization of results respectively to professionals and citizens: the former could not be able to use achieved scientific advances for their application on the territory, the latter could remain passive people in decisions regarding the environment they inhabit, without the possibility for accessing to accurate information on natural hazards from which they must and can defend themselves.

The authors will show how the different modalities of financing and managing of two research projects have influenced the achievement and the usability of the results, with diverse consequences in the social contexts where these results would find their suitable application. In addition, through the two experiences, they will highlights the importance of collaboration between research and professional world for pursuing goals of public usefulness.

THE SCIENCE OF RUMORS

CRESCIMBENE Massimo¹, LA LONGA Federica¹, LANZA Tiziana¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: massimo.crescimbene@ingv.it

Key terms: rumors; hoax; social psychology

This work, with a soft scientific cut, talks about rumors, hoaxes and urban legends.

Social psychology, more elegantly, uses the latin word rumor (rumour in British English) which means sound, voice, gossip.

Rumors, in social, economical, political, cultural and scientific communication, indicate a news, presumably true, that circulates without being confirmed or made evident.

The scientific history of rumors is briefly described starting from Ancient Rome period, throughout the Second World War and the Internet era, up

to today.

We will try to answer some questions that can be useful to scientists today. What are rumors? How are they born? How do they spread? By which laws are they regulated? How to fight them?

A final question regards the collocation of rumors into modern science. Science today is divided into hard and soft science (that lacks generally a basic mathematical structure), these terms, respectively, indicate natural sciences, which investigate nature, and social/human sciences, that investigate man in all his facets. Maybe rumors can be imagined as a bridge suspended between two banks: "scientific truth" and "human truth".

Key terms: communication in geosciences; public expectations; public needs

The case of Raffaele Bendandi should be considered a paradigmatic example of the importance of the communication of geosciences and of the ethical importance covered by such issues in terms of public expectations. Nowadays the social perception of threats deeply changed from the past. Furthermore, the communication advancements allow everybody of being informed in real-time. Consequently a proper information leads to an increasing confidence about the future, while a millenarian approach, often proposed via web, should strongly affect the benefit trusted in science. At the edge of year 2012, where speculation and prophecies are disseminated by media, the case of the the Italian scientist Raffaele Bendandi (died November first 1979) clearly represents a case study to be more deeply investigated by the scientific geo-community.

HOW TO TURN THE RUMOR OF THE MAY 11, 2011 EARTHQUAKE IN ROME (ITALY) IN TO A DAY OF INFORMATION ON EARTHQUAKES: THE OPEN DAY AT INGV

AMATO Alessandro¹, CULTRERA Giovanna¹, MARGHERITI Lucia¹, NOSTRO Concetta¹, SELVAGGI Giulio¹, 11MAYOPENDAY Team¹

1 - INGV

Presenter e-mail: alessandro.amato@ingv.it

Key terms: Earthquake information; Seismic Risk reduction; Rumors; Science education

A devastating earthquake has been predicted for May 11, 2011 in Rome. This prediction was erroneously ascribed to Raffaele Bendandi an Italian self-taught natural scientist of the last century. During the previous months, the INGV has been overwhelmed with requests for information about this presumed prediction by Roman inhabitants and tourists. Given the considerable mediatic impact of this expected earthquake, the INGV decided to organize an Open Day of its headquarters in Rome devoted to the public who wanted to learn more about the Italian seismicity and the earthquake as natural phenomenon. The Open Day was preceded by a press conference two days before, with the purpose to present the Open Day and to have a scientific discussion with the journalists about the earthquake prediction and Italian seismic risk assessment.

About 40 journalists from newspapers, local and national tv's, press agencies and web news attended the Press Conference and hundreds of articles appeared the following days, advertising the 11 May Open Day. The INGV opened to the public all day long with the following program:

- ° meetings with INGV researchers to answer scientific questions
- ° visiting to the room of seismic monitoring, open 24h/7 all year
- ° guided tours through interactive exhibitions on earthquakes and Earth's magnetic field
- ° 5 afternoon conferences on general topics from the social impact of rumors to seismic risk reduction
- ° 13 new short videos on YouTube / INGVterremoti to explain the earthquake process and updates on various aspects of seismic monitoring room
- ° distribution of books and brochures.

Surprisingly, we had about 3000 visitors up to 9 p.m.: families, school classes with and without teachers, civil protection groups, journalists. The initiative, built up in few weeks, had a very large feedback, also thanks to the media highlighting the presumed prediction. We thank all the INGV colleagues who have made this initiative possible, in particular the Press Office, the educational and Outreach laboratory, the Graphics Laboratory and SissaMedialab.

THE INGVTERREMOTI CHANNEL ON YOUTUBE

AMATO Alessandro¹, ARCORACI Luca¹, CASAROTTI Emanuele¹, DI STEFANO Raffaele¹, INGVTERREMOTI Team¹

1 - INGV

Presenter e-mail: alessandro.amato@ingv.it

Key terms: Earthquakes; Science communication; Preparedness; Seismic hazard

On February 2010 we launched an experimental video channel on YouTube (youtube.com/INGVterremoti) in order to improve our communication strategy on earthquake risk and preparedness. The main goals of this initiative are to inform people about the ongoing seismic activity in Italy and in the world, to communicate the results of scientific research in various seismological fields, and to increase people's knowledge on seismic hazard.

In the first 15 months of activity, we published 43 original videos, thanks to the collaboration of many INGV seismologists. The videos are organized in 8 play lists: a) earthquakes in Italy; b) earthquakes worldwide; c) the 2009 L'Aquila earthquake; d) ongoing seismic activity; e) tsunami; f)

earthquake prediction; g) seismic hazard; h) 11 May 2011 (major earthquake predicted in Rome). To date, the total number of views is about 360,000, with two peaks of more than 20,000/day after the Japan earthquake and before the presumed prediction of a major earthquake in Rome on May 11, 2011. The most popular videos (6) have been viewed more than 20,000 times.

We think that this initiative has increased people's knowledge and awareness on seismic risk, although at the moment only on a specific target of citizens (but growing). In the future we will improve the technical aspects of our video-communication and broaden our audience. We learned that specific events, when the attention is high (either real earthquakes or unfounded news) are the best moments to move forward an improved risk communication strategy.

50 YEARS AGO: THE VAIONT NIGHT.

SPAGNA Valerio¹

1 - Self employed

Presenter e-mail: vspagna@inwind.it

Key terms: Vaiont disaster; landslide; flood; first aid men

A geologist at the beginning of his career in the early 60s is a teacher of Mineralogy and Geology at the Agordo "Follador" Mining Institute, in the Dolomites area.

It was 50 years ago when he observed the building of the Vaiont dam and now tells us the night of October 9, 1963 when he rushed to the Piave Valley, together with the first aid teams, in front of the Longarone remains.

Did the dam collapse? Everybody thinks so but the moon wasn't shining enough to understand what had happened.

Only the first faint light of dawn revealed that the dam was still standing: it only edged the water, shaping the tremendous wave that was raised by the Mount Toc landslide entering the basin at one hundred kilometers per hour. The dam edge contributed to project the wave on the opposite versant where the water mass, once released from the narrow Vaiont canyon, raised compact in the air grazing the Casso village and precipitated as a massive block on the Longarone area.

Everybody, with hate and despair, looked upwards at the residual water streamlets overflowing along the dam concrete wall. Over the white bare esplanade people appeared extremely small. Pitiiful people gathered around the bodies wrenched from the devastated houses, denudated and buried in the mud.

GEO-ETHICS AND MAJOR CIVIL WORKS

RODA Cesare¹

1 - Università di Udine

Presenter e-mail: roda@uniud.it

Key terms: Geo-ethics; Underground vaste storage; Major civil works

The design of works that considerably involve ground and underground, as the ones intended for the nuclear waste depository, preliminarily needs geological and geophysics surveys to be carried out, with elaboration and interpretation of the acquired data.

The breadth of such investigations, the dimension of the temporal and financial effort, the interpretation difficulties and the range of indeterminateness that usually persists even after the most accurate surveys, increase more than linearly with the work relevance. The purposely planned investigations constitute a research activity.

Singling out the validation procedure of the results coming out from the survey activity propaedeutical for major civil works' design (mostly those that get even with environment, life quality or merely the collective imagination) is a relevant question.

The validity of the scientific surveys' results may be ascertained only by the scientific community, whose competences and knowledge allow to attest the research adequacy compared with the state of the art.

Geologists that perform surveys for the project of major works must publish on scientific reviews the results of their investigation.: this may become a relevant geo-ethic rule.

U1-3 Orale Solarino, Stefano

10.1474/Epitome.04.1026.Geoitalia2011

IMPACT FACTOR, H-INDEX, CITATION INDEX, PRODUCTIVITY INDEX: ARE RESEARCHERS STILL FREE TO CHOOSE WHERE AND HOW TO PUBLISH THEIR RESULTS ?

SOLARINO Stefano¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: stefano.solarino@ingv.it

Key terms: Evaluation index; Citation; Impact factor

During the last few years many tools to quantify the scientific importance of a research have been proposed and developed. They are based on the public output of the research, that is on its publication, and the most acknowledged probably are the Impact factor, the H-index and the citation index.

The impact factor is a number attributed to each scientific journal and consists in the average number of citations per published article. It is updated every year with the citations received in the two previous years and may significantly vary from time to time. The citation index is the number of citations of a single scientific article; it increases from the first appearance of the paper every time it gets quoted on a JCR journal, and has no upper limit. The H-index is a rather complex index which reflects both the number of publications and the number of citations per publication. In particular, it identifies the H papers have been cited at

least H times.

These tools apparently fulfil the motivated need to evaluate, in an objective way, the level of innovation, originality and continuity of the single researcher and may be used to compare the performances of different research agencies within the same scientific fields. However, it is clearly evident that the evaluation provided by these instruments not always corresponds to the real impact of the research, like it happens, as an example, for those publications that are frequently cited because they contain errors possibly not pointed out in the peer-review process. Moreover, the evaluation provided by these tools is sometimes used in contexts which are way different from their original field of application, like the distribution of financial supports or the attribution of duties to researchers. Finally, the same index may be computed using similar criteria on different databases, leading to confusion and contradictions. In this contribution are described the principal anomalies, problems and failures of the evaluation schemes, the most evident being the difficulties in evaluating the role of a single researcher in "pool" projects and papers and the need to find a way to recognize similar topics and studies published by the same researchers on more journals. It is then discussed the "selecting" effect that the evaluation indexes may have on the research. In fact, in the attempt of getting the highest possible score, there is a tendency to avoid studies that deal with small areas, scientific problems that have less peculiar characteristics or provide very practical results. In all the cases mentioned above the article describing the study will likely appear on "minor journals" (with low impact factor), will have, as a consequence, a low citation index, will not significantly contribute to the H-index and/or will only be published on reports.

Moreover, a discussion on the role that these evaluation indexes may have in the world of research is presented. Particular attention is paid to the consequences in the field of the geothetics, where scientific, technological, methodological and social-cultural aspects in a order different then what expected in pure meritocracy have to be considered. A few suggestions on how to render the usage of evaluation indexes if not more effective at least more adherent to real importance of the research are finally proposed.

10.1474/Epitome.04.1027.Geoitalia2011

THE ROLE OF GEOLOGISTS IN CULTURAL AND HUMAN PROGRESS.

LUCCHESI Stefania¹, GIARDINO Marco¹

1 - Università degli Studi di Torino

Presenter e-mail: srstefanialucchesi@libero.it

Key terms: Geoethics; Environment; Sustainability; Scientific communication

Geology, like any science, has a key role in the development and progress of human culture and society. In this context, scientists, professionals and practitioners of Earth Sciences must inevitably confront themselves with the purposes, methods and results of their works, concerning relationships between man and environment, that is dealing with ethic questions.

In this paper, we want to underline how geologists should not be dedicated only to environmental conservation, georesources prospection and civil protection activities. Nor they should merely put in place what today stated by international laws, in accordance to basic principles as "subsidiarity" (Maastricht, 1992), "precaution" (UNCED, Rio de Janeiro, 1992), and "responsibility" (Jonas, 1990).

An essential basis of any geo-environmental action is the enhancement of beauty and goodness inherent in nature. For this reason it is fundamental the role of geologists: their studies may let people know and then discover the beauty and goodness dimensions of the Kosmos. To give meaning to any operational choice, it is necessary, especially among younger generations, to encourage an "affective" dimension toward Nature, along with a capability to be amazed by it. An aid to this purpose can be found in some cultures, generally those from less developed countries than ours. Those populations have a greater awareness of the close relationship between humankind and Earth (e.g. Mother Earth), man not being seen as "other" than the environment, but part of it, together with the all community of living beings.

In the recent MuseoTorino project, a web-based and multimedia product by the Turin Municipality for the 150th anniversary of the Unification of Italy, a new scientific divulgation mode of the "history of a city" was used to communicate the constant relationship between the history of the Earth and of the humans, in a dimension of unity and continuum of space-time-life.

Therefore, the work of geologists is not limited to a merely pragmatic vision, which aims to provide a service, but as a harmonious collaboration between man and nature, between living and nonliving. In this relationship and inter-dependence, typical of a complex system like our planet Earth, man rediscovers his dignity and his role. He is a subject capable of safeguarding and responsibly managing the assets of his home-Earth for a progress aimed at improving the conditions of life and human dignity.

Geologists may also promote respect for "human rights" through appropriate educational and training actions in the knowledge that the Earth and its resources are a common heritage that must be shared among the community of living beings. For example, an erroneous policy of the international exploitation of gold deposits in Mendoza (Argentina), which would compromise the water quality of a vast inhabited area, was thwarted thanks to a widespread information and awareness on the problem.

In a society where a poor distribution of resources is often cause of conflicts between nations, geologists may also play an important role in promoting justice and peace, through a good management of resources. Furthermore, as the safeguard of the Earth, home of all peoples, is a common target of different cultures, geologists can take a significant role in multi-ethnic and multi-cultural dialogue, encouraging opportunities of meeting on environmental issues among people of different backgrounds and cultures.

Last but not least, is the vision of the Earth system that geoscientists can, more or less consciously, convey by means of their scientific communication and/or popular publications. In fact, they can lead to different ideologies (catastrophism, fatalism, mythologizing...) or myths such as "urban legend" that often affect people from a psychological and sociological point of view. For this reason geologists can play an important role in "service of truth".

U1-5 Orale Borgomeo, Edoardo

10.1474/Epitome.04.1028.Geoitalia2011

WHY I STUDY EARTH SCIENCES

BORGOMEO Edoardo¹

1 - Imperial College London

Presenter e-mail: edoardo.borgomeo08@imperial.ac.uk

Key terms: environment; students; ethical responsibility

In my presentation I will explain the reasons why I chose to pursue a university degree in Earth Sciences. Although this topic might seem unrelated to geoethics, it is somehow connected to it. I will show how my decision to study Earth Science was indeed influenced by "geoethical" reflections even though I did not consider them as such when I made my decision. I will start the discussion with the word "environment" because, although much abused and quite vague, it is the word that focused my attention on the Earth Sciences. That is, I came to appreciate the importance of the Earth Sciences after I became aware of the extent to which human activities are changing our environment. I will explain how, without any visionary ambitions, I felt the ethical responsibility to explore the nature of the Earth to understand the role of humans on it. I will then discuss what contributions young people can give to the study of the Earth, especially in relation to the pressing issue of environmental change.

U1-7 Invitato Graziano, Gian Vito

10.1474/Epitome.04.1029.Geoitalia2011

THE GEOLOGIST'S ETHICS PROFESSIONAL: COMPETENCE, CODE OF ETHICS AND LEGALITY.

GRAZIANO Gian Vito¹

1 - CONSIGLIO NAZIONALE GEOLOGI

Presenter e-mail: presidente@consigionazionalegeologi.it

Key terms: code of ethics; management of the territory; normative

The greatest sensibility and attention to the geoenvironmental problematic underline the urgency to face, with new awareness and responsibility, some matters, like the management of the territory, the exploitation of the georesources, the energetic problem list, the defense from the natural risks. Civil community asks ready and exhaustive answers. The technical-scientific competences of the geologist, conjugate with practical shared deontologiche in the respect of the normative in force, can give back trust to the citizens, support to the political decisions, safety and raising of our professionalism. The Italian territory is a great economic, social and cultural resource, that must be defended and valorized with the contribution of the geologist. New strategies are needed, aspired of action and operational tools. The CNG is working in this direction.

U1-8 Orale Ryzhova, Ludminla

10.1474/Epitome.04.1030.Geoitalia2011

GEOETHICS IN ORGANIZING A SYSTEMIC APPROACH TO EXPLOITATION OF THE NATURE

RYZHOVA Ludminla¹

1 - State Geological-Explorative University, Moscow, Russia

Presenter e-mail: msgpa@msgpa.edu.ru

Key terms: geoethics; geosphere; trend-technologies; environmental disasters; natural resources

Under the conditions of worsening environmental situation and complicated problems of exploiting the nature, geoethics as a novel scientific direction attains a special importance. As an individual scientific direction proposed by the scientists from the Czech Republic (V.Nemec, L.Nemcova), geoethics had been formed in 1992 at the International Mining Pribram Symposium (Czech Republic). The development of geoethics follows the way of differentiation of directions: the theoretic one (V.Nemec, M.Komarov, G.Gold, A.Trembetsky), the applied one (V.Ryzhov, L.Ryzhova, A.Krasavin, M.Kuz'min et al.), the social-economic one (V.Gur, N.Grigor'ev, G.Senatskaya V.Yusim et al.). According to the definition in the Encyclopaedic Dictionary "The Globalistics", GEOETHICS is a combination of moral-legal norms and rules of the multilevel system in the development of the GEOSPHERE such as geopolitical, social-economic, informational-technological ones. The whole material system of the natural environment components, of the natural resources (atmosphere, water, soil etc.) developing as a part of the whole complex, possesses a certain stability, homeostasis, and capability of self-restoration in exposure to external factors including human activity.

Optimal utilization of the main resources i.e. mineral deposits, time (non-replenishable resources), personnel, information, capital (own and attracted funds, credits and investments), is the factor of efficacy enhancement of resources' utilization, exploration, and development of mineral deposits.

The efficacy of resources' utilization is determined by the level of applied technologies (in production, management and information) to maintain high rates of economic growth and creation of a competitive price of the final product in solving the following express-problems:

- needed enhancement of natural-resource prognosis;
- the development of standards, regulations, technical-environmental-social risks;
- introduction of novel trend-technologies;
- analysis, prognosis of international markets of raw materials;
- Prevention of environmental disasters

Natural resources and first of all mineral ones make up the basis of wellbeing of countries and determine the future of the world civilization. Taking into consideration impossible replenishment of natural resources, formation of the need in mineral raw materials is determine by the reasonable sufficiency principle.

U1-9 Orale Di Loreto, Eugenio

10.1474/Epitome.04.1031.Geoitalia2011

GEOLOGISTS AS PUBLIC EMPLOYEES AND GEOETHICS

DI LORETO Eugenio¹

1 - Consiglio Nazionale Geologi e Regione Lazio, Area Difesa del suolo

Presenter e-mail: eugenio.diloreto@consigionazionalegeologi.it

Key terms: professional ethics; norms; public employees

In Italy there are 14.500 geologists, regularly enrolled in the professional register. Two thousands of them work as public employees in central Institutions (ISPRA, INAIL, ANAS, etc.) and local administrations (Regions, Provinces, Municipalities, Basin Authority, etc.).

These public geologists perform activities related to the territorial planning

and to the control of the pursuance of norms, provided in the specific competence area of the public body for which they work. In these contexts, they have to interact with political decision makers, private citizens and external professional figures, for making technical evaluations and studies related to feasible projects. For playing their role in the best way, they must have the following requirements: a specific basic training and ability to give appropriate answers to the questions submitted, but in any cases they must ensure professional ethics. The importance of the ethical aspects in their work appears especially when they must assess the technical-geological-environmental compatibility of human activities on the territory (construction of buildings, roads, tunnels, dams, railroad, polluting industries, etc.) in relation with the correct use of geo-resources (rocks, water, minerals). The author exposes his own work experience of thirty years in the local administration on these topics.

U1-10 Orale Peppoloni, Silvia

10.1474/Epitome.04.1032.Geoitalia2011

PROPOSALS FOR DEVELOPING GEOETHICS IN ITALY

PEPPOLONI Silvia¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: silvia.peppoloni@ingv.it

Key terms: Geoethics; dissemination; scientific community; society

In recent years among geoscientists there is a growing awareness that their scientific and technical choices in each sector of activity (public, professional, industrial, research or teaching) can have significant repercussions on the territory and on the citizens that inhabit it and therefore that it is opportune to accompany these choices with appropriate reflections.

Starting from the necessity to reconsider the way of man's relationship to the planet Earth, the geoscientists are wondering about the role played in the social context in which they operate, about their responsibilities in taking decisions on the use of natural resources, on the exploitation and protection of the Geosphere, when they are required to give correct information on hazards, to support the emergency management or to make society aware about the value of own territory as a common heritage to share.

Up to 2007 in Italy, many researchers and practitioners have dealt with these issues, but the debate never took place in a coordinated and organized way. In addition, the occasions where to develop these themes were dedicated in wider sense to philosophical, epistemological and social aspects related to the Geosciences.

The need to develop a debate on Geoethics with better coordination has been confirmed by the success of the session entirely devoted to Geoethics, hosted for the first time in Italy within the VII Forum of Earth Sciences (Rimini, 2009). The significant number of intervened speakers and discussed topics showed the desire and the importance of going ahead in this cultural path in our country. In any case, it became evident the necessity to organize more effectively those who want to devote to these issues, improving their coordination, expanding the network of contacts and creating more opportunities for the debate.

To this end, some ideas are proposed, that aim to create a common space of reflection on Geoethics issues, offering a convenient time for the research and the discussion, a place for organizing and setting the activities, which represents a starting point for the dissemination of these issues within the national and international scientific community and civil society.

U1-11 Invitato Lanzinger, Michele

10.1474/Epitome.04.1033.Geoitalia2011

GEOETHICS AMONG THE DEEP CONCEPTS OF THE EXHIBITION PATH OF MUSE - MUSEO DELLE SCIENZE - TRENTO

LANZINGER Michele¹

1 - Museo delle Scienze (Trento)

Presenter e-mail: michele.lanzinger@mts.tn.it

Key terms: international museology; science and society; sustainability

In the spring of 2013 the MUSE - Museum of the Sciences will be opened in Trento, Italy. This new structure inherits the experience of the previous Tridentine Museum of Natural Sciences in relation to the naturalistic research on the local environment and proposes a cultural program focused on the themes of sustainability in the relationship among nature, science and society. Geosciences play an important role in the interpretation of factors that require humanity to pay attention to the impact on the biosphere and geosphere and this is one of the most relevant and deep issues of the new project. Muse is currently under construction within an urban requalification project of Trento city and is realized through the efforts and the financing of the Autonomous Province of Trento.

U1-12 Orale Piacente, Sandra

10.1474/Epitome.04.1034.Geoitalia2011

THE STUDY OF LANDSCAPE: FROM HOLISTIC APPROACH TO SOCIAL CONCEPTION OF KNOWLEDGE

PIACENTE Sandra¹, BADIALI Federica²

1 - Università degli Studi di Modena e Reggio Emilia, Dipartimento di Scienze della Terra

2 - Università degli Studi di Modena e Reggio Emilia, Dipartimento di Scienze della Terra, PhD School in Earth System Sciences

Presenter e-mail: piacesan@gmail.com

Key terms: Transdisciplinary approach; Topological identity; Sustainable reevaluation

We present three examples of study and improvement of the landscape, in which the transdisciplinary approach is not implemented using a simple juxtaposition, but through a conscious integration between different areas. This new approach give a new and more correct interpretative key which unites, while it makes distinctions, replacing the "disjunctive thought". Our society is complex and in a state of constant change. Rapid movement and transitions make distances seem to vanish, and the link with our own territory, the place where we belong, might be expected to disappear. On the contrary, the more familiar a place is, and the more it is overshadowed by exotic or faraway places, the more this link become

stronger, as if we were researching for our own topological identity. And it is really this identity that should emerge: it is important to underline that through history, life, social structure, religion, culture in general, it has always been possible to find the roots and the more immediate fundamental expressions in the physical landscape, in the geological forms and aspects, in the rock material and in their aesthetical and functional characteristics, exalting and conferring them deep meanings and values.

By these premises, a correct communication to the public becomes the fundamental complement of the scientific research: for the scientists, it is an essential aspect of their work, for the citizens it is an orientation of life. Naturally, it will be possible to integrate cognitive tools in the territory, suitable and accessible to all (informative and educational materials, information panels, brochures, guided tours), without exaggerating with an over-dose of equipments, above all logistics and structures ones. This attitude would be able "to denaturalize" and to make "artificial" the landscape, because of the luck of the characteristics that had suggested the improvement of it.

1° Example. Sustainable tourism and understanding of the relationships man-landscape in the Ecomuseum of Hill and Wine of Castello di Serravalle (Bologna). Studying the landscape of Castello di Serravalle, hilly zone of wines DOP and DCOG production, it is still possible to observe the signs of the mutual and continuous interaction among man and environment, which persists here since over 2.000 years. This was at the origin of the Ecomuseo: an effective tool both for a sustainable tourist exploitation and for spreading knowledge and awareness of the local cultural patrimony among the residents.

2° Example. The Lago Bracciano of Montese (Modena): reevaluation of a marginal Apennine area among archaeology, landscape and history. Using good archaeological and document data (Etruscan-Italic finds, nineteenth-century news on a lake now disappeared, local legends) partly known but never correlated, integrated by geologic and geognostic data, and chemical and geochemical analysis, it was possible to trace essential elements for the reconstruction of the landscape in areas historically frequented and used by the local communities. In this way, the premises for a tourist exploitation of a marginal and seemingly insignificant area created, giving again a cultural and historical value to a site that deserves.

3° Example. Geological signs and poetic textures in the Frignano Park. The project of a geological-literary itinerary starts from the hypothesis that there is a poetic and cultural specificity in the Modena Apennines, linked to more markedly morphological and geological features of the territory. The landscape is seen as the main space of thought; the possible itineraries that from real ones become symbolic ones and vice versa; Geology and Literature as a viaticum, for a new knowledge's pilgrim. And the poetry, with his words, creates a more articulated, complex and fascinating geographical map to discover, than the topographical one.

U1-13 Orale Ferrari, Graziano

10.1474/Epitome.04.1035.Geoitalia2011

THE MALLET PROJECT: FROM AN EARTHQUAKE LABORATORY TO LABORATORIES ON THE TERRITORY

FERRARI Graziano¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: ferrari@bo.ingv.it

Key terms: Natural hazard; Education; Environmental laboratory

On 16th December 1857 an earthquake devastated a vast area of Basilicata and part of Campania (Southern Italy): more than 180 villages, over an area of more than 20,000 km², suffered very serious damage to the buildings, to the extent that most of the houses had to be abandoned. Whole towns and villages spread out across an area of 3,150 km² were razed to the ground. Altogether over 6,000 houses collapsed or became uninhabitable and about 11,000 people died.

The Irish engineer Robert Mallet was a witness and an extraordinary "scientific chronicler" of this earthquake's effects. In the months of February and March 1858 he undertook a scientific mission to the area most badly hit by the earthquake, drafting an extraordinary diary in the process, in which his technical-scientific observations are not separated from the descriptive and literary ones. Upon his return to England, Mallet put down his observations in a weighty opus, which he published in London in 1862 with the title: The Great Neapolitan Earthquake, The First Principles of Observational Seismology.

With this title Mallet gave a name to the nascent science of earthquakes: Seismology.

The report by Mallet on the 1857 earthquake also represents, from different standpoints, a unique "observatory" on the landscape and the various social, economic and cultural aspects of the area worst hit by the earthquake.

The part of the territory of the provinces of Salerno and Potenza hit by the earthquake is one of the few areas of the Mediterranean that has been capable of keeping its natural and cultural legacy intact and integrated in the economic and social structure.

As a result of this ancient "harmony" this area offered the unique opportunity to create a privileged "observatory" over its natural environment as well as its historic and present-day anthropology, finalised to fostering a conscious participation of the area's inhabitants in the territorial context.

Within the framework of the idea of a "Mallet Laboratory" project there has been the opportunity to set up a network of study centres in the territory of the two provinces (Salerno and Potenza), capable of promoting research characterised by a great national as well as international breadth, starting with the world of schools and local communities. The publication of the work entitled Viaggio nelle aree del terremoto del 16 dicembre 1857. L'opera di Robert Mallet nel contesto scientifico e ambientale attuale del Vallo di Diano e della Val d'Agri (6 vols. and 3 DVDROM), was published during the period 2004-2009.

This edition is part of a project officially started one year earlier in 2003, a concrete sign that strategies promoting research and environmental education have been achieved. These aspects are indeed of great importance in the drafting and the enforcement of plans for safeguarding the territory, in which the regional administrations of the Italian State, first and foremost the Regions and the Province, are increasingly called upon to operate. Objectives, the results and perspective of the Project Mallet Laboratory will be presented.

THE PER (PARK OF RENEWABLE ENERGY) GEO-ETHICAL PROJECT: A LARGE WIDESPREAD COMMUNITY OF RENEWABLE ENERGY

PRODUCERS.SIBI Patrizia¹, VALLETTA Mario²

1 - Dipartimento di Ecologia e Sviluppo Economico Sostenibile - Università della Toscana

2 - CTS del Rocca di Cerere European Geopark

Presenter e-mail: sibipat@libero.it

Key terms: sustainable community; renewable energy; energy producers; social participation

We cannot separate the human being from his life environment and therefore we cannot change one without changing the other, transform the world without changing ourselves (G. Bateson, 2000)

If today changing the world means, first of all, to build sustainable communities in which the lifestyle is in harmony with the natural vital processes, this goal requires us to modify our conceptions and world relations. In the first place it is necessary to change our bad habit to think and act exclusively in terms of aim and usefulness, that is in anti-ecological terms. We have to gather the transformation strength of every action instead, and learn to accept the uncertainty, the unforeseen event, the fate as factors of innovation and creation. The geo-sciences describe us the complex natural systems and their constant evolution. At the same time, they reveal us the organizational and conservative principles regulating these systems.

So these scientific knowledge show us the ethical direction of our social actions: to cooperate with nature's ability to sustain life and the natural resources essential to preserve life itself. This purpose has oriented the proposals of P.E.R. (Park of the Renewable Energies) for a few years. The P.E.R. was born thanks to few people with a strong environmental awareness currently living inside the park. The P.E.R. is located in the province of Terni, between Todi and Amelia, in the territory of Guardaia, at 575 meters above sea level. It is a rural area, far from factories and from areas with industrial agriculture, inside a Community Interest Site (SIC), in 6000 hectares of wood.

It is an environmental technology park with innovative integrated systems for the production of renewable energy. These systems are utilized for both farm activities and educational experiences with the visitors of the Centre. The buildings, including an eco-hotel, are equipped with solar panels, photovoltaic panels, wind generators, geothermal engines and sophisticated systems for gray water recovery and for recycling of organic waste. The site is totally independent from any supply network, including water supply; this makes it an interesting example of eco-sustainability. Recently, the park has launched a public invite: to become part of a great widespread community for the production of renewable energy, to promote energy conservation and sustainable lifestyles. This empowerment process that transforms consumers into energy producers - but also in those ones who spread the culture of sustainability - could, over time, give life to a community that really lives according to the geo-ethical principles of bio-sustainability.

The route for the identification and dissemination of the PER Community is an interesting example of the generative process in which actors, rather than doggedly pursuing a predetermined objective, a model to be implemented, "look for directions and values that are inherent in the means available" (Bateson, 2000), including communication networks and methodologies of social participation.

In this perspective, the experience brought by the PER deserves to become an interesting object of observation and reflection for its green ethics. The components of the new community focus their attention on the effects of actions and relationships rather than on ways to reach a predefined goal. This ecological approach promises unexpected new creations: there is a chance we will see the birth of a sustainable form of social organization adapted to the human community at last!

A HIPPOCRATIC OATH FOR GEOLOGISTS?MATTEUCCI Ruggero¹, GOSSO Guido², PEPOLONI Silvia³, PIACENTE Sandra⁴, WASOWSKI Janusz⁵

1 - Dipartimento di Scienze della Terra - Sapienza Università di Roma

2 - Dipartimento di Scienze della Terra A. Desio - Università statale - Milano

3 - Istituto Nazionale di Geofisica e vulcanologia - Roma

4 - Dipartimento di Scienze della Terra - Università di Modena e Reggio Emilia

5 - Istituto di ricerca per la protezione idrogeologica del CNR - Bari

Presenter e-mail: ruggero.matteucci@uniroma1.it

Key terms: Hippocratic Oath; Geologists; Geoethics

The Oath of Hippocrates is the first and the most popular moral code for the physicians. Throughout varying historical fortunes, from its almost complete oblivion in the Middle Age to its rediscovery and high recognition in the Renaissance, the Oath, written in the second half of the fifth century B.C., continues today to be pledged in many Faculties and Schools of Medicine and in many professional associations throughout the world, both keeping to the original text or one of the modernized versions. It is widely regarded as a cornerstone of the medical approach. Historically, the Oath of Hippocrates marks the first sharp changeover to a rational approach to the illness and to the human health; for this reason it is reserved only to people who is able to operate because of their scientific knowledge of medicine. Human health and defence against the illness always are seen as one of the basic goods of Mankind; so, the Oath enforces the ethical duty of a rational and positive use of the power possessed by the individuals because of their capability to apply scientific knowledge on the other men, becoming patients. Every oath entails a personal moral engagement. But, the public Hippocratic Oath sworn by the physicians over the world has marked through the centuries the awareness of an assignment of universal value, that goes well beyond the professional duty, becoming a mission that calls for the total willingness to operate in art and consciousness where and when need arises.

The awareness of the sacred value of the Human life is profoundly rooted in every man. The awareness of the value of our planet as the unique and often not renewable resource for Human life has emerged rather recently and not yet on a worldwide scale. Also the understanding of the planet as a living system, with its natural and unavoidable processes, including those (geo-hazards) with dangerous effects for man, is anything but widespread and well established. And, only now governments are reaching a greater appreciation of the guiding role of the scientific approach for the management of our planet, of its health and for the defense against dangerous events.

From that derives the special responsibility of those who possess the knowledge of the geological processes and the power arising from (or,

better, which ought to arise from) it; this responsibility goes beyond a merely correct professional conduct.

Geologist is like a physician. He or she are ethically involved; he or she must be fully and consciously engaged, wherever and whenever geological knowledge can provide a contribution to solving problems linked to the sustainable use/management of land and the Earth's resources. This means to be ready to go beyond geologist's professional duty and economic convenience, willing to counter any political, industrial and social interests conflicting with the health of the planet; being conscious that the latter, in the short or long time, represents the real interest of the society; aiming to assure a harmonic interaction between geologists, governments and population, in considering the cost-benefit ratio, the technological capabilities, and the public media. For these reasons, the authors, who are members of the recently set up Commission of Geoethics of the FIST (Italian Federation of Earth Sciences), consider it useful to submit to the Italian geological community the proposal for the introduction of a voluntary Hippocratic Oath for geologists, through which they would solemnly and publicly declare their consciousness to be the repository of the geological knowledge and of its entailed ethical duty.

10.1474/Epitome.04.1038.Geoitalia2011

SPREAD OF ENDEMIC DISEASE AND GLOBAL CHANGES: PROPOSITION OF RELATIONSHIPS DEVELOPED IN A TWIN PARTNERSHIPVIALE Michela¹, FERRERO Elena¹

1 - Dipartimento di Scienze della Terra - Università degli Studi di Torino

Presenter e-mail: michelaviale@msn.com

Key terms: Twin partnership; Dengue fever; Education to Sustainability; Global changes; Cape Verde

A project of twinning between schools of the Piedmont Region (Italy) and the Republic of Cape Verde, explored in the first stage the geomorphological aspects of the territory, developed in the next stage an investigation on pupils and students' conceptions about the geological risks in the area. A further educational research on students' perception of waste and its dangers has highlighted the connection between the physical characteristics of the territory, the different ways of managing waste and the correlation with socio-economic problems, showing many similarities between the two partners.

A sudden event such as the spread of Dengue fever, which appeared for the first time in Cape Verde in 2009, revealed that the inappropriate management of waste can be considered a major cause of the spread of this disease. Dengue Fever, also known as break-bone fever, is an infectious tropical disease caused by the Dengue virus. Its vector, the *Aedes aegypti* mosquito, has found an optimal environment for its life cycle in the context of Cape Verde, with the persistence of water in abandoned waste objects.

How can we connect topics of Earth Sciences with the spread of this disease? The link is not obvious, but it has been explored and illustrated in this stage of the partnership. Activities with pupils and students provided an opportunity to investigate how some global phenomena like climate changes (with an increase in local rainfall and higher temperatures) are related to local events, such as the spread of Dengue fever.

Both twin partners have been involved in this process of understanding, with the support of didactic tools that proved to be valuable aids. The Cape Verdean students presented their preventive strategies, according to the instructions given by the Cape Verde Ministry of Health; the Italians students were involved in developing and reinforcing the emotional and empathetic value of the partnership both in terms of knowledge and friendship.

Some methods used to struggle with the mosquito vector's diffusion may interfere adversely with primary natural resources (air, water, soil): is it possible to fight this disease in a sustainable way?

Preventive strategies are conditioned by the geomorphology of the territory and the by the complex relationships that connect geosphere and biosphere. For this reason, it is important to be aware of the risk of breaking those delicate balances activating unexpected consequences. The strategies proposed by the Cape Verdean students demonstrate awareness of these risks, since they are involved in a clear example of a sustainable campaign against Dengue fever.

The roles played by both partners have linked knowledge about the natural dynamics of our planet with the development of appropriate behavior, thus contributing to the formation of responsible citizenship to preserve and protect the environment. The partnership also encouraged students to develop sustainable management strategies against the disease, and consequently against waste, actively involving them at school, at home and in their community.

2 - Dipartimento di Scienze della Terra, Università di Torino

Presenter e-mail: elena.ferrero@unito.it

Key terms: Geological heritage; Piemonte; Science exhibits; Nature trails; Didactic tools

The multidisciplinary research project "PROGEOpiemonte" ("PROactive management of GEOlogical heritage in the PIEMONTE region: innovative methods and functional guidelines for promoting geodiversity knowledge and supporting geoconservation activities ("PROGEO-Piemonte"; coord. M. Giardino) aims to achieve a new conceptual and operational discipline in the management of the geological heritage of the Piemonte Region by means of the development of techniques for recognizing and managing its rich geodiversity at the local and regional scale. After a systematic review of inventoried geosites, 9 strategic geothematic areas will be investigated to represent the geodiversity of Piemonte, each characterized by high potential for scientific studies, enhancement of public understanding of science, recreation activities and for economic support to local communities. Geological history, climate and environmental changes, natural hazards, soil processes and georesources will be popularized not only with geosites but also with museum collections, evidences of mining

activity and quarrying, science exhibits and nature trails. The recognition of the economic value of geodiversity will lead to the production of regional guidelines for Geoconservation integrated quality management system, suitable for tourism and sustainable development strategies. An international advisory board will evaluate yearly project advancements, proposed strategies and products.

One of the main target of the project is to improve public awareness on major earth science challenges, both from the hard and applied Earth Sciences point of view. Since the general public, both the young and adults, have a sort of illiteracy with respect to Earth Sciences, we plan to get them involved in an easy but complete way in to the subject. We experienced in the last few years two approaches to disseminate and share geodiversity and geoheritage contents in Piemonte; the first one involved local partners, such as primary and secondary schools (proposing specific research-action curricular activities) or science museum (both at the local and regional level), for the design of scientific exhibits focused on specific subjects related to the impact of dramatic geologic events (vulcanos, earthquakes, floods, coastal hazards, etc) on human presence and activity; the second one was focused on road exhibits (European researcher's night, ESOF-European Science Open Forum- science in the city) where several scientific experiments, dealing with multi-faceted geological subjects, were developed such as the following: plate tectonics experiments; models of slope instabilities; the discovery of the fossil record and the reconstruction of past climate changes; the exploration of the decorative stones of Torino's historical buildings; awareness of fibrous mineral (asbestos) and mineral particles impacts on health; classification of mineral collection by using the five senses. These live experiments or games are the ideal start for the present project, and we plan to improve both their scientific content and the general organization. From these past experiences we will focus on new outcomes of the project, that will include didactic tools for educators, schools and public in general, together with more traditional museum exhibits, real and virtual geological tracks, interactive websites and training courses for geonaturalistic guides. The produced material will be shared with teachers for local school projects and natural science museums of Piemonte. Moreover, long-term objectives and short-term targets for geodiffusion actions will meet the requirements of local communities in the geothematic areas. Local partners will offer human and financial resources for the achievement of the geodiffusion objectives.

Last but not least, geological literacy of children, young persons and adults will thus have a positive deep impact on every day life and on our future.

RESEARCH AND EDUCATIONAL OUTREACH

D'ADDEZIO Giuliana¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: giuliana.daddezio@ingv.it

Key terms: natural hazard; research; education

The Istituto Nazionale di Geofisica e Vulcanologia (INGV) is one of principal Italian institution dealing with Earth Sciences research. INGV is also in charge of the real-time seismic and volcanic surveillance, and of the early warning and forecast activities. Italy is a seismic and volcanic country and it is therefore important the social role of a correct information on natural hazards and its implication on social and cultural aspects. The Laboratorio Didattica e Divulgazione Scientifica of the INGV organizes intense educational and outreach activities in the consciousness that preparedness is the best way to live with and to mitigate natural hazards.

These activities partially respond to a significant demand from the Society; one question is which are the most effective and authoritative approaches to be developed to fulfill this demand. The *Annuario Scienza e Società 2011*, even if outlines a scarce level of scientific knowledge among citizens, highlights a growing demand for information on science and technology. For the majority of people the main source of scientific notions are newspapers, where the exposition of science-related news is constantly increasing. On the other hand, public Conferences that allow a direct relationship with researcher represent the most reliable scientific informative contest, as well as the Web sites of scientific institutions and the researchers blogs. These data emphasize the importance of the social role of science institutions and the need of an active and responsible involvement of research in educational outreach. This represents one of the aim of our educational activity. This talk give an overview of our activities with regards to research-community interactions.

U1-19 Orale Magagna, Alessandra

10.1474/Epitome.04.1041.Geitalia2011

INTERACTIVE ACTIVITIES TO STIMULATE DEBATE AND CRITICAL THINKING ABOUT ISSUES RELATED TO EARTH SCIENCES AND SUSTAINABLE DEVELOPMENT

MAGAGNA Alessandra¹, GIANNATEMPO Cristina¹, FERRERO Elena¹

1 - Università degli Studi di Torino

Presenter e-mail: alessandra_magagna@yahoo.it

Key terms: Earth Science education; Sustainable Development; Exhibition; Action-research

During the International Year of Planet Earth (2007-2009), the Department of Earth Sciences (University of Turin) and the Museum Craveri of Natural History (Bra, Cuneo) promoted the project "Understanding how the Earth works: from local situations to global processes". In this context, two geothematic exhibitions about Cape Verde were designed, both accompanied by guided tours and practical laboratories addressed to students of different ages (from nursery to secondary school), as well as workshops dedicated to in-service teachers. The exhibition "Knowing the volcano in order to live together with it" (February - April 2008) was the subject of an action-research carried out as part of a master's degree course in Natural Sciences. The research concerned the design of interactive activities related to the exhibition, the collection and analysis of data on the performance of these activities during the guided tours conducted with the students.

The aims of the interactive activities were to generate emotional involvement, to stimulate interest and curiosity, to develop debates among visitors, to widen view points on topics of relevant scientific and social value: volcanism, hazards and sustainable development. The activities included discussions about questions with many possible answers, in order to trigger a process of discovery driven by the rise of

multiple viewpoints. During the tours the museum guides (people involved in the action-research) moderated the discussions, helping both students and teachers in debate as well as in personal reflection.

The action-research project undertaken enabled us to assess the effectiveness of this teaching strategy, in order to establish possible modifications on activities during their execution as well as in view of future events.

To achieve this goal the research followed different ways: a quantitative analysis was completed on the worksheets elaborated by students during these activities, as well as the satisfaction questionnaires filled by students and teachers. From the qualitative point of view, the level of interest and participation of pupils and teachers were monitored during tours and, in some cases, it was possible to have a feed-back concerning the implications in the following classroom work.

In this research, the qualitative aspects were crucial: despite the quantitative data analysis allowed to study the mental representations on socially relevant themes in students of different ages and to collect multiple points of view in this regard, the interpersonal relationships that occurred with students and teachers during and after the guided tours provided the best evidence of the value of interactive teaching strategies adopted. For example, the guided tours stimulated interest for the topics discussed: this was demonstrated both during the visits, through questions and observations, both in the classrooms, through the request for further details. Some special cases allowed to investigate these aspects. The exhibition was subsequently staged at other institutions, where the activities were offered again, with positive feedback. In conclusion, the effectiveness of the interactive activities and of the teaching strategies proposed was proved, as well as the possibility to re-propose them outside the context of the museum for which they were conceived.

10.1474/Epitome.04.1042.Geitalia2011

STRATEGIES FOR SEISMIC RISK REDUCTION: OUTREACHING SCIENTIFIC KNOWLEDGE OR PROMOTING AWARENESS, TO EDUCATE?

LA LONGA Federica¹, CAMASSI Romano¹, CRESCIMBENE Massimo¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: federica.lalonga@ingv.it

Key terms: risk education; outreach; science teaching; awareness

This work develops a critical reflection on the activities for information, training and education conducted by a group of researchers of the INGV in recent years.

In particular, our analysis, from an epistemological point of view, is between:

- science outreach, the link between science and the school;
- science teaching and its role of contact between science and school;
- risk education, imaged as a process able to develop a culture of risk in relation to the territory in which we live.

These issues are critically analyzed on the basis of experience gained since 1995.

The educational methodologies tested in "peacetime", out of seismic events, with the EDURISK Project are compared with those experienced during the emergency in Abruzzo.

Increasingly today, we refer to prevention as a primary strategy of defense against risk.

But very often the responsibility of making prevention falls on the others as government, institutions, local authorities and the citizen perceive themselves as powerless against the inevitability of natural events and refer to the rulers for the implementation of effective prevention policies.

As researchers, what are the most effective actions we can take to influence the risk reduction and motivate the choices of people? Before an event occurs, how can we influence the views and choices that people do or not do to reduce the risk?

The effectiveness of our interventions must be based on scientific information, on a specific training, or must be reached to develop values, actions, awareness?

Our interventions must be oriented and developed to inform, to train or to educate?

U1-21 Orale Manni, Riccardo

10.1474/Epitome.04.1043.Geitalia2011

THE PALAEOLOGICAL MUSEUM IN AN APPROACH GEOETHIC

MANNI Riccardo¹

1 - La Sapienza University

Presenter e-mail: riccardo.manni@uniroma1.it

Key terms: palaeontology; museum; fossils; mystification

The protection of scientific data with respect to incorrect interpretations or misrepresentation has ethical significance, especially when it depends on the information to the public. Striking were the cases of Man of Plitdown and the Indian researcher Vishwa Jit Gupta. Man of Plitdown was a sensational case in which one or more researchers deliberately altered the fossils found causing serious damage to image both the academic world and the scientific theories. The event organized by Gupta was equally sensational, because mystifying the paleontological data, he put the crisis in different palaeogeographic and palaeoclimatic models well established. But the mystification and alteration of scientific data can be made even in a more insidious way, because they often inconspicuous, where the fossils are preserved, that is in the Museum of Palaeontology. In fact, when a specimen is badly restored or is assembled incorrectly, the information given is altered and distorted.

The Paleontological Museum, frequently have fossils that are perfect at first sight. Only a closer look it turns out that often have been largely restored. There are parts rebuilt and then colored so well that at first you do not always notice it. The information of what is artificial reconstruction and what is original material must be immediate and clearly perceptible. It is always necessary to specify when a cast replaces an original finding. Other times you see skeletons assembled in questionable positions, as if the still image of a slow-motion. It is frequently the case of dinosaur skeletons that seem ... fly. More frequently, the skeletons are assembled according to theories no longer in vogue, partly because the replacement is often costly and difficult. Just think of the bipedal dinosaurs: until a few years ago it was believed that they had the same posture of "kangaroo". It is now believed, after detailed analysis of functional morphology, bipedal dinosaurs have tail and neck more or less parallel to the ground. However, many museums display their dinosaur skeletons still with

posture of kangaroo and the visitor is convinced that their posture is exactly that of the kangaroos.

It is clear that all these cases stem from an incorrect and more widespread understanding of the role of the paleontological museum and its exhibitions. At the end a fossil must be beautiful regardless. A vision that should not be accepted because the representation of the fossil, as evidence of past life, is sacrificed in this case in favor of aesthetics and an imaginative approach and unreal. It would be appropriate to better define a code of behaviour for the restoration and for the display of the paleontological material so that the visitor has a representation of what is exposed more possible near to reality.

U1-22 Orale Pannaccione Apa, Maria Ilaria

10.1474/Epitome.04.1044.Geoitalia2011

ETHICAL APPROACH TO SOCIO-ECONOMIC INFORMATION SOURCES IN PRESENT VULNERABILITY AND RESILIENCE STUDIES: THE MT. CAMEROON CASE (MIA-VITA PROJECT [FP7-ENV-2007-1])

PANNACCIONE APA Maria Ilaria¹, KOUOKAM Emmanuel², BUONGIORNO Maria Fabrizia³, MBE AKOKO Robert³

1 - Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy
2 - Ministère de l'Industrie, des Mines et du Développement Technologique, Cameroon
3 - University of Buea, Cameroon

Presenter e-mail: mariailaria.pannaccioneapa@ingv.it

Key terms: Vulnerability; Social recovery; Resilience; Mt. Cameroon volcano; FP7 MIA-VITA project

The study of the vulnerability facing natural and man-made hazards with the related resilient answers belongs to the complex and articulate field of social sciences called Disaster Anthropology. Vulnerability is generally defined as the weak point facing an aggressive event difficult to manage. Resilience is the subsequent capacity for self-repair after a sustained stress (natural or anthropogenic).

Consequently, the theoretical model of economic resilience is the ability to restore an economic background able to support the gradual recovery of social benefits since the disaster.

Moreover, the presence in the territory of different systems of production (natural ecosystems and / or technical) should suppose multi-resilient communities.

The mathematical nature of these economic theorems makes difficult their practical application inside an ethno-anthropological contest and can easily conflict with the cultural traditions of those potentially resilient societies or with the inability to apply a practical recovery system due to socio-structural causes.

An example is given by some urban and rural family structures settled around the Mt Cameroon volcano, in which the general psychological pressure increases both for the constant exposure to natural hazards and the vulnerability arising from its social environment (e.g. castes, forced housing allocation, cultural estrangement to local chiefdom, etc.). The rational and carefully weighing choice of the heuristic model to be adopted in the study of social vulnerability is therefore an extremely complex task with many interpretive obstacles.

In 2009, within FP7-MIA-VITA (Assess and Mitigate risk from volcanic impact on terrain and Human Activities), was launched the 1st fieldwork mission for the study of socio-economic development of communities living around Mt Cameroon, completing 108 interviews at several social groups of different ethnicity and religion. The resulting information will be re-tested and verified during the 2nd fieldwork mission 2011 for completion of the study area.

The major attention and sincerity in answers observed in social groups with a common cultural background, as for the chiefdom, seems to confirm as the above suggested.

U1-23 Orale Piccione, Caterina

10.1474/Epitome.04.1045.Geoitalia2011

MEMORIES OF THE PAST CONTRIBUTE TO PREVENTION PHOTOGRAPHY CAN BE A DIRECT MEANS FOR THE PUBLIC UNDERSTANDING OF SCIENCE

PICCIONE Caterina¹
1 - INGV

Presenter e-mail: caterina.piccione@ingv.it

Key terms: prevention; memories of the past; photography

There are thousands of ways to achieve a sustainable future for our Planet: some of them follow high-value scientific research activities, others simply aim at increasing people's awareness of what can and should be done to improve our and our children's quality of life. The easiest way to develop this specific kind of "spread culture" consists in bringing back to life what was preserved of the history of a population and of a territory, by representing it with a renewed form and by making it a "food for thought".

The National Institute of Geophysics and Volcanology (INGV), followed this approach and decided to publish two volumes whose objective was to make people more aware of the geological and volcanic risks in some specific areas of our country. The immediacy of photography was used to tell the stories of volcanoes and earthquakes, to represent past events becoming "memories" and to use them as a basis to build a better future. "Terre di Fuoco" (Lands of fire) and "Terremoto Calabro-Messinese, 1908-2008" (Earthquake in the Calabria and Messina areas, 1908-2008) are the two photographic books published by INGV in cooperation with Alinari, the oldest firm in the world working in the field of photography and image communication. The pictures selected to be included in the two books had a double significance: on one side they had to convey to the reader the immediacy of emotions that other persons had felt and lived; on the other side they had to make people understand the importance of prevention.

The fascination of history, the importance of memories of the past and the extraordinary strength of images help the reader build a link between past, present and future, where the lesson learnt from the past centuries and from the study of the earth and its energy helps understanding which steps should be taken to achieve a "sustainable" future.

U1-24 Orale Pirro, Mario

10.1474/Epitome.04.1046.Geoitalia2011

A WAY OF MAKING GEOETHICS IN THE CONTEXT OF HIGH SCHOOL THROUGH SPECIFIC "EDUCATIONAL PROJECTS"

PIRRO Mario¹, SAMMARINO Paola², FELICCI Antonio²

1 - INGV

2 - ITS Geometri "E. Fermi" (Tivoli - Roma)

Presenter e-mail: mario.pirro@ingv.it

Key terms: didactics; ethics; outreach

With no doubt the work of the geologist, both as a public employee and as a freelancer, is to be carried out through actions in line with the ethical rules that directly affect the problems involved.

In this regard, the recent reform of High School in Italy provides for a new organ, called "scientific committee", as part of its structural reorganization. It has the aim of proposing to the students of each institution some educational activities, targeted to the deepening of the disciplines tackled during the studies and to the inclusion of young people into employment.

In this context, the geologist can certainly give a scientific contribution based on his geo-environmental knowledge and his direct experience acquired over time. This could allow him to develop "educational projects", carried out over a three-years period, so that the students are able to acquire important knowledge about various topics related to Earth Sciences (e.g., on environmental hazards, etc.).

In this session we will present the geo-didactic project started at the ITSG E. Fermi in Tivoli (Rome), centred on the rediscovery of the "Lapis tiburtinus", from its formation to its use throughout history.

SESSIONE U2

Scienze della Terra e didattica: verticalità, didattica laboratoriale e contesto di senso

U2-1 Orale Occhipinti, Susanna

10.1474/Epitome.04.1047.Geoitalia2011

EARTH SCIENCES AD SCHOOL: "VERTICAL" CURRICULA, , "HANDS ON" PRACTICES AND CONTEXT OF MEANING

OCCHIPINTI Susanna¹

1 - Assessorato Istruzione e Cultura Regione Autonoma valle d'Aosta

Presenter e-mail: s.occhipinti@regione.vda.it

Key terms: "vertical" curricula; "hands on" practices; context of meaning

The teaching-learning process of Earth science needs to be strongly supported by different tools. Teachers' community must give a greater attention to scientific curricula, passing by a careful choice of knowledge, a graduated vertical develop of levels and of scientific languages, a planned use of tools and methods.

Earth science curricula are characterized by a lack of identity and are often overshadowed by the life and physical sciences; Earth science topics are spear into geography, history, and even biology. It is necessary to give them more coordination and relevance: not only Plate tectonics but also meteorology, cartography, hydrology, Earth history and evolution, even pollution and energy, and Environmental education are related subjects.

Then it is possible to develop a curriculum where levels and standards are well organised and structured, where the necessary, progressive and growing knowledge is proposed at each level of education, in a not repetitive and constructivist way, with the main goal to understand the complexity of Earth system. To obtain this result we need good materials and tools and to teach in a more effectively way. Each subject needs appropriate instruments to be teach and learned. It is well known, and widely demonstrated, that these instruments are nowadays oriented on teaching methods based on hands-on experience on the inquiry (Inquiry-Based Science Education) and the use of the problems (Problem-Based Learning). A collection of Inquiry based instrument for Earth sciences, either with rough materials or with specialised instruments, with already known protocols or, if possible, by new ones. The goal is to find out the more effective experimentations, discoveries, protocols, approaching methods to teach knowledge, to promote students' abilities and to build competences and scientific literacy. It can be interesting also to propose good instruments to evaluation and to certificate acquired skills, for all level of education, to prepare to university skills: the impacts on student learning must be adequately evaluated.

A network of teachers with a Earth science formation, who are, for their cultural shape, well oriented in a "scientific working method", in a "scientific habits of the mind," and "inquiring from evidence" could work together to supports a dissemination of good practice-teaching and to improve a sensibility, even a "passion" in students towards Earth sciences subjects: a stone is not only a rock samples, but also a document of physics and chemical evolution, a mineral is a "living" object, rich of charm and of tales; a mountain is alive and changing exactly like animals and plants living on "her".

The goal is to establish strong connections between schools and the territory, in order to use the existing facilities for curricular activities, as a spread laboratory. Earth sciences have the big chance that is the most visual of all disciplines and that everyone is interested in the natural world with which we interact every day. The goal is to establish a strong connection between the school and the scientific community. For too long, research has been a priority in this community, who has spent most of its time communicating with other scientists in a language that only scientists understand.

Scientists have neglected the need to communicate with people other than themselves and first with the education system. It is essential that broader public understand the Earth science and its significance: education is the only route to achieving this goal. The challenge for scientists is to build educational opportunities that take advantage of this public interest without losing the priority of the science. We could work, in this way, to change the common idea of a complex and difficult science, up to date only in the occasion of big natural disasters, while on the contrary "it is basic to know our past, to face our future".

Presenter e-mail: luca.benciolini@uniud.it

Key terms: elementary school; conceptual changes; petrographic description

In order to investigate how children think of rock samples, what are their spontaneous ideas and their conceptual changes during qualitative description of geological materials, the Museo Friulano di Storia Naturale in collaboration with the Università di Udine submitted two classrooms of fifth grade-students to a specific test. Fortyseven students without a specific background in Earth Science but with a curriculum in object description were asked to give I) a written description of a rock sample; II) a drawing of the sample; III) a written short story about the sample.

Main results are:

A) The shape of rock piece received many attention, and careful description. Samples were identified for their external form as expressly stated in a short story: "the stone slipped and broke thus forming a new stone type";

B) Fossils or clasts in a conglomerate were considered as attached to the sample, not as the sample components;

C) Similarities were evaluated revealing in turn fabulous or interpretative intentions. As an example, in the first case sentences like "this stone is like a mouse", "it has a flavor of licorice" were reported. Interpretative sentences are: "this stone is like a mountain" "it seems a dinosaur" "it smells like a cave";

D) Geological objects as foliations, strata, laminations were reduced to a one-dimensional description and were consequently identified as "lines, strips, petroglifs";

E) Minerals correspond to any specific color seen in the rock, but any difference was recognized between color of the mineral and color of the altered sample surface;

F) About 50% of the works did not demonstrate specific correspondence between the drawing and the written description. Drawing was often more detailed than the written description. Drawing often reflected the actual sample complexity and heterogeneity. Obvious heterogeneities such as magmatic contacts were correctly represented by drawing, but they were not worth of any attention in the written description. On the contrary, written works sometimes contain careful descriptions of the clastic sedimentary process but these criteria were applied to a travertine, without any relation with observed characters.

G) Short stories were often concerning adventures in a gemstone research or catastrophic geological events (earthquake, floods, landslides and so on). All students talked about stones having human properties and skills (movement, words, feelings and so on).

According to previous researches on misconceptions in geoscience, we consider that: results A) and B) reveal how difficult is thinking of a heterogeneous object as a complex system; result D) attests the problem of a three-dimensional thinking; stories reporting catastrophic events and "human" stones (G) suggest how difficult is thinking of long and continuous evolution-events that are out of the human experience, or more in general they reveal difficulties in thinking of geological times. We suggest that drawing activities could represent useful strategies for stimulating specific skills in observing reality, comparing with previous ideas and emerging conceptual changes. Finally, drawing geological objects could introduce pupils to a holistic perspective. We also suggest that most of these misconceptions mainly depend on the lack of field and laboratory experience. By standing in front of an outcrop, drawing it, and sampling it with a hammer, the rock surface should suddenly become representative of an interior essence, not only of an external side.

FOSTERING COMPETENCES THROUGH EARTH SCIENCE EDUCATIONBIANCHI Cristiana¹

1 - Centro Formazione Insegnanti Provincia di Trento

Presenter e-mail: cristiana.bianchi@gmail.com

Key terms: competences; Earth System Science; learning

This paper will show the links between Earth Science and the competences reference grid that teachers are learning to use as a guideline for their curricula. Specifically, concerning the "Cultural Axes" provisions (Muir 2007) and the European guidelines on Lifelong Learning Key Competences (December 18th 2006), Earth Science helps develop competences related both to the observation, description and analysis of natural and man-made phenomena as well as to gaining an understanding of the concepts of "system" and "complexity". This discipline helps develop data collection skills through direct observation of natural phenomena; the data are then organized and represented appropriately, so they can be interpreted using models. This can be achieved by adopting laboratory - based teaching methods or at least active teaching methods, and by using experimental tools and approaches that help to understand phenomena and their interactions. Earth Science must be approached using cross sectional knowledge, but traditional disciplines shouldn't be ignored, as they play a key role in gaining understanding of complex interactions: the challenge teachers must face is to provide learning scenarios that bring both these aspects

into focus.

The recent introduction of a discipline called "Integrated Science" (see the Guidelines for New High Schools - 2009) in school curricula could prove useful to this goal.

MEDIA COMMUNICATION IN SUPPORT OF EARTH SCIENCE EDUCATIONMURELLI Valentina¹, CATTADORI Matteo²

1 - Linx - Pearson Italia

2 - Museo Tridentino di Scienze di Trento

Presenter e-mail: valentina.murelli@gmail.com

Key terms: citizenship; media; general communication

Out of school all citizens, both adults and the younger, more inexperienced, find in the media - tv, newspapers, the web - a source of scientific information. Over the past two years many issues related to Earth science have made the news and have caught the attention of the public by appearing on the most popular media: the earthquake in Haiti and the one in Japan, which was followed by a devastating seaquake, the scare story about the earthquake that assumedly should have hit Rome on May 11th 2011, the eruption of the Eyjafjallajökull volcano in Iceland, the catastrophe theories about 2012. This concentration of events provides a unique opportunity for all science communicators, science teachers included, to consider the amount of space dedicated to Earth science in large - scale media science communication and think about the role that this could play in Earth science education.

The aim of this paper is to offer a critical study, on a qualitative rather than on a quantitative scale, of Earth science media coverage. We believe that this could provide useful elements that, by catching students' attention and by raising their curiosity, would support educational projects which encourage scientific citizenship. A set of questions regarding both areas of communication and education, followed by a critical comparison between the two, guide the study.

THE MINERALSPAPINI Paola¹

1 - Istituto Comprensivo "Primo Levi" di Impruneta

Presenter e-mail: paolageo2000@gmail.com

Key terms: vertical Science Curriculum; crystalline habitus; amorphous state; natural processes; physical properties

This is a study based on Minerals and the active involvement of Lower Secondary school pupils, developed along a vertical Science Curriculum, where the teaching-learning of Earth Science is effectively and significantly performed through laboratory practice.

The choice of minerals, and especially crystals, is also due to their beauty: their regular shapes, their colours and transparencies are aspects that capture the students' curiosity and attention. Any crystal, no matter big or small, retains its nature and can tell its story; it's up to us learning to understand it. Last but not least, crystals are natural solids which are suitable to being studied without the claim of becoming mineralogists; pupils can work on them both in their purely geometric and chemical-physical aspects, working in contest and being actively involved in their learning process.

Due to the cross-disciplinary teaching content and all the skills involved, the path can be successfully linked to other subjects such as Technology, Geometry, Art and History.

The activities within the project called The Minerals have been shared and experienced by all Science teachers of our school who are involved on the vertical curriculum of our institution.

The purpose of this course of study is that students are aware that minerals:

- are natural substances, solid and consistent
- are the result of a natural process
- can be studied and classified according to some physical characteristics
- have influenced human history.

THE I-CLEEN PROJECT (INQUIRING ON CLIMATE & ENERGY). ENHANCING AN ENQUIRY-BASED APPROACH TO EARTH SYSTEM SCIENCE IN ITALIAN CLASSROOMSCATTADORI Matteo¹, BIANCHI Cristiana², LIONELLO Paola³, MACARIOMaddalena⁴, SCAPELLATO Barbara⁴

1 - Museo Tridentino di Scienze Naturali

2 - Centro Formazione degli Insegnanti di Rovereto (Trento)

3 - Scuola Media "Nuova Europa" I.C. Dro (Trento)

4 - Università degli Studi di Camerino

Presenter e-mail: mcattadori@gmail.com

Key terms: Cooperation; Liferay; Open Educational Resources; Climate; Energy

In the last years, the world of Italian school underwent some slow but deep transformation processes. One of the negative consequences - documented by specific studies - was the further weakening of the use of inquiring educational practices (or kinds of lessons) by science teachers. This occurred in a scholastic framework already traditionally little inclined to those.

The I-CLEEN project (Inquiring on CLimate & Energy, www.icleen.museum) was born in 2008 with the intent to react to (and contrast) this process (trend) by initiative of a staff of science teachers from different regions, all with many years' experience, coordinated and supported by the local museum, the Natural Science Museum of Trento - Trento, Italy.

I-CLEEN is a free instrument of cooperation for Italian teachers, aimed to support and enhance the practice of the inquiring education in explaining themes in range of Climate and Energy and generally about Earth System Sciences. This project is a consequence of what has been experienced and done in Italy by its creators within the Educational and Outreach program of ANDRILL (ANtartic geological DRILLing).

The core of the project is a database of resources potentially useful to a teacher preparing an inquiring lesson. These are selected by a staff

following a specific selection policy. There are also lessons ready to be used in the classrooms, prepared according to a specific editorial standard. These are composed by a paper for the teacher and a paper for the student.

The database is technically an information gateway and it is constantly enriched thanks to a job of critical research in the teachers' practices or the worthiest international educational web projects. These are published in Italian or in bilingual format (Italian-English), always through explicit authorization by the authors and under a Creative Commons license when possible.

This contribution illustrates details about this service which is on-line since December 2009 and is characterized by a peculiar use of the informatics technologies. Indeed, both the parts composing the project (site, resources database, publishers, and users) and their respective activities (editing, publishing, cataloguing, administration of web contents and users) are fully dealt by one open source web platform called LifeRay, purposely implemented for this project.

Also the undertaking and the study of international projects and reference standards were accurate and broad, both in designing and developing the service (DESIRE project - Development of a European Service for Information on Research and Education) and creating the metadata (DCMI standard - Dublin Core Metadata Initiative - and LOM standard - Learning Object Metadata, IEEE 1484.12.1 2002).

The i-CLEEN Project was recently awarded with the GOLD AWARD in the section Mathematics, Science and Technology of the new E-Learning Award 2010 contest. The competition was organized by European Schoolnet, the institution belonging to the EC and the Education Ministries of the member states, which promotes the use of the ICT in schools.

POTENTIALITIES AND LIMITS OF THE INTERACTIVE WHITEBOARD (IWB OR LIM) IN THE INQUIRY BASED LEARNING OF EARTH SCIENCES.

MACARIO Maddalena¹

1 - University of Camerino (Italy) - Science and Technology School - section of Geology

Presenter e-mail: maddalena.macario@unicam.it

Key terms: Interactive Whiteboard; teaching tools; Earth Sciences; Inquiry Based Learning

In the last few years a new multimedia device is taking place in the Italian School, as well as in other European countries. This is the Interactive Whiteboard (IWB or LIM in Italian), a powerful innovative teaching tool which is a whiteboard and at the same times also a beamer and a computer. Using the IWB, the Earth Sciences teacher of every kind of school can perform engaging lessons integrated with lab activities, in order to plan a complete inquiry-based curriculum. The multimedia resources, which are easily available in the web, are very useful in this approach. For example there are a lot of animations, applets and flash videos that can help the students in understanding some of the most difficult topics, like plate tectonics, faults origins and so on. Another very important resource is the multimedia material which is furnished by the Publishers as attachment of the textbooks in use. However, we stress the fact that the imagination and the ability of the teacher, but also his knowledge skills and expertise, are the essential elements that let the IWB become a dynamic, versatile teaching tool, which is able to help the teacher in leading effective and solid lessons. Every session can be saved, and then it can be recovered and expanded in the future. It is also possible to share the lesson with the students by mailing list, in order to perform remedial or revision activities. Moreover, this will be of great help for the students with handicap problems, like dyslexia or dyscalculia. Nevertheless, like every informatics technology the IWB has some limits. Giving the students a lot of passive information is the main risk, in fact most part of inputs are visual aid. As a consequence, possible loss of mind elaboration, abstraction power, and thinking skills might occur. This is a problem that every teacher must be ready to face. The teacher communities, which are growing in connection with the websites of the IWB proprietary brands, provide a huge quantity of prepared lessons, ready to be downloaded and to be implemented. In the same websites there are also e-learning courses and tutorials about the basic use of the instrument. In this way, the IWB may become a solid alternative partner of the well-known teaching tools of the trade, as chalk-cleaner-blackboard.

10.1474/Epitome.04.1055.Geoitalia2011

THE "GEONATHAZ" PROJECT AND THE ENHANCEMENT OF AN INTERNATIONAL EARTH SCIENCE COMPETENCE ON NATURAL HAZARDS

GIARDINO Marco¹, PEROTTI Luigi¹, CLAGUE John J.²

1 - Earth Sciences Department, University of Torino, Italy

2 - Centre for Natural hazard Research, Simon Fraser University, BC, Canada

Presenter e-mail: marco.giardino@unito.it

Key terms: Natural Hazards; cross-cultural understanding; internationalization of natural hazards curricula

Organizational frameworks for didactic activities and student mobility between didactic institutions are considered as critical solutions for enhancing student education and for strengthening international competence in natural hazards research. Particularly, geoscience partnerships among schools, university, government and private-sector institutions may offer expertise and material support for the integration of traditional field-based activities and Geomatics techniques. In this perspective, the "geoNatHaz" project develops a Transatlantic Exchange Partnership (TEP 2009-2012) in the framework of the EU-Canada program for co-operation in higher education, training and youth. The project aims to improve knowledge and skills required for assessment and management of natural hazards in mountain regions. It facilitates exchanges between a consortium of universities from European Countries and Canadian Provinces, to enhance international competence in natural hazard research.

The project promotes cross-cultural understanding and internationalization of natural hazards curricula through common lectures, laboratory exercises, and field activities. Six field courses are in program over the three-year period of the project - three in Europe and three in Canada. The course topics are: (1) impacts of climate change on natural hazards in

high mountains, (2) deep-seated rock-slope rock-slope deformation, (3) mitigation of landslide hazards in mountain valleys, (4) applications of new technologies in natural hazard research, (5) frequency-magnitude relations and risk assessment, (6) earthquake hazards and risk in mountain regions.

For development of transferable technical skills and cultural competence on Natural Hazards, a serie of supporting organizations provided their high technical value and live connections to the territories of NW-Italy and Western Canada where field activities have been performed. The GIS and Geomatic Laboratory (Geosilab) of the University of Turin and the Geotechnics and Photogrammetry laboratory at Simon Fraser University, trained participants in mapping and digital representation of natural hazards. Thanks to some "lucky circumstances", the distinction between hazard and risk and the environmental differences between Canada and Europe have been "lively" analyzed during the summer schools, without suffering harmful consequences of active instabilities. Participants in the Mount Meager area, an uninhabited sector of the Coast Mountains of British Columbia have experienced the effects of a high-magnitude hazard. Here, the second largest rock avalanche ever occurred in Canada happened just one week before the geoNatHaz field trip, leaving an available, open-air laboratory for large-slope instabilities. In contrast, geoNatHaz students could cross-examine the high-risk area of Mount Blanc: either in the upper glacial part of the mountain or at the lower elevations of Courmayeur, where natural hazards have a higher probability to cause injury to inhabitants and tourists, or damage to infrastructures.

Outcomes of the geoNatHaz project has been disseminated through the electronic and print media, results being of considerable interest not only to academics or professionals, but also to school teachers and students. Geological hazards literacy of children, young persons and adults has a deep impact on every day life and on our future. Didactic materials have been prepared for science exhibits (e.g. European Researcher's Night), where geoNatHaz results have been presented to visitors through interactive demonstrations, such as the web-GIS exploration of natural hazards in the NW-Alps and the Canadian Cordillera. The produced material could be shared with teachers for local school projects and natural science museums. Moreover, outcomes of the project could be useful to develop didactic tools for training educators and schools teachers.

EXAMPLE OF A COMPLEX MULTIMEDIA LABORATORY ON LIBYAN WATERS

GRILLO Barbara¹, MERLAK Enrico¹

1 - Dipartimento di Geoscienze - Università di Trieste

Presenter e-mail: grillo.barbara@gmail.com

Key terms: multimedia; water; chemical analysis; laboratory; Natural Sciences

A video of 25 minutes long presents a workshop held on the study of chemical and physical characterization of salt water taken in Libya. The first 10 minutes the samples resume in Libya, the second 10 minutes the school tests and the latest advice from a geologist expert in groundwater at the University of Trieste, which confirms what the students have found. The objective was to understand the existence of different water in the world and how to do basic analysis. Four classes were involved in a Scientific Liceo, two first and two seconds, with very satisfactory results. Each has returned results in classical relations and Power Point presentations. The aim was to engage students in a complex laboratory using innovative way to develop the concept of water during the course of Chemistry and Natural Sciences, as well as to assess the ability of the boys to organise themselves in the group and their learning with multimedia techniques. All activity has been taken with the camera, which remains as a reminder to boys and the school as a promoting educational tools.

BOSSOLETO: EXTREME ENVIRONMENT AS DIDACTIC LABORATORY FOR SECONDARY SCHOOLS

UGOLINI Francesca¹, MACARIO Maddalena², RASCHI Antonio¹, MASSETTI Luciano¹

1 - CNR - IBIMET (Italian Institute of Biometeorology)

2 - University of Camerino - Science and Technology School - Section of Geology

Presenter e-mail: f.ugolini@ibimet.cnr.it

Key terms: greenhouse effect; extreme environment; didactic laboratory; school

Bossoleto is a small doline located in the Siena-Radicofani basin (Tuscany, Italy). The area is characterized by high hydrothermal circulation with several thermal sites of water rich in carbonate. Close to Rapolano Terme, Bossoleto has the peculiarity to be an undisturbed biotope, where the high concentrations of carbon dioxide in atmosphere have been modifying the biotic communities and affecting the environment. Atmospheric CO₂ changes over the year and the day, however over 800 ppm during daylight and reaching in certain conditions nighttime concentrations of almost 70%. So far, Bossoleto is considered a worthy site for microbiology, geology, plant physiology research investigations. The Institute of Biometeorology has a long experience on ecophysiological research in that site and counts several collaborations with foreign institutions. Moreover, years ago, it started to carry on didactic activities with local schools due to the appreciated characteristics. Bossoleto might be considered a natural didactic laboratory to understand greenhouse effect and observe the effects of high concentrations of CO₂ on the environment with a multidisciplinary scientific approach. Geology, meteorology, ecology, botany, plant physiology, chemistry, physics are the matters linked to its features and a multiplicity of activities can be performed: scientists deepening seminars and explanations, experiments in loco or hands-on activities of longer duration. In the past didactic activities for instance, pupils run experiments on CO₂ chemical and physical properties, measured the real greenhouse effect due to the higher concentration of the greenhouse gas at the bottom of the doline, monitored the differences in growth and allocation of organic matter in plants exposed to high CO₂, compared to ambient concentration (pupils planted barley seeds in pots, they exposed half of them to high CO₂ in Bossoleto and half at school at ambient concentration), saw the effects of

high concentrations of CO₂ on plant and species distribution inside Bossoleto and on animals. To conclude, visiting Bossoleto, pupils approach to real scientific results but also get knowledge through observation, experimentation and by doing.

10.1474/Epitome.04.1058.Geoitalia2011

NATURAL HAZARDS IN THE SCHOOL OF THE VERTICAL CURRICULUM: IS THERE A LINK WITH THE WORLD OF RESEARCH ?

SOLARINO Stefano¹

1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: stefano.solarino@ingv.it

Key terms: Natural hazards; Vertical curriculum; School network; Research

Many subjects are naturally tuned to the vertical curriculum. The humanities are characterized by evolutionary steps similar to those of the individual. In history, for example, the elementary knowledge of the events of ancient history must be substituted or at least supported by the capability to critically interpret the most recent historical occurrences, developing in a vertical succession the knowledge, ability, competence, skill and control. One important exception is that of civics: it is not likely to form a well educated citizen in steps. It is possible to add details and information, for example regarding the right, in successive close examinations but since the first, preliminary approach the students must learn the rules, statutes and regulations that guide the civilian living. Earth Science is similar to civics: the future citizen must understand and take consciousness of the most probable hazards of the own territory as soon as possible, no matter if it is earthquake, volcano, chemistry or hydrogeology. The sooner he or she gets acquainted with the risk the sooner he or she will learn how to behave to protect and survive. This is the main argument against a vertical evolution of the teaching hazards in Earth Science: in fact taking of consciousness is, generally speaking, the result of a long route while in this case is the starting point, followed then by the scientific aspects and close descriptions. Since the language and level of technical details must be in accordance with the age of the students, repetition of concepts is inevitable and this is the second element against the realization of a vertical curriculum. The third element is the fact that the peculiarity and characteristics of each territory makes difficult to build up a national curriculum. It is in fact not reasonable to teach in deep details hazards that are not present in an area, but if more than one is present any risk deserve attention despite the time to devote to other scientific issues.

In the teaching of Earth Science the presence of an "expert", that is of a researcher dealing with the arguments mentioned above, can thus significantly contribute to the formation. A scientist is naturally growing by goals more than cycles, as exactly foreseen in the vertical curriculum. To transfer the research method to the school can effectively contribute to the evolution from learning student to informed citizen. In fact, in the first approach and by using a proper language, the researcher can inform and form responsible students without any real interaction with and impediment to the standard school courses, and the classes given by the researcher with remain as a standalone experience. In a second step of the educative progress, the researcher can contribute not only to a close knowledge but also to the correct mood of approaching the scientific questions by sharing the "scientific habitus" that leads any research activity.

However, the educational duty is not the main one for a researcher and it is not plausible to hypothesize the presence of a researcher at school as constant or even repeatable. Specific tools and approaches are then needed to ensure a large cooperation between research and school worlds.

In the last decade, many programs and projects have been carried out to reach this aim; these attempts have produced many books, multimedia, manuals or have consisted in innovative approaches like lending to schools semi-professional instruments or letting the students do some very basic research in order to understand the problems that researcher are daily supposed to solve.

In this presentation the details of some of these projects, already ended or under way, are discussed together with the description of how they contribute to the establishment of a network among schools.

Key terms: Beigua Geopark; educational toolbox; European & Global Geopark Network; geological laboratory; geological cartoon end comic

From 2004 Beigua Park - Geopark, proposed in the catalog of educational offerings for schools, programs devoted to Earth science. The experience in the European Geoparks Network has allowed a fruitful exchange of good practices and activities that led to an expansion of supply. Over the years there have been several collaborations with geological teaching Italian protected areas are members of CAPO (Coordinamento Aree Protette Ofiolitiche).

In particular we have developed educational tools and structures to understand the dynamics of the Earth: educational exhibits for recognition of rocks and minerals at the Information Point "Bruno Bacoccoli" near to Cogoleto, paleontology lab inside the "Visitor Center Palazzo Gervino", dedicated to the heritage paleontology of the Oligocene. There have been several publications for students: the "notebook of Rock Detective" and the comic story "Aldo's basalt". Many kits for experiments were designed and made to understand the hydrogeological process, to recognize copy without spoiling, minerals and fossils through various techniques of cast.

U2-14 Orale Marsili, Antonella

10.1474/Epitome.04.1060.Geoitalia2011

EDUCATION FOR SCIENCE: THE INGV EDUCATIONAL LABORATORY FOR SEISMOLOGY

MARSILI Antonella¹, CRISTOFARO Paola², D'ADDEZIO Giuliana¹, CASALE Paolo¹, BURRATO Pierfrancesco¹

1 - ISTITUTO NAZIONALE DI GEOFISICA E VULCANOLOGIA - ROMA
2 - ISTITUTO COMPRENSIVO "VIA TIBURTINA ANTICA" ROMA

Presenter e-mail: antonella.marsili@ingv.it

Key terms: HANDS ON; SKILLS; SEISMOLOGISTS

Teaching often favors scientific content rather than scientific methodology in order to approach specific problems and students are confused and demoralized by science teaching because they do not understand the reasons why they have to study boring and difficult scientific issues. Students believe that science teaching is far from reality, away from their interests and attractions.

Nevertheless it is very important to develop process abilities to perform investigations and to achieve conclusions.

Educators and experts assert that students learn best when they are motivated to identify a sense in the educational proposed activities.

There are many teaching methods for science: some teachers underline the importance of testing, others prefer planning, others think that is important for student to have a direct contact with researchers.

The educators' community agree to use educational laboratory activities like the experiences named "hands on" to learn science; this approach is also included in the indications provided by the Italian Educational Ministry (MIUR). Students have to simultaneously work with "their minds and hands", becoming authors of the development of their scientific experience.

The aim of this work is to discuss the INGV educational laboratory experience highlighting the educational dimension dedicated to the promotion of scientific method and robust skills to approach seismology and successively seismic hazard.

The INGV educational proposal adopts the laboratorial dimension and it is addressed to high school students. This experience enables students to build experimental abilities, to develop a critical thinking and, in particular, to use their skills. During the educational laboratory activities, small working groups of students make the necessary operations to calculate the earthquake epicenter following the same working methodology used by seismologists before the computer advent. Students work with real data collected from Italian earthquakes. They also use their own mathematical knowledge transforming them in seismological skills. Within the working groups the students use the same instruments: compasses, set square, ruler and mathematical knowledge that the seismologists used long time ago. Being "seismologists for a day" means to understand how to work in rational and scientific way, which are the problems and the related solutions, what is an acceptable error. In this framework, the goal of the INGV educational laboratory is to provide a working methodology to transform knowledge into specific skills rather than a set of notions.

5 - Universite Laval (Canada)
6 - University of British Columbia (Canada)
7 - Università degli Studi di Pisa (Italy)
8 - University of Ottawa (Canada)
9 - Dublin City University (Ireland)

Presenter e-mail: r.rossetto@sssup.it

Key terms: Environmental sustainability; student mobility; transatlantic cooperation

The project aims to train 60 scientist/engineers with emerging sustainable engineering and science principles and technical tools, and at the same time to foster cooperation and collaboration among 3 Canadian and 4 European universities.

Students will come from 3 different countries and will follow technically rich international curricula in a transatlantic exchange symbiotic experience. Planned activities include: research and industrial projects, learning emerging engineering disciplines and advanced technologies, language learning and cultural broadening.

The EU-CANADA Programme "Cooperation in higher education, training and youth" Transatlantic Exchange Partnerships finances the activities, which started on October 30th 2009 and will end on September 30th 2012. The project is wholly student-focussed and the funding requested is used almost in its entirety to fund mobility of students.

The EU partners are Dublin City University and Trinity College (Dublin, Ireland), Scuola Superiore Sant'Anna di Studi Universitari e di Perfezionamento and Università degli Studi di Pisa (Pisa, Italy), while the Canadian partners are Laval University (Laval, Quebec), University of Ottawa, (Ottawa, Ontario) and the University of British Columbia (Vancouver, British Columbia).

The project will assist students becoming technically and socially skilled when studying, monitoring and solving environmental problems worldwide. Interactive communication tools for long distance learning are also being developed.

With respect to student's technical and academic development the objectives may be summarised as follows:

- to validate institutionally and professionally international exchanges;
- to create a strong self-sustainable network of university partners by solidifying existing links and approaching universities with organisms where students can apply acquired knowledge;
- to increase, among young people, the awareness of global environmental problems;
- to provide high-level quality teaching on sustainable concepts, methods and technologies;
- to offer students new professional skills: the ability to work in pluri-disciplinary fields to treat and solve problems with holistic, integrated approaches, to be able to communicate with different levels of societal stakeholders.

With respect to student social development the objectives are:

- to promote better understanding of foreign institutions, culture and language;
- to improve the quality of transatlantic student mobility with respect to variety and quality of supervision and social interactions.

All mobility is transatlantic involving 10 students/university during 2nd and 3rd year of the project. The targeted students are undergraduates and graduates from the following backgrounds: engineering (chemical, civil, geological, agricultural and mining); sciences (biological, hydrological, geological - earth, agricultural and chemical). The trainings takes the following forms: (i) academic enrolment (ii) industrial training (iii) research training (iv) laboratory work. The organisational activities to be undertaken by the partner institutions include:

- review of courses offered and courses contents;
- harmonization of course contents, updates and integration in a global curricula;
- courses credit equivalencies among participating universities;
- network communication mechanisms;
- preparation of students before travelling;
- student mobility (for undergraduate and masters students 10 students/university);
- registration on courses 4 months duration;
- industrial/research co-supervised training (for master's students);
- gathering of academics once per year.

Expected outcomes are also to compare, improve and reach integrated teaching contents and training activities in the area of Environmental Sciences and Engineering.

Key terms: FORMAL SCIENCE EDUCATION; OUTREACH AND EDUCATION; POLAR SCIENCE; EARTH SCIENCE

ANDRILL (Antarctic geological DRILLing) is an international and integrated research project involving the USA, New Zealand, Germany and Italy. The core concept of its Educational and Public Outreach Program was to embed a group of international science teachers in the midst of the research allowing them to participate in every phase of the mission. Their primary goal was to develop effective and innovative educational approaches for the explanation of the scientific and technical aspects of the drilling program.

ANDRILL, as inaugural 2006 and 2007 drilling seasons resulted in two high-quality and nearly continuous 2400 meters of sediment cores. The Educational and Outreach, E/O program, thanks to a comprehensive cooperation between participants (teachers and scientists), spawned a list of educational projects that is still growing strong after 5 years. In Italy, this experience triggered the creation of a network of subjects and institutions, lead by the National Museum of Antarctica, who's focus is the development of a more effective and inspired approach to climate education. The main activities carried out were: (1) *progettosmilla.it*, a gem project (online/classroom) involving over 2000 students across the Italian territory; (2) the Italian version of "Flexhibit", another ANDRILL-related educational US-made project; (3) the organization for the 2011 and 2012, of a Polar Summer School for science teachers to help them to incorporate polar research in the formal education. The School will be held in Genoa from July 18-22, 2011 and free for 12 science Italian teachers. The School will select one teacher that will take part in the Italian Antarctic Expedition (2011 - 2012).

EARTHQUAKE FOR KIDS - I TERREMOTI SPIEGATI AI RAGAZZI

PACE Bruno¹, DI MARCO Stefano², FRONTERRE Annalisa², D'AMATO Davide¹, CHIODETTI Cinzia², PAGLINO Francesco², VISINI Francesco¹
 1 - Dipartimento di Scienze, Università di Chieti-Pescara
 2 - Centro Turistico Studentesco CTS - Settore Scuola ed Educazione Ambientale

Presenter e-mail: b.pace@unich.it

Key terms: L'Aquila earthquake; Earth Science; Education; Awareness campaign

The idea of the project born from the desire to (re)build trust in science and, in particular, in Earth sciences among the young people of Abruzzo, who have recently experienced in first hand the tragedy of the earthquake of 6 April 2009. As often unfortunately happens, the earthquake has caused loss of lives and destruction. But this time the rage, bafflement and indignation for what happened have had recipients details: scientists, who, in an attempt to repeat the unpredictability of the earthquake, have, and this is the accusation, reassured the citizens of L'Aquila said that there was nothing to worry about.

So the confusion that exists for the common people respect to these topics, together added at a communication error by specialists, has meant that it generated a tremendous mistake. The result is that now it more difficult, in this context, speaking in scientific terms of earthquakes.

Objectives of the project are therefore the diffusion of knowledge of Earth science among young people, particularly those affected by the earthquake of L'Aquila 2009, and restoring their trust in science and experimenting with new methods of non-formal education.

It intends to achieve these objectives through the realization of a path that includes three different actions:

Junior Conference

The Conference will take place in L'Aquila, intended for Abruzzo's guys between 11 and 18 years, and will be managed with the methodology of the simulation game. The aim is to create an opportunity to compare the ideas and knowledge involved in managing an emergency situation, like the seismic phenomenon.

A team of research and science popularize will prepare a game scenario in which will describe the characterization of an area subject to frequent seismic activity, and through which it will offer at the students a variety of input on the genesis of earthquakes, the actions monitoring, on the geology of the area, the types of prevention and the procedures of risk management.

Then the simulation will be developed through game dynamics, in which the guys, followed by some specialized operators, will make personal decisions, typical of the stages of seismic prevention and emergency management.

The final phase of the simulation require that the "actors" in the game have to prepare and share a "Plan of risk management and emergency" and propose a program for communicating to the citizens.

2) Touring Exhibition

All secondary schools of the L'Aquila's "crater" will be invited to participate at the realization of a traveling photographic exhibition that will illustrate the effects of the earthquake. Schools may send photos and / or text, which will be organized together and prepared for a traveling show that will be sent to schools and to science museums or who request it. In this way the exhibition will continue to be used even after the conclusion of the project.

3) Earthquakes for Kids Webpage

To bring in a simple and funny way the kids to the theme of earthquakes and the prevention will be created and developed a dedicated portal, combining scientific rigor clearly disclosed to explain in a simple and addictive earthquakes to children.

The main result from the project is to be able to attract young people to the Earth Sciences, and both the methodologies and the tool. But also scientific thought necessary to understand and gain knowledge in relation the natural world in which we ourselves live.

So bring the experience, even dramatic, of young people, like the case of L'Aquila earthquake victims, at the work of scientific research and making them participate in establishing a collaboration, exchange and dialogue between the world of science, sometimes very far from the new generations, and the school, often with too many difficulties to be open outside.

UNICAM_EARTH : A RESEARCH GROUP ON TEACHING EARTH SCIENCES IN THE ITALIAN SCHOOLS

OCCHIPINTI Susanna¹, SCAPELLATO Barbara¹, MACARIO Maddalena¹
 1 - School of Science and Technology, Geology Division, University of Camerino;

Presenter e-mail: s.occhipinti@regione.vda.it

Key terms: Inquiry based method investigation; vertical curricula; schools and museums

The Geology group of the University of Camerino (School of Science and Technology) has recently formed a research group whose aim is to address the teaching of Earth Sciences in the Italian schools (elementary, middle and high schools) also in the light of the recent changes of the law. The group, unique in Italy, is composed of high school teachers in Science, now PhD students in the curriculum Earth Sciences, as well as Geology researchers and the curators of Unicam Museum of Natural Sciences.

The purpose of this research group - named UNICAMearth - is to produce and experiment new activities and resources for the schools by using the Inquiry Based Science Education (IBSE) teaching approach. This approach follows the recommendations of the Rocard Report of the European Commission (2007)

The UNICAMearth group is focus to become a reference point for the Earth Sciences teachers in the Marche region and in Italy. The PhD projects in particular will concentrate on the relationship between school and research, with the aim to help the teachers to use the IBSE method and to promote active collaboration between school, museum and university. As a service for the school and the territory, the UNICAMearth group will promote seminars and working groups, stages and training courses, museum and laboratory activities in order to create a network of sharing best practices.

A mailing list will be available to the teachers and everyone is interested in joining the UNICAMearth group and the Geology web site (www.unicam.it/geologia/unicamearth) will contain all the information and the resources produced.

MOTHERSHIP EARTH

COLLI Angela¹, PNUCCIA Spadaro²
 1 - ANISN PAVIA
 2 - head of CREA, the Municipality of Pavia

Presenter e-mail: luriboni@libero.it

Key terms: cooperation; Global World; energy sources; teaching-learning style; WebQuest

To ensure the preservation of life on earth we must recognize that 'we are all on the same boat' (with no distinction between different areas and countries): for this reason we must identify the problems and aim to solve them through far-reaching policies and shared goals. C.R.E.A. (Reference Centre for Environmental Education), sponsored by Lombardy District (Italy), represents a reference point for planning and implementing activities about environmental education. Different projects and activities are offered to the citizens of Pavia: the aim is to share good practices to promote a better lifestyle. CREA has worked for many years together with teachers and with schools of all levels located in the Municipality of Pavia. During the Academic year 2010-2011 CREA planned and realized "MOTHERSHIP EARTH": a project in cooperation with the ANISN section of Pavia in the first two classes of a high school and in the third of a middle school of the town:

Objectives:

° Develop knowledge and skills necessary to live in a Global World. Promote changes in attitudes and behaviour, both at individual and collective level.

° Spread the awareness that major issues currently affecting mankind can be tackled and solved through close cooperation not only between countries but also between various disciplines and cultures. Working arrangements and themes.

Since the 1980s, science has changed its approach in dealing with environmental phenomena, from a linear logic, based on Aristotelian-Galilean paradigms, to a systems theory, which is associated with the complexity theory. Edgar Morin defined ecology as 'the first new science able to tackle the relationship between life and death, science and conscience and between mankind and nature, above and beyond the simplifying thought that hid vital issues from us for such a long time' (E.Morin, 1990).

With the new generations of "digital natives" we need to overcome the traditional way of teaching. We should be aware that our students may use their brain in different ways and have a range of learning styles: by using a variety of presentation, activity and assignment we can appeal to

this diversity.

In our project we adopted an "active" research-based teaching-learning style to bring young people to reflect and act on issues of vital importance for the future, including protection of the territory and sustainable development. We looked for information together with students in a critical way to design and implement daily activities. The themes were chosen along with the classes participating to the project and focused on problems relatives to different energy sources' uses and to their impact on the territory. After the accident occurred in Fukushima students interest focused especially on "nuclear energy".

Every class realized a WebQuest: an inquiry-oriented lesson format in which most or all the information that learners work with comes from the web. Students critically evaluated information they found about the subject they had chosen and designed actions using information gathered. Times.

° 1 hour: meeting with teachers to present the project and to choose the theme for the webquest to realize with the students;

° 1 hour: meeting for presentation and setting of the class;

° 2 hour meeting in the school computer laboratory to develop the WebQuest;

° final event (conference, event) for public presentation of the products realized by the students.

Results

WebQuest influenced students' learning performance positively. For the future we will implement the project, proposing the realization of outdoor WebQuest: in real situations, students could acquire much more knowledge and experiences, with the aim to improve their lifestyle for the health of our MOTHERSHIP EARTH.

DIVULGAZIONE VS TELEVISIONE

TOZZI Mario¹

1 - Consiglio Nazionale delle Ricerche

Presenter e-mail: reserve@islepark.it

Key terms: divulgazione scientifica; televisione; audience

Quanti si fermerebbero a leggere di faglie o di fotosintesi clorofilliana o di funghi in genere, se non venissero confezionati all'interno di una storia? Questa considerazione sembra basilare per qualsivoglia intervento scritto o parlato che si prefeggia lo scopo di divulgare le scienze della natura: altrimenti quale pubblico si interesserebbe perfino a decaloghi per un miglioramento ambientale futuro, se non ci fossero storie da raccontare? Sono storie ben note a chi si occupa di scienze della natura, ma mentre di alcune si può ricordare lo spunto o l'autore, altre si perdono a tal punto in quel patrimonio collettivo di sapienza e coscienza da nascondere definitivamente la fonte. Di tutto questo geologi e naturalisti possono e debbono essere i raccoglitori e i divulgatori.

Ci si può domandare se filtrare "scienza" attraverso i mezzi di comunicazione di massa perché arrivi a un pubblico a essa generalmente estraneo comporti un costo accettabile in termini di rigore scientifico oppure no. Il rischio c'è --ovviamente-- ed è grosso: con l'abbandono progressivo dell'intento pedagogico il *senso scientifico* tende a collimare sempre più facilmente con il *senso comune*, come dimostra il contemporaneo abbandono --per esempio in televisione-- dell'esperto-conduttore a favore del conduttore di provenienza extra-scientifica. In contesti di questo tipo c'è il pericolo di un "ripiegamento" negativo della scienza su se stessa, una chiusura che non permetta un accrescimento delle conoscenze e che, d'altro canto, non induca neppure una maggiore spendibilità quotidiana delle informazioni scientifiche.

Saremmo cioè alle solite: la divulgazione che diventa intrattenimento televisivo a discapito dei suoi stessi scopi (ma sono mai stati ben definiti e/o ha un senso farlo?) non incrementa la cultura scientifica --in questo paese cronicamente latitante-- e, anzi, si traduce nel sacrificio della scienza sull'altare del dio barbaro dell'*audience* a ogni costo. Ma, d'altra parte, è giusto lasciare lo spettatore senza quei dubbi, quei veri e propri errori che stanno alle spalle di molte affermazioni scientifiche, legandolo ai meccanismi di causalità lineari in grado di attrarre maggiore interesse dei problemi di fondo? La versione cinematografica del Giurassico crichtoniano, con le annessi ricadute televisive, ha portato comunque vantaggi in termini di divulgazione, al di là del richiamo spettacolare e della rappresentazione drammatica e largamente inesatta dell'estinzione dei dinosauri. D'altra parte il pubblico delle trasmissioni scientifiche televisive è composito, fatto anche di giovani colti, o almeno curiosi, di esperti di settori affini (o distanti), di potenziali lettori di libri a carattere scientifico non necessariamente divulgativo, pubblico che non dovrebbe essere privato neanche di quelle spiegazioni circostanziate che meritano certe eccezioni alla "regola" difficili da spiegare anche per gli stessi scienziati.

Potrebbe però esistere una terza via fra l'eccessiva semplificazione che produce deterioramento del patrimonio di conoscenza scientifica e la divulgazione astrusa che serve solo a comunicare fra esperti, non aumenta la base di pubblico e di interesse e non produce nessuno sviluppo culturale diffuso. Si può recuperare l'eguaglianza informazione-intrattenimento che, si dimostra nel libro, produce i risultati migliori in termini di divulgazione, allargamento della fascia di pubblico interessata e gradimento. Non mettere in difficoltà chi ascolta la scienza divulgata e insieme esprimere il *senso comune* può essere fatto anche senza quell'arrocamento della scienza, a cui pure tante volte si è assistito. Soprattutto quando l'obiettivo non è quello di formare degli esperti scienziati, ma quello --peraltro non meno difficile-- di fornire chiavi di accesso ai principi-base, aggiornare le conoscenze e suscitare un interesse anche in chi, a quella data fascia oraria, avrebbe guardato *telenovelas* o *chat-shows*.

SCIENCE COMMUNICATION AND THE WEB 2.0: A NEW OPPORTUNITY.

CURZEL Elisabetta¹

1 - Museo tridentino di scienze naturali

Presenter e-mail: elisabetta@gmail.com

Key terms: communication; web 2.0; social network; internet

Is there any place for science in the participatory web? Social networks - an instrument of entertainment, sharing, and information that engages millions of people all around the world - have been pushing scientific communicators to ask themselves this and other questions, such as: how is it possible to handle scientific information in the Internet? How can we make it recognizable? How can we create a reputation of trustworthiness? Several institutions have recently signed up to create "profiles", i.e. virtual identities, on some of the most used social networks such as Facebook, Twitter or YouTube. Followed by thousands of fans, they can be conceived and managed as channels of broadcasting, complementary to the traditional press offices, or as platforms of discussion and dialogue. Handled with care and accuracy, the web 2.0 can be a precious instrument, in the service of scientific culture: a source to question to better know the territory, its characteristics and its risks; a virtual place for intelligent and informative entertainment; a way to ease the access to specialized or generalist websites devoted to science communication.

10.1474/Epitome.04.1068.Geoitalia2011

HOW TO COMMUNICATE PALEONTOLOGY - THREE DIFFERENT INTERACTIVE EXHIBITIONS AT THE NATURAL HISTORY MUSEUM OF THE PISA UNIVERSITY

LANDINI Walter¹, BIANUCCI Giovanni², SORBINI Chiara¹

1 - MUSEO DI STORIA NATURALE - UNIVERSITA' DI PISA

2 - DIPARTIMENTO DI SCIENZE DELLA TERRA - UNIVERSITA' DI PISA

Presenter e-mail: landini@dst.unipi.it

Key terms: PALEONTOLOGY; NATURAL HISTORY MUSEUM; INTERACTIVE EXHIBITIONS; VISUALLY IMPAIRED ACCESSIBILITY

In the past few years the Natural History Museum of the Pisa University widely renewed its own paleontological exhibitions thanks to a CIPE grant, obtained in 2002. In just eight years three new permanent exhibitions have been opened: "Back to the Past - a 500-million-year trip to Monti Pisani" in 2006; "Dinosaurs in the Charterhouse" in 2008 and "Archaeocetes - Cetaceans of Land and Sea" in 2010.

These three exhibition paths, although different from one another, are joined by the search for new ways of Museum communication, aimed to transmit the scientific contents thought directed involvement, interactivity and multisensoriality.

The first exhibit, in order of opening, explores the geo-paleontological evolution of the Monti Pisani and its founding idea is the full-immersion of the visitor in the topic dealt, through the novelistic tool of the "trip in the time" materialized in a steel and glass footbridge. This time path passes through three rooms completely transformed in scenarios of a far past: three open dioramas dedicated respectively to the Monti Pisani in the Permo-Carboniferous, in the Triassic and in the Pliocene succeed one another in a sequence, both physical and temporal, encircling the visitor first in a tropical rainforest, than in a wide coastal desert and finally in an underwater landscape populated of giant sharks, seals and dolphins now extinct.

The reconstructions speaks by themselves, just helped by some few original specimens and by a touch screen monitor available to provide additional information and generating the background sounds of the different environments.

In the exhibition dedicated to the dinosaurs from Patagonia, on the contrary, more classical models, as the large skeletons of *Amargasaurus* and *Carnotaurus* exposed in the external courtyard, have been melted with elements that recall the temporal narration of the Monti Pisani exposure, as the large window that opens on a past of 80 million years ago. But it is interactivity to represent the main topic of this exhibit. In fact in the central part of this path the story of a fossil has been physically reconstructed from the moment of its discovery in the field to its exhibition in the museum, through all the various phases of excavation, restoration and duplication. This last sequence is shown in the real paleontological laboratory of the Museum, through windows that, when a technician is working in the lab may be completely opened, deleting any barrier between the truth of the exposed action and the visitor.

The exhibit dedicated to the archaeocetes differs from the others because projected according to some concepts of the universal design. This makes it suitable to visually impaired people but also winning for all the other categories of visitors, allowing an access to the information not only visual but above all tactile and sonorous. In this exhibition all the elements are disposed along a linear path, placed close at hand on a raised platform bordered by a guide leading the visitor and evidencing, through tactile marks, the presence of objects to be touched or buttons to be pushed to activate the audio sources.

Besides the search for new exposure modalities, another element joining these three exhibits is their being place of didactic workshops. The Natural History Museum of Pisa, in fact, follows the modern theory according which its rooms should be places where "to stay interacting" more than "to cross just watching". In particular the exposures dedicated to dinosaurs and archaeocetes have been equipped with didactic spaces dedicated to children 3 to 7 years old where the information to be learned becomes game experience through both activities and didactic supports especially realized for this purpose and also using the elements of the exhibit that, in this way, becomes more comprehensible and communicative.

10.1474/Epitome.04.1069.Geoitalia2011

THE NEW SCIENCE MUSEUM OF TRENTO REGION: GEOSCIENCES AND SUSTAINABILITY IN THE MUSE PROJECT

LANZINGER Michele¹, LAURO Claudia¹

1 - Museo delle Scienze (Trento)

Presenter e-mail: michele.lanzinger@mtsn.tn.it

Key terms: International museology; Science and society; Lifelong learning; Geoscience communication; Planetary sustainability

In 2013 in Trento a science museum of latest concept, one that integrates nature, science and technologies, with attentive eye on ethical and social issues, will open to the public. The museum will tell the natural history of the Dolomite region and gradually wide to reach a planetary scale, linking the local natural heritage and research expertise to the most important achievements of science.

The MUSE (Museum of Science) will thus be a combination of natural history museum, science museum and science centre. The building, designed by Renzo Piano, will rise in a former industrial area, within a context of urban re-qualification, promoted by the Municipality of Trento. The MUSE represents the result of the Museo Tridentino di Scienze Naturali development which yielded, in the last 18 years, many successful cultural and educational initiatives and remarkable results in the naturalistic research of alpine ecosystems, Earth Sciences and Prehistory. The basic idea of the new museum is the relationship between the alpine natural environment and the planetary sustainability, through a "glocal" approach. The sustainability and the topics related (energy, resources, climate, water, nature conservation, natural hazards, transport...) play a special role and also inspire the architectural plan of the museum. The MUSE building displays a mountain skyline profile and the exhibition area is made up of two portions: the taller is dedicated to Alpine themes, on a journey from glaciers to the valleys floors, and to the mountain land modifications produced by the human action; the wider area, on the lower floors, deals with the global relations between Science and Society. The topic of Geosciences and its relation with sustainability are present in different exhibition floors. On the 4th floor peaks and glaciers of alpine landscapes are encountered. This section shows the state of health of glaciers and its importance both for the mountain's people and for the global climatic system: they are susceptible to climatic variations, a fundamental fresh water resource and contribute to the production of hydroelectric energy. The 2nd floor is almost entirely occupied by Alpine geology and Dolomites are paid of special attention. The Quaternary glaciers let to describe climate change in the past and how it modified the Alpine landscape and ecosystems. Then the natural geomorphologic evolution of this territory, increased by several anthropological factors, introduces the theme of geological risk and landscape's vulnerability and protection in Trentino, focusing on some processes, like landslides, floods, avalanches and earthquakes. Moreover the specificity of some minerals and rocks of this area introduces the theme of the thousand-year relationship between Man and Earth's resources. The 1st floor presents the ancient human settlers in the Alps. The land use and the anthropic impact on the alpine environment from the late glacial to the present is also exposed. The use of land to yield goods and services is infact the most substantial human alteration of the Earth system. In this way the concept of sustainability, green footprint, natural system resilience are introduced, linking the historical perspective to the contemporary and global overview presented in the following gallery. At last the basement hosts an exhibition on the story of Planet Earth, starting from its origin within the Solar System. It focuses on evolution of animal and plant life on Earth, through their fossil evidences. All the concepts above will give life to an exhibition made up of natural objects, multimedia, hands-on exhibits and also of scientific laboratories open to the public, where visitors can meet researchers. A museum designed around its visitors, for various reasons: to have a wide appeal on citizens and tourists, to families in particular; to be a major partner in support of school education; and finally to be renown for its benefits in terms of lifelong learning.

U3-8 Orale Pratesi, Giovanni

10.1474/Epitome.04.1070.Geoitalia2011

FOR AN AESTHETICS OF SCIENCE: NEW EDUCATIONAL FORMULAS IN THE EXPERIENCE OF THE NATURAL HISTORY MUSEUM OF THE UNIVERSITY OF FIRENZE

PRATESI Giovanni¹

1 - Museo di Storia Naturale - Università degli Studi di Firenze

Presenter e-mail: g.pratesi@unifi.it

Key terms: Aesthetics; Science; Mineralogy; Museum; Exhibition

Historians of science have not given much attention to the role of passion in science. As a matter of fact, there has been an implicit acceptance of a sharp dichotomy between the two cultures of reason and passion. Starting from such dichotomies - and going through the Goethe's fascination with the mineral kingdom - we will analyze the experience of the Museum of Natural History of the University of Firenze where the promotion of the mineralogical collections is passed through a comprehensive and thorough renovation of the exhibition, solutions museological and educational proposals. At the same time was made an innovative exhibition, in which there are specimens belonging to the Collection Adalberto Giazzotto, which complement the scientific and didactic proposals with a merely aesthetic proposal. The mineral collection of the Natural History Museum of the University of Firenze - containing over 50000 specimens - ranks among the world's finest due to its very broad representation of rare species and large number of specimens described in the scientific literature. Furthermore, the presence of holotypes, Island of Elba collection and pegmatite minerals from Brasil make known this Museum to all collector. In order to give a greater visibility at the about 800 mineral specimens on public view, the Mineralogical Section deserved a new exhibition which has been projected by Arch. Piero Roberto Papi. At the entrance, the visitors are welcomed with an amazing view of the best specimens from the Ponis collection and an exciting display of back-lighted thin slices of agate and liddicoatite. Showcases on meteorites, lithology, crystal growth, polymorphism, pseudomorphism, crystal chemistry, crystallography, physical properties, mineral deposits and use of minerals and rocks add to the educational and visual experience. Finally the systematic collection shows over 200 beautiful specimens, from all over the world, arranged according to their structural and chemical properties. On the other hand, thanks to the sponsorship of the "Ente Cassa di Risparmio di Firenze", the notable Giazzotto collection - including about 550 specimens of large crystallized minerals collected and selected for their exceptional aesthetic quality - has been transferred to the Natural History Museum as the "Cristalli" exhibition. The layout, the showcases (projected by Arch. Guido Spezza e Giancarlo CATALDI), the lighting system and the organization of the specimens enhance the spectacular quality of the specimens and the emotional impact of their wonderful array of shapes and colors. The exhibition includes a sequence of four halls: the first, named "The Treasury", is the largest and cannot fail to impress the visitor with its beautiful arrangement of specimens of all shapes and colors; the second, "The Italian collection", shows remarkable specimens from some of the most famous Italian localities; in the third and in the fourth halls, respectively "Masterpieces 1" and "Masterpieces 2", exceptional specimens are exhibited in individual glass cases. The rearrangement of the Giazzotto collection is very important from the point of view of the conservation of natural heritage. Large perfect crystals

are absolute rarities that must be preserved for the future generations both for their beauty and for their scientific interest. The show in the end, means to open a reflection on the concept of "subsurface ecology". Most of the crystals in the show, actually come from exhausted mines. It is quite evident how the growing demand of the world economy for energy and raw materials, is driving to a rapid and generalized exhaustion of layers and mineral resources.

TRAVELLING EXHIBITION, A WAY TO DISSEMINATE THE KNOWLEDGE ON POLAR SCIENCE

OSSOLA Carlo¹

1 - MUSEO NAZIONALE DELL'ANTARTIDE

Presenter e-mail: carlo.ossola@fastwebnet.it

Key terms: OUTREACH AND EDUCATION; POLAR SCIENCE; EARTH SCIENCE

The Italian Antarctic Museum (MNA) has organised 2 travelling exhibitions to attract the interest of public, media and mainly students and make them awareness of the role that Polar Regions play for our Planet. This purpose was coherent with the mission of MNA of training a new generation of researchers and technicians specialised in polar science. The first exhibition was mainly scientific; the main goals were to show to the public the Italian and International research in Antarctica and to describe how interesting is, by a scientific point of view, the most remote and wild land in the Earth. Posters, interactive exhibits, clips, geological and biological materials collected in Antarctica, helped visitors to learn about the main biological, geological and physical features of the continent.

The second exhibition was an outdoor photographic exhibition that carried the visitor through Antarctica's spectacular landscapes. The project was curated by Carlo Ossola and Lucia Simion, photographer and science writer. 40 breathtaking images told a story about the different kind of ice, on the life over and under the sea, on the living and working conditions. Both exhibitions were made in order to be easily transported, quickly assembled and dismantled and with low costs for the institutions (museums, schools, Municipalities, etc.) interested in host them. The scientific exhibitions had been hosted in many cities in Italy (Palermo, Rome, Rovereto, Bergamo, Piacenza, Forlì, Rieti) but also in Warsaw, Budapest, Alexandria in Egypt.

In each venue Museum's curators trained local guides so that they were able to explain to visiting students the main features of Antarctica and the scientific topics. In some venues Museum organised conferences with antarctic researchers or videoconference with Italian Antarctica's research stations.

In the last venue located at S. Agata di Militello - Sicily, we tried another way to speak to classrooms. The Museum with the collaboration of local Institutions such as Rotary International, Municipalities, Schools, organised meetings with teachers from the Provincia di Messina in order to show them topics and aims of the exhibition, give them instruments and educational materials. In this way, they explained students about the main features of Antarctica and the Italian research and prepared them to the visit.

Afterwards we trained about 30 students from some scientific departments of the University of Messina so that they could work as guides during the classroom visits at the exhibition.

And it has been really a success! More than 3000 students visited the exhibition during 20 days.

U3-10 Orale Celi, Monica

10.1474/Epitome.04.1072.Geoitalia2011

AWARENESS RAISING AND EDUCATION IN THE FRAME OF THE EUROPEAN LANDSCAPE CONVENTION: THE ROLE OF MUSEUMS

CASTIGLIONI Benedetta¹, CELI Monica²

1 - Università degli Studi di Padova

2 - Museo di Storia Naturale ed Archeologia di Montebelluna (TV)

Presenter e-mail: direttore@museomontebelluna.it

Key terms: European Landscape Convention; Education on landscape; Museum

The European Landscape Convention (proposed by the Council of Europe and open for signature in Florence, on 20th October 2000) represents nowadays an international reference point for research, action and education on landscape. Landscape is defined as "an area, as perceived by people, whose character is the result of the action and interaction of natural and/or human factors"; the Convention aims to safeguard, management and planning of all landscapes in Europe (not only the exceptional ones), through the implementation of policies and the involvement and of local communities, subjects of rights and responsibilities. The first specific measures (art. 6, a and b) provide awareness raising and education of a large public, in order to increase people's knowledge of landscape dynamics and their attitude towards landscape values.

Starting from some experiences of education on landscape in school contexts - at different levels - the authors present its main targets and features. Education on landscape concerns all these three aspects: intellectual education (knowledge oriented), emotional education (finding out about the feelings and values) and motorative education (knowing about doing, how to practice) (Pedroli and Van Mansvelt, 2006), in the perspective of education on sustainable development. From a methodological point of view, landscape literacy is firstly aimed to achieve the ability of reading the landscape as a basic step in an interdisciplinary approach. Different levels of deepening knowledge on some landscape aspects (natural as well as human ones) can be then proposed.

Theoretical and practical suggestions and recommendations are available in the guidelines "Education on landscape for children", edited by the Council of Europe.

The project 3KCL - Karstic Cultural Landscapes carried on in 2004-05 by the Museums of Natural History and Archeology of Montebelluna, in the frame of the Culture2000 program, represents a best practice in education on landscape. It was aimed to deep knowledge on karst landscapes and to

disseminate this knowledge to a large public, through a strong involvement of school children. The Museum played a very important role in this project as a cultural mediator among research world, school world and the wide public.

In general, museums can play an important role concerning education on landscape. They conserve the natural, historical, ethnological, artistic etc. elements of an area and of its landscape; moreover they co-operate directly in the research with university and other research agencies, to study the collections and the landscape itself; finally, museums use this achieved knowledge and information in formal and informal educational contexts.

The museums are indeed strategic and fundamental places for the educational processes; billions of people, adults and children, young and old people, students and families, visit exhibitions, participate to conferences, experiment in laboratories, study in museums' libraries. Museums can therefore play an important role in promoting positive cultural dynamics, particularly proposing debates and discussions about our history and future. All museum's activities (research, conservation, education, exhibitions and communication) can help in achieving these aims, in raising awareness and in promoting the change of attitudes. Museums are special places to discover and interpret the yesterday's and today's landscapes and to design with awareness the future.

EARTH SCIENCES EDUCATIONAL EXPERIENCES: OBJECTIVES, APPROACHES AND EVALUATION AT THE SCIENCE MUSEUM OF TRENTO.

BERTOLINI Maria¹

1 - Museo delle Scienze - Trento (ITALY)

Presenter e-mail: bertolini@mtsn.tn.it

Key terms: geosciences education; museum education; pedagogical approaches; evaluation

The Museo delle Scienze is actively working in the education area for about 18 years, involving an yearly through its activities and educational projects almost 62,000 people coming mainly from the schools of the Province of Trento and the nearby regions. The number of educational activities in the field of earth sciences are about 40 and pick up each year about 5,000 users (8% of total users). The types of activities are diversified in subject, length of time, location: they range from educational workshops, excursions in the natural environment, the projects, the thematic visits to the permanent and temporary exhibitions, lecture and talk and training courses for teachers.

The project aims to make a digression on the educational proposals in the field of earth sciences, illustrate the types of proposals, the cognitive, affective and operative objectives, tools, exhibits and materials used, methods and educational approach adopted. It will reflect on the strengths and weaknesses identified during twenty years. Will present the general data, the trend, evaluation made through the questionnaires of satisfaction to teachers and referents of the participating groups. Finally, we will focus on the educational work of Explainers: the selection and training procedures adopted by the museum to further develop their professional, communication, educational and relational skills. The data and information collected over time allowed to define some guidelines to be adopted in the design and implementation of educational proposals, and identifying the duties and skills required as a basis for educational work in museums.

2 - Museo Civico di Scienze Naturali, Geologia - Bergamo

Presenter e-mail: apaganoni@comune.bg.it

Key terms: didactics; water; kits; music

The researchers of the Institute of Geology of Bergamo Museum realized coordinated activities to support the International Year of Planet Earth. Some experimental laboratories into a museum open to all visitors and attended by more than one hundred people, the production of a music DVD connected with water, the realization of regional meetings, were steps of this project but the main effort was in the school. It was designed, distributed of a handy kit in primary schools. It was very appreciated and used mainly in schools without laboratories or educational collections.

The minilab was produced in the form of an easily transportable box with tools and instructions that allows 20 experiences directly in the classroom to understand the significance of physical and chemical water. The kit has been designed and implemented on an experimental basis by the researchers of the Museum, in charge of the educational activities. These experts have introduced hands-on approach that leads students accompanied by teachers to learn through experimentation making direct observations and experiences

Thanks to the help of Soroptimist International 132 kits were gift to all primary schools in Bergamo and it's Province.

The case contains the cans, pipettes, test tubes, deionized water, salt and sand, a thermometer (-20C +100C) and many others tools.

AN "OUTDOORS LABORATORY" IN THE EARTH SCIENCE DIDACTICS AND EDUCATION: THE EXAMPLE OF THE "ARDITO DESIO" GEOPALEONTOLOGICAL MUSEUM OF ROCCA DI CAVE (PRENESTINI MOUNTAINS, LATIUM)

GROSSI Francesco¹, AMADORI Chiara¹

1 - Dipartimento di Scienze Geologiche, Università degli Studi Roma Tre

Presenter e-mail: fgrossi@uniroma3.it

Key terms: Apennines; Upper Cretacic; museum; geosite; didactics

The "Ardito Desio" Civic Geopaleontological Museum of Rocca di Cave (Rome) is located at the southern Preneptini Mountains, and its geopaleontological collections are strongly connected to the territory. The Rocca di Cave area has a great paleoenvironmental and paleogeographic

significance since it stands out as the westernmost end of Upper Cretacic neritic "laziale-abruzzese" shelf facies. Furthermore, it is the almost unique witness for the presence of a Cenomanian-Santonian edge in the western part of the shelf, whose fossil reefs were characterized by typical associations with dominant bivalves (rudists and others), gastropods, corals, sponges and rare sea urchins.

The safeguard and the enhancement of the Rocca di Cave geopaleontological heritage is implemented by several initiatives and structures linked to the "Ardito Desio" Museum, dedicated both to the younger visitors and to general public. For school classes, in the Museum there is an oral presentation together with direct, reaching a higher involvement and pointing to a much wider interactivity. Last year, more than 4000 visitors (mostly school classes) have crowd museum's rooms, in a tour designed as an imaginary travel back in time through subsequent jumps, from recent to Pangea supercontinent age, with detail to the Upper Cretacic. The integrated approach is powered by the presence of 3D-reconstructions and palaeogeographic globes, adding to the theoretical multimedia lessons and several posters. The direct observation of the territory and its morphology is enhanced by the 360°-view obtained from the Rock's tower: that allows visitors, not only the little ones, to correlate the observed landscape to the morphologies and, with the next step, to the geological meaning. Apennine reliefs, Albani Hills volcanic district's deposits, Campagna Romana, all the visible landscape elements, accompanied by most relevant toponyms, are reported in a strip placed on all the terrace perimeter.

The guided tour doesn't stop inside the museum, it continues along a series of geopaleontological paths evidenced by signs, all of them around Rocca di Cave. A real outdoors interactive laboratory, where visitors can touch rocks and fossils: the children were driven to an active participation and to a full involvement. This goal is facilitated by the materials given to the visitors that also include drawings, explanatory notes referable to the paths; a part of the graphic products is dedicated to elementary school and based on comics: representing fossils as protagonists of funny episodes allows children to approach an unknown world with elements which they growing up every day together. In the near future, it's planned to improve both the didactic material dedicated to the outcrops, and the number of paths. Among the new projects there is the first issue of the scientific journal linked to the Museum, "I Quaderni del Museo", intended for distribution in schools and for a general audience. The journal provides insights on topics closely correlated to the Rocca di Cave geology, a further interpretative key of the natural environment, besides divulgation columns and general geological interest topics. Again, particular attention is directed to younger readers, with a central double page full of games, cartoons and comics.

The geosites conservation and the knowledge organization in museums should be flanked by the growing attempt to approach both adult citizens and younger one to the Italian natural heritage, thus to educate citizenship much more responsible, mature and careful to environmental respect and to its history.

4 - Istituto Statale d'Istruzione Specializzata per Sordi "A. Magarotto", via Callegari 6, 35133, Padova

Presenter e-mail: rossana.todesco@mtsn.tn.it

Key terms: earth science divulgation; educational path; visual and hearing impairment

For many years Museo delle Scienze has been investing on scientific communication experimenting new divulgation way to create a dialogue among nature, research and society. Reaching more categories of visitors and give them a chance to understand and thus appreciate the geological treasures of the Dolomites, broadly speaking means to approach them to the Earth sciences, to build a dialogue on the basis of purely scientific matter close to everyday life and to face issues of strategic importance as land management and exploitation of resources. Starting from this year the Museo delle Scienze wants to approach in a constructive way also to the disability world with the purpose of involving people with difficulties in the sphere of communication such as the blind, visually impaired and the deaf. This is to facilitate the integration into the cultural fabric of a marginal band, but not negligible, of the population through the vehicle of culture. Thanks to a sponsorship from the Fondazione Cassa di Risparmio di Trento e Rovereto has began the project "Museum routes, enhancement and enjoyment of the geological heritage of the Autonomous Province of Trento for people with a visual and aural impairment" coordinated by Museo delle Scienze, which uses a network of partnerships with organizations working in the disability field (National Deaf and Italian Blind Union), in the technology research (Fondazione Bruno Kessler) and in design of natural pathways (Forest Service of the Municipality of Trento and Nature Conservation Service and Environmental Improvement of the Autonomous Province of Trento) in order to identify the most effective techniques to be adopted to communicate to disabled people geological and environmental notions. The project aims to create a permanent open-air museum tool addressed to all the target audience but also appropriate for users with disabilities, supported by educational activities in place, which will be proposed again in the Museo delle Scienze exposition area. The area identified for development of the project is located adjacent to the Alpine Botanical Garden of Viotte (Monte Bondone, Trento), satellite site of Museo delle Scienze. This is an educational path with the aim to highlight the geological peculiarities of the province of Trento and the Dolomites area.

The bases of the project had already been laid during the summer of 2010 by putting in place several rock blocks, also of enormous dimension, taken from the quarries and from yards of the Autonomous Province of Trento. The monoliths create a simplified geological map of Trentino, where block groups represent different geological lithology of the province main massifs mountain. The phases of the project trail have been launched following the directions of Museo delle Scienze regarding the choice of the most significant geological objects and instructions of disabled people with regard to the methods and techniques of mediation, and the development of technological support.

In support to the path have been planned hands-on type workshop

activities, so as to facilitate visitor in understanding the relationship between geologic objects and their geological area of origin. The path opening by the end of summer 2012. We are currently contextualize the arguments concerning the geological evolution of the Trentino region in a spatial level, intervening in order to adjust the path with facilities for the visually impaired people (gravel and guide ropes). The next phase will be focused on scientific mediation dedicated to sensorial disabled people and to the identification of rests for that purpose. It means absolutely to support the traditional teaching materials (panels, paper guides, maps, etc.) with new interactive tools, in line with the modern techniques of sciences divulgation. The very last phase, that go before the opening one, will focus on the testing of the structure and on the managing of the teaching activities and workshops.

THE DOLOMITES. HERE'S HOW THEY WERE BORN! A PROJECT FOR SMALL PUBLISHING SCIENTIFIC CURIOUS READERS WHO WANT TO HAVE ANSWERS TO ALL THEIR "WHY?"

PESCOLLDERUNG Margherita¹, QUARTANA Paolo²

1 - fuoricittà edizioni
2 - Tati & Tate World

Presenter e-mail: info@fuoricittà.com

Key terms: publishing; geoscience education; Dolomites; awareness of nature; environment

The Dolomites. Here's how they were born! it was inspired by a request from the primary schools to create scientific material arising awareness and education of the territory.

The publishing house "fuoricittà editions" along with "Tati & Tate Illustration World" has chosen to explore an area particularly close to them, the Dolomites mountains, declared UNESCO World Heritage in the year 2009. The foundation Dolomites UNESCO has sponsored this project with their logo on the cover.

The books are thought as educational material dedicated to children of 5+ y.o. their parents, schools, museums etc.

There are several considerations about the development of this project, i.e. the importance to communicate to children values such respect and conservation of the Earth and related resources. There is a need to reinforce the intelligence and the critical attitude of children because at this age, they are extremely open to neurobiological stimulation.

The books are part of a series, designed with the intention of explaining complex concepts through simple texts and valuable hand-drawn illustrations, all scientifically sound, close to the child view.

Yet they offer interesting scientific ideas that intrigue the young reader who, together with parents, relatives or teachers can then deepen the topics at school, visiting museums or just discuss it at home

Young readers of these books have the opportunity to personalize, making drawings and collages on dedicated pages. Indeed the graphic project has a playful approach so children have the opportunity to develop drawings capabilities and different learning processes. Thus stimulating children to learn and get answers they are eager to get about scientific topics (...why this, why that? ...).

On the Internet portal of the publishing house will be available the scientific information of the specific theme of the book, with more texts, pictures and videos. In addition there will be curiosity for young readers, and other designs to download.

This project has been created with the scientific support of the Science Museum of Trento and in particular of geologist and paleontologist Marco Avanzini.

The protagonist of the publishing project "The Dolomites" is Dò a white kitten with a particular alive hat that remember the ornaments of transhumance and traditional costumes of the Dolomites. In his adventures is accompanied by wild animals (marmots, chamois etc.) or by characters even recalling personalities really existed (eg. Leopold von Buch).

First book: The Dolomites. Here's how they were born! Dò meets Leopold (von Buch) who explains the evolution from the Triassic sea to the actual mountain peaks using the subject of a fossil fish. Dò learns the origin of the name "Dolomites".

Second book: The Dolomites. The flowers of the Dolomites. Dò, together with the magic marmot Mari, discovers the flowers growing at various altitudes. In the eyes of Dò, in this case small like an ant, the flowers appear to be real giants.

Third book: The Dolomites. Animals of the Dolomites. Dò and Mari venture into a daring descent along a river from its source to the valley, using a log as yacht. During their journey they take on board different animals to get together to celebrate at the farm.

Fourth book: The Dolomites. The fossils of the Dolomites. Dò is invited to a special banquet, to inaugurate the world's largest safe, along with fellow scientists and researchers. The food flow is presented in a particular way using fossils of different ages.

Follow publications will try to give all the answers to the various "why?".

"MAGIE DI PIETRA": PHOTOGRAPHY AS A TOOL OF DIVULGATION OF THE GEOLOGICAL LANDSCAPES OF TICINO (SOUTHERN SWITZERLAND)

ANTOIGNINI Marco¹, DECUYPER Hélène¹
1 - Museo cantonale di storia naturale, Lugano

Presenter e-mail: marco.antognini@ti.ch

Key terms: Photography; Divulgation; Geological landscapes

In the framework of the «International Year of Planet Earth» initiative, the Natural History Museum of Ticino in Lugano (southern Switzerland) published a book with high quality panoramic photographs of the most scenic geologic features of this region. The book is the result of a collaborative work between a professional photographer and a geologist. The aim was to stimulate interest in the Earth sciences within the general public bearing in mind that a photograph can reveal geologic stories in a spectacular way. It is a visual tour through the geology of the alpine scenery landscape of Ticino driven by the artistic point of view of a photographer. This approach will interest the amateur naturalist without any great knowledge of Geology.

In order to outline the complex geologic history of this part of the Alps, 18 sites have been selected belonging to the three major geologic provinces of Ticino: the Gotthard Massif, the Penninic and the Southern Alps. Some

among these are renowned localities such as the Gole della Breggia (first Swiss GeoPark) or the Monte San Giorgio (UNESCO site), whereas other ones are less known sites scattered through much of the mountainous landscape of this remarkable area. Each site is described by a short multilingual text (Italian, French, German) that highlight a general and prominent geological process displayed by rocks in the field (e.g. glacial erosion, complexly folded strata on a mountain cliff, sculptured turrets of dolomitic outcrops). The exemplary colour photographs, presented in landscape format (28 x 19 cm), are also supported by simplified geological maps and sections giving a concise account of the processes that shaped the bedrock of southern Switzerland. The technical terms likely to be unfamiliar to the general reader are explained in a glossary.

"GEOLOGICA" - THE NEW GEOLOGICAL SECTION OF MUSEO DI STORIA NATURALE E ARCHEOLOGIA DI MONTEBELLUNA (TREVISO, ITALY)

, VACCARI Giorgio¹, CELI Monica²

1 - Museo di Storia Naturale ed Archeologia di Montebelluna (TV)
2 - Museo di Storia Naturale e Archeologia di Montebelluna (TV)

Presenter e-mail: direttore@museomontebelluna.it

Key terms: geology; science education; museum exhibition

The new exhibition is based on two assumptions: the role of geoscience in the educational plan for the future of society and the importance of the tools of scientific research in Earth science, to meet the challenges of sustainable development.

The exhibition is organized around the theme of geodiversity, who see the variety of geological environments the basis of the variety of life on Earth, and represents scientific, social, cultural values as substrate of unique geo-historical witness.

The layout incorporates four interpretations, already been developed in the Mineralogy section and Life Sciences section: morphology, classification, evolution and relationship with man.

Exhibition will cover two blocks: the first the earth's crust and the rock cycle and the second the local geology (pre-Alpine foothills, hills, plains and Montello).

With manipulable objects and locations through direct experimentation, we want to clarify and make more comprehensible complex abstract concepts (tectonic movements, stratigraphy, etc.) using the latest multimedia technology (interactive video, audio, touch screen) and in full compliance with the application of Kolb's learning styles.

10.1474/Epitome.04.1080.Geoitalia2011

HOW TO COMMUNICATE PALEONTOLOGY - INTEGRATION BETWEEN DIDACTIC WORKSHOPS AND EXHIBITIONS AT THE NATURAL HISTORY MUSEUM OF THE PISA UNIVERSITY

LANDINI Walter¹, SORBINI Chiara¹, BIANUCCI Giovanni²

1 - MUSEO DI STORIA NATURALE - UNIVERSITA' DI PISA
2 - DIPARTIMENTO DI SCIENZE DELLA TERRA - UNIVERSITA' DI PISA

Presenter e-mail: landini@dst.unipi.it

Key terms: PALEONTOLOGY; NATURAL HISTORY MUSEUM; DIDACTICS FOR SCHOOLS; INTEGRATE WORKSHOPS; MULTISENSORIALITY

The recent inaugurations of three new permanent paleontological exhibitions stimulated the Natural History Museum of the Pisa University to renew and upgrade its own didactic offer to schools as regards Palaeontology and, above all, to modernize its organizational modalities. Fundamental under this aspect has been the experience matured during thematic events of great popular participation as the Festival of Science in Genoa (2005, 2006, 2007), the Mondadori Junior Festival in Verona (2007) and the Parma Science (2010), in addition to events of local interest as the Energy Forum in the St. Rossore park (Pisa, 2006) and the Pisa Book Festival (2008).

Three are the didactic models applied according to the age of the classes. The youngest students (3 to 7 years old) have special spaces, dedicated and purposely equipped, inside the exhibition rooms (dinosaurs and archaeocetes) where the contents are transmitted through game activities that all the children carry out personally (e.g. simulated digging, drawings, collages, puzzles and thematic games), punctuated by short explanations of the materials on exhibition (e.g. the reconstructions of archaeocetes).

Didactic workshops for students 8 to 13 years old are a balance of a first part in which learning realizes through explanations and practical experiences to be executed by some of the students using didactic supports (e.g. static and/or dynamic 3D models) purposely projected and realized; and a full immersion, not only visual but also sonorous and tactile, in the "lost world" narrated in the exhibits that become not just a place of passing though and passive observation but of interaction and active understanding.

Finally for the high school students, but also for adults, it is this last part to take the windward with a guided visit in which the single elements of the exhibition become occasion of observation, learning and of a deepening especially focused on the topics chosen by the teachers of each class who can select in advance, interacting with the didactic operators, the topics they want to be dealt more in detail.

In the last eight years, each time a new exhibit was inaugurated, one or more workshops were added to the didactic offer of the Museum: the opening of "Back to the Past - a 500-million-year trip to the Monti Pisani" in 2006 was followed by the introduction of two new workshops (one for students 8 to 13 years old and one for the high school); the inauguration of "Dinosaurs in the Charterhouse" in 2008 included the opening of three new didactic activities (respectively for 3 to 7 and 8 to 13 years old students and for the high school); finally the newest exhibit "Archaeocetes - Cetaceans of Land and Sea" in 2010 has been accompanied by the opening of two didactic workshops (for 3 to 7 and 8 to 13 years old students), moreover it enriched the already present workshop on the living cetaceans by including the exploration of real objects in the part on the evolutionary origin of whales and dolphins.

Teachers positively answered to these innovations and, since the school year 2006-07, the classes requesting workshops on Paleontological subjects have been almost 500. Significant is the case of the workshops on dinosaurs: even if they were included in the didactic offer since the participation of the Museum to the Science Festival of Genoa (school year 2005-06) their requests increased of the 27% (from 64 to 81 classes per year) in correspondence with the opening of the exhibition on the

dinosaurs from Patagonia.

Moreover, in addition to the regular workshops for schools, the practical experiences connected with the new exhibitions are presented to the larger public during several special events.

A recent example is the "Night of Dinosaurs" held on May 14th 2011: this nightly opening of the Museum recorded more than 1200 people participating to a thematic program including children workshops, practical experiences, movies and guided tours on the dinosaur subject.

LET'S DISCOVER SNOW!

CASAROTTO Christian¹

1 - Museo Tridentino di Scienze Naturali

Presenter e-mail: casarotto@mtsn.tn.it

Key terms: education; snow; avalanches; climate change

Affirmed centre of ideation, design and production of didactic projects with certified quality, the Museo Tridentino di Scienze Naturali directs its activities toward formative, up to date, and innovative proposals for pedagogic and communicative methodologies, meeting the constantly evolving requirements of school and society.

Didactic initiatives distinguish for innovative methodologies based on *hands-on* approach: during guided tours, laboratory activities, and field excursions students directly interact with naturalistic objects and laboratory equipment to experience the various phases of scientific research. Didactic proposals are based on student involvement and imply the use of materials which stimulate a direct interaction with the studied phenomena. Special attention has recently been given to Primary School teachers whose didactic programs were integrated with an *ad hoc* project, planned and led in cooperation, dedicated to the discovery of the **snow environment**.

The snow, decoration of the winter alpine landscape, represents a climatic and natural element - at times dangerous - and an economic support to the winter tourism. It is thus worth educate school-age children to nivology, with the aim to inform about and prevent from hazards and to exploit it commercially.

To such purpose the Museum and Primary Schools teachers have developed on the following contents: i) the snow: what it is and how it forms, ii) how snow can be studied, iii) the social value of snow, iv) snow ecological and touristic importance, v) stability of the snow blanket, vi) education to winter environments.

The project was organized in two meetings, in class and then in mountain environment, near the school. During the first meeting, with the aid of a power point presentation, the basic concepts of snow science have been passed through by means of a comic history. A snowman - the principal character - helped in adapting terminology and calibrating the scientific contents, and made easy technical concepts such as formation and metamorphism of snowflakes, their study and interpretation. Students have also been introduced to research instruments that, during the second meeting, were used to describe the properties of the snow blanket and to determine its degree of stability. These, in turn, helped to teach about the correct behaviour to be adopted in order to prevent avalanches.

In the second meeting students experienced the unusual winter environment where reciprocal cooperation and team spirit have been fundamental to solve problems.

Divided up in small teams, students performed meteorological observations, executed excavations, produced stratigraphic profiles of the snow blanket and studied form, dimension, density, and resistance of the snow crystals. An educated test of the snow blanket stability was then performed.

The main goals of these activities have to be found in the *Lisbon Strategy*, where the *lifelong learning* concept has been fixed as an inalienable target for the Society. The permanent learning strategy fit in the scheme of a European Union as a knowledge-based developed society, where sustainable economy, social cohesion together with environmental protection have to be pursued for present and next generations.

AN "HOME-MADE" GEOLOGICAL TRAIL: THE EXPERIENCE OF THE LICEO GALILEI (TRENTO) SCHOOL GARDEN

FERRETTI Paolo¹, AVANZINI Marco¹, BERNARDI Massimo¹, PETTI Fabio

Massimo¹, MAGANZINI Nicola², TODESCO Rossana¹

1 - Museo Tridentino di Scienze Naturali

2 - Servizio Conservazione della Natura e Valorizzazione Ambientale della Provincia autonoma di Trento

Presenter e-mail: ferretti@mtsn.tn.it

Key terms: Liceo Galilei geological trail; Trento; Trentino geology; Dolomites; science communication

Since the last two decades, the Museo Tridentino di Scienze Naturali (MTSN), in line with its institutional mission, deals with the field of education and training in order to promote the cultural and social growth, and common education (scholastic and permanent) within the field of natural sciences and specifically of Earth sciences.

Through a wide range of information campaigns and educational activities carried out at the headquarter and in the numerous territorial seats, over time the MTSN has expanded and established a network of relationships with schools and society in general.

Some schools, from mere users of educational activities, are becoming partners and inspiring new projects. This is the case of the Liceo Galilei in Trento, where starting from an idea developed by a group of science teachers in May 2009, the MTSN, in cooperation with the "Nature preservation and environmental valorization Service" of the Provincia Autonoma di Trento, has inaugurated a peculiar geological trail on the hill behind the school.

The aim of this project was to artificially recreate a didactic trail that can be used in all seasons and accessible to students with disabilities, where the simplified stratigraphic succession of the Trentino province can be shown, with particular reference to the Dolomites, recently declared UNESCO World Heritage Site.

For some time the MTSN carries out didactic activities in the Dolomites area, mainly at the geological trail Dos Capel - the prototype of Italian geological trail - and at the Geopark Bletterbach. In this places, due the high altitude and for the summer closing of schools, only in the summer season the good fruition of the trail is allowed.

The Liceo Galilei geological trail was performed by putting in place 13

monoliths representing to the most important rock formations in Trentino and in the Dolomites. The blocks were selected and taken from quarries or from forest yards of the Provincia Autonoma di Trento.

The "Nature preservation and environmental valorization Service" of the Provincia Autonoma di Trento has been involved in designing and performing special steel supports fixed to a concrete base buried in the ground, to guarantee stability and good visibility of the blocks. For each monolith an explanatory panel quoting the name of the rock formation, age, composition, depositional environment and possible use of the rock was prepared.

The trail (length: 500 m; drop: 50 m) develops along paths with natural bottom, characterized by a slight slope. From the bottom, where the oldest rocks were positioned (Southern Alps metamorphic basement, Permian plutonic and volcanic rocks, Val Gardena Sandstones) one can climb running up toward younger rocks, represented by tertiary formations (limestones and volcanic rocks).

The tour ends at a panoramic point overlooking the Trento valley and Monte Bondone, allowing to complete the trail with the topics of orogenesis, here well represented by the Monte Bondone anticline, and morphogenesis, with a view of the Adige valley shaped by glacial exaration and of the Torrente Fersina alluvial fan on which the city of Trento rises.

The trail has been successfully tested in October 2008 in the occasion of the training courses, organized by the MTSN, for teachers of Primary and Secondary Schools.

It can be accessed by reservation at the Educational Services of MTSN that offer guided tours; for autonomous tours an agreement with the secretariat of the Liceo Galilei is needed.

Despite the organizational difficulties due to completion of work in some areas of the garden, during the first school year (2010-2011) MTSN has accompanied 11 classes, for a total of over 200 students. Over the next few years, when the project will be completed, a sharp increase in visits is expected, hoping to be opened to the public at least during the school opening hours.

5 - RESERVE GEOLOGIQUE HAUTE PROVENCE

6 - CENTRO STUDI E FORMAZIONE VILLA MONTESCA

7 - CENTRE FOR EDUCATIONAL INITIATIVES ASSOCIATION

Presenter e-mail: rosella.nave@ov.ingv.it

Key terms: natural hazard; earthquakes; volcanoes; education; preparedness

Promoting the geological heritage and educating people on natural phenomena can play key role in disseminating information and good practices to minimize the effect of possible disasters.

To put it into action in 2010 has been developed the project RACCE (Raising earthquake Awareness and Coping Children's Emotions), granted by European Commission, Civil Protection Instrument, which involves as partners: Vesuvius Observatory (Section of INGV), Natural History Museum of Lesvos Petrified Forest (Greece), Reserve Geologique de Haute Provence (France), Greek National Earthquake Planning and Protection Organization, Centro Studi e Formazione Villa Montesca (Italy), Center for Educational Initiatives Association (CEI -Bulgary) and as Coordinator the Natural History Museum of Crete (University of Crete - Greece).

The project's aim is to raise awareness, improving knowledge on natural hazardous phenomena, (mainly seismic and then volcanic hazard) and simultaneously, to educate relative groups (teachers, parents, civil protection volunteers, etc.) on the best practices to deal with seismic and volcanic risk and also on responses able to palliate the children emotional burden in case of a serious events.

The main objectives of the project are: to identify, share and implement best practices and methodologies gained from previous EU projects and partners' activities; to develop and realize innovative initiatives and actions aiming to raise awareness and increase knowledge of pupils on earthquake and volcanic hazards; to train teachers, parents or other relative groups also to be able to contribute to children palliation in case of seismic/volcanic hazard. Main deliverables of the project would be the elaboration of an innovative and mobile experiential Educational Project connected with school curricula and a Travelling Exhibition. Project is expected to contribute in sharing information in raising awareness and minimizing the impact of such disasters and finally, in the establishment of a voluntary network of operators and beneficiaries in the areas involved to constantly share, discuss and apply the outcomes.

Key terms: Earth Science; School; Divulgation

In the frame of the divulgation activities carried out by the Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Palermo (INGV-Pa), we have performed a stage for 100 students of a Secondary School of the same city. The first part has been theoretical and dealt with lessons about various aspects of Earth Sciences, open to numerous questions coming from the students. The dramatic events of Japan (March 2011), happened just few days before the lessons, have been the trigger to handle with the themes of volcanic and seismic risk, their natural origin and impact on our society. The second part has been developed in the laboratories of INGV-Pa, where all the students, shared in groups of 10, took actively part to experiments and experiences regarding the chemical and isotopic analyses of natural gases and waters. They have also learnt the

usefulness of these analyses for volcanic and seismic surveillance. Each student has been involved in 6 hours of theory and 6 of practise, while 10 among researchers and technicians of INGV-Pa participated as teachers. At the end of the stage, the students have done some oral talks at their school, resuming the experiences done. The students demonstrated great interest in the Earth Science problematics as well as in the laboratory experiments. In the next autumn, 10 students among those who participated to the stage, selected by their teachers, will spend a week at INGV-Pa beside researcher and technicians to live the real life of the scientific research.

MAP OF 150 YEARS OF SEISMIC HISTORY IN ITALY

PIGNONE Maurizio¹, MOSCHILLO Raffaele¹, NOSTRO Concetta¹

¹ - INGV, Centro Nazionale Terremoti

Presenter e-mail: maurizio.pignone@ingv.it

Key terms: 150 years seismicity Italy; 150 years Italy; seismic history of Italy; map 150 years

This map shows the strong earthquakes of the last 150 years in Italy. From the unification of Italy to this day, our country was struck by 170 earthquakes strong, very strong or even catastrophic. Of these, 12 were destroyed (Maximum intensity of MCS [Mercalli-Sieberg-Cancani] IMax > X) and have caused a total of over 130 000 victims. The earthquake of 1908 (M 7.2, Imax X-XI) in Messina and Reggio Calabria was the strongest of the past 150 years with more than 80 000 victims and the almost total destruction of two cities. The most recent earthquake occurred in Abruzzo April 6, 2009 (M 6.3, Imax IX-X). This map has been designed and produced by the Laboratorio di Cartografia Digitale e Sistemi Informativi Geografici di Sede Iripinia of INGV. It's been used GIS technology (ESRI ArcGIS 10) for the organization of seismic data. The map is available at www.gm.ingv.it

10.1474/Epitome.04.1086.Geoitalia2011

THE GEO-PALEONTOLOGICAL SITE OF MONTALBANO JONICO SECTION (LOWER-MIDDLE PLEISTOCENE) WITHIN THE RISERVA NATURALE SPECIALE "I CALANCI DI MONTALBANO JONICO"

CIARANFI Neri¹, GALLICCHIO Salvatore¹, GIRONE Angela¹, MAIORANO

Patrizia¹, MARINO Maria¹

¹ - Dipartimento di Geologia e Geofisica, Università degli Studi di Bari Aldo Moro

Presenter e-mail: girone@geo.uniba.it

Key terms: geosite; Montalbano Jonico section; Pleistocene; Ionian Stage

The lower-middle Pleistocene Montalbano Jonico composite section crops out in the southernmost part of the Southern Apennine Foredeep. It is a well-exposed and continuous succession, about 500m thick, consisting of muds and muddy silts with nine interbedded volcanoclastic layers (V1-V9) (Ciaranfi et al., 2001). The vertical distribution of both invertebrate fossil assemblages and teleostean otoliths points out changes in the primary environmental parameters, particularly bathymetry, sedimentation rate and oxygen concentration. The observations allowed the reconstruction of several deepening-shallowing cycles within a general regressive framework. Five "sapropel" layers have been identified by benthic foraminiferal assemblages (Stefanelli, 2004) and they have been correlated to insolation cycles i-112, i-104, i-102, i-90 and i-86 (Ciaranfi et al., 2010). Radiometric Ar/Ar ages of 801.2±19.5 ka (Maiorano et al., 2010) and of 719.5±12.6 ka (Ciaranfi et al., 2010) have been obtained for V3 and V5, respectively.

The developed astronomical tuning of the section recently proposed by Ciaranfi et al. (2010) revealed that the Montalbano Jonico section covers an interval from 1240 ka to 645 ka through Marine Oxygen Isotope Stage (MIS) 37 to MIS 17-16. The upper portion of the section contains MIS 19, which is known to occur close to the Matuyama/Brunhes reversal, and may represent a suitable horizon for the definition of the GSSP (Global Boundary Stratotype Section and Point) of the "Ionian" Stage at lower-middle Pleistocene boundary (Maiorano et al. 2010). Considering the important scientific and panoramic valences of the Montalbano Jonico area, the researchers of Bari University and the community of Montalbano Jonico village worked all together in order to popularize and preserve this significant geo-stratigraphical heritage. Indeed, in January 2011, the "Regione Basilicata" ratified a specific law (L.R. 3/11) with the aim to protect the Montalbano Jonico area, thus establishing the *Riserva Naturale Speciale "I calanchi di Montalbano Jonico"* for its peculiar geo-stratigraphical value.

We present a project for the realization of the geo-naturalistic routes in order to improve the accessibility of the area and promote the natural secrets of this spectacular badland and its scientific role. The geo-stratigraphical site of Montalbano Jonico represents an interesting didactics laboratory for all community components and a proper opportunity to improve environmental education.

GEOLOGICAL MAPS AS TOOLS FOR POPULARIZING GEOCIENCE

CONTENTS. THE CASE STUDY OF MIDDLE TANARO VALLEY (PIEMONTE, NW ITALY)

PEROTTI Luigi¹, GIARDINO Marco¹, GHIRALDI Luca², DEBIAGGI Ermanno²

¹ - GeosITlab - Dipartimento Scienze della Terra - TORINO

² - Regione Piemonte - Museo Regionale di Scienze Naturali ed Ecomusei

Presenter e-mail: luigi.perotti@unito.it

Key terms: Tanaro; Mapping; Cartography; Popularization; Educational

Over the last 15 years within the scientific community has raised the awareness of the importance of geological heritage. Several methodologies have been developed for the identification, classification, evaluation and conservation of sites with a specific interest for the Earth Sciences.

Recently, some working groups have focused their attention on the promotion and valorization of geological heritage, through the development of projects whose goal is to popularize the geo-scientific information in order to make easier for a generic public the comprehension of features and process proper of a certain area. Promotional activities are manifolds and concerning different popularization products, such as itineraries, educational panels, publications, etc. Maps are often employed as part of the cited products because they represent a medium for the interpretation of geo-scientific data and serves popularization purposes. This kinds of maps may be defined as "interpretative maps": "an educational activity which aims to reveal meanings and relationships through the use of original objects, by firsthand experience and by illustrative media, rather than simply to communicate factual information" or in a simple words "an attempt to reveal the truths that lie behind the appearances" (Tilden, 1957). The main goal is to translate and transferring on the map specialized information to a general audience in order to facilitate the understanding of phenomena and processes that transform and shape the landscape over time, using illustrations and explanatory text, where appropriate. On the basis of assumptions cited above the Torino's Natural Science Museum and the GeosITLab of the Department of Earth Sciences started a project whose aim is to develop a cartographic tool able to popularize geological and geomorphological information of the Middle Tanaro Valley (located in the South-East sector of the Cuneo Plain, Piemonte, NW Italy).

Key requirement for this kind of work is the knowledge of processes and natural phenomena that have changed and shaped the territory over time. Through the deep analysis of the geological, geomorphological and structural components, a process of decoding, together with appropriate simplifications, has been implemented in order to attempt a reconstruction of the morphological evolution of the Middle Tanaro Valley's landscape.

Before the map implementation, the mapmaker chooses the information that has to be communicated on the basis of what's going to be revealed with the map, the specific target audience and the map's purpose. Another important question concerns the visual representation of geo-scientific data. Specialist of geoscience tends to represent data using standard operating procedure that can be difficult to read by an audience not involved in Earth Science disciplines. Geoscientist involved in mapping project should, therefore, have knowledge concerning visual information transmission, and hold the necessary communication know-how with the chosen media. For this reason a graphic designer has been involved in the project that led to the realization of geo-didactic map of Middle Tanaro Valley.

The two-sided map developed, shows both the situation at the present day, where the main geomorphological features have been emphasized and represented with a simplified legend, and a chronological succession of landforms realized with six bird's eye view drawings supported by synthetic text explanations.

It is a product expressly set-up for educational purpose, whose aim is to provide a simple and effective way to explain the geological and geomorphological processes of one of the most interesting sectors of the whole Piemonte region.

Presenter e-mail: alfio.vigano@ing.unitt.it

Key terms: Seismic network; Accelerometric network; Trentino;

Seismology; Earthquake hazard

The Trentino seismic network was installed by the Provincia Autonoma di Trento (PAT) after the relevant Gemona del Friuli (6th May 1976, M. 6.2) and Riva del Garda (13th December 1976, M. 4.1) earthquakes. The seismic network, which has been active since 1981, is today composed of 7 seismic stations uniformly distributed on the region. Besides, an accelerometric network has been installed since 2005, after the national seismic code and seismic zonation approved during 2003, with stations mainly located in the Southern Trentino. Digital recordings, acquired at remote stations, are transferred to a central server (Geological Survey Laboratory) where they are archived to be processed.

Aim and scope of the seismic and accelerometric networks are the following: i) give automatic alerts, particularly for strong earthquakes, ii) register and localize the seismic events of Trentino, iii) provide data for territory planning (e.g., seismic microzonation), iv) collaborate with other national/international seismic networks within the project "Antelope" of the NE Alps.

The results from the elaboration of seismic and accelerometric data are made available through an Annual Seismic Bulletin, a dedicated Web page (www.protezionecivile.tn.it) and scientific publications. Moreover, the PAT Geological Survey is involved in events devoted to study natural hazards (in particular, earthquake and/or landslide hazards) and to show monitoring and prevention activities planned for the Trentino area. In the period 2009-2010, a specific experience was about a thematic exhibition hold in Trento (Museo Tridentino di Scienze Naturali) to show regional seismicity and its monitoring.

GEOCULTURAL ITINERARIES IN THE MEDIEVAL HAMLET OF SANTA LUCIA DEL MELA (PELORITANI MTS. NE SICILY)TORRE Rosario¹, CARABETTA Maria Teresa¹, CIRINÀ Valentina¹, MACCARRONE Beatrice¹, MESSINA Antonia¹
1 - Università degli Studi di Messina

Presenter e-mail: torre.rosario@libero.it

*Key terms: Peloritani Mts., Calabria-Peloritani Arc; Santa Lucia del Mela Medieval Hamlet (NE Peloritani Mts., Southern Italy); Geological, Geomorphological and Historical Heritage; Geocultural Itineraries*The Medieval Hamlet of Santa Lucia del Mela, with 4800 people, occupies a surface of about 83 km², which extends along the three hydrographic basins of the Mela, Floripotema and Muto Torrents.

The Mela Torrent, which is the most important, originates in the Pizzo Acqua Bianca (1211 m). Its name derives from the Greek "Melas" meaning "black, dark", due to the several eclogite bodies alternate to marbles and schists in the two hydrographic versants of the Valley and in the river bed alluvial deposits.

The complex geological history of this Territory is also responsible for its heterogeneous morphology. It belongs to the orogen Calabria-Peloritani Arc, and is made up of a pile of Alpine tectonic units, called, from top to bottom and from N to S, the Aspromonte, Mela, Piraino and Mandanici Units. Proterozoic high-grade metamorphic and plutonic rocks outcrop in the area which are affected by Variscan and, locally, also Alpine re-equilibrations up to low-grade rocks, and Palaeozoic medium- to low-grade metamorphic rocks. The first lithotypes belong to the Aspromonte Unit, where Variscan augengneisses prevail and the second to the other Units, where Variscan marbles, schists and phyllites prevail. In particular the Mela Unit extensively outcrops, with thick levels of Variscan marbles, schists, gneisses, and relicts of Eo-Variscan eclogites.

The area is also known for the abundance of metallic deposits, such as Pb, Zn, Cu, Fe, Ag, Au, W etc., which are still observable in the V.ne Pomara and in the Cerasiera Torrent, along the tectonic contacts. Preserved old mines are also present in V.ne Malonato and Pizzo Nevola.

The territory is characterized by widespread and significant epigeal and hypogean karst phenomena which developed within the thick Mela Unit marbles, such as the beautiful "Sautu i Lapa" cave and the spectacular canyons of Rocche Strette in the middle tract of the Floripotema Torrent, the V.ne Pomara, V.ne Ferrà and V.ne Monastri in the middle-low tract of the Mela Torrent, the "Ula Funna" in the middle tract of Muto Torrent. For scenic landscapes and spectacular geomorphological characteristics, the following sites are listed: Makkarruna Hill (370 m) on which stands the Hamlet of Santa Lucia del Mela, with the Arabian-Suevian-Aragonese Castle; Rocca Timogna (1127 m) the top of which shows the outline of a crouching lion; Rocca Vernava (1048 m), the top of which exhibits the characteristic profile of a human face; the remaining spectacular mountains of Pizzo Acqua Bianca, Pizzo Croce (1214 m), Pizzo Acqua Menta (1107 m) and Mt. Poverello (1279 m).

The numerous springs and waterfalls, e.g. the "Salto di Ferrà", the "Schicciu a Saitta", the "Ula Funna" have the same importance. The "Demanio Forestale Mela" and the "Affluenti del Torrente Mela Site of Community Importance" are also situated in this territory due to biotic aspects, where many endemic species of flora and fauna are preserved, such as the rare and giant Woodwardia radicans fern growing in both the "V.ne Mandrazza" and the "V.ne del Lacino".

The Santa Lucia del Mela municipality holds a very important historical heritage, including archaeological relics from the Hellenistic Age, Roman tombs, the Castle with three towers containing the preserved Madonna della Neve Sanctuary which dates from 1673, the Cathedral of 1094, the Churches of Santa Maria Annunziata and San Nicola (XV century), the Capuchin Church and Convent (XVII century), the Basile-Vasari Palace of 1599, the Bishop's Palace of 1608 and the San Giovanni medieval hamlet, sited along the Floripotema Torrent. Recently, the area has also been investigated as the site of the famous Artemis Phakelitis Temple.

The studied territory, although located in the "Milazzo-Valle del Mela Area of high environmental risk", exhibits a considerable cultural system promoter of innovative conservation and management models which also include thematic itineraries for a qualified fruition of its Geo-cultural Heritage.

Presenter e-mail: alessandro.borghi@unito.it

Key terms: applied petrography; ornamental stones; geological heritage; Piemonte

The multidisciplinary research project "PROGEO Piemonte" aims to achieve a new conceptual and operational discipline in the management of the geological heritage of the Piemonte Region by means of the development of techniques for recognizing and managing its rich geodiversity at the local and regional scale. Within the project, 9 strategic geothematic areas will be investigated to represent the geodiversity of Piemonte, each characterized by high potential for scientific studies, enhancement of public understanding of science, recreation activities and for economic support to local communities. The recognition of the economic value of geodiversity will lead to the production of regional guidelines for Geoconservation integrated quality management system, suitable for tourism and sustainable development strategies.

In Turin, the stone has always characterized the strong architectural identity of the city. From Roman times to the '700, marbles were the rocks used in construction of greater value. Starting from '800, granites and other silicate rocks were progressively used thanks to the development of technologies for their processing.

The great variety of ornamental and building stones found in Turin is certainly due to the highly composite geological nature of Piemonte region where very different geological domains crop out: the western portion of the metamorphic Alpine chain, the sedimentary basin of Langhe and

Monferrato and a small sector of the Northern Apennine.

In the framework of the "PROGEO Piemonte", the aim of geothematic area 9 is the compilation of a detailed list of the many historic and contemporary Piemonte stones, which over the centuries have been used in buildings and architecture.

The main ornamental stones used in Turin will be identified and characterized from petrographic and mineralogical point of view in order to identify the geological units of provenance as well as the quarry sites. For the minero-chemical characterization of the main rock types, different analytical techniques will be applied such as the scanning electron microscope, the electron microprobe, the micro-fluorescence, the cathodoluminescence and the confocal Raman. The main agents of deterioration, such as air pollution, human activity and (micro-)organisms, will also be studied. The role of different compositional and structural features of the bedrock in the biodeterioration process on the ornamental stones surface will be investigated in detail.

The creation of a comprehensive database for the Piemonte rocks used in buildings of historical and contemporary highlights of the city of Turin is expected as the final product of our research. The data base will include the full name of the rock (commercial and scientific), the location of the quarry site, the main applications in buildings and monuments of Turin, the macroscopic and microscopic description illustrated by extensive iconographic material.

Main emphasis will be given to the rock types used for external application as they are easily observed during touristic city tours. Moreover, some significant rock examples that decorate the inside of churches and buildings will be also identified and reported on the proposed database.

The project also includes the study of many ancient villas in the Northern slope of the Turin Hill, built on a succession of flat terraced surfaces, corresponding to relicts of Pleistocene alluvial plains involved in the hill uplift.

The research, finally, aims to disseminate the knowledge on stones both in science teaching and in cultural tourism, but the results will also be useful and available to people involved in territory planning and to operators involved in restoration activity.

LET'S FIND OUT THE SECRETS HIDDEN IN A GLASS OF WATERPENNISI Maddalena¹, ADORNI-BRACCESI Alessandra¹, DELL'OMODARME Daniela²

1 - Istituto di Geoscienze e Georisorse, CNR

2 - Scuola Media Duca D'Aosta, San Frediano a Settimo, Cascina, Pisa

Presenter e-mail: m.pennisi@igg.cnr.it

Key terms: Middle school science project; Water; Front presentation; Experimental activity

CNR in Pisa is periodically open to the public and interested students who wish to learn about topics in computing, life and earth sciences. "Let's find out the secrets hidden in a glass of water" is a Middle School Science Project created in 2010 through the cooperation of the Istituto di Geoscienze e Georisorse and the teachers from the Scuola Media, San Frediano a Settimo, in Cascina, Pisa.

The purpose of the project is to:

- educate school age children on the importance of water as a precious resource to the community and the environment; and
- provide students with a laboratory experience not commonly provided in schools, to assist them to determine the characteristics of water as found in nature and from the tap.

The project involves a power point presentation (24 slides) that results in a discussion between teachers and students and is followed by an experimental activity (approx. 2 hours).

The power point presentation commences with basic concepts: the physical and chemical characteristics of water, its distribution on the surface of the earth, the water cycle, and the relationship between water and geology. The concepts of aquifers are introduced together with the relationships between rock and water chemistry. Potential toxic elements from geogenic sources and pollution are introduced and their effects on health discussed. The students are also shown the huge discrepancies in global water resource distribution. They are shown how to promote sustainable every day water usage and the relationship of water usage to the environment.

The second part of the project takes place in the chemical laboratory. During the experiment the students familiarise themselves with some of the materials commonly used in a laboratory - beakers, micropipettes, pH colour - fixed indicator sticks and flasks. The concepts of salinity, alkalinity and acidity are investigated. The children measure conductivity, pH and temperature from several water samples that included rain, tap and bottled water as well as commercially available liquids - cola, milk, juice. The values obtained are recorded on laboratory data sheets and then inserted in the final report compiled by each student.

The instruments used in the laboratory are pH-meters and temperature sensors linked to conductivity. NaCl solutions (with different molar concentrations) are used to measure the increase of salinity in rain, surface, ground and sea water, respectively. Other reagents such as methyl orange, weak ammonia solution, lemon and vinegar are used to change the pH of the solution. Measurements are taken of the change in pH.

The students are highly satisfied as shown by their active participation in both the theoretical and experimental parts of the project. The cost of running the project is moderate. If there is an interest from other middle schools, the power point presentation, list of chemical materials, and laboratory data sheets will be willingly provided upon request.

Presenter e-mail: r.murgia@imc-it.org

Key terms: scientific dissemination; educational project; coastal marine environment; evolution adaptation; biodiversity

In recent years, the number of students studying natural science has been

decreasing all over Europe. In particular in Italy, this decrease in environmental related topics enrolment is caused primarily by a reduced interest in scientific topics and secondarily by the lack of job opportunities in such field. The International Marine Centre (IMC) foundation and the Institute for Coastal Marine Environment, (IAMC-CNR) collaborated for several years in educational activities for the diffusion of marine science. During the last 10 years, more than 2000 students from primary and secondary schools were involved in different theoretical and practical didactic activities carried out by the marine researchers.

The project "Mare Nostrum" (8th May - 12th May 2010) promoted the dissemination of scientific culture bringing students, aged 16 to 17, closer to the "world of research". 45 students of the "Liceo Scientifico Galileo Galilei" of Civitavecchia had the chance to get closer to the world of marine research at the IAMC-CNR laboratories at Torregrande (Sardinia).

Students learned about the advantage of the applied research and how a researcher is carried out following different steps (hypothesis, field and lab work and data analysis) with the constant support of the senior IAMC-CNRIMC researchers.

The high environmental richness and variability of Western Sardinian coast (coasts, lagoons, beaches, open sea) is an ideal scenario to demonstrate how to use environments multidisciplinary approach in different situations.

The interactive theoretical lessons prepared the students to the practical activities in field related to the monitoring and management of coastal environments. Students were divided in small groups and each group had to choose one of the following topics: oceanography, sedimentology or ecology of lagoons and coastal marine systems. The educational project finished with a meeting with other Italian students (from the Oristano "Liceo Scientifico Mariano IV Arborea"), who had the same experience at the IAMC-CNR laboratories. Students from both schools discussed the obtained results and showed them in presentations, in order to compare the achieved scientific knowledge.

This experience gave students the opportunity to open their minds and to increase their scientific, cultural and social experiences. The practical activities have to be considered fundamental to show students how the world of marine science can be interesting.

Furthermore, this project aims at offering the Oristano students the opportunity to go to the University of Viterbo to live and work for one week as university researchers.

These activities contribute to implement the strategy network between students of different European regions for sharing knowledge and experiences.

THE HISTORY OF GEOLOGY AS COMMUNICATIVE TOOL FOR SCIENTIFIC EDUCATION IN THE EARTH SCIENCES

VACCARI Ezio¹

1 - Università dell'Insubria, Varese

Presenter e-mail: ezio.vaccari@uninsubria.it

Key terms: history of geology; geological education; museums; geosites; itineraries

The aim of this paper is to introduce and evaluate the role of the history of geological sciences for the scientific communication and a sustainable education in the field of the Earth Sciences. Some possible example will be presented and discussed within the following topics: reassessment of historical collections in geological museums, as tools for approaching and understanding scientific debates; results of historical research-work on seismic, volcanological and hydrogeological events, as tools for achieving a correct knowledge of the real extent of the so called (by the media) "catastrophic events" or "irreversible changes"; the planning of historical routes of the geosciences (for example in mountain areas such as the Alps or the Apennines), in order to provide a new network of geotouristic itineraries with didactic and informative purposes.

U3-2 Orale Losi, Claudia

10.1474/Epitome.04.1094.Geoitalia2011

DRAWING UP ON TIPTOE: THE CONTACT BETWEEN ART AND SCIENCE

LOSI Claudia¹

1 - Italy

Presenter e-mail: losiclaudia@gmail.com

Key terms: art; amazement; metaphor; landscape; experience

The close and complex relationship between art and science is certainly not a novelty. Much has been written and discussed on the matter (recently in Italy: Effetto Terra, edited by Maria Perosino, Johan & Levi, 2010).

While still a student, along with a couple of travelling companions (Matteo Meschiari and Francesco Benozzo), I began to reflect on how to translate some of our considerations on the relationship between man and earth in visual terms, leading us to run the Studio Italiano di Geopoetica from 1996 to around 2000, following in the footsteps of the multidisciplinary experience that the Scottish writer Kenneth White had undertaken years before with the Institut International de Géopoétique.

It was on this occasion that I decided to use needle and thread to reproduce the structure of the lichens photographed during my excursions (Tavole Vegetali, 1995). I consulted scientific handbooks to identify them, or to understand what kind of terrain they grew on and I walked on. Just as I do now, I shifted between the coring of real soil and ice and the metaphorical perforation of imaginary places. On my wanderings through the Dijon countryside, around Montbard and the birthplace of Georges-Louis Leclerc, Comte de Buffon, I took a dozen shots of some partially buried tanks belonging to a long-abandoned trout farm and, once printed, I sewed onto each one a stage of the drifting apart of the continents: ideally these continental plates would also return to the surface (Marmagne, 2001).

One of my first group works was the Arthur's Seat Project (1999-2001): I

asked six Serbian women and six Albanian women to sew 12 fragments of a drawing onto fabric showing the stylised shape of Arthur's Seat, the volcano near the centre of Edinburgh which has been dormant for thousands of years. In the 18th century, J. Hutton put forward his theories on the evolution of the earth's crust, partly on the basis of his observations of this highly particular place as a student (J. Repcheck, The Man who Found Time. James Hutton and the Discovery of the Earth's Antiquity, 2003).

And then the latest project which came to a close a few months ago: Balena Project, which consisted of a life-size fin whale that I constructed out of fabric, padding and air balloons. This was a very complex project which originated partly from walking through the sandy gullies of the Piacenza hills, where Pliocene fossils may still be found, and where - a few centuries ago - the bones of a number of cetaceans were uncovered beneath the vineyards after thousands and thousands of years.

As regards the relationship between science and art, I'm interested in the endless source of amazement represented by both cognitive and technological tools, but also the "sharp-edged" approach with which the sciences study the world around us. That world that makes us what we are. As Marina Wallace says, the artist today looks towards science as a source of visions, through a different language, one often metaphorical or metonymic.

I believe that for the artist it is a question of drawing up on tiptoe, of adopting a panoramic view through which to put together things which might or might not have anything to do with each other, and then create fruitful links between them. Thus the micro-landscape of a lichen growing on a rock has to do with the dilated view of a faraway era of the continental drift; the clay modelled into the shapes of aquatic animals by children, shapes which are then left to be washed away on a riverbank and which serve as a narrative motif for the passage of both practical and theoretical knowledge.

Hence, those who have no real grasp of the subject wantonly pick out pieces of the information provided by those who, instead, leave no stone unturned in their meticulous search for detail, and then elaborate them using an entirely different language. Clearly, the operation requires a certain degree of recklessness.

GEOLOGICAL SCIENCES IN LE NUVOLE

FRUGUGLIETTI Salvatore¹, DE CAPOA Enrico¹, MUSICÒ Vincenzo¹, COCIFOGLIA Fabio¹

1 - LE NUVOLE SOC. COOP. - NAPOLI

Presenter e-mail: info@lenuvole.com

Key terms: SCIENCE COMMUNICATION; THEATRE AND SCIENCE; SCIENCE IN SOCIETY- SCIENTIFIC CITIZENSHIP; KNOWLEDGE'S SOCIETY; PHILOSOPHY OF SCIENCE

Le Nuvole, Theatre of Innovation for Children in Naples, founded in 1985 and since 1996, following the happy encounter with IDIS - Città della Scienza (which since 2001 is the first Italian science center), deals with communication of science, so with educational activities for the public school that theatrical communication events for the public school and beyond.

The history of science communication of Le Nuvole begins with the management and conduct guided tours and educational activities.

The first development was the thinking that guided tours may be different performances. That is how the "show-visits, which are still valid experimental models of science communication. Not yet a show, but no more than a simple tour: it gives more attention to the gesture, the word, the mime, narration and animation. All this to intrigue and charm.

Following the visits show (VS) have been joined by the events of theatrical communication of science (TCS), a piece of theater scientific topic, which for the simple logistics and the possibility of staging in non-conventional areas are significantly appreciated by the local science.

Among the cases are related, directly or indirectly by the geological sciences Le Nuvole offer

Geoquiz - (VS) - 5 billion years in 18 questions. Geology becomes a quiz show on network structure on the basics of geology for primary schools. The formula takes advantage of the game between two teams, educational purposes, the innate spirit of emulation and competition for kids.

Two wires, one expert and a facilitator, directing a team game involving two groups of students, enabling dynamic knowledge of Geology. Called upon the students to choose topics and reflect on the themes: the permeability of soils, continental drift, the globe, the erosion, the internal structure. The winners who answered and have obtained the highest score will receive the applause and a symbolic diploma.

Naples, discover the city - (VS) A visit touring show in public areas of the Science Centre of Naples, using the Neapolitan traditions and beliefs, told the site. An intriguing way to use a place of science to describe the geology of the Campi Flegrei.

Lottery nuclear - (TCS) Risk communication and construction of citizenship scientifically aware -

Not only nuclear energy but also environmental protection and planning, assisted reproduction, GMOs, stem cells, high-speed trains: the more science and technology advancing rapidly, especially since society seems to resist. Such questions can not tolerate nor a "technocratic response" or an "ethical response." What is needed is rather a "policy response", because each technology incorporates a vision of man, nature, society, are indispensable sites, transparent and accountable institutions and procedures through which to reach a public choice between alternatives.

Biodiversity - (TCS) Entertainment was born from a co-production, even metaphorically, focuses on "work together" to build responsible citizenship. Among the topics dealt with environmental sustainability and protection of soils.

The European society is currently experiencing a situation of constant changes in political, social, cultural and technological developments and, especially, is experiencing a crisis in relations between citizens and scientific culture.

The theatrical communication of science can make science more accessible and understandable, encouraging the intermingling of two cultures (scientific and humanistic) that have long been uneasy relationship so much that it was believed, rightly, that it was dangerous to have two cultures that do not could or could not know to communicate.

INTERNATIONAL EARTH SCIENCE OLYMPIAD - THE 1ST EDITION

IN EUROPE

GRECO Roberto¹, COMITATO ORGANIZZATIVO Ieso 2011², COMITATO SCIENTIFICO Ieso 2011³
 1 - Ministero dell'Istruzione, dell'Università e della Ricerca
 2 - LOC IESO 2011
 3 - LSC IESO 2011

Presenter e-mail: robertogreco01@yahoo.it

Key terms: International Earth Science Olympiad; Education; Earth Science

International Earth Science Olympiad - IESO is one of the 10 International Scientific Olympiad. This project was developed by International Geoscience Education Organization - IGEO.

IESO is an annual competition for secondary school students (students not older than 18 years in July 1st of the year of the Olympiad). The students have to test their skills in all major areas of Earth sciences, including geology, geophysics, meteorology, oceanography, terrestrial astronomy and environmental sciences. The theoretical examination includes problems which are developed to measure the participants knowledge and understanding in Earth science areas. The practical examination consists of task which are designed to assess participants' abilities to carry out scientific investigations in earth science inquiries. The examinations are prepared by specialist in Earth sciences and Earth science education, who also provide solutions and evaluation guidelines. Each delegation is made of 4 students (young than 18 years old the 1st July of the year of the Olympiad) and 2 mentors. Mentors must be specialists in Earth science and Earth science education and capable to serving as members of the International Jury. Official language of IESO is English, however the mentors could translate the written examinations and related materials from English to the participants' native language. The main aim of IESO is to raise student interest and public awareness of Earth science and even to enhance Earth science learning of students. With IESO the organizer hope to award talented and gifted students in Earth science and to promote the improvement of teaching Earth science in schools. Last but not least encourage friendly relationships among young learners from different countries and promoting international cooperation in exchanging ideas and materials about Earth science and Earth science education. IESO is the only International Olympiad that include an International Team Field Investigation - ITFI. Past International Team Field Investigation have included developing stratigraphic sequences, evaluating living on the Mt. Mayon volcano, and evaluating the fault escarpment of the Chi-Chi earthquake. In 2010 in Indonesia, the International Team Field Investigation focus on sustainability and the use of underground water.

The IESO is one of the last science Olympiads established. The first edition was held only in 2007 with the support of countries with a strong emphasis on Earth science in their national curriculum.

Republic of Korea guest the 1st IESO edition in 2007, then:
 208 2nd Philippine, theme: Cooption in Addressing Climate Change (the word "cooption" refers to a combination of competition and cooperation).
 2009 3rd Taiwan, theme: Human Environment
 2010 4th Indonesia, theme: The present is the key to the future.
 2011 5th Italy, theme: Earth science renaissance, science, environment and art

2012 6th Argentina
 2013 7th India

In 2011 for the first time IESO will be held outside Asia, in Europe. That could be a great occasion to involve more European country to participate in this competition and a great occasion for Earth science education expert to know each other and grow a European network.

U3-5 Orale Mundula, Matilde

10.1474/Epitome.04.1097.Geoitalia2011

EARTH SCIENCES FOR THE EDUCATION TO CITIZENSHIP. EXAMPLES OF PARTNERSHIP BETWEEN SCHOOLS

MUNDULA Matilde¹, FERRERO Elena², VIO Elisabetta³, VIALE Michela²
 1 - ANISN, ITCG "FERMI"
 2 - DIPARTIMENTO DI SCIENZE DELLA TERRA UNIVERSITA' DI TORINO
 3 - IC AIRASCA

Presenter e-mail: matilde.mundula@gmail.com

Key terms: Earth Science education; International partnership; Developing countries; Water

The project involved pupils, students and teachers - belonging to different communities - in a meeting work which, through an inquiry dedicated to natural environment, will help everybody to become aware of its own role as "citizen" and to act consciously with equal dignity. The project, supported by the University of Turin (Earth Science Department) and the Piedmont Region, had the aim of starting an educational path in partnership with Developing Countries, and was based on the framework of the main guidelines of Geology (complexity, interaction, dynamism, fragility, cycles...).

One example, carried out in the school year 2009/2010, involved more than 250 students from Italian schools (Turin and Airasca) and a school of a deprived district in Salvador de Bahia (Brazil). The aim of the project is to improve the learning skills and the enthusiasm of students in troubles by means of an interactive didactic, based on field and laboratory work. Direct perception and observation of their environment, starting from the physical components, has the goal of introducing it to the twin partner, living in another continent, produces a highly motivational task.

The project extended to the area of Earth Sciences, focusing on the theme WATER. The activities included both individual tasks and team work, focusing the attention on the location of water on the territory and on its action of transformation, highlighting the risks that may occur. A tight correspondence took part between students and teachers belonging to the different schools and a lot of drawings, texts, teaching materials and pictures have been exchanged through the net.

A second path has been realized between the students of a technical school near Turin (Italy) and the students of Cape Verde. They were both involved in an inquiry about water management in the area in which they live (Prealpi di Piedmont for Italian students, Fogo Island for students of Cape Verde), and in general about the actions carried out by Municipalities in order to manage and to defend water from waste and damage and more widely to protect the natural environment.

The starting point has been the Charter of Earth. We introduced the students to its general themes and asked them to investigate which indications are actually realized by the local Municipality and how. This work has been completed by a workshop dedicated to the global climate change and to perceive clues showed in our countries. Each step required an active participation of the students in the

teaching-learning process (fieldwork, identification and choice of sources, self managed teamwork, sharing of final products and assessment, a new partnership with new friends), creating - as a consequence - an emotional involvement that has never failed during this experience.

U3-6 Orale D'Addezio, Giuliana

FROM RESEARCHERS TO COMMUNITY: EDUCATIONAL AND OUTREACH ACTIVITIES OF THE L'ISTITUTO NAZIONALE DI GEOFISICA E VULCANOLOGIA

D'ADDEZIO Giuliana¹, LABORATORIO Didattica E Divulgazione Scientifica¹
 1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: giuliana.daddezio@ingv.it

Key terms: outreach; research; awareness; information

The Istituto Nazionale di Geofisica e Vulcanologia (INGV) is currently the largest European scientific institution dealing with Earth Sciences research and real-time surveillance, early warning and forecast activities in geophysics and volcanology. The Laboratorio Didattica e Divulgazione Scientifica Group of the INGV organizes every year intense educational and outreach activities with schools of different grades and with general public to convey scientific knowledge and to promote research on science and nature. Since Italy is a place prone to seismic and volcanic activities our activity focalize in particular on causes of earthquakes and volcanic eruptions and how to behave properly during these events. This approach derived from the consciousness that preparedness is the best way to live with and to mitigate natural hazards.

We schematize our outreach activities in three main topics:

- 1) Schools at INGV; more than 40,000 students have visited our Center in Rome, and demands increase each year; the visit consists of a theoretical lesson in a conference hall supported by multimedia tools, and practical experiences based on exhibitions and hands-on experiments focused on earthquakes, plate tectonics and the inner structure of the Earth. A special experience is the visit to the control room of the INGV National Seismic Surveillance where the students can see in real time the seismic activity and how it is important its continuous monitoring 24-hours a day all year round.
- 2) Week of the Scientific Culture and The European Night of Researcher; every year our Institute is opened for special national and international events to the general public, in order to show our laboratories, to talk about new researches on Earth Sciences and to explain the Volcanic and Seismic risk and the related surveillance activities.
- 3) Expositions and Science Festivals; we can bring on the road, in concomitance with the Science Festival in Genoa, Italy, or in cooperation with Museum and Academies, a self-designed portable museum with experiments, models and instalments projected for teaching and learning plate tectonics, seismology, volcanology, seismic and volcanic hazard and geomagnetism.

In this talk we give an overview of these activities, showing also how enthusiastic the audience participation is and how Science Divulgate is necessary to stimulate the interest of the widest possible range of public and to justify the employment of Public Funds for Research and University.

U3-7 Orale Eva, Elena

10.1474/Epitome.04.1099.Geoitalia2011

GEOPHYSICAL INSTRUMENTS AS LEARNING TOOLS: PROS AND CONS

EVA Elena¹, SOLARINO Stefano¹
 1 - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: elena.eva@ingv.it

Key terms: Geophysical instruments; School; Teaching; Educational projects

It is well acknowledged that the best way to learn is to practise. Learning a foreign language needs conversation, improving visual arts benefits from drawing, learning information technology would be impossible without training on a computer and so on. Nevertheless, in Italian schools, physics, biology and earth sciences laboratories are becoming poor and poor, so that for students to experience becomes very difficult if not impossible. This remark not only applies to experiments that are seldom applicable in everyday life, like watching a cell on a microscope, but also to phenomena which we experience several times in a life, like rain or wind or, fortunately not as frequent, earthquake. Apparently, thus, having the chance to watch, manage and use an instrument to measure some of these quantities can turn to be a valuable tool for a better learning.

In the last decade several projects, mainly financed by the European Community, were born with the aim to buy and lend to schools semi-professional instruments. The financial support has been granted to universities and research agencies with the aim to organize a network of interconnected schools sharing and exchanging data and activities. The results of these activities have been included in manuals or books, often after a comprehensive discussion held during meetings among teachers and researchers.

The idea behind these projects is that preparedness is an efficient (and certainly the most recommendable and cheap) way to face emergencies. Education and training are thus two ingredients to help the students, that is the future citizens, to perceive the scientific information formerly confined in the research laboratories, in particular in the domain of the environmental risk.

Within the projects the students were taught how to install, run, manage, fix (in case of minor failures) the instruments (weather and seismic stations, hydrological kits), to collect the recorded data and to organize them in databases. The schools were then proposed activities to be carried out with the dataset resulting from the recordings or let free to design their own experiences. Many activities were also aiming at designing and building home-made instruments or to assemble facilities to show the science behind natural phenomena.

In this presentation we try to make a thorough analysis of the advantages and disadvantages of these projects and especially of the related activities, with a particular attention to the importance of having an instrument available for teaching / learning. As a general comment, the availability of an instrument requires much more than the regular school time and, especially at the beginning of the experience, a much greater effort from researchers and teachers. An organization of duties and responsibilities among the students is needed for a correct management of the instruments and databases. All these aspects of course concur to a growth from students to citizens, from curiosity to responsibility, from spectator to protagonist.

Unfortunately, the initial thrill is substituted quite soon by a lack of interest, coinciding with the second phase of the projects, that is when the researcher let the student teams go ahead on their own. It turns out that the most negative aspect of these projects is the lack of spatial and temporal continuity: in fact projects have a limited duration (in general three years, rarely they are renewed) and often students do not transfer their knowledge and skills to the younger ones.

U3-8 Orale Lanza, Tiziana

10.1474/Epitome.04.1100.Geoitalia2011

AN ECOMUSEUM EXPERIENCE IN THE CASTELLI ROMANI AREA FOR DIDACTIC PURPOSES

LANZA Tiziana¹, CRESCIMBENE Massimo¹, LA LONGA Federica¹, PIZZICANNELLA Enrico², TORTORICI Giacomo², PIZZINO Luca¹, FREPOLI Alberto¹

2 - Ente Parco dei Castelli Romani (Rocca di Papa)

Presenter e-mail: Tiziana.Lanza@ingv.it

Key terms: Ecomuseum; Environment; Science Theatre; Earth education; Science Communication

Among the different methodologies to educate people to the planet sustainability, the Ecomuseum is one of the most innovative and advanced. It offers the opportunity of using different didactic modules such as drama and museography in order to obtain the full involvement of the people to be educated. In the Ecomuseum, visitors are not just the observers but also interactors and in a wide perspective even the watchmen of the territory where they live. In Italy already exist eighty Ecomuseums, two already established in the Lazio Region. One of those, the one in the Agro-pontino area, is already operating at a large scale and in a European context with great results. Following the same path, the Istituto Nazionale di Geofisica e Vulcanologia in Rome chose an area, the Albani Hills, to implement a pilot-project for the establishment of an Ecomuseum in one of the Lazio Region areas rich of natural landscapes and history. In collaboration with the Ente Parco dei Castelli Romani a program for Lyceum students was implemented during a year (2009-2010). The students of two classrooms of the Mancinelli and Falconi Institute in Velletri (III Classical Lyceum and III Socio-Pedagogical Lyceum), aged 16, chose an itinerary in the volcanic-origin area around the Nemi Lake to be developed in three items: the Roman Ships Museum; The lake itself; and the Diana Nemorensis Temple's ruins. The final goal was interpreting the territory with the help of scenic actions. It was a sort of opened-air theatre where history, legends and their historical figures - mainly Caligula and the Goddess Diana - described the area from the different points of view: geological, historical, naturalistic and even gastronomic. The project evaluation was assigned to a Socio-Pedagogical Lyceum, under the supervision of INGV Didactic Lab. Results are encouraging even if innovative way to gain students enthusiasm should be thought since only a small group of students participated actively to the project. For future experiences it is important to succeed in involving as many teachers as possible to have more hours at disposal to be dedicated also to the dramatization.

U3-9 Orale Stanchi, Silvia

1 - DIVAPRA - NatRISK Via L. da Vinci 44, 10095 Grugliasco, TO

2 - DIVAPRA - Via L. da Vinci 44, 10095 Grugliasco, TO

Presenter e-mail: silvia.stanchi@unito.it

Key terms: scientific communication; soil; laboratory; education; outreach

In the last years, scientific education has become more and more popular, as showed by many initiatives with different target audience, themes, and aims.

In the 18th World Congress of Soil Science (Philadelphia, 2006) the importance of scientific communication was underlined, and it's now evident that the future of soil science is strictly related to communication and education strategies, mainly for the young public. Also the European Union remarked the importance of soil awareness raising for the large public.

The NatRISK (Research Centre on Natural Risks in Mountain and Hill Environments), the DIVAPRA (Department of Reclamation and Valorization of Agro-forestry Resources) of the Faculty of Agriculture of Turin, the LNSA (High Altitude Alpine Soil and Snow Laboratory) ideated many activities focusing on soil awareness raising, and they have been carrying on outreach activities for almost a decade.

The main activity is the DI-VERTISUOLO, a soil lab created for schools, that registered a big success also among the general public.

The DI-VERTISUOLO is a portable lab for soil exploration, observation, and study that doesn't require any specific devices and lab instruments. It was presented in several events and places such as: World Soil Day (Fontainemore, AO, 2005); European Union Researchers' Night; ESOF-European Science Open Forum, Barcelona, 2008; Environment Day, Asti, 2009; expositions hosted by Mosso Scientific Institute - Col d'Olen and Savoia Alpine Hut - Oropa, <http://www.gboropa.it/Divertisuolo.htm>; Campus 2009; many schools.

Thousand people were already involved (students, teachers, trainers, large public).

The main objective is getting people familiar with soil themes and complexity, with an interactive funny approach. Teachers and trainers are involved in the experiments, that can be carried out at home or school with a simplified home-made lab-kit.

Some soil properties are presented and described: the main soil environmental functions; soil physical and chemical properties (color, structure, consistence); the role of water in soils...

All the activities are adapted to the age and background of the target audience.

U3-10 Orale Sibi, Patrizia

10.1474/Epitome.04.1102.Geoitalia2011

THE VISITOR CENTER OF THE VALLE DEL TREJA REGIONAL PARK (RM): A GATEWAY TO THE GENERATIVE NETWORK OF PARK ECOSYSTEM.

SIBI Patrizia¹, SCIACCA Elena², VALLETTA Mario³

1 - Dipartimento di Ecologia e Sviluppo Sostenibile - Università della

Tuscia

2 - Parco Regionale Valle del Treja - (provincie di VT e RM)

3 - CTS del Rocca di Cerere European Geopark

Presenter e-mail: sibiapat@libero.it

Key terms: River-ecosystem; park management; ecological literacy; interactive room; ecological thought

The future challenge passes through the process of ecological literacy of the human communities. (F. Capra, 2004)

This ambitious, although necessary, goal involves the development of skills equally spread among the human communities: to be able to recognize the systemic nature of every phenomenon, to look for the networks of energy connections which determine the existence of biotic and a-biotic factors, to support the processes which make life on our planet possible.

In front of this cultural need expressed by all mankind, even if at different levels, every type of environmental communication and scientific spreading should become an ecological literacy opportunity. Everyone needs a lot of chances to train himself to the ecological thought, to the connecting thought, to experience the feeling to be part of the whole.

In the context of the communication activities promoted by the Valle del Treja Park organization, the authorities and the officials of the Park, in cooperation with the Environmental Educational Laboratory of the DECOS Department of Tuscia University, planned an interactive room for visitors. In the park visitor center, at the ground floor of the baronial palace in Calcata, everybody will be able to discover the secrets of the park through multimedia workstations. It will be possible to bring to light the mechanisms and the processes characterizing this specific ecosystem, to find out the evolutionary events which produced it, to discover how the park could become in the future in relationship to the behaviours of the community living there and to the park management effects.

The Valle del Treja Park is a little regional park established in 1982 by the Lazio Region. It cover 628 hectares in the municipalities of Mazzano Romano (RM) and Calcata (VT) along the Treja River course.

This is an area of geological and hydrogeological importance: the landscape is characterized by gorges carved by the waters in the soft tufa of the volcanic complex of Sabatini. So, these morphological and lithological features, along with the micro-climate of the groves, determine the particular landscape, vegetation, fauna and the whole ecosystem of the Park.

This natural area is particularly rich in biodiversity and cultural resources, but it is also particularly 'sensitive' to the effects of human activities and of tourist flow.

For these reasons we believe that the park can be a useful laboratory for ecological literacy. In the Valle del Treja Park every visitor, of any age, will be able to experience - by means of appropriate tools - the ecological approach to natural systems and to realize that and how even small actions done by man can change the balance of the park ecosystem.

10.1474/Epitome.04.1103.Geoitalia2011

STRATEGIC ROLES FOR THE GEOSCIENCES IN ADDRESSING MAJOR CHALLENGES OF THE 21ST CENTURY

LAMBERT Ian¹, WYBORN Lesley²

1 - Geoscience Australia and Secretary General, 34th IGC

2 - Geoscience Australia

Presenter e-mail: ian.lambert@ga.gov.au

Key terms: multidisciplinary systems approaches; addressing challenges; digital age

There are many challenges in meeting the needs of societies while sustaining Earth systems. Difficult decisions have to be made and there is increasing scrutiny of their effectiveness and validity. With increasing levels of education, societies are more capable of questioning what they see as poor decisions and policies.

There are emerging opportunities for applications of the geosciences in multidisciplinary systems approaches to underpin important decisions and policies on issues such as mineral and energy resources, groundwaters, soils, competing land uses, geohazards and emergency management. Ongoing advances in web technologies and in data transfer standards are making geological and geospatial data and information much more accessible online and reusable for purposes beyond those they were originally collected for. In parallel, the rapid increases in available computing power and in open source processing algorithms are enabling geoscientists globally to analyse and model these data. In combination, these new developments are rendering multidisciplinary approaches much more effective and transparent.

Government geosurveys and research agencies need to play pivotal roles in ensuring that the geosciences are accepted as important components in integrated approaches to address issues relating to natural resources, land use and hazards, in particular. Universities also need to play vital roles in instilling the importance of high quality multidisciplinary systems science. This presentation will illustrate, at a high level, how geoscientists in Australia are involved in addressing a number of major challenges faced by the nation. It will link these examples to areas of focus within the scientific program for the 34th International Geological Congress to be held in Brisbane, Australia 5-10 August 2012 (www.34igc.org). While this large and prestigious meeting will cover the whole spectrum of the geosciences, it will feature a wide range of sessions on the influential roles the geosciences can play in the digital age.

THE GEOLOGICAL RISK PREVENTION THROUGH THE DISSEMINATION IN SCHOOLS

DI PATTI Carolina¹, D'ARPA Carolina¹

1 - Museo Geologico "G.G. Gemmellaro", Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo

Presenter e-mail: dipatti@unipa.it

Key terms: Geological risk; environmental protection; educational activity

In Sicily the 80 % of the region is under seismic, volcanic, hydrogeological and geomorphological risks. All the 390 sicilian municipalities have been defined seismic from D.P.C.M. n.3274 and, among these, 29 are considered within the category 1 of the risk. Hydrogeological risk is the most common in Sicily, as evidenced by the high density of landslides

about 1 every 50 km².

Earthquakes, volcanic eruptions, tsunamis and floods are the expressions of the energy of the planet Earth. The man is unable to live in harmony with the Planet and he is often the reason of the huge disasters and the victim at the same time.

To save the planet Earth the man has to take a responsible behaviour. Local territory knowledge is essential in order to protect themselves from it. For this reason is necessary to develop the attention to the environmental protection with educational activity that guide people to conduct awareness.

The "G.G. Gemellaro" Museum has conducted two experimental courses to explain the geological risk in the region. The first was carried out with the teachers of primary school and the second with the pupils of the primary school. To understand the dynamics of the earth and the geological phenomena, the course was structured in three teaching units: Volcanic risk - The aim was to understand origin, dynamics and evolution of volcanism, with a focus on Italian territory. The methods of forecasting volcanic events and the possible preventive measures feasible have been shown.

Seismic Risk - This teaching unit was aimed at understanding the causes and distribution of earthquakes and the risks associated with them, starting from the structures of the Earth and the "plate tectonics". Preventive measures and forecasts, which could reduce the flow of destructive phenomenon, have been exposed.

Hydrogeological risk - Among the geological risk, this is the most dangerous for his high social-economical impact. This term refers to the risk of the occurrence of extreme weather events that lead to different types of instability and are closely intertwined to landslides and flooding. The course was divided into a theoretical and a practical parts.

The theoretical part was held in the classrooms, the practical part in the territory. To achieve these objectives were carried out lectures with the help of multimedia products, case studies, brainstorming and guided tours.

In the course for teachers were provided the tools of knowledge and expertise for future programming. In the pupils' course many laboratories have been carried out which have led to the creation of a model for the understanding of "plate tectonics" and a scale model of a volcano. A volcanic eruption has been simulated in order to understand the risk associated with the urbanization of volcanic areas heavily populated

GEOSCIENCE AWARENESS: THE USE OF THE GEOGRAPHIC INFORMATION BY MEANS OF WEB VIEWERS

CAMPO Valentina¹, CIPOLLONI Carlo¹, CONGI Maria Pia¹, DELOGU Daniela¹
1 - SERVIZIO GEOLÓGICO D'ITALIA ISPRA

Presenter e-mail: valentina.campo@isprambiente.it

Key terms: geoscience awareness; geology; web viewers

Geoscience organizations especially the national geological survey represents the geoscience community of a country. The Geological Survey of Italy - ISPRA - collects, documents, manages and interprets geological information, which is used by companies, authorities, organizations and others and has among its tasks to disseminate knowledge about geology and its applications: the primary goal is to make our geological information more accessible via web services such as map viewers. To do this the Geological Survey of Italy (SGI) has provided a geoport in which a viewer allows viewing the data collected in the form of maps. It's also possible to consult databases, reports, other publications, etc. The users, students, citizens, and technicians, using the geoport can find the data about geology of our area, soil depths, geophysics, natural hazard assessment, and other fields related to the earth sciences. Our aim is to develop human resources and to create awareness of the role of the earth sciences among the mass population of the country about geosciences and its contribution to our life and society to enhance and protect our quality of life. To plan as safe a society as possible, we need to take account both of the hazards that exist in nature and the ones we ourselves have created and geological information can be used to try to prevent and minimize the effects of different types of hazards, such as landslides and floods.

For publication the data must be documented to describe the methods or techniques used to collect, process, and analyze data, the structure of the output, description of accuracy and precision; standards for metadata. Metadata (information that characterizes and describes data, including how, when, and by whom the data were collected) are one tool used by the SGI to maximize information quality, utility, objectivity, and transparency of third-party data. Metadata plays a key role in describing the specific quality procedures that were followed, as well as documenting methods and techniques used in studies.

Our map viewers gallery is designed to offer easy access to some of the information available in our databases. Many of these applications also provide an overview of what additional information you can order from us. When using our map viewers, which are free of charge, you navigate via digital maps and select the geological information you are interested in. We realize own web map application with different technologies, also open source, to highlight or simplify the content in relation with the type of end-user.

Key terms: geological maps; training events; digital learning; microscope

The adventure that brought us into contact with the children and the schools started as a joke around 2000 when a school district of Rome invited us to keep a lesson on fossils to primary school students. Then we have had the opportunity to open a new world to children, that of microfossils, but at the same time they have opened a new world for us, one of the schools, the wonder and excitement that takes the kids every time resting eyes on a microscope. Their enthusiasm was so contagious that led us to continue having these meetings with them even if we had absolutely no experience in teaching.

Excited and encouraged by the feedback we thought about the possibility of taking this activity a bit more seriously and, as a Geological Survey of

Italy - Department of Soil Protection we deal with the implementation of the Italian geological maps, we thought we could tell them what is our work and how to realize a geological map.

The opportunity has been offered by the participation in some events, both national and international, as the various editions of the "Conference of Environmental Agencies" that were held in several Italian regions; the 1st International Festival of Elements ground/air/water/ fire that took place in Parma; the Educational Project City of Rome; the 4th edition of the Geography Festival in SAY & DO event organized in Florence by the Tuscany Region; some lectures at primary schools "Giovanni XXIII" and "Edmondo De Amicis" in L'Aquila, finishing with the creation and development of a complete teaching plan agreed with professors of the "Renato Fucini" school of Rome.

The participation in training events incentive us to give more and to enrich our lesson with new arguments every time. Indeed, although at the beginning we have been concerned of fossils and paleontology for their ability to arouse curiosity and always stimulate the imagination of children, then we started telling the geological mapping and tried to explain them more engaging and accessible the basic concepts of geology. To make the principles, such as the graphical representation of a three-dimensional world, more appealing is not easy. To play down the concept of geology "lesson", the disclosure of geological mapping and awareness of different issues concerning the Earth sciences, in the 4th "Geography Festival" they have been addressed both through lectures, both with a quiz based on knowledge of geology, geography and geo-renowned scientists and with educational activities even with the aid of optical microscopes.

A very interesting experience was realized in cooperation with Telecom Italy during the Public Administration Forum based on the applications of digital learning, developed with the use of open source software Moodle, in science and in particular to those of Earth sciences.

In this case we have created a cycle of "experimental" lectures" as part of a public school digitization project. The digital platform allows the teachers to create online educational courses also having the ability to coordinate interactions with students.

The interest in children led us in the years to improve our "participation" seeing more and more active in finding different ways of communication depending on their interests and age. For example, we could experience among primary school children using the microscope to observe the associations of the various marine microfossils in the past, because it arouses as well as interest, curiosity and wonder. The high school prefer to be involved in competitive quiz game.

Over the years we have seen that working with children aged between eight and twelve years is very challenging and rewarding for us because we were often surprised with their questions almost never trivial and sometimes very complex.

WHO TALK ABOUT SCIENCE?

GHIARA Maria Rosaria¹

1 - Centro musei delle Scienze Naturali Università di Napoli Federico II

Presenter e-mail: mghiara@unina.it

Key terms: scientific communication; informal education; professional training

Spreading of sciences still has great limits in our society. Conquering the stage on the occasion of discoveries which generate wait for the resolution of problems that trouble mankind, or, otherwise, on the occasion of dramatic and catastrophic events. Issues are often explained roughly and generally without any consideration of the general context, offering in this way an incomplete view of scientific problems, and what is more depreciable, aimed just to press human sensibility. 25 years are elapsed from the alarm launched by Royal Society with Bodmer report on Public Understanding of Science (1985) which warned against potential deterioration in relations between science and public opinion. Then the most logical solution seemed to be teaching scientists to "speak" to the public in an understandable way, in order that they could gain more and more accurate scientific knowledge. Someone tried to run for cover with the creation of CoPUS (Committee for the Public Understanding of Sciences) which carried out a program of public understanding of science but, back in the '90s was in crisis. A crisis increasingly evident, so much so that in 2000 the third report of the House of Lords entitled "Science and Technology", recognized the failure of the project because, not only the scientific literacy was not increased but the suspicion grew even aversion towards scientific research. Unfortunately, having pressed scientists to learn how to communicate with public has not delivered desired results. Science is not yet considered as a major factor in promoting national welfares. Most people, in fact, continues to feel scientific disciplines as not properly "cultural" and to be deaf to the right assertion that "no public communication of science means a not real democratic society of knowledge" (Greco & Pitrelli, 2009). Earth Sciences divulgation, in this respect, is certainly a particularly eloquent case. Because in most cases it deals with catastrophic natural events inevitably relating this kind of collective misfortune. Moreover not always the catastrophic event is adequately documented and proposed in the natural and complex evolution and geodynamics of the Earth. Earth Sciences need a much greater disclosure. In a nutshell, the communication on the issues concerning the earth sciences should be reserved to professionals who care not only to provide a global vision but also to detect and stress existing connections. It is essential therefore to train and educate rigorously scientific communicators, according to precise and shared criteria, to achieve the goal to establish an appropriate role for scientific cultural mediators (Tran & King, 2007; Tran, 2008; Rodari & Merzagora, 2009). On the other hand what does it mean to know or understand science? Maybe to know a lot of scientific facts? Many theories? Its methods? We understand that it is not possible to transform common people in small chemists, physicists or biologists. Neither one can reduce science to a mere technical knowledge or, on the other hand, to empty entertainment, renouncing its primary educational role (Israel, 2008). But we can, at least, try to get the public more aware of the influence that science exerts on society.

THE MILITARY GEOGRAPHY AND GEOLOGY IN ITALY FROM THE NATIONAL UNITY TO THE SECOND WORLD WAR

LAURETI Lamberto¹

1 - Dipartimento di Scienze della Terra e dell'Ambiente - Università di Pavia (Italy)

Presenter e-mail: laureti@unipv.it

Key terms: military geology; military geography; applied geology

This paper will present a bibliographic review of the more significant works about the application of the geographical knowledges and earth sciences to the military operations. Besides the well known concepts referring to the importance and the role of the Geography (as remarked in the ancient times by the same Strabon, I, 1, 16), it is not useless to remember that the cartographic representations have always been an important tool in the terrain recognition, surveyed mainly in order to help the military operations. So it is possible to assert that the history of cartography follows strictly the development of the military technologies. In Italy, the studies about the application of the geographical knowledges to the war operations begins to develop about the half of the XIX century, on the wake of the ones issued in other european countries, as Prussia, Austria, France, etc. Among the more noteworthy italian works (normally written by high officers) we can draw attention toward some precursory ones (of Annibale da Saluzzo, 1845, Francesco Orsini, 1852) and the italian translation of the treatise of the french T. Lavallée (1852). After the national unity, in the last quarter of the XIX century, we must point out the works of Giovanni Sironi (1873), Giuseppe Perrucchetti (1874-1881, Giovanni Riva-Palazzi (1883-1885) and Carlo Porro (1898). Very numerous are also the contributors by the academic geologists, mainly during the operations of the First World War, as Enrico Fossa Mancini, Federico Sacco and others. Then, during the twenty years before the Second World War, the teaching of Geography and Geology become duty organized by the military academies and schools and based on the monumental set of the monographies of the brigadier general Delfino Deambrosio (1920-1935).

Presenter e-mail: aldino.bondesan@unipd.it

Key terms: Military Geography; Geomorphology; Venice; Fortification

Starting from XVI Century and during the Austrian occupation of Venice, fortifications were built on many of the outlying islands of the lagoon and in the mainland. It is a fortified Venice that few are aware of. Today only a part of the city's huge and complex defensive system had survived. This valuable group of buildings for decades had been designated exclusively for military purposes and was little known. Now that the military authorities have ceded a good many of these forts, it has been possible to convert them into cultural sites and places of tourist interest. They are now part of the new historical naturalist itineraries between the lagoon and its hinterland, winding along a very estensive and most picturesque route. The main fort - of extraordinary architectural, naturalistic and archaeological interest - is Forte Marghera, the oldest and most imposing of those of the entrenchment around Mestre, occupying over 40 hectares. It was the first fortified work built for the defence of Venice against attacks from the land and is placed at the inner border of the lagoon, connected with the center of Mestre through the old "Fossa Gradengia", the present Canal Salso. Many other forts surround the city of Venice, from Forte Manin to Forte Bazzera, where we find the powder magazines, the last remaining ones of the whole system, and dating from the First World War. On the lagoon side, the defensive system used to extended to the Arsenale, the vast complex whose work-shop fitted out the powerful Venetian mercantile war fleets that so facilitated the city's rise to greatness. Between one island and another stands the strategically sited Forte Sant'Andrea at the entrance to the lagoon, the Forte San Felice at Chioggia, the Forte Ca' Roman on the littoral at Pellestrina. Then, typical octagonal forts defends the ports of the lagoon: the "Octagons" of Alberoni, Campana, Poveglia and Caroman. An historical map analyses was performed in order to identify the main defensive constructions. They were described and georeferenced. Each fortification has been linked with the topographical and geomorphological context in which it was built, considering its strategical significance.

THE ROYAL ARMY MILITARY ROAD AMONG THE FORTRESSES OF XIX CENTURY IN THE PELORITANI MTS. (NE SICILY, ITALY)

CARUSO Vincenzo¹, MACAIONE Elisa¹, MESSINA Antonia¹

1 - Dipartimento di Scienze degli Alimenti e dell'Ambiente - Sezione Scienze della Terra, Università di Messina - Messina (Italy)

Presenter e-mail: karuso@tiscali.it

Key terms: Peloritani Mts.; Calabria-Peloritani Arc; Military Roads; Geo-cultural Heritage; Fortresses and Milvestones

The present study focuses on the geo-historical reconstruction, evaluation and fruition of the Peloritani road network realized by the Military Genius in the late 1800s. These peculiar structures were traced with the intent of linking several spectacular Fortresses erected in the hills along the Sicilian and Calabrian coasts of the Messina Straits, as very important defence

structures against military attacks from the Tyrrhenian and Ionian Seas. The Peloritani Mts. extend from the extreme NE of Sicily to the Taormina-St. Agata di Militello tectonic Line, separated from the Italian Peninsula by the Straits of Messina and delimited to the north and east by the Tyrrhenian and Ionian Seas respectively, and to the south by the Alcantara Valley and Mount Etna.

Their very articulated morphology involves the Ionian and Tyrrhenian coasts and a scenic inland made up of hills and mountains belonging to the Calabria-Peloritani orogen and consisting of Proterozoic to Palaeozoic metamorphics and plutonics and of Mesozoic sedimentary covers, unconformably covered by Lower Miocene to Modern deposits. These relieves are cut by deep valleys, where an intersected fluvial network develops. The ridge, with an average altitude of 1.000 m, extends in a NE-SW direction, from Dinnammare (1.127 m) to Montagna Grande (1.374 m), defining the watershed, and continues with an E-W trend, up to the joint with the Nebrodi Mts.. The geological landscape is characterized by steep reliefs, very deep valleys, acute peaks and a hierarchical hydrography with torrent-like water courses. Marine and alluvial terraces are widespread at different sea levels. The Lagoon Systems of the Peloro Cape, with the Ganzirri and Faro Lakes situated on the Ionian and Tyrrhenian coasts respectively, are also present, located in the extreme NE of Sicily.

Due to their strategic geographical position, emphasized by the Messina Straits as the gate to the Sicily and Mediterranean Basin, the Peloritani mountains were the centre of civilizations and the scene of very important battles.

In spite of several natural and anthropic events which took place during approximately 130 years, elements of the defined military roads which have been preserved are still "legible" and due to which it is possible to reconstruct the history of the Peloritani "Regie trazzere" today with the aim of promoting environmental itineraries in a territory very rich in geological and morphological harmony, and where landscapes immortalize both the thick Mediterranean scrub and wonderful woods.

The defined "Royal Army Military Road" has a specific and characterizing identity. It is significant to note that, with its architectonic and artistic features, such as bridges, retaining walls, tunnels, arcades, milestones, pluvial water convey systems, cisterns, etc., it constitutes a monumental complexity, indicating among other aspects the technical construction and the natural materials used in an important architectonic project carried out by the Italian Military Genius of the late 1800s.

Today this road today represents an important and indispensable heritage for Messina and the surrounding communities and also for tourists, because it links several old picturesque villages and allows people to benefit from the luxurious vegetation and superb landscapes on the Ionian and Tyrrhenian coastlines.

"Knowing the history of a territory, of a site, of an object allows us to understand its very value". This is the spirit responsible for the present research carried out with the aim of reconstructing, documenting and illustrating the geo-cultural characteristics present along this Military Road.

3 - Italian Society of Military Geography and Geology, Italy

Presenter e-mail: aldino.bondesan@unipd.it

Key terms: MILITARY GEOLOGY; GEOPARK; DESERT GEOMORPHOLOGY; BATTLE OF EL ALAMEIN; SAHARA

In 1942, between the end of June and the beginning of November, a series of battles and war actions took place in the Egyptian Desert (namely, Western Desert), near the location known as El Alamein. The third, and final, El Alamein battle began at 20.40 on October 23rd when the awaited British offensive started. After 12 days of hard fighting Montgomery's VIII Army broke into Rommel's defenses, and the Axis troops began a long and difficult retreat which finally ended-up in Tunisia, in May 1943. During the El Alamein battle, which lasted until November 4th, and the next few days, about 30,000 Italian and German prisoners were captured, while, as a whole, the Axis had 9,000 men killed or missing and 15,000 wounded. On the British side, Montgomery's VIII Army losses accounted for 13,560 killed, missing, or wounded men. This study concentrates on the project of a historical-geological park at El Alamein which is under construction taking into account the geological-historical analysis of the reciprocal relationships between the terrain and the development of military operations. The area of interest encompasses the sites in the Egyptian sector of El Alamein (Western Desert), where three battles took place in 1942, in particular the southern front where the Folgore and Pavia divisions fought. Former investigations were performed according to a multidisciplinary approach, in tight collaboration with researchers having expertise varying from military history to archaeology, from geophysics to topography, from geopolitics to sociology, etc. A Geographical Information System was implemented in order to document and reconstruct the battlefield by means of remote sensing and geological-geomorphological field survey and mapping. The study was integrated by an historical analysis of the battle and of the North African Campaign. A comprehensive study of the battlefield has allowed analysis of the geological and geomorphological factors that influenced the military operations and the environmental consequences on the actions of war.

SOLDIER TRACKS IN A FIRST WORLD WAR FORT (VALMORBIAWERK, TRENTO, ITALY)

AVANZINI Marco¹, BERNARDI Massimo¹, PETTI Fabio Massimo¹

1 - Museo Tridentino di Scienze Naturali, Trento

Presenter e-mail: avanzini@mts.tn.it

Key terms: footprints; First World War; Bergshue; dolomitic fortifications; Austro-Hungarian army

Traces have commonly been defined as evidences of the activity (or work) of organisms. In this perspective, human traces document a range of very

heterogeneous and diverse activities.

A research carried out by the Museo Tridentino Scienze Naturali in some bunker systems along the First World War Front in the Pasubio-Lavarone area (Trento) led the discovery of several soldier footprints and traces (Valmorbia, Luserna, Dosso Sommo, Sommo Alto, Cherle, Celva, Nagia Grom, Mt. Testò). Data coming from track analyses are used as a tool for better reconstructing everyday life activities and this follows in the steps of a modern perspective on human ichnology whereby it is considered an interdisciplinary science that interacts with different academic traditions such as various natural sciences as well as social sciences, archaeology and history.

The best preserved footprints are those preserved in the "Valmorbiawerk" Fort (Forte di Pozzaccio in Italian documents) located on the right hand side of the Vallarsa Valley, approximately 8 km from Rovereto in the Trentino-Alto Adige region (Northern Italy). The fort was meant to be housed entirely in a rocky promontory of the Jurassic Calcarei Grigi Group, within a thick (25-30 m) layer of compact oolitic limestones. The building would perfectly fit the rock morphology and due to its innovative features it can be considered a forerunner of the underground bunkers of World War II.

The battery would be situated in the central part of the fort, a long and narrow concrete body where two 10 cm howitzers contained in 30-cm-thick nickel steel swivel domes and one observatory would be located. Underneath, connected by a 15 m shaft, would lay the heart of the fortified system, which was divided into four main caves separated by 10-m-thick rocky walls. These caves would house the troops (3 officers and about 100 soldiers), engine rooms plus provision and ammunition depots.

According to the original plans, the fortification's caves were meant to be covered by brick walls, to have a raised floor, a metal cover and an advanced electric heating system. All the connecting tunnels and the artillery sites were meant to have an efficient system for collecting dripping water, which would then be carried to reservoirs and tanks by pipes and concrete channels.

When the building work was interrupted, only some of the above features were completed.

One of the caves, which were meant to be a storage room, has along its perimeter a 30 cm wide concrete curb that preserve 28 partial or complete boot tracks.

Basing on their morphology and the hobnail layout, the tracks are interpreted as impressed to the right and left boots of the same person. The layout and the shape of the tracks perfectly match the mountain footwear used by the Austro-Hungarian army ("Bergshue"). Using the average ratio of foot length/height of 15 % proposed by Topinard in the mid-1800s, and according to the most recent known data (foot length/stature ratios between 13.47% and 15.98%), the trackway indicate a trackmaker height ranging between 1.77 to 1.80 m. Basing on shoe wearing, the locomotor pattern displayed by the trail can be considered normal except for a slight lateral functional prevalence of the foot. This latter characteristic suggests a slender (from 70 to 80 kgs) and tall soldier with slightly varus knee as possible producer for the trail. The speed of the trackmaker varies between 1.67 and 1.80 m/s.

The curb ends in concrete stairs that lead to a site armed with mountain cannon. It is possible that the man wearing the boots was a soldier at the firing site or another one, perhaps delivering orders, who would have used the nearly solidified curb while the workers were busy in the central part of the cave.

These tracks represent an unusual record of life inside an Austro-Hungarian fortress of the First World War and they also raise the likelihood of other similar findings in dolomitic fortifications.

WWI AND WWII IMPACT IN THE NORTHERN SECTOR OF THE TRIESTE KARST

VISINTIN Luca¹, FURLANI Stefano², BONDESAN Aldino³, CUCCHI Franco¹

1 - Università di Trieste

2 - Università di Padova & Università di Trieste

3 - Università di Padova

Presenter e-mail: lucavisintin@alice.it

Key terms: *Mount Hermada; geomorphology and war; Trieste Karst*

The Northern sector of the Trieste Karst was a significant area both during the WWI and the WWII, the former because it represented the battlefield of the military operations in the spring of 1917, the latter because the coastline of the Gulf of Trieste hosted a number of military artefacts built to defend the territory after the armistice on the 8th September.

We aim at studying the impact of these artefacts on the landscape after respectively 50 and 100 years from the events through a detailed mapping of the remains.

During the WWI, the area was theatre of the operations of the Royal Italian Army in the 1917. Its advance had to drastically stop after forcing Austrians troops from their protected positions, along the Isonzo River.

The Austrians were capable of pivoting on a lofty mountain system, consisting of various lines of high peaks, each of which was a dominating base connected with its neighbour; so that, taken together, they formed a formidable defensive line. On the Trieste Karst, the Third Army, commanded by the Duca D'Aosta, took the enemy's first line (Coren & Francese, 2009). A number of military fortifications, like trenches and barracks, have been built, mainly on the Mount Hermada, but also along the coast. Even the continuous gunshot blown-up on the Mount Hermada seems to have modified the general topography of the area, lowering the top of the hill up to 16 m.

During the WWII, military fortifications have been built mainly after the 8th September 1943, when the German command provided to defend the Trieste area forecasting a landing of allies in the Northern Adriatic Sea. A number of military observatories, trenches, Bunker, anti-aircraft guns were located along the coast between Sistiana and Duino. The remains are still visible, but usually are covered by vegetations. Moreover, a submarine base was located in the Bay of Sistiana (Furlani et al., 2009) and some military structures connected to the base are preserved.

THE GEOMORPHOLOGICAL MAP OF THE SOUTHERN SECTOR OF THE EL ALAMEIN BATTLEFIELD (EGYPT)

BONDESAN Aldino¹, VERGARA Maurizio¹, FURLANI Stefano¹, MASSIRONI Matteo²

1 - Dipartimento di Geografia "G. Morandini", Università di Padova, Italy

2 - Dipartimento di Geoscienze, Università di Padova, Italy

Presenter e-mail: aldino.bondesan@unipd.it

Key terms: *MILITARY GEOLOGY; GEOLOGICAL MAPPING; EL ALAMEIN BATTLEFIELD; EGYPT*

The desert between El Alamein and the El Qattara Depression hosted a series of battles and war actions that can be considered decisive for the North African Campaign. The four months between the end of June and the beginning of November 1942 mark the turning point of the WW2 and the end of the Axis dream to invade Egypt. The location of the battlefield was selected following the geographic features: this sector of the desert narrows to a passage of only 60 km and it is restricted by the Mediterranean Sea, to the North, and by the inaccessible Qattara Depression to the South.

The recent availability of high resolution satellite imagery of large portions of the Western Desert allowed to study the geological and geomorphological features of the El Alamein battlefield and to create two detailed maps. We analysed, in particular, the Southern sector since it was actually the main location of the El Alamein Project, which aims to study and recover the territory interested by the battles.

The geomorphological analysis was performed using some common tools of the GIS software applied to a DTM obtained by SRTM data, while geological limits were obtained mainly by the comparison of ASTER images following the results of a number of Authors in other desert areas. From a geomorphological point of view, the area is characterized by a limestone plateau at about 200 m a.s.l. (Naqb Rala). To the South, the Qattara Depression reaches -145 m a.s.l. The central part is a flat area, gently dipping to the North and incised by depressions, locally called Deir. The northern part is characterized by the presence of Pleistocene hills, called kurkar, which represent the old Nile delta.

From a geologic point of view, the southern part is the oldest one. The El Moghra Formation and the Marmarica Formation outcrops in the Naqb Rala and in the central part, while the Northern part is characterized by Pliocene and Pleistocene limestones, that are respectively the Hagif Formation and the Alexandria Formation.

The availability of these detailed maps will represent a useful instrument to study the war events connected to the three battles of El Alamein and to define their impact on the landscape (as, for example, the extensive minefields laid during the war).

UPPER JURASSIC AMMONITES FROM THE FIRST WORLD WAR FORT LUSERN (TRENTINO-ALTO ADIGE): THE LAKOM COLLECTION

PETTI Fabio Massimo¹, SARTI Carlo², BERNARDI Massimo¹, DEFLORIAN

Maria Chiara¹, FERRETTI Paolo¹, TODESCO Rossana¹, AVANZINI Marco¹

1 - Museo Tridentino di Scienze Naturali, Via Calepina 14, 38122 Trento, Italy

2 - Museo Geologico Giovanni Capellini, Via Zamboni 63, 40122 Bologna, Italy

Presenter e-mail: fabio.petti@mtsn.tn.it

Key terms: *Military geology; First World War; Austro-Hungarian army; Ammonites; Upper Jurassic*

During management activities of the Museo Tridentino di Scienze Naturali (MTSN) palaeontological collections, a systematic review of the ammonite association collected from the Upper Jurassic of Cima Campo (Trentino-Alto Adige) was undertaken. Most of the specimens were collected during the First World War by the Captain of the General Staff of the Austro-Hungarian army Eduard Lakom. The ammonites, stored at the Museo Tridentino di Scienze Naturali, were originally part of a larger collection assembled by Lakom during the building of Fort Lusern between 1908 and 1912.

The Fort Lusern stands on the rise of Cima Campo (1549 m a.s.l.), just above the village of Luserna. The area was considered strategic by the Austro-Hungarian army because it dominates the Altopiano della Vezzena and the eastern sector of the Altipiani di Lavarone. The construction of the fortress, approved in 1905, began on July 15, 1908 and was completed on October 20, 1912, through the incessant work of hundreds of men. The Fort had a volume of 200,000 cubic meters and was composed of a main-building and two outposts: the Viaz (1507 sl.m. m) to the east, and the Oberwiesen (1517 m a.s.l.) to the west. Armament consisted of four tower howitzers positioned in armored revolving domes, four rapid-fire guns and 19 machine-guns M07/12.

The presence of the 'Lakom ammonites' within the palaeontological collection of the MTSN is due to the initiative of the Italian geologist Giovanni Battista Trener (1877-1954). During a geological survey commissioned by the k.k. Geologische Reichsanstalt, from 1900 to 1914 (Tomasi, 2004), Trener repeatedly studied the stratigraphy of the Altipiani di Lavarone and the Cima Campo areas (Trener, 1910, 1913a, 1913b). When Trener became acquainted with the Lakom collection, got in touch with the Austrian captain in order to study his fossil material which turned out to be of great interest both for the large number of samples and for their excellent preservation (some preserve their own shell). The Lakom collection included also brachiopods, bivalves, shark and Lepidotus teeth, and reptile bones (Trener, 1910).

The systematic review of the Cima Campo ammonites, allowed to identify 11 genera and 15 species attributed to middle Oxfordian-lower Kimmeridgian interval. All the ammonites were collected from the upper member of the Rosso Ammonitico Veronese Fm., mainly (57%) from the basal interval of the "upper member", attributed to the lower Kimmeridgian (from the Silenum Zone to the Herbichi Zone). A large number of ammonites belong to different species of the genera *Benacoceras* and *Trenerites* (Silenum Zone) whose type-locality, as reported from literature, is the Cima Campo outcrop (Sarti, 1993). Oxfordian and upper Kimmeridgian ammonites are relatively rare.

THE SIEGE OF MALTA: GEOGRAPHY AND WAR

FURLANI Stefano¹, SCHEMBRI John², BONDESAN Aldino³

1 - Dipartimento di Geografia, Università di Padova

2 - University of Malta, Malta

Presenter e-mail: sfurlani73@gmail.com

Key terms: Geography and war; Second World War; Malta

During WWII, Malta was a significant military and naval fortress, because it was the only Allied base between Gibraltar and Alexandria. It became a very significant way station for Britain toward Egypt and the Suez Canal. It offered a safe haven for British shipping and it gave an excellent staging platform of offensive thrusts against naval, land, air and shipping targets in the central Mediterranean.

The opening of a new front in North Africa in 1940 increased the military value of the island, since British air and sea forces could attack Axis ships transporting supplies and reinforcements from Italy. In May 1941, Field Marshal Erwin Rommel warned that "Without Malta the Axis will end by losing control of North Africa". The Axis resolved to bomb by attacking its ports and towns, cities and Allied shipping supplying the island. Malta was one of the most intensively bombed areas during the war. The Luftwaffe and the Italian Regia Aeronautica flew a total of 3,000 bombing raids over a period of two years. A combined German-Italian amphibious landing (Operation Herkules) would probably have been successful in the occupancy of the island, but it was never carried out. In the end, Allied convoys were able to supply and reinforce Malta, while the RAF defended its airspace.

In November 1942, when the Axis had lost the Second Battle of El Alamein, attacks on Malta were rapidly reduced.

In this work, we have examined the position of the more than one-hundred anti-aircraft guns and other defensive structures on Malta to analyze their geographical distribution, geological substrate and their location for their significance in defending vulnerable geomorphologic areas such as harbours, bays, inlets and valleys with respect to the protection and the successful defence of the island during the war.

WAR STRATEGY, HISTORY WRITING AND KARST ABYSSES FEAR AS REGARDS THE "FOIBE TRAGEDY" DEBATE

DELLE ROSE Marco¹

1 - Consiglio Nazionale delle Ricerche - IBAM

Presenter e-mail: m.dellerose@ibam.cnr.it

Key terms: mass killing; karst landscape; national monument

Inside the earth sciences community, the wide limestone plateau between Slovenia and Italy, named Kras in Slovenian and Carso in Italian, is known to have given the name to the "karst landscapes". As a consequence, it is also referred as the Classical Karst. Some other areas encompassed between Italy, Slovenia and Croatia belong to this type of territory. Dolinas, caverns, ponds, sinkholes and abysses are the main characteristic features of such landscapes. The aforementioned areas had been the "conflict theaters" of a number of II World War episodes, which the current hegemonic Italian historiography referred, as a whole, to the so called "foibe tragedy".

Usually the term "foiba" (pl. foibe, in Italian) is used to indicate deep natural sinkhole or doline. It may also refer to a chasm of a river at the place where it goes underground. Nevertheless, especially in Italy, "foiba" is commonly associated with the mass killings perpetrated by local and Yugoslav partisans, during and shortly after the II World War, against Italians and other real or perceived enemies of the incoming Tito communists. According to the Italian Minister of the Interior "thousands of soldiers and civilians, many of them still alive, were thrown into [the foibe]. The wave of blind violence and summary executions, which involved partisans (Italian anti-fascist partisan organizations), Germans, fascists and Tito's army, lasted until 1947" (www.interno.it). After the end of the Paris Conference, which resulted in the Peace Treaties signed on 10 February 1947, thousands of Istria, Fiume and Dalmatia residents became victims of a forced migration from their regions of settlement. However, during the Cold War and until the disintegration of Yugoslavia and Soviet Empire, the question of the "foibe tragedy" sinking into oblivion. To start from the '90, the history writing process of the above mentioned facts have been constantly accompanied by a political quarrel. At the same time, the Italian Government, by means of adequate laws, has designed the foibe of Basovizza and Monrupino as national monuments. Finally, to keep memory of foibe and of the post-1947 exiles, in 2005 the Italian Republic set aside a memorial day called "Giorno del Ricordo", a civil celebration held on 10th February every year.

By the point of view of the military history studies, it seems to be necessary to question about the "reasons" which could have determined the mass killing. Ethnic hatred and war revenges appear to be plausible causes, although Yugoslav army would have not had any "war usefulness" by such massacres. Moreover, in term of partisan "guerrilla economy", capture, deportation and killing by means of throw into abysses of many hundred of people could be unreal. Perhaps, just to clear such hurdle, some Italian scholars invoke an "ancient use" of the foibe to human killing by Slavonic populations. However, the approval of such disputable hypothesis could lever, for instance, on the ancestral fear to fall over abysses, and it will become "common sense". As a matter of fact, the "evocations of the 'Slav other' and of the terrors of the foibe made by state institutions, academics, amateur historians, journalists and the memorial landscape of everyday life [are] the backdrop to the post-war renegotiation of Italian national identity" (G. Sluga, 1999, Italian National Memory, National Identity and Fascism). More pertinent for the historiography is the analysis of each singular documented episodes of killing into foibe, especially in relation with the features of site and landscape. The case study here proposed regards an episode of throw into abyss with a presumed survivor, occurred on May 1943 probably at a foiba near Plomin (Croatia). Such abyss is now used as water well for a

thermoelectric power station (Pol Vice, La foiba dei miracoli, 2008). Several questions can be raised as regards the truthfulness of the episode and its possible contribution to historiographical process.

A GEOPHYSICAL RESEARCH FOR WW2 BURIAL SITES IN THE TOLMINO AREA (SLOVENIA)

FRANCESE Roberto¹, BONDESAN Aldino², FURLANI Stefano²

1 - Istituto Nazionale di Oceanografia e di Geofisica Sperimentale - OGS, Trieste (Italy)

2 - Dipartimento di Geografia "G. Morandini", Università di Padova, Italy

Presenter e-mail: aldino.bondesan@unipd.it

Key terms: MILITARY GEOLOGY; geophysical surveys; WW2

The Tolmino area was formerly in Italy and belongs now to Slovenia. It was one of the main battlefield during WW1 and today many are the remnants still preserved as fortifications, galleries and cemeteries. During WW2, after the end of the war, 79 Italian soldier were killed and buried in mass graves. The historical reconstruction through the attestation of survivals indicated some possible sites of burial. A geophysical investigation was performed to detect mass graves along the Tolminka River, in fluvial sediments, and at the foot of the karstic hills close to the town of Tolmino. Here, some of the ancient war galleries, hosting also guns, were probably used as site of burial.

The present work shows the result of the GPR and ERT prospection in different areas.

LATE CARNIAN-EARLY NORIAN AMMONOIDS FROM THE BERLIN-ICHTHYOSAUR STATE PARK AND WEST UNION CANYON (SHOSHONE RANGE, CENTRAL NEVADA, USA)

BALINI Marco¹, JENKS Jim A.², SILBERLING Norman J.³, MARTIN Riccardo¹
 1 - Dipartimento di Scienze della Terra, Università di Milano, Via Mangiagalli 34, 20133, Milano, Italy
 2 - 1134 Johnson Ridge Lane, West Jordan, Utah 84084, USA
 3 - 1235 Estes Street, Lakewood, CO. 80215, USA

Presenter e-mail: marco.balini@unimi.it

Key terms: Carnian; Norian; Ammonoites; Biostratigraphy; Paleobiogeography

The Berlin-Ichthyosaur State Park (BISP) in central Nevada is a protected area known worldwide for its unusual record of the large-size ichthyosaur *Shonisaurus popularis*, consisting of 37 specimens collected from the Luning Formation by C. Camp, during excavation between the mid 1950's and 1960's. This site, however, is also of great interest for invertebrate paleontologists, because exposures of the Luning Formation in West Union Canyon, both inside the BISP and on adjacent U.S. Forest Service land, also yield very rich and very well preserved Upper Carnian and Lower Norian ammonoid faunas. These faunas, described by Silberling (1959), were crucial for the development of the North American Triassic standard scale (Silberling & Tozer, 1968), which up to now is still the most complete scale for the Triassic System. The latest two ammonoid zones of the Carnian stage of the North American standard scale, namely the *Klamathites schucherti* and *K. macrolobatus* chronozones, were defined at this site. Moreover, the sedimentary succession exposed at this site also provides a rich record of the earliest Norian *Stikinoceras kerri* chronozone, whose type locality is Brown Hill, on the Peace River in British Columbia (Canada). Despite its importance, no further investigations have been carried out at this site during in the last 50 years, but the relatively recent efforts to select a GSSP for the Norian Stage have necessitated the re-examination of this succession, since it is known to be one of the best Carnian/Norian boundary sections in the world.

Field work has been planned on the basis of a two year program. Detailed notes and measurements by N.J. Silberling have provided the groundwork for the first field survey, which included preliminary bed-by-bed sampling of the outcrops and identifying potential sites for trenching during the second year.

The initial field survey, carried out in October 2010 on both sides of West Union Canyon, concentrated on the upper part of the "shaly limestone member" of the Luning Formation and on the overlying "calcareous shale member".

The southern side of the canyon, within the BISP, provides the best record of the *K. macrolobatus* chronozone, which is represented by several beds yielding ammonoids of the *Tropites* group, namely *T. crassicastratus*, *T. nevadanus* and *Anatropites* div. sp. Higher in the section, the ammonoid fauna shows a sudden change and is dominated by *Tropites* species. The first occurrence of Norian ammonoids like *Guembelites jandianus* and *Stikinoceras* is recorded some tens of meters above, but exposures are generally poor.

The best exposure of the *S. kerri* chronozone is on the northern side of the West Union Canyon on Toiyabe National Forest land, but the *K. macrolobatus* chronozone is not exposed on this side. Ammonoids, dominated by *Guembelites* and *Stikinoceras* div. sp., have been collected from several fossil-bearing levels.

The collected ammonoids fit perfectly well with the faunas described by Silberling in 1959, but they differ somewhat from coeval faunas of the Tethys and Canada. The genus *Gonionotites*, very common in the Tethys and British Columbia, is for the moment unknown in Nevada. More in general, the Upper Carnian faunas are dominated by *Tropitidae*, while *Juvavitidae* are lacking.

Acknowledgments

The US Forest Service and the Nevada State Parks Department are warmly thanked for allowing us to carry out paleontological sampling in the Berlin-Ichthyosaur State Park and the protected areas of the Toiyabe National Forest.

HALOBIA SPECIES (BIVALVES) AS TOOLS OF CORRELATION BETWEEN LATE TRIASSIC (CARNIAN-NORIAN) SUCCESSIONS IN TETHYS AND PANTHALASSA

LEVERA Marco¹

1 - Dipartimento di Scienze della Terra "Ardito Desio", Università di Milano. Via Mangiagalli 34, Milano, Italy 20133

Presenter e-mail: marco.levera@yahoo.it

Key terms: *Halobia*; Upper Triassic; Carnian/Norian boundary; world-wide correlations

Within the Triassic, four GSSPs remain to be established. Among these, the Carnian/Norian boundary interval has seen significant research activity over the last years, especially on the two GSSP candidate sections: the west-Tethyan Pizzo Mondello (Sicily, Italy) and the east Panthalassan Black Bear Ridge (B.C., Canada). Amongst the various possible markers, ammonoids, conodonts and halobiids seem to offer the best correlatability between the two sections, as well as with other section world-wide. Ammonoids are often considered as the primary tools for palaeo-bio-chronological studies and worldwide correlations, but they not always occur. In fact, both the Pizzo Mondello and Black Bear Ridge sections have a rich conodont record and a rich halobiid record, but are somewhat lacking in ammonoids.

The biochronologic significance and correlation potential of the Triassic flat

clams of the genus *Halobia* has been demonstrated at regional and global scales. In fact, many species are widely distributed and exhibit high speciation rates, with a resolution comparable with that of ammonoids in terms of duration of the biozones.

Sufficient data on key halobiid species have been collected through the comparison of the halobiid fossil record from the two GSSP candidate sections, as well as others from Tethys and Panthalassa. These allow precise correlation of more than one species within the C/N boundary interval between the west-Tethyan and eastern Panthalassic realms. At Pizzo Mondello, ten halobiid forms occur (from base to top): *Halobia carnica*, *H. lenticularis*, *H. simplex*, *H. superba*, *H. cf. rugosa*, *H. radiata*, *H. austriaca*, *H. styriaca*, *H. beyrichi* and *H. mediterranea*. Most, if not all, of these taxa and their succession are repeatable throughout much of the western Tethys, especially in Austria, Lucania, Greece and Montenegro. The halobiid sequence at Black Bear Ridge includes, from base to top, six species: *Halobia septentrionalis*, *H. ornaticissima*, *H. radiata*, *H. selwynii*, *H. austriaca*, and *H. cordillerana*. Likewise, most of these taxa provide strong correlations across eastern Panthalassa and especially throughout far-eastern Russia.

Within the C/N boundary interval, several species occurring at both sites offer good potential for global correlation and may provide potential markers for the Norian GSSP. The first is *H. radiata*, which spans from the latest Carnian (Tuvalian 3) to the basalmost Norian (first zone of the Lacián 1). *H. radiata* is indeed one of the most cosmopolitan halobiids from this time interval and has often been considered as a good marker for the upper part of the *Anatropites spinosus* Zone in the Tethys and the *Klamathites macrolobatus* Zone in North. At Pizzo Mondello, the first occurrences of *H. austriaca*, *H. styriaca*, and *H. beyrichi* closely follow one another. *H. styriaca* is common in the western Tethys (where it occurs in a well defined lithological interval that can be traced at least from Austria to Italy, Greece and Turkey), eastern Tethys and western Panthalassa, but it has yet to be reported in western North America. *H. beyrichi*, in its turn, is a relatively common species in the Tethys, while it is only known from a few occurrences in the terranes of North America and British Columbia, and it is not known to occur in craton-bound strata such as at Black Bear Ridge. On the other hand, *Halobia austriaca*, much like *H. radiata*, is a more wide-spread taxon, occurring in the tropical western and eastern Tethys, throughout Indonesia and the western Panthalassa, the Boreal of northeastern Russia and throughout the North American Cordillera. The succession of *H. radiata* and *H. austriaca* represents an interval which can be recognized at a global scale. Moreover, the first appearance datum of *H. austriaca* seems to be the best proxy of the base of the Norian Stage in world-wide correlations.

Presenter e-mail: angelo.tripodo@unipa.it

Key terms: Upper Triassic; Sicily; Ammonoidea; Pinacoceratidae; taxonomic revision

The Triassic ammonoids studied by G.G. Gemmellaro are one of the most important collections housed in the homonymous museum of Palermo University. The collection was assembled by Gemmellaro or by his co-workers between the end of 1800 and the first years of 1900 and consists of 780 specimens. All the ammonoids have been described in the monograph "I cefalopodi del Trias Superiore della regione occidentale della Sicilia" (Gemmellaro, 1904) which provides the final report on the taxonomic and stratigraphic studies performed by Gemmellaro on the Triassic cephalopods. Gemmellaro described 49 genera, including 4 new for the science, further divided in 230 taxa, including 166 new species. The knowledge of the Triassic ammonoids has been notably improved since the beginning of the XX century, especially in the last 40 years, with several contributions on Tethyan and north American faunas.

Unfortunately the rather rich literature does not take into account the faunas from Sicily, whose knowledge is still based on the Gemmellaro monograph.

Three years ago we started a taxonomic revision of the Gemmellaro collection in the framework of a PhD thesis (Tripodo, 2011). Here we present the redescription and revision of the specimens belonging to the family Pinacoceratidae and their comparison with the Pinacoceratidae from northern Alps.

The genus *Pinacoceras*, type species *Pinacoceras metternichi* (Hauer, 1846), was established by Mojsisovics, 1873 on specimens from Hallstatt Limestone divided in 6 groups and 34 species. For some tens of years the genus *Pinacoceras* grew up as a "basket" including a wide variety of species sometimes rather different with respect to the type species. From the beginning of 1900 the genus *Pinacoceras* has been splitted by the separation of the most diverse species as new genera like *Eupinacoceras*, *Parapinacoceras* and *Placites*. No one of these revisions took the specimens from Sicily into consideration, then the Gemmellaro specimens are still referred to *Pinacoceras*.

Gemmellaro described 4 species but actually only 3 are stored in the Museum: *P. zitteli* Gemmellaro, 1904, *P. suessi* Gemmellaro, 1904, *P. haueri* Gemmellaro, 1904.

The Sicilian species show some differences with respect to *Pinacoceras* s.s. (type species *P. metternichi*) and the other genera of the family. In particular the Gemmellaro specimens differ from *P. metternichi* for the coiling, namely the Uw/D ratio, and the more simple suture line. The difference in the suture is of very great significance as the complex suture is one of the most typical features of *Pinacoceras*, that is well known to represent the highest complexity developed by Triassic ammonoids. Similar features have been found in *P. rex*, from the Carnian of northern Alps and suggest the separation of this species, together with *P. zitteli* and *P. haueri*, as a new genus. The new genus will be dedicated to the memory of Enzo Burgio (1946 - 2001), curator of the Geological Museum "G.G. Gemmellaro" of the Palermo University from 1995 to 2001.

The chronostratigraphic position and evolutionary relationships of the new genus with the classic lineages of *Pinacoceras* documented in the Hallstatt Limestone of the northern Alps are discussed. On the basis of the available data the new genus seems to be restricted to the Upper Carnian.

2 - Dipartimento Scienze della Terra e del Mare (DiSTeM) - Università di Palermo - Museo Geologico "G. G. Gemmellaro" - Corso Tukory, 131, 90134 Palermo

Presenter e-mail: antonio.cusumano@unipa.it

Key terms: *Jurassic; Ammonites; Sicily*

New data of Middle-Upper Jurassic sequence from the Tardara Mountain, near Sambuca di Sicilia (Agrigento Province) have been described in this paper. The deposits, constituting the succession of this area, are part of the Monte Magaggiaro-Pizzo Telegrafo Unit that belongs to a large tectonic unit located in the outer part of the Apennine-Magrebide chain. During the Mesozoic Era, this Unit was part of the Saccense Domain, an area palaeogeographically located along the southern margin of Tethys.

The Jurassic sequence of Stretta Arancio outcrops on the flank's top of the deep and narrow canyon formed by the Carboj River. The studied succession consists of about 7 m of pelagic limestones from Middle to Upper Jurassic, covered by Upper Cretaceous *Globotruncana* limestones of "Scaglia" type. The oldest deposits cropping out, paraconformably on the dolomitic limestone of Inici Fm. (Lower Jurassic), consist of 5,5 m of gray-pink *Bositra* packstone-wackestone referable to Bathonian-Callovian. These layers include specimens of *Homeoplanulites* Buckman and *Phylloceras kunthi* Neumayr. The Middle-Upper Jurassic boundary is marked by an hardground surface. Above this surface, 40 cm of gray packstone with Protoglobigerinids containing only rare *Sowerbicerias* and referable to Upper Jurassic (Oxfordian). The sequence follows up with about 50 cm of gray packstone including *Pictonia* cfr. *perornatula* Schneid wich support a Kimmeridgian age for these strata. The succession is overlain by 40 cm of milky-white micritic limestone with calponellids, Upper Tithonian-Lower Cretaceous in age. The sequence ends with whitish calcilutites with planktonic foraminifera of "Scaglia" type.

The revision of two historical collections, come from the Tardara Mountain and housed in the "Gaetano Giorgio Gemmellaro" Museum of the University of Palermo, have been useful for the present study.

The former and older of the two collections was studied by Mariano Gemmellaro (1919) and it is composed of 27 specimens, attributed to 5 genera. All the taxa studied by M. Gemmellaro were referred to the *Macrocephalites macrocephalus* Zone (early Callovian stage). The second collection, studied by Francesco Bruno (1954), consists of 46 specimens, attributed to 13 genera. In this work numerous taxa have been described. The species identified by Bruno were referred to a chronostratigraphic range spanning from Callovian to Tithonian.

After the revision, some of the original determinations were confirmed, many others, instead, have been taxonomically revised and attributed to different genera and species. The analysis of the collections studied has shown, for the M. Gemmellaro Collection, a prevalence of species and genera stratigraphically attributable to the Middle Jurassic (Bajocian-Callovian) while, in the Bruno Collection, genera and species are more related to the Upper Jurassic (Oxfordian)-Lower Cretaceous (Valanginian).

Biostratigraphic study of Tardara Mountain has allowed to recognize the chronostratigraphic age from Middle to Upper Jurassic and to assign the fossil assemblages to the Mediterranean Province.

The taxonomic study of collecting ammonites and the systematic review of the historical collections has led to identify the presence of some species reported for the first time in Sicily or in the Tardara area and to extend their original stratigraphic range. Furthermore, this study has allowed to increase knowledge on faunal associations of the area related to the pelagic carbonate platform system of Saccense Domain for the Middle Jurassic-Lower Cretaceous stratigraphic range.

SACCOCOMA: A BENTHIC OR PELAGIC CRINOID?

MANNI Riccardo¹

1 - La Sapienza University

Presenter e-mail: riccardo.manni@uniroma1.it

Key terms: *Saccocoma; crinoids; Jurassic; benthic; pelagic*

The crinoids of the genus *Saccocoma* Agassiz, 1836 are characterized by certain characters that distinguish it from many others. In fact there is not stem, the cup consists of very thin radial plates, the ventral cavity is very wide, the proximal brachials have well developed lateral expansions, the distal brachials have long ventral processes.

All these characters have been studied by the scientific community and researchers have hypothesized different life styles.

Jaekel (1892) suggests that the lateral expansions of the proximal brachials are in reality used to swim (schwimmplatten). In practice Jaekel believes that *Saccocoma* used the arms as the birds use the wings and so doing *Saccocoma* was able to "swim".

Milson (1994) based on geological data, considers *Saccocoma* a benthic crinoid.

Manni, Nicosia & Tagliacozzo (1997), after taphonomic and functional morphology analyses, consider *Saccocoma* a benthic crinoid partially sunken inner the sediment of the sea bottom.

Hess (1999) proposes, based on direct observations of articulated specimens found at Solnhofen, the assumption of Jaekel.

Seilacher & Hauff (2004) propose a "snap-swimming model" based on anatomical and taphonomic observations. In practice according to these authors *Saccocoma* curled the distal parts of the arms and then unwind rapidly, so doing the crinoid would be able to "swim".

Brodacki (2006), based on anatomical studies, considers the classic model proposed by Jaekel as to be the most likely, but slightly modifying the angle of arm movement.

In summary, there are two proposed models, one purely pelagic and benthic another.

The pelagic model requires the movement of arms or as a kind of bird's wings (theory of Jaekel and of Hess), or the movement of the arms snap (theory of Seilacher & Hauff). Both assumptions, however, after the motion include a phase in which the crinoid "sail" in order to filter the water in peace. This soaring and parachute effect would have been favored by the expansion of its proximal brachials.

The benthic model (theory of Milson and of Manni, Nicosia & Tagliacozzo) simply requires that the crinoid remains sunken into the sediment to filter out. In this case the expansions were perhaps the function of protection from external agents (sediment, predators, etc.).

The pelagic model, however, is not without its critics and problems, such as on the other hand the same Brodacki (2006) recognizes. In fact, the expansions are too close to the cup and too stiff to move efficiently crinoid. In addition, the parachute effect is disturbed by the horizontality of the proximal brachials, especially the second primibrachial, which is the brachial type which has developed the lateral expansions exceedingly. All these assumptions on the life are based on *Saccocoma tenella*, that, because it is found articulated into the Solnhofen limestone, has been well studied. However, if we consider other *Saccocoma* species, we realize that there are several problems that undermine the pelagic model. For example *Saccocoma vernioryi* has thorns on the radials and a second set of expansions, transverse to the first, on proximal brachials. *Saccocoma longipinna* shows flat and very long expansions on proximal brachials. These additional expansions or disproportionately development could reduce the parachute effect because the crinoid is more weighty, although this may not necessarily be a handicap.

It is evident that the lifestyle of *Saccocoma* is far from been identified and that further studies are necessary.

Key terms: *Formazione Qom; Iran Centrale; Paleontologia; bivalvi; echinodermi*

La formazione marina dell'Oligo - Miocene di Qom è risultato dell'ultima trasgressione marina in Iran centrale e si divide in 5 membri differenti (A-E). Questa formazione, al meno nella parte centrale del bacino (intorno della città di Qom) è costruito per due cicli sedimentari (membro A-C2-D) che sono risultati, fondamentalmente di successivi movimenti verticali prodotti nel bacino sedimentario.

Dentro dei macrofossili più significativi della Formazione in Takhte Chakab (SW della città di Qom in Iran Centrale) si può incontrare numerosi generi d'echinodermi e bivalvi che hanno una grande importanza paleontologica. Inoltre i generi più frequenti di echinodermi e bivalvi riconosciuti (*Scutella*, *Clypeaster*, *Echinolampas*, *Spatangus*, *Kuphus*, *Ostrea* e ...) indicano il rapporto contemporaneo con il Mare Mediterraneo e Qceano Indiano.

In questo lavoro si fa un studio sistematico dei fossili ritrovati (presentazione di 15 spec di bivalvi e echinodermi) e in base del contenuto paleontologico e sedimentologico della Formazione si dimostra che questa Formazione è stato depositat in una clima tropicale a subtropicale.

Presenter e-mail: ruggero.matteucci@uniroma1.it

Key terms: *Miocene; Siliceous Sponges; Paleoenvironment*

A thick Miocene depositional complex characterized by its high content in spicules of siliceous sponges (Guadagnolo Fm.) crops out widely along the margin of the shallow-water or emerged carbonate platform of the central Apennines. Skeletal bodies or fragments are also present, but not frequently. Panseri (1950) recognized for the first time the spiculitic content in the small outcrop of Rocca di Cave (Preneestini Mountains).

The Rocca di Cave site has been recently revisited and skeletal fragments were found. In spite of the poor preservation, skeletal remains have been recognized as pertaining to the Hexactinellids.

Aphrocallistes (Order Hexactinosida, Family Aphrocallistidae) is the most frequent genus, as in other Miocene deposits of the Apennines. Dictyonal eurentoid or/and farreoid skeletal framework and lynchiscid nodes (Order Lynchiscosida) are also frequent. No skeletal fragment referable to *Laocoetis* (Order Hexactinosida, Family Craticularidae), a frequent component in other Miocene successions of the Apennines, has been found. Spicules are very abundant, forming in some levels a dense framework within the rock. Their state of conservation is often poor, because of dissolution and fragmentation. Monaxons, triaxenes, desmas and polyaxons are the most frequent types; in addition, ornamented (annulate, tuberculate) spicules are present.

Aphrocallistes, and eurentoid and farreoid (mostly *Farrea*) groups are well represented today; *Aphrocallistes* and *Farrea* live today in all oceans, with an extremely wide bathymetric range. Representatives of these two genera, along with *Heterochone* (a genus of the Family Aphrocallistidae) constitute the main framework of the hexactinellid build-ups recently recognized along the Pacific Ocean coast of Canada, at depths between 200-300 metres.

The siliceous sponge assemblage of Rocca di Cave suggests some similarities with modern depositional environment which today favours the exceptional development of the *Aphrocallistes-Farrea-Heterochone*

community.

APPLICATION OF GROUND PENETRATING RADAR TO LOCATE SIRENIAN REMAINS FROM EARLY PLIOCENE OF ARCILLE (GROSSETO, ITALY)

TINELLI Chiara¹, RIBOLINI Adriano¹, BIANUCCI Giovanni¹, BINI Monica¹, LANDINI Walter¹

¹ - Dipartimento di Scienze della Terra, Università di Pisa

Presenter e-mail: tinelli@dst.unipi.it

Key terms: *Mammalia; Pliocene; Sirenia; Ground Penetrating Radar*

We report the preliminary description of recent discoveries of Pliocene marine fauna from Arcille (Grosseto, Italy) and application of Ground Penetrating Radar to locate fossil vertebrate.

During the past years four partially articulated sirenian skeletons were found in shallow siliciclastic deposits exposed in the Arcille area. All these fossil remains can be referred to *Metaxytherium subapenninum*, an extinct species of haliteriine dugongid (Mammalia, Sirenia) spread along the northwestern coasts of Mediterranean Basin and became extinct in the upper part of the Pliocene because of the progressive climatic cooling occurred after 3.1 Ma (Sorbi et al., 2008).

Planktonic foraminiferal assemblages are consistent with an attribution of the sirenian specimens to the lower part of the Zanclean, in particular to the MP12 zone of Cita (1975) dated between 5.08 and 4.52 Ma (age after Lourens et al., 2004).

Three specimens were collected in a sand quarry and one of this is almost complete.

The fourth specimen, discovered in a sunflower field near the quarry, was collected as a consequence of a preliminary georadar prospection. This technique is a non destructive method based on propagation and reflection of electromagnetic (EM) waves and it is sensitive to variations of the EM parameters in the subsol, especially the dielectric constant and electric conductivity (Davis and Annan, 1989).

The GPR survey was performed using the Radar System device of IDS Company, equipped with a monostatic antenna of 200 MHz. Two adjacent areas have been mapped. Time slices at various depths indicated the presence of several reflective zones: one of this was located at the centre of the first area at 0.20 m from surface. The other zones were smaller and not persistent and rapidly changing in shape with depth. In the second area, two small zones were recorded.

We decided to verify the nature of this GPR signals through an excavation. In correspondence with the central reflective zone of the first area, some fossil bones emerged: in particular, the skull with tusks, the mandibles with teeth, some cervical and dorsal vertebrae and a considerable number of ribs. Other bones (humerus, radius and scapula) were found in correspondence with smaller reflective zones of the same area. In the second area, we discovered several caudal vertebrae in correspondence of one of the two reflective zones.

The results obtained from this study are very interesting, although further experimentations are required for a better refinement of this surveying method for paleontological research.

PLEISTOCENE COLD-WATER CORAL FACIES IN A TECTONICALLY ACTIVE SETTING: AN EXAMPLE FROM THE MARGINS OF THE MESSINA STRAITS (SOUTHERN ITALY)

VERTINO Agostina¹, ROSSO Antonietta², BALDANZA Angela³, SCIUTO Francesco², DI GERONIMO Raffaella², SANFILIPPO Rossana²

Key terms: *Cold-Water Corals; Pleistocene; Messina Straits; Facies; Bathyal*

Cold-water coral (CWC) ecosystems are widespread in modern oceans and have been the focus of intensive geo-biological and oceanographic research in the last decades. However, the internal structure of CWC mounds/banks and the driving forces behind their start-up, growth and demise are still little known.

The Pleistocene deposits cropping out along the margins of the Messina Straits represent a unique opportunity to investigate, in a tectonically active setting, carbonate facies related to CWC ecosystems and their modifications through time. The results presented herein pertain to four stratigraphic sections cropping out in the Scoppo - S. Corrado locality (Messina). Field observations combined with detailed litho-biofacies analyses show that clinostriated coral rudstones, interfingering with marls and sandy marls, are truncated by overlying matrix-supported polymict breccias. The Early Pleistocene (MNN19 b and 19 c biozones) coral rudstones (CR) overlie Messinian brecciate evaporitic limestones and are mostly made up of centimetre- to decimetre-sized fragments of the frame-building scleractinian corals *Lophelia pertusa*, *Madrepora oculata*, *Desmophyllum dianthus* and dendrophyllids (*Enallopsammia scillae* and *Dendrophyllia* spp.). These deposits contain also rather common isolated coripectid plates (*Scillaelepas carinata*, *Pachylasma giganteum*), brachiopods (e.g., *Gryphus vitreus*, *Terebratulina retusa*), molluscs (e.g., *Putzeysia wiseri*, *Spondylus gussonii*), echinoderms (mostly *Cidaris cidaris*) and, subordinately, bryozoans (e.g. *Tessaradoma boreale*, *Cabereia ligata*, *Palmicellaria elegans*, *Idmidronea* sp.), ostracods (*Pseudocythere caudata*, *Paradoxostoma simile* and *Sclerochilus contortus*) and serpulids

(*Metavermlia multicristata*, *Semivermlia pomatostegoides* and *Neovermlia falcigera*). The coeval marls, depleted in scleractinian fragments and enriched in coripectid plates, locally include layers with abundant octocorals, brachiopods and echinoids. Both coral rudstones and marls show typical species of bathyal or deep circalittoral-to-bathyal environments. The matrix-supported breccias which overlie and truncate the CR-marl deposits are characterized by abundant bioclasts (mostly *Lophelia*, *Madrepora* and *Enallopsammia* fragments) and polymict lithoclasts which include the CR-marl themselves.

Due to their geometry, sedimentary structures, composition and texture the Scoppo-S. Corrado CR can be interpreted as the fossil counterparts of modern CWC rubble ("on reef" facies), presumably accumulated along the slopes of topographic and/or structural highs. The interfingering coripectid/octocoral/brachiopod marls and sandy marls can instead be compared to modern CWC "off-reef" facies, lateral to coral rubble, which are typically characterized by mud- and/or sand-dominated deposits. The polymict breccias, herein interpreted as debris flow deposits, together with evidence of synsedimentary faulting during coral rudstone deposition imply a highly unstable depositional environment.

Key terms: *Small mammals; NW Italy; Late Toringian; Biochronology; Palaeoenvironment*

Late Pleistocene vertebrate fossil assemblages have recently been reported in the neighborhoods of Moletto (Ottiglio Monferrato, AL). This discovery is of particular interest as Late Pleistocene vertebrate assemblages are very rare in Piedmont, and so far limited to Moncucco Torinese (Alessio et al., 1992) and Roaschia (Zunino, 2002).

The fossils discovered in Moletto, relatively abundant and well-preserved, were extracted from three karst fissures (M0, M1, M2) carved in the Burdigalian-Langhian limestones known as "Pietra da Cantoni". The assemblages include mollusks, small and large mammals.

On a biochronological basis whole Moletto assemblages may be attributed to the late Toringian (Late Pleistocene). The lower limit of 135 ky is the same for the three assemblages (presence of *Arvicola amphibius* vel *scherman*), whereas the upper limit is 35 ky for M0 and M2 (due to the presence of *Stephanorhinus* sp.) and 11 ky for M1 (due to the absence of Holocene taxa as *Micromys*, *Mus*, *Rattus*).

The palaeoenvironmental framework provided by the study of small mammals, which indicates a forested environment and a relatively cool climate, may further restrict the chronological range of the Moletto assemblages to MIS 5b, 5d, 4, or to the last part of MIS 3.

Key terms: *Pelycosauria; Caseidae; Permian; stratigraphy; taphonomy*

Some bones of a post-cranial skeleton of a huge caseid (Synapsida, stem-Eupelycosauria) were found in 2008 in the Permian Cala del Vino Formation (Alghero, NW Sardinia) during a field-camp organized by the Pavia University. The find, that represents to date the sole Pelycosaur remains from Italy, is very important also taking into account the extreme rarity of Paleozoic vertebrates (Reisz and Laurin, 2001). The information of the discovery was immediately released (Ronchi et al., 2008a, b) and an upgraded report on the state of the research has been communicated at 20ème Journée Thématique de l'Association des Géologues du Permien et du Trias (Sacchi et al., 2009).

The finding represents a significant biochronological constraint to better define the age of the Cala del Vino Formation in the studied area, where, according to M. Durand (pers. comm.) is the lower portion of the formation that crops out, paraconformably covered by the Early Triassic Conglomerato del Porticciolo. Up to now, The Cala del Vino Fm. had not a precise chronostratigraphic attribution and, also recently, it was dubitatively ascribed to Early Triassic times (e.g. Sciuinich, 2001) or to "undefined Late Permian (Tatarian) times" by Cassinis et al. (2003). The presence of a large caseid allows for the time being to lower the fossil bearing level to a stage not younger than lowermost Wordian.

Careful taphonomic analysis was performed on the well-preserved caseid remain. The extraordinary preservation of osteological material, found both still embedded or loose on the outcrop surface, allowed us to infer a parsimonious multiphase biostratigraphic process able to explain a complex set of observed phenomena. These include the discovery of bone embedded at different depth, some isolated and others in articulation, and the presence of still articulated proximal portions of fragile aeal arches along with bones broken before being buried (i. e. vertebrae, ulna, ribs etc.). The finding of foot distal portions is also peculiar taking into account that these bones are usually among the first that are displaced from the body during the decay processes. The identical kind of preservation, the non-repetitive nature of skeletal element and the non-random distribution of body parts allowed referring all the analyzed osteological material to the same individual. The certification of the unitary nature of the discovery allows us to proceed with the classification of the Sardinian caseid. The phylogenetic analysis is currently in an advanced state with the identification of several caseids synapomorphies and some autapomorphies features that suggest the attribution of the Sardinian specimen to a new genus and species.

Key terms: Jurassic; Ammonites; Stratigraphy; Sicily

Contributions on the Middle-Upper Jurassic (Bathonian-Kimmeridgian) pelagic successions of Sicily have been numerous during the recent years. Most of the studies are focused on several historical sections known since Gemmellaro (1882) with the main purpose of setting a better definition of sedimentological features, ammonite associations and their taphonomic analyses, the presence and extension of discontinuity surfaces and their meaning in terms of sedimentary dynamics.

These studies have been developed on some key sections of the "Trapanese platform" in Western Sicily, and have provided a basic framework on the paleogeographic evolution of the carbonate platform to pelagic basin systems in this area.

In the so-called "Saccense Domain", southern Sicily, only the section of "Contrada Diesi" (CDS) has been studied with these methods and compared to the Trapanese ones. This section (Baldanza *et al.*, 2002, D'Arpa & Meléndez, 2006) consists of about 9 m of massive calcilutites (Buccheri Fm.) spanning from Bathonian to Oxfordian. They are covered by some 2,7 meter thick sequence of stromatolitic and calcarenitic limestones of Kimmeridgian age, which are in turn followed on top by Tithonian beds.

Differences between the Saccense and Trapanese successions are notorious: the thickness of the different chronostratigraphic units, the span of the middle Callovian-lower Oxfordian stratigraphic gap and the presence of Submediterranean ammonite taxa and the specific diversity. In particular the anomalous presence of representatives of the subfamily Perispinctinae (usually only occasional in the Mediterranean Province) and the presence of a wide "registratic" ammonite gap at the Lamberti-Mariae Zone (uppermost Callovian to lowermost Oxfordian) in the succession from CDS are particularly relevant.

In order to set a detail taxonomic and taphonomic analyses in the Jurassic of the Saccense Domain, a new section has been recorded some 8 km east of CDS, along an abandoned quarry named "Cava ex Capraria" (CCS) near the village of Sambuca di Sicilia (Agrigento Province). It comprises a 26 meter thick sequence of Middle-Upper Jurassic ammonite-rich limestones passing upwards into the upper Tithonian-Lower Cretaceous unit (marly limestones with calpionellids).

Preliminary data show that the Section of Cava ex Capraria spans the same stratigraphic range as that of Contrada Diesi. Also the extent of gaps (from Bathonian to Tithonian) is comparable although the recorded units are generally thicker in CCS than at CDS. Moreover the Kimmeridgian strata consist of pelagic calcilutites whilst in Contrada Diesi they are represented by stromatolitic limestones. Ammonites successions in both sections are generally comparable. However, in CCS the best represented intervals are close to the Oxfordian-Kimmeridgian boundary and in the Lower and Middle Kimmeridgian beds whilst in CDS the ammonites are more abundant in the Bathonian, Callovian and Oxfordian strata.

The current research has been accomplished on Qom-Formation in Takhte chakab, in Central Iran. The studied section is equal to patterned Formation of Qom, at the age of Oligo-Miocene. The said section is 370 meter deep and it is composed of a range of Sandstone, thin to thick bedded Limestone, Marl, Gypsum and in some points it is made of

conglomerate. Qom-Formation, in this section with the same slope boundaries, is between the lower and upper red Formations. According to our research based on the existence of Foraminifera benthic, the age of this section is determined the lower Oligocene-Miocene. According to Stratigraphy studies, all introduced units in Qom-Formation include f, e, d, c4, c3, c2, c1, b, a was found in the said section. During desert operation, forty-nine 60 samples was extracted that the study on them based on Foraminifera leads to the recognition of 26 genus, 9 species and finally 3 biozones which are as follows:

- 1) Meandropsina iranica Assemblage Zone Henson 1950.
- 2) Miogypsina sp. Archaias sp. Vavulinid sp. Assemblage Zone
- 2a) Elphidium sp. Miogypsina sp. Assemblage Subzone

Key terms: Pliocene; Sirenia; Ground Penetrating Radar; 3D scanning

Like most of the paleontological discoveries, the new fossils recently identified in Tuscany were found almost by chance. We used the standard procedure for collecting large vertebrate fossils associated to two technological applications: georadar prospecting and in situ survey of the fossiliferous surface with 3D scanning instrument (Zscan, Menci) based on photogrammetric method.

In 2007 and 2010 four partially articulated sirenian fossil skeletons were found in Arcille (Grosseto, Italy). They are referred to *Metaxytherium subapenninum*, a sirenian species that lived in the Mediterranean and became extinct in the upper part of the Pliocene (Sorbi *et al.* 2008). Micropaleontological analysis based on planktonic foraminifera allowed us to date the specimens to the lower Zanclean.

Three specimens were found in a sand quarry in 2007, while the fourth was discovered in 2010 in a sunflower field near the quarry. The sirenians found in the quarry were suddenly recovered. First, all bones have been exposed on the surface and hardened with special chemicals, then, we isolated the skeletal remains from the surrounding rock by digging a trench around them. The remains were covered with a layer of wet paper towels and burlap strips soaked with plaster, applied one at a time on the covered bones. After the plaster has hardened the block was further undercut. We built a wood frame to protect the bones; the block was later transported with a grab truck.

The discovery of the fourth sirenian occurred through a preliminary georadar prospecting. Once having obtained the first results, in order to conduct the excavation we used GPR maps, that highlighted several reflective zones. Once ascertained the presence of bones in the subsoil, we compared GPR and paleontological data by using an excavation map. This was formed by a grid divided in squares where the position of each bones was recorded and then compared with the location of the reflective zones. We verified that most of the reflective zones corresponded to areas where fossil bones were discovered. Despite the good result of this application, more tests must be conducted in different geological and paleontological settings.

The other technology used was photogrammetry with a 3D scanning instrument (Zscan, Menci). This method, using a calibrated metric digital camera, collects triplets of overlapping images, from which it extracts a cloud of points and then, through specific software based on an innovative proprietary algorithm for multifocal image analysis, it constructs 3D model.

It is used in different application fields, like archaeology, engineering, but its use in paleontology is just beginning (Landini *et al.* 2010). It is possible to apply this technique both to fossil sites and remains. The advantages range from saving the original setting of the fossil site that could be damaged during the excavation, to making 3D imaging of fossil remains in order to take morphometric measures on virtual bones instead of original fossils, especially the holotypes.

We applied this method to the fourth sirenian found in the sunflower field. We placed a tripod, mounted under a slide bar and put the camera on a ruler. Then we did several 3 shots sequences ("triple") from different positions in order to entirely cover the site and the skeletal remains to be modeled.

Key terms: Amphibia; Caudata; middle Pleistocene; diatomite basins

The industrial exploitation of Pleistocene diatomite deposits in the neighboring of Rome has provided scientists with a large amount of fossil flora and fauna, sometimes in a remarkable state of preservation. Extremely detailed palaeobotanical and palynological studies have been produced since the mid of the last century, which allowed researchers to outline a palaeoenvironmental reconstruction of this area during the middle and upper Pleistocene. Vertebrate macrofossils and especially large-bodied mammals have been recovered from diatomitic basins in the Riano area and a large sample of smaller faunal entities, such as invertebrates and small vertebrates (fishes, amphibians, reptiles, mammals) is known as well. Indeed, Caudata were limited so far to a couple of localities, with only two taxa, namely *Lissotriton vulgaris* cfr. ssp. *meridionalis* from the middle Pleistocene of Riano Flaminio (Rome) and a coeval *Triturus cristatus* from Baccano (Rome). The discovery of an almost complete salamandrid specimen is therefore relevant as it adds new data to the urodeles fossil record of the Italian peninsula.

The new specimen has been discovered at Fosso di San Martino locality, about 45 km North of Rome. The stratigraphic succession of the Fosso di San Martino crops out in the eastern sector of the Sabatini Volcanic District (SVD; Latium, central Italy; 0.8-0.1 Ma) and consists of a ca. 60m-thick sedimentary succession with alternating diatom-rich silts and sandy silts, plus diatomites. Several primary pyroclastic layers from the ultrapotassic Quaternary volcanism of the Roman Province interfinger with the diatomitic deposits. The fossiliferous diatomites rest on top of a pyroclastic flow deposit erupted during the ancient SVD volcanic activity (i.e., Tufo Giallo di Prima Porta unit, radiometric 39Ar/40Ar age 514±3 ka, Karner et al. 2001) and is overlain by a pyroclastic flow deposit from the early SVD volcanic activity (i.e., Tufo Rosso a Scorie Nere unit, radiometric 39Ar/40Ar age 449±1 ka).

Although the specimen may be considered as an almost complete one (total length 42 mm), the preservation of single bones differs depending on the sector of the body. The specimen mainly consists of a thin brownish organic layer, even though few portions of the skeleton are preserved tridimensionally, as for some sectors of the dental bone. The head is longer than wide, elongated along to the main axis of the body. The cranial roof is virtually lost, and neither dermal nor neural bones are recognizable. Dental bones bear a row of small conical teeth. The postcranial skeleton is made of a fairly complete vertebral column, a complete set of ribs, a portion of the front girdle, front and rear limbs, and an almost complete tail. Up to 14 vertebrae have been counted in the trunk. The phalangeal formula observed on the manus is 2-2-3-2, associated to the following pedal formula ?2.3.3.?

The taxonomic allocation of the new specimen was proven to be extremely difficult owing to a set of accompanying causes. The most relevant one is related to the anatomic features (skull bones, vertebrae), which are either deformed, lost or too badly preserved to give definite taxonomic clues. Additionally, the specimen is probably not fully grown in somatic terms. So far, preserved anatomic features made it possible to restrict the field of potential attributions to the Salamandridae family. The fossils is still under examination and a detailed study is in progress.

THE "BUNTSANDSTEIN" GROUP OF SARDINIA: A COMPLEX OF HETEROGENEOUS UNITS DEPOSED UNDER DIFFERENT ENVIRONMENTAL, MORPHOTECTONIC AND CLIMATIC (?) CONDITIONS

COSTAMAGNA Luca Giacomo¹

1 - Dipartimento di Scienze della Terra, Università di Cagliari, Via Trentino 51, 09127 Cagliari (Italy)

Presenter e-mail: lucakost@unica.it

Key terms: Buntsandstein; Paleogeography; Sedimentology; Sardinia; Triassic

In Sardinia red bed "Buntsandstein" thin deposits are scattered: they are Early to early Middle Triassic in age and represent the start of the Alpine depositional cycle. The age of their base grows younger from W (late Early Triassic, Sardegna NW) to E (Middle Triassic, Sardegna SE).

Sedimentological and petrographical comparisons of the diverse outcrops suggest the "Buntsandstein" evolution, depositional environments, sediment sources, tectonics and even perhaps the dominating climate varied from place to place, as well as the landscape morphology behind. All the "Buntsandstein" successions pass finally to the "Muschelkalk" carbonates. In NW Sardinia the 30 m thick Verrucano Sardo Fm. (Early-Middle Triassic) conglomerate to sandy deposits are formed by conglomerates, sandstones and scarce pelites: they laid down in a continental-transitional braid-delta context rapidly evolving to a marine tidal flat environment. Those deposits are quartz-rich and very mature especially in the lower part of the unit: the conglomerates are usually rounded and quartzose (quartzrudites); sandstones are well-sorted sublitharenites passing upwards to moderately well-sorted litharenites. In SW Sardinia (Arborea) the 20 m thick Punta S'Arredelli Fm. (Late Anisian) is built of a fining-upward sequence of alternations of conglomerates, coarse sandstones and pelites. Channelized bodies are rare. Towards the top, rare calcareous thin layers and former evaporitic, now calcitized beds are interspaced. This unit deposited in a braided stream environment. The conglomerates are polygenic and angular to subrounded; the sandstones are moderately to well-sorted litharenites. Still in SW Sardinia (Iglesiente), the 25 m thick Riu Is Corras Fm. (Late Anisian) is formed by alternations of unchanneled conglomeratic debris flows alternated with calcrite beds whose former protilites were open-frame conglomerates or former (lacustrine?) limestones: rare, thin intercalations of bioturbated sandstones and siltites are also present. Here an alluvial fan delta developed. Conglomerates are polygenic and built of rounded pebbles and small cobbles; sandstones are well-sorted litharenites. In SE Sardinia, the 18 m thick Escalaplano Fm. (Latest Anisian) shows only a thin localized metre-thick basal conglomerate: upwards it passes to extremely regular, plane-bedded greenish, reddish and locally blackish siltites and clayey siltites containing scattered sandstone beds; bioturbation and mud-cracks

are rare. Rare shallow channels filled by sandy deposits have been found. Scattered pinkish evaporitic thin layers (mainly produced by diagenetic recirculation of former syndepositional levels) are also present. This setting suggests a smoothed landscape initially feeding low, cone-shaped, depositional bodies made of gravelly lobes built of few, thin sheet-floods: they rapidly were followed by a low energy mudflat playa-like environment crossed by rare channels. The scarce conglomerates and polygenic with angular to subrounded pebbles; the sandstones are well-sorted litharenites. All those "Buntsandstein" units, despite their similar age and stratigraphic position, display environmental and petrographic differences suggesting different ruling factors, as landscape morphology, tectonics and perhaps climate. As examples, in the Iglesias area the Riu Is Corras Fm. the coarse massive deposits showing no fining-upward trend suggest an articulated landscape and a coeval tectonic activity; these characters contrast with the Escalaplano Fm. quiet muddy environment of SE Sardinia featured mainly by a wide depositional flat. So the markedly diverse compositional maturity of the siliciclastics sampled in different Sardinia territories may suggest variable transport duration, different feeding areas, or even diverse local climates. So, considerations and analysis are ongoing to settle discrepancies in the Sardinian "Buntsandstein" setting.

THE MIDDLE JURASSIC "TETHYAN" UNCONFORMITY IN EASTERN SARDINIA (ITALY): EVIDENCES OF TECTONO-SEDIMENTARY CONTROL OVER THE BASEMENT ALTERATION PROFILES AND THE TRANSGRESSIVE DEPOSITS

COSTAMAGNA Luca Giacomo¹

1 - Dipartimento di Scienze della Terra, Università di Cagliari, Via Trentino 51, 09127 Cagliari (Italy)

Presenter e-mail: lucakost@unica.it

Key terms: Jurassic; Paleogeography; Sinesedimentary tectonics; Sedimentology; Sardinia

Sedimentological, stratigraphical and petrographic investigations were carried on both upper sedimentary and lower metamorphic rocks located on opposite sides of the "Tethyan" Middle Jurassic unconformity surface of Eastern Sardinia. They evidenced that sedimentation/alteration processes over the transgressed metamorphic Variscan basement have been ruled by different factors, in their turn influencing each other. The Variscan metamorphic basement located below the unconformity shows different alteration stages depending on the lasting of the emergence and on the lithologic type composition on which the surface rests. Thus the basement may be affected by alteration processes ranging from thin alteration halos coating the surfaces of unaltered rocks to well-developed and thick Fe-rich hot-humid paleosols. The unconformably overlapping Middle Jurassic Genna Selole Fm. (at most 50 m thick) was laid down by evolving fluvial to deltaic-lagoon-marine processes: it is formed by three lithofacies: 1: massive to crude-bedded, locally cross-bedded conglomerates to breccias and coarse to medium grain-sized, cross-bedded sandstones (monogenic quartzose to polygenic conglomerates and breccias; quartzarenites to sublitharenites) related to fluvial (longitudinal?) braid bars; 2: medium-grain sized to fine sandstones (quartzarenites to sublitharenites) and quartzsiltites lens and beds and thinly laminated black clays and silty clays linked to deposition in coastal marshes crossed by meandering channels; 3: fine to rare mid-grain-sized sandstones (quartzarenites), carbonates and thin levels of blackish carbonaceous clays with interspaced oxidized surfaces testifying emergence times and connected with the passage from the deltaic-lagoon transitional environment to the marine carbonate shelf. Comparing different sections, these lithofacies may A) be all represented or not; B) have variable thickness; C) be arranged in thick cycles suggesting rise and sink of independent basement sub-highs. A tidal influence on the lithofacies 2 and 3 is suspected but the coeval tectonic movements make it difficult to unravel. Sometimes the Genna Selole Fm. may be missing and the upper carbonate Dorgali Fm. rests directly over the Variscan basement. In this case metamorphic rock or quartz pebbles and cobbles may be scattered in carbonate deposits. The thickness of the Genna Selole Fm. and the alteration profiles underneath were controlled also by the paleomorphology of the Barbagia high, a rugged structural feature emerging in Eastern Sardinia during Middle Jurassic times for the opening of the Tethys Ocean eastward. The surfacing of this high under an aggressive climate triggered the erosion of thick early Mesozoic to Paleozoic successions. The whole Barbagia high was in its turn quite immediately split in diverse rising and sinking minor blocks by the Middle Jurassic extensional tectonics: the sinking ones were interested by depositional processes so the Genna Selole Fm. accumulated thickly and rapidly there and no alteration profiles developed on the basement below; conversely erosive processes kept going on the rising ones, thus the following marine transgression covered them directly through the Dorgali Fm. carbonate shelf deposits without any significant continental siliciclastics interposed: here alteration worked deeply on the basement. The petrographic composition of the siliciclastics of the Genna Selole Fm. shows variations according to the geographic and tectonic location: in the southernmost areas (Tacchi) quartz-rich deposits prevail largely, while northwards (Ogliastra, Baronia) litharenites and arkoses grow in importance. Moreover, while the siliciclastic feeding in the southernmost areas stops quite rapidly passing upwards to carbonate marine environments, in the north it shows up intermittently with abundant quartz grains in the carbonate succession so testifying the persisting presence of emerged surrounding basement highs.

EARLY JURASSIC CARBON CYCLE ANOMALIES IN THE EASTERN SOUTHERN ALPS

MASETTI Daniele¹, FIGUS Billy¹, JENKYN Hugh C., POSENATO Renato¹, ROMANO Roberta¹

1 - Department of Earth Sciences, University of Ferrara

2 - Department of Earth Sciences, University of Oxford

Presenter e-mail: daniele.masetti@unife.it

Key terms: Early Jurassic; Isotope stratigraphy; Southern Alps

A major reorganization of Early Jurassic Tethyan palaeogeography took place around Sinemurian-Pliensbachian boundary time with the drowning of many carbonate platforms. Detailed investigations of the Jurassic succession of the Trento Platform indicates that the upper

Sinemurian(?)-Pliensbachian Rotzo Formation of the Calcarei Grigi Group is missing in the northern and eastern sector where the pelagic lower Rosso Ammonitico (Bajocian-Bathonian) directly overlies the Hettangian-Sinemurian Monte Zugna Formation. A coeval depositional hiatus occurs also in most of the northern portion of the shallow-water Friuli Platform, suggesting that the Pliensbachian hiatus is ubiquitous in the easternmost outcropping sector of the Southern Alps.

An integrated stratigraphy is being developed across an E-W-oriented transect that crosses the entire Eastern Southern Alps from the western margin of the Trento Platform, through the Belluno Basin, to the Friuli Platform. In the Trento Platform four different sections have been selected: Madonna della Corona, Val Gola, Rotzo and Monte Grappa, corresponding to three different types of successions. The Madonna della Corona section represents the western margin of the Trento Platform, adjacent to the Lombardy Basin, where the marginal upper Sinemurian(?)-Pliensbachian oolitic body (Oolite di Massone) encircles the finer grained lagoonal *Lithotis*-bearing deposits of the Rotzo Formation that became more significant eastward. In the Val Gola section and Rotzo stratotype, the Rotzo Formation overlies the Calcare Oolitico di Loppio. In Monte Grappa, as well as in the whole eastern sector of the platform, the Rotzo Formation is replaced by cross-bedded crinoidal calcarenites (Encrinure di Fanes) accumulated on top of a plateau in its early post-platform drowning phase.

Chemostratigraphic investigation of bulk limestones from the Madonna della Corona, Val Gola and Rotzo sections indicates an abrupt and marked negative carbon-isotope shift located in the topmost portion of the Calcare Oolitico di Loppio, in close stratigraphic proximity to the FO of *Orbitopsella*.

This negative excursion is also recorded in skeletal calcite (belemnites) from the Sinemurian-Pliensbachian boundary in England, where black shales are locally developed. Taken together, these data are consistent with the hypothesis that a global disturbance in the carbon cycle was connected with modifications of the Early Jurassic Tethyan palaeogeography, particularly as regards platform drowning. This negative carbon-isotope excursion must record injection of isotopically light carbon, either as methane and/or carbon dioxide, into the ocean-atmosphere system. Whether this carbon derives from volcanogenic sources, from metamorphism of organic-rich sediments, or from dissociation of gas hydrates is currently unknown. The negative carbon-isotope excursion in sections from Madonna della Corona and Rotzo both correlate with similar excursions in oxygen-isotope ratios, which could either be an artefact of diagenesis or record increases in marine sea-surface temperature. Palaeoenvironmental changes, in concert with extensional tectonics, may have instigated drowning of certain Tethyan carbonate platforms around Sinemurian-Pliensbachian boundary time.

Taken together, these phenomena recall the well-known Toarcian Oceanic Anoxic Event, which may also have been instrumental in the drowning of those Tethyan carbonate platforms whose subsidence rates were relatively high.

INTEGRATED ANALYSES OF SYN-TECTONIC BASIN FILL TO CONSTRAIN THE DEFORMATION EVOLUTION IN A FOLD AND THRUST BELT: FIELD EXAMPLES FROM THE SICILIAN CHAIN.

AGATE Mauro¹, AVELLONE Giuseppe¹, GASPARO MORTICELLI Maurizio¹, GUGLIOTTA Carlo¹

1 - Università di Palermo, Dipartimento di Scienze della Terra e del Mare

Presenter e-mail: mgasparo@unipa.it

Key terms: Sedimentary Basin; Synsedimentary tectonics; Sicily chain; Late Miocene Early Pliocene

The Late Tortonian to Early Pliocene structural and stratigraphic evolution of north-western sector of the Sicilian thrust belt (SFTB) is the subject of this paper.

As it has been widely demonstrated by many Authors, (Bally et al., 1966 with references among other) during the fold and thrust belt building the compressional deformation propagates "in sequence" from the internal to the external zone involving from the top to the bottom deeper and deeper structural levels. As a consequence, the effects induced by deformation that developed at different structural levels (multiple décollements) and ages, will be recognized on the field as an interference structure due to the superimposition of successive tectonic events. Therefore, in a fold and thrust belt two main compressional events can be commonly detected, that are respectively: 1) a former shallow-seated thrusting followed by 2) a later deep-seated transpressive deformation. A such tectonic evolution have been documented by the following Authors in the sicilian chain: Roure et al. (1990); Oldow et al (1990); Catalano et al. (2000).

We focus our attention on the relationships between tectonics and sedimentation of some syntectonic basins, developed above the Sicilian orogenic belt during the transition between the shallow-seated and the deep-seated-transpressional events, in order to better understand the geological processes occurred during this topic transitional phase. A set of new field-based data concerning sedimentologic, stratigraphic and structural analyses performed on the sedimentary fill of three syntectonic basins located in the inner sectors of the Sicilian thrust belt have been used for the paper aim. These basins are: (i) the Scillato Basin (SB, north-central Sicily); (ii) the Ciminna Basin (CB, north-western Sicily) and (iii) the Lascari Basin (LB, northern Sicily). Each of these basins is representative for a specific portion of the late Tortonian to early Pliocene geological record characterizing the study area. In particular, evidences for a syn-depositional tectonics have been recognized in the Late Tortonian clastics filling the Scillato Basin, in the Messinian evaporites filling the Ciminna Basins and in the Early Pliocene deep-water limestones filling the Lascari Basin.

Interpretation of our data allowed us to hypothesize that: 1) an almost continuous contractional to transpressional deformation (since Early-Middle Miocene to Late Pliocene time) can be outlined in this sector of the SFTB also according with what documented by Oldow et al. (1990) in western Sicily; 2) in the study sectors of the SFTB the transition between the shallow-seated event and the deep-seated-transpressional event occurred during the Middle-Late Tortonian time (reasonably after the Castellana Scula Fm. deposition). The deep-seated, transpressional structures were already active at least during the latest Tortonian (as documented in the SB) and continue during both the Messinian and Early Pliocene (as demonstrated in the CB and LB). The latter tectonic event goes on almost till the late Pliocene (Abate et al. 1991).

SHORELINE MIGRATION FROM INLAND CROTONE TO THE IONIAN CALABRIAN SHELF (SOUTHERN ITALY) DURING THE LAST 250 KYR

ZECCHIN Massimo¹, CERAMICOLA Silvia¹, GORDINI Emiliano¹

1 - Istituto Nazionale di Oceanografia e di Geofisica Sperimentale - OGS, Trieste

Presenter e-mail: mzecchin@ogs.trieste.it

Key terms: Shoreline; Marine terrace; Glacio-eustasy; Uplift; Crotone Basin

A reconstruction of the shoreline migration in the Crotone area from Middle Pleistocene onwards is here presented, based on facies analysis of marine terrace deposits, the uplift history, and submerged seabottom features observed on sub-bottom data (Chirp 2-7 kHz) along the present day shelf.

The Crotone Basin, located on the Ionian side of Calabria, began to open between Serravallian and Tortonian times. It is interpreted as a forearc basin of the Calabrian accretionary wedge. The uplift of the basin initiated in the Middle Pleistocene (ca. 0.4 Ma), with an average rate in the order of 1 m/ka. The interplay between regional uplift and glacio-eustasy since MIS 7.5 (ca. 230 ka B.P.), produced a staircase of marine terraces, located between 230 to 10 m above present sea-level.

Facies analysis of the marine terrace deposits, together with the reconstruction of inner edges at the base of uplifted palaeo-coastal cliffs, allowed the recognition of shoreline positions during peak interglacials corresponding to MIS 7.5, 7.1, 5.5, 5.3, 5.1 and 3.3. In addition, the LGM (MIS 2) shoreline position along the shelf margin, and another shoreline inferred to be related to the abandonment of a submerged palaeo-coastal cliff during melt-water pulse (MWP) 1A (14-14.3 ka B.P.), were recognized on sub-bottom data.

The scenario here presented suggests a stepped seaward (to the SE) migration of the shoreline from MIS 7.5 to 2, due to a long-term forced regression related to the uplift of the area, followed by a rapid retrogradation to the present day position, related to the post-LGM glacio-eustatic rise. MIS 7.5 and 7.1 shorelines formed in an area characterized by relatively flat topography, and thus favouring the local development of barrier islands and lagoon-estuarine systems. In contrast, MIS 5.5 to MIS 2 shorelines formed in high-gradient settings, at the base of coastal cliffs. This change from low- to high-gradient topography was probably linked to the continuous uplift of the area, producing prominent relief after MIS 7.1.

NEW CORRELATIONS OF SEQUENCE STRATIGRAPHIC PATTERNS IN THE SOUTHERN ALPS ACROSS LADINIAN/CARNIAN BOUNDARY

CAGGIATI Marcello¹, FURIN Stefano², GIANOLLA Piero¹

1 - Università di Ferrara

2 - Geotema Srl, Ferrara, Italy

Presenter e-mail: marcello.caggiati@unife.it

Key terms: Southern Alps; Triassic; Sequence stratigraphy; Carbonate Platforms

New on-field studies, focused in the Southern Alps, allowed for new insights on third-order depositional sequences on Upper Ladinian/Lower Carnian interval. In order to study the response of mixed carbonatic and siliciclastic systems to relative sea level variations, four areas have been investigated: Lozio area (BS), M. Sciliar and Denti di Terra Rossa groups (BZ), Braies and Sesto Dolomites (BZ), and the area between Val D'Aupa and Val Dogna (UD).

The sections were correlated through the identification of all sequence stratigraphic units and bounding surfaces of different system tracts, constrained by new bio-chronostratigraphical data supported also by radiometric dating close to the Ladinian/Carnian boundary. In all studied areas it was possible to identify a 3rd order depositional sequence, evolved between Upper Ladinian Regoledanus subzone and Lower Carnian Aon sbz, equivalent to La 3 in Gianolla et al. (1998). Falling Stage System Tract (FSST) is well recognizable in basins, thanks to deposition of high-density mainly siliciclastic to volcanoclastic turbidites of Wengen Fm., often with sharp erosive bases. Simultaneous collapses of the slope produced confined megabreccia wedges at the toe-of-slope. Subaerial exposures of carbonate platform top (Esino and Sciliar Fms.) are expressed by mature paleo-karst filled with bauxites (eg. Dogna Valley, Tre Scarperi Mt.).

The lowest system tract (LST) is characterized by terrigenous prograding complexes, often organized in thickening-upward patterns switching from fine sandstones, siltstones and marls to coarse sandstones and conglomerates. Locally, in the Dolomites region, low-angle carbonate prograding clinobeds interfingered with these terrigenous deposits can be observed, testifying the presence of fringing reefs and also renewed carbonate production in the platform interior. On the basis of ammonoids and conodonts findings, FSST and LST can be dated at the base of Regoledanus sbz.

The following transgressive system tract is characterized mainly by fining-upward sequences, with a decrease of carbonate input and a transition to marly and dark pelitic layers, clearly identifying the retreat both of terrigenous and carbonatic coastlines. In the Dolomites and Lombardy area, maximum flooding surface has been attributed to Regoledanus sbz by ammonoid findings.

Above these fine sediments, in all studied sections an increase in carbonate input and calcarenites, expresses a re-occurrence of optimal conditions for carbonate production due to the highstand position of relative sea-level. Strata stacking patterns show thickening-upward trends culminating in breccia layers underlying cinostratified bodies. Although some differences exist among platform margins and slopes carbonate factories in different regions of Southern Alps, i.e. microbial mounds and automicrite factories (subordinate corals) of Cassian Dolomite vs. coral-tubiphytes dominated and early marine cementation of Concarena slopes, timing of renewed carbonate input in basins seems almost simultaneous in all areas and can be confined from Canadensis to Aon sbz.

Identified system tracts and bounding surfaces are well defined in time framework and possible differences in depositional environments and conditions can be attributed to regional conditions, due both to tectonic and paleogeographical settings; for example, diversity in c.f. and type of prograding geometries can be linked to depth, oxygenation, nutrient amount, currents of the basins, that in turn can be linked to the paleogeography (barrier-effect of wide platforms, connections with more open seas, relative position of emerged lands, etc.). The same factors are probably responsible for the presence, confined only to some areas, of LST carbonate platforms.

PALEOENVIRONMENTAL AND TECTONIC EVOLUTION OF THE LIASSIC CARBONATE PLATFORM SUCCESSION OF MT. MARANFUSA (CENTRAL WESTERN SICILY)

INTERBARTOLO Francesco¹, SULLI Attilio¹

¹ - Dipartimento di Scienze della Terra e del Mare - Università di Palermo
 Presenter e-mail: interbartolo@unipa.it

Key terms: Calcrete; Paleokarst; Neptunian dike; Injection dike

The upper part of the Liassic carbonate platform succession (Inici Fm., Hettangian-Sinemurian), outcropping at Mt. Maranfusa (central western Sicily) consists of a sequence of peritidal limestones, overlain by Jurassic to Cenozoic pelagic limestones and their siliciclastic Tertiary covers. The good exposure of this succession, pertaining to the trapanese domain, in the area between Palermo and Sciacca mountains, allowed to study in detail the facies sequences and structural features of the carbonate platform and of the sedimentary dikes, in order to improve knowledge on its paleoenvironmental and tectonic evolution. The Inici Fm. is constituted by subtidal cyclic sequences of wackestone-packstones with gastropods, megalodonts, oncolids, grain aggregates, dasycladacean algae and benthic foraminifers, followed by dismicrites with psolitic levels of intertidal environment, and at the top, when they are present, bioclastic calcarenites with birdseyes of supratidal environment.

At the top of the cycles we recognized often a peculiar type of layers constituted by:

- 1) dark gray, compact and well cemented limestones with blackish clasts. The microfacies analysis shows packstones consisting of carbonate grains and bioclasts coated with thin regular to highly irregular, laminae of brownish or yellowish micrite, creating small subspherical nodules, or irregular masses, named glaebole, often associated with pisoid.
- 2) millimetric reddish calcite laminae, locally deformed by elongated cavities, filled with greenish vadose silt, and bordered by radial fibrous cement. The crystals grow toward the inside of the cavity and crystallize at the expense of the silt fills.

We classified for the first time the levels 1 as calcrete, while levels 2 were indicated as paleokarst.

The facies sequences of the Inici Fm. are shallowing upward; the environment is attributed to a tidal flat and to the neighbour lagoon, pertaining to an inner carbonate ramp.

The recognized calcretes are of pedogenic origin and were classified as alpha and beta calcrete (Wright, 1994). The paleokarsts for their characteristics were classified as paleopeleoethems, which are important stratigraphic markers because they indicate periods of non-deposition and/or erosion during sea-level changes. Both the layers indicate phases of emersion during the deposition of carbonate platform succession. The study succession is crossed by three fault systems: NNW-SSE trending dextral transensional fault system, NNE-SSW trending sinistral transensional fault system, both late Lias-middle-late Miocene in age, often reactivating previous normal faults, and E-W trending transensional fault system (Miocene). The first two fault systems are cut by neptunian dikes (Fischer, 1964), filled by several generations of Toarcian-early Miocene pelagic sediments layers. Another system of dikes, parallel to the stratification, is created by planar slip in the carbonate rocks; they are filled by pelagic sediments (late Lias-Dogger in age). The neptunian dikes are of tectonic origin with evidence of reactivation of faults, while parallel dikes (injection dike, Castellarin, 1982) are interpreted as to be due to flexure of the platform during the Jurassic tectonic events.

So, in this paper we assert, for the first time, that the horizontal layers, previously described by many authors only as horizontal dikes, can be actually interpreted as: a) layers that are effectively horizontal dikes; b) pedogenic calcretes; c) paleopeleoethems.

As a consequence we identified some episodes of emersion in the evolution of the Trapanese carbonate platform during the Liassic.

² - Laboratorio de Tectónica Andina, Universidad de Buenos Aires, Argentina

Presenter e-mail: ausonio.ronchi@dst.unipav.it

Key terms: provenance; geochronology; foreland basin; subduction; Andes

During the Late Cretaceous, in the Neuquén basin (Patagonia, Argentina) the change from a retro-arc extensional setting to a foreland compressional one, is interpreted as the result of a decrease of the subduction dip of the Pacific Plate under the South American continental

margin, between 36 and 41° S latitude (Ramos & Kay, 2006; Tunik et al., 2010). This important geodynamic event is evidenced by the re-arrangement of the alluvial drainage pattern that filled the basin in the same time span.

Through an integrated study of depositional facies, sandstone provenance and detrital zircons geochronology, the presented work investigates how the Cretaceous surface evolution of this basin system is linked with the history of the Pacific subduction zone at depth.

The obtained results clearly show that the basin turning from extensional to compressional is registered by a regional scale unconformity in the depositional record, and is coupled with an abrupt switch of sandstone composition from continental block sandstones fed by the foreland (to the east) to magmatic arc sandstones fed by the Andean Cordillera (to the west), followed upsection by a progressive return toward continental-block compositions, though to be the result of the uplift of the peripheral bulge in the foreland, as a consequence of the Late Cretaceous thrust front migration.

These repeated changes of sandstone detrital provenance occurred in a basin having a persistent longitudinal distribution pattern in the depocentre region, where, conversely, repeated facies changes from higher energy river channel deposits to lower energy alluvial plain facies should reflect repeated variations of the base level.

Therefore, we infer that the Cretaceous evolution of the Neuquén Basin could provide a nice example of surface response to deep geodynamic processes, as well as of interference between tectonic and eustatic forcing into a tectonically active alluvial plain environment.

MIOCENE EXTENSION IN THE SIMBRUINI MTS. (CENTRAL APENNINES)

FABBI Simone¹

¹ - Università degli Studi di Roma "La Sapienza"

Presenter e-mail: simone.fabbi@uniroma1.it

Key terms: Miocene; Apennines; Submarine escarpments; syn-sedimentary tectonics

Evidence of pre-orogenic Tertiary deformation across the Simbruini Mts. (Latium-Abruzzi domain) is more common than previously believed. Several authors identified pre-orogenic tectonic phases both at regional and local scale. Active extension was inferred during the Cretaceous [1] [2], Paleogene [3] and the early Miocene [1]. Centamore & Rossi [4] hypothesized the continuous development of extensional structures during the Cretaceous to Miocene interval. New field data clearly indicate that in this area the early Messinian [3] compressive phase was predated by a middle-late Miocene extensional phase, as inferred by Compagnoni et alii [5] and by Bigi & Costa Pisani [6] in a neighbouring sector. This is evidenced by peculiar stratigraphic, structural, geometric and sedimentological features. In the north-eastern Simbruini Mts., the "Breccia della Renga" fm.(BDR), a ruditic unit made of chaotic boulder beds to well bedded breccias/arenites and associated pelites, rests unconformably on the Cretaceous to lower Miocene carbonate platform succession being partly lateral to the lower Messinian turbidites of the Roveto Valley. This unit has a late Tortonian-early Messinian age, based on calcareous nannoplankton biostratigraphy and on sedimentological and geometrical relationships with the turbidites. The BDR, which were sedimented under severe tectonic control, provide clue for identifying Miocene faults: 1. Faults producing up to ~0.5 km displacement in the substrate are sealed by unfaulted BDR; 2. Surfaces truncating bedding of the substrate with a high cut-off angle, also bearing diffuse phosphatic nodules and crusts, are covered unconformably by upper Tortonian Breccias and associated pelites; the phosphatization is interpreted as an evidence for submarine exposure during the Miocene. The surfaces themselves can be interpreted as normal fault paleoescarpments [7]. 3. The depocenter of the upper Tortonian BDR is located westward of a main alignment formed by the above mentioned paleoescarpments and by SW-dipping normal faults in the Cretaceous substrate, sealed by breccias. In the study area it is possible to identify at least two major extensional NW-SE trending lineages that controlled sedimentation and spatial distribution of the BDR. The main alignment (Villaromana-C.le La Fossa) is ~25 km long and represents the eastern margin of the principal depocenter of the Tortonian breccias. The second lineage (F.te Lubro-Campolungo), located westward, is ~10 km long and is subparallel to the main one with a spacing of ~3 km. It represents the external margin of a narrow elongated basin filled by Messinian breccias and pelites. This tectonic activity could be related with the initial flexuration of the foreland as a response to the advancing Apenninic chain.

Key terms: Hot-spring travertines; Albegna Valley; Tuscany

Travertines, non marine carbonates of calcium carbonate precipitation under thermal-hydrothermal condition are produced by CaCO₃ precipitation due to degassing and evaporation of the spring waters; nevertheless biological influence may also stimulate precipitation. Hot-spring travertine deposition in Central Italy is considered mainly to be related to the magmatic and hydrothermal activity linked to the Plio-Pleistocene extensional tectonics developed during the opening of the Tyrrhenian Sea. Central Italy has extensive travertine accumulations all younger than 400 kyrs that include present-day deposits.

In the Neogene Albegna Basin, southern Tuscany (central Italy), travertines are present in several deposits, distributed along faults and fractures. They were chiefly deposited as fans and wedges with terraced slopes and are located at different topographic heights (from about 25 up to 700 m a.s.l.).

The travertine body under study (Pleistocene- Holocene) is well exposed within an active quarry situated on the Manciano sector of the Albegna Valley.

Three meter-scale travertine units separated by two clay levels were identified in the "Saturmia Travertine Quarry" suggesting an intermittent accretion of the travertine body. These travertine units exhibit terraced slope, smooth slope depositional systems and filling topographic depressions. The terraced slope system (30-35 m thick) consists of terrace walls (several cm to 2 m high), pools (1-15 m wide), pool rims (few cm to 1 m high) and waterfalls (2-3 m high). The smooth slope consists of non-terraced and low-angle slope on which the terrace pools did not developed. More than thirteen carbonate fabrics at the cm-scale were distinguished in the field. These occur in different depositional environments (i.e., fast- vs. low-flowing water). Crystalline crusts (from cm to a few dm thick) are common of rims and walls, vertical surfaces of waterfalls of the terrace pools. These were also characteristic of smooth slope, where water supply and flow velocity are fast.

Shrubs, mm to cm arborescent structures that expand away from the substrate, are typical components of pools of terraced slope (relatively low energy areas).

In horizons of reduced topographic relief (ponds) and of low-angle dip of smooth slope systems, cm-scale alteration of different fabrics occurs including: shrubs (few mm to 20 cm), mm to cm elongated rafts, undulated sub-millimeter stromatolite-like structures, honeycomb, pisoids, micrite layers, rounded and elongated bubbles.

Petrographic analysis displays diversified microfabrics. Shrub structures usually consist of peloidal micrite. Crystal shrubs display a dendritic crystalline morphology and undulated extinctions. Calcite crystals (generally micritized) show a range of morphology from feather to ray crystals and dominate the crystalline crusts. Thin or crude laminated micrite/microspar forms stromatolite-like structures. Honeycomb like-structures consist of thin micrite/microspar laminae aggregated into packages with large subspherical/lenticular discontinuous cavities bulged up by large gas bubbles or insect larvae.

The microfabrics show 15-30% porosity, partially closed by spar calcite (likely of meteoric origin), micrite and microspar. The occurrence of biofilms in actively forming travertines at Bagni di Saturmia (12 km far from Saturmia Travertine quarry) confirms the hypothesis of the possible presence of an organic framework in some fabric of the studied fossil travertines.

The study of Albegna River Basin travertine provide fundamental information in terms of geometry and lateral and vertical evolution of the sedimentary bodies, depositional facies, carbonate fabrics their diagenesis and porosity that can have implications for comparable carbonate reservoirs in the subsurface.

MULTIDISCIPLINARY ANALYSIS OF THE PLIO-PLEISTOCENE CLAY DEPOSITS IN UMBRIA (CENTRAL ITALY): PRELIMINARY REPORTBIZZARRI Roberto¹, BALDANZA Angela¹, CAMBI Costanza², SABATINO Giuseppe², VINTI Giuseppe¹

1 - Dipartimento di Scienze della Terra - Università di Perugia

Key terms: Clay deposits; Multidisciplinary approach; Stratigraphy; Quaternary; Central Italy

Marine and continental clay deposits, dating from Pliocene to Late Pleistocene, widely crop out in the Umbria territory (central Italy). They belong to several lithostratigraphic units, the identification of which is in some cases still debated. The available allow to define almost homogenous outcrop areas, both in marine and continental deposits (Ambrosetti et al., 1987, 1995; Basili, 1997; Coltorti & Pieruccini, 1997; Girotti & Mancini, 2003). Four main clay units are usually defined: the Fabro Unit and the Chiani-Tevere Unit, which accommodate the Pliocene and Pleistocene marine sedimentary cycles, respectively, and the F.so Bianco Unit and Fighille Unit, which hold the wider outcropping continental clays in south and north Tiber Valley. Subordinate clay intervals also characterize the other Lithostratigraphic Units. In fact, clay deposits have been often used in cartography, as well in the geological models, independently on their meaning in terms of sedimentological, biostratigraphic, mineralogical features, and of paleoenvironmental context. New sedimentological and stratigraphic data are now available, and the former scenery needs a deep revision (Baldanza et al., 2011, with references), at least for marine deposits. On the other hand, geotechnical and mineralogical features vary both with stratigraphic range and paleoenvironmental context (Candio et al., 1992). The results of an ongoing research project, based upon a multidisciplinary approach and aimed to a whole re-evaluation of Umbria clay sediments are here presented. Several sections have been sampled, both in marine and continental clay deposits and sedimentological, stratigraphical, geotechnical and mineralogical analyses have been carried out, aimed to a comprehensive characterization of clay Units. Analyses are focused on micropaleontology, grain-size, Atterberg's limits, XRD. The results of this multidisciplinary analysis will be useful in cartography, geotechnical

studies, industry of ceramic and lateritic, archeometry and territory planning. Finally, this multidisciplinary approach, based upon a stratigraphic redefinition, contributes to the paleoenvironmental restoration and geological modeling.

Key terms: petroplinthite; paleosol; marine terrace; micromorphology

According to WRB a petroplinthic horizon is a continuous, fractured or broken layer of indurated material, in which Fe (and in cases also Mn) is an important cement and in which organic matter is either absent or present only in traces. Petroplinthic horizons are closely associated with plinthic horizons from which they develop on exposure to repeated wetting and drying. From a genetic viewpoint, plinthite forms by segregation of iron, in a horizon that is saturated with water for some time during the year. It normally forms in a horizon below base of a slope or in flat or gently undulating landscape. At the present time (petro)plinthite is commonly found in soils forming in subhumid tropical climates with distinct wet and dry seasons. The aim of this work is to document the evolution of costal complex paleosol developed in NW Italy during the Quaternary, and discuss the genesis of its associated petroplinthic horizon within the context of the environmental changes. These events affected the soil at different levels and most of the transformation has been recorded at the microscopic scale. The studied complex paleosol was observed close to the inner margin of marine terrace of Natta which has height of 75 m above sea level near Celle Ligure (SV, Northern Italy). On the terrace surface is possible to observe both marine and continental deposits that cover the Oligocene polygenic conglomerate bedrock. The Natta pedosedimentary section, more than 4 m thick, can be regarded as polycyclic pedocomplex which contains different paleosols. These paleosols have been truncated, reworked and have been supplied with an input of sediments during their development. The strong development of the pedosedimentary sequence is mainly due to superimposed pedogenetic phases (e.g. overlapping of illuvial horizons) in an accretional landscape. In particular the petroplinthic horizon represents the pedogenesis in response to seasonal fluctuation of the water table, the petroplinthite has no genetic link with the weathered bedrock. In this light, the plinthitisation/ferruginization derived from iron enrichment and accumulation from an external upslope source and mainly by post-depositional precipitation of neo-formed iron and alumina oxyhydroxides (hisingerite), deriving from the dissolution of pre-existing hematite in detrital laterite fragments. These probably derived by complete erosion of Pliocene lateritic soils (duricrust) in higher landscape positions. Therefore, each pedostratigraphic level reflects environmental changes resulted from complex interactions between rapid uplift and climate change controlled processes.

Key terms: Tyrrhenian Sea; Calabria; grain-size; benthic Foraminifera; trace elements

This study examines the grain size, chemical composition and benthic foraminiferal assemblages in marine sediments collected along the Tyrrhenian coast of central-southern Calabria. The sampling has been carried out along sixteen transects (from Bagnara to Falerna), at depths ranging from 50 m to about 400 m. Sediments consist of mud (silt+clay) and sand. Most of the samples show a preponderant silt fraction (43.20 to 84.85%). Clay fraction oscillates between 4.05% at Briatico and 44.11% at Gulf of Sant'Eufemia. Its content increases with depth in almost all transects. Sand fraction is well represented in the area between Gioia Tauro and Bagnara (13.08%-45.47%). The percentage of sand is inversely proportional to clay content and is not a function of depth. According to Flemming's classification (2000), sediments can be divided

into two groups: the first, including samples collected in the south area of Gioia Tauro, shows a higher sand content and falls in the range "Very silty sandy mud"; the latter, including the most sediments collected in the north area of Gioia Tauro, is mainly composed of silt and clay fraction and includes samples which can be prevalently considered as "Very silty slightly sandy mud" and "Clayey silt".

Optical microscopy examination revealed that size fractions higher than 63 microns include both terrigenous and biogenic components (mostly Foraminifera).

The benthic foraminiferal assemblages reflect effects of bottom topography. The presence of a scarp in the south area of Gioia Tauro influences the benthic association of the deep samples which are characterized, as well as the shallow samples, by typical species of shallow waters. This effect is less evident in samples collected in the north area of Gioia Tauro. The most abundant species are *Uvigerina mediterranea*, *Elphidium crispum*, *Amphycorina scalaris* and *Præglobobulimina ovata*.

Fraction less than 2 microns was also analyzed for the composition of 37 elements including major, trace and rare earth elements. Mn has the highest values (437-3840 ppm), followed by Zn (213-1209 ppm), Cu (65.7-440.5 ppm), Sr (117-338 ppm), Ba (63-202 ppm), V (69-112 ppm), Ni (37.3-103 ppm), Cr (38-93 ppm) and Pb (37.2-80.8 ppm). Metals show a different trend: Cu, Th, V, Sc, La, Zn, Ni, Co, Au, Cr, Hg show a decreasing concentration gradient from the coast toward the open sea, except for La at Pietra Galera, Zn at Agliastro and Pellegrina, Ni, Co, Au, Cr and Hg from Briatico to Pellegrina; the Pb, Mn, As, Sr and Ca concentrations increase offshore, except for Pb at Falerna, for Mn and As at Pellegrina and for Se and Ca at Gioia Tauro.

Key terms: analogue modelling; passive margin; lithospheric-scale extension; rifting

The crustal-scale structure of rifted passive margins represents an issue of relevant academic and commercial hydrocarbon-industry interest, and has been extensively investigated in the last decade, using both geophysical prospecting and numerical and analogue modelling.

In spite of the efforts, some basic questions are still open to debate, mostly concerning the amount and mode of crustal and lithospheric thinning, and the possible depth-dependency of lithospheric stretching. Although hampered by obvious limitations, sandbox analogue modelling has proven to be an effective way to investigate lithospheric-scale extension, and particularly to visualize the 3D modelling evolution. This contribution presents the results of a set of lithospheric-scale sandbox modelling experiments aimed at investigating the relationship between brittle faulting and ductile thinning in the crust and mantle.

Modelling has been performed in a sandbox using a 4-layers set-up, with alternating layers of sand and silicone putty, representing the brittle and ductile rheology, respectively, of crust and mantle. The reference lithosphere is "cold", i.e., it has a low geothermal gradient. The layer-cake has been set so as to float above a glucose solution, that represents the asthenosphere, and the density of modelling materials has been appropriately scaled, in order to reproduce crustal and mantle rocks of a realistic lithospheric structure. Lateral anisotropy in the viscosity of the lower crust has been introduced in some 3D models.

The sandboxes used are made of plexiglass and have a width of ca. 30 cm and a length ranging from 40 to 50 cm. One of the short walls of the sandbox is pulled using a computer-controlled motor to impose extension at a velocity of 1 to 3 cm/hour; this wall is attached to two moving side-walls that help pulling the sand/silicone layer-cake. Two end-member sets of models have been performed, based on the relative length of the two mobile side-walls: a) the two side-walls are of the same length and rifting is produced along a line parallel to the pulled wall, joining the tip of the side-walls; and b) the two side-walls have different lengths and, thus, an oblique rifting is produced. In the latter case, weak seeds in the brittle mantle are used to impose segmented boundaries. During extension loose sand has been poured at regular time intervals to simulate syn-rift sedimentation.

Laser scanning of the top surface has been performed at regular time intervals so as to monitor the surface faulting in the rift zone. At the end of extension (typically 12-20 cm), the models have been frozen and cut into vertical serial slices, so as to analyse the fault geometry in the volume unaffected by side-wall shearing, and to study the eventual 3D variations imposed in the model set-up.

The results show pure shear affecting the ductile mantle lithosphere, in the initial stages, which is subsequently followed by a necking of the ductile lithospheric mantle and lower crust that join together, following the sharp breakup of the brittle mantle. A simple shear deformation, typically dominated by one major extensional fault that soles out into the underlying ductile unit, characterizes the brittle upper layer. Typically, some degree of asymmetry in the fault system and in the sedimentary basin is observed in the brittle upper layer. Limited portions of weaker brittle mantle appear quite effective in localizing the main ductile mantle deformation, imposing the large-scale geometry of the rift system. Lateral heterogeneity in the viscosity of the lower crust, on the other hand, affects the faulting of the overlying brittle layer, and may promote some degree of asymmetry in the rift fault patterns.

Key terms: Calabrian Arc; Seismic lines interpretation; Extensional tectonics; Lanfs

During the last two decades, extensional systems driven by low angle normal faults (LANFs) have been progressively documented in the westerly part of the Italian peninsula (western Tuscany, Umbria and Campania-Lucania Apennines). In western Calabria (Ver-bicaro-San-Donato and Coastal Range areas), LANFs have been recently invoked by several authors to explain the omission of entire units from the orogenic pile; there is not agreement instead, about their attitude and time of activity. In this work we present the sur-face and deep geophysical evidence of an east-dipping LANF outcropping along the east side of the Calabria Coastal Range and bounding westward the Crati valley graben (CVB). This LANF, here named North Calabria Detachment Fault (NCDF), has as surface expression the NS-striking S. Fili - S.Marco Argentano fault and the NNE-SSW-striking S. Sosti-Saracena fault. Both these regional lineaments are well known in their outcrop features, the timing of activity and their kinematics. Nevertheless no literature data exist on their subsurface geometry and on the cross-cut relationships with the antithetical west-dipping faults dissecting the inner slope of the Sila massif.

We reconstructed the trajectory at depth of the NCDF and the geometry of the CVB through the interpretation of three commercial reflection lines (acquired by the Fiat RIMI - in the Esaro Permit) recently made public by the V.I.D.E.P.I. project (unmig.sviluppo-economico.gov.it/videpi). In particular, two WE-striking transversal lines and a longitudinal NS-striking line have been interpreted and depth-converted down to 3 sec TWT (corresponding to nearly 6 km depth). Our geological interpretation suggests that the NCDF is a regional east-dipping detachment fault characterized by a marked down-dip staircase trajectory. The NCDF outcrops at a dip-angle comprised between 30° and 40° which rapidly decrease to <15°. This shallow flat, 1 to 2 km depth, passes downward to a 40°-dipping ramp located just to the west of the present alluvial plain of the Crati river (2 to 4 km depth). The deepest detectable segment of the fault shows a dip-angle of nearly 25° which corresponds to the average value for the NCDF. The studied seismic sections clearly show that the CVB is a wide graben structure developed within the hanging wall of the NCDF and that it is split by a complex set of conjugate west-dipping and east-dipping high-angle normal faults, splaying from the basal detachment.

Some of these splays influenced the syntectonic sedimentation and caused growth and tilt-ing of the clastic fill. The analysis of these effects on the recognized seismostratigraphic units allow to define the order of nucleation of the major splay faults even if their accurate timing is hindered by the lack of calibration boreholes.

A detailed surface mapping and a comparison with other public and well calibrated seismic lines in the northern Crati Valley, have been performed to constrain our stratigraphic interpretation. Among the synthetic splays of the NCDF, the Torano-Roggiano-Firmo and the Mongrassano Scalo - Ferramonte faults show evidence of Late-Quaternary activity. The Bisignano-Luzzi antithetical fault shows also a great importance on the geometry of the CVB infill during the Calabrian.

A balanced geological section, elaborated through the Move Software (Midland Valley Package), allowed us to verify that our interpretation is restorable at the pre-extensional stage and that the minimum displacement occurred on the detachment during the Quaternary amounts to 4,5 km. The NCDF assumes the role of a first-order, probably active, ex-tensional feature of the southern Apennines and its recognition suggest new perspectives for a review of the geological and seismo-tectonic setting of the Calabrian arc.

CRUSTAL ARCHITECTURE AND BASIN DEVELOPMENT ALONG THE SCOTIA-ANTARCTICA PLATE BOUNDARY

CIVILE Dario¹, LODOLO Emanuele¹, VUAN Alessandro¹

1 - Istituto Nazionale di Oceanografia e di Geofisica Sperimentale (OGS), Trieste - Italy

Presenter e-mail: dcivile@ogs.trieste.it

Key terms: South Scotia Sea; Conjugate margins; Structural setting; Tectonic development

The Scotia-Antarctica plate boundary is a complex margin that juxtaposes thinned continental and transitional crust elements, separated by restricted oceanic basins and deep troughs, some of them representing pull-apart basins. The blocks, once adjacent each others, were part of the continental link between the southern South America and the Antarctic Peninsula, and are now distributed along the periphery of the Scotia Sea. They have been severely deformed and stretched during the tectonic processes responsible for the Scotia Sea formation, initiated in the late Oligocene. This was particularly relevant along the southern margin of the nascent Scotia Sea, where intense strike-slip tectonism was active since its early development. The E-W trending South Scotia Ridge hosts part of the plate boundary, and is composed by a series of submarine elevations (Terror Rise, Pirie Bank, Bruce Bank, Discovery Bank and Herdman Bank), some of them separated by small basins (Protector, Dove and Scan basins). East of the Discovery Bank, the boundary of the Scotia Sea is structurally much less constrained because of the paucity of geophysical and geological data, and its inherent complexity, as seen from satellite-derived bathymetric maps. Geophysical data have shown that before South America-Antarctic Peninsula break-up, the most probable candidate for the conjugate margin of Tierra del Fuego is the Terror Rise, an elevated topographic rise now located just to the north of the western part of the South Scotia Ridge, and possibly the Ona Rise, a morphological elevation that lies just to the west of the Terror Rise. The southern boundary of the Scotia Sea became the left-lateral Scotia-Antarctica plate boundary since the early development of the oceanic plate.

A compilation and reappraisal of available multichannel seismic profiles acquired along the southern margin of the Scotia Sea has allowed identifying and mapping the main morphological and structural features of this segment of the plate boundary. In general, data show that the complex style of deformation of the South Scotia Ridge was generated by the combination and superposition of several transcurent and compressional tectonic events. We propose here an evolutionary sketch for this margin, dominated since the Early Miocene by the northward

subduction of the Weddell Sea oceanic crust and by prevalent transcurrent motion between the two principal South America and Antarctic landmasses.

Key terms: Marine Geophysics; Active tectonics; Taranto Gulf

In this contribution we illustrate the preliminary results of the Teaticoa_11 cruise carried in the southern Taranto Gulf and aimed at investigation of recent faults. Within this sector of the Apennines, studies on-land documented recent and unsuspected transpression (Ferranti et al., 2009), but identification of active faults is difficult because most are located offshore. Although major transcurrent faults were previously recognized offshore (Del Ben et al., 2007), their recent tectonic history is yet obscure. The investigated area displays a ridge-basin pattern, characterized by the Amendolara bathymetric high, bordered on the south by a steep scarp and by the elongated Sibari basin.

High-resolution multibeam data allowed to locate with great confidence the major tectonic structures, and to scrutiny evidence of sea bottom ruptures and gravitational effects. Widely distributed mass-movements are represented both by large-sized scars along the major fault-line scarps, and by sediment collapse above gliding horizons located on tilted strata. Terraced surfaces were mapped on the summit of the bank, and can be correlated to glacial-stage position of the sea-level, the counterparts of the interglacial terraces exposed on-land. Preliminary evaluation of the inferred undersea terraces age indicate limited regional uplift, and deformation related to local active structures.

High-resolution sparker profiles across the mapped structures provided vital insights to unravel their recent history. The stratigraphic signature of deep fault activity is recorded by depositional sequences within satellite basins and on the flanks of submarine ridges, and is represented by debris flows, growth fans and forced shift of depoaxes. This activity interlaces with the effects of regional processes, expressed by the vertical stacking of highstand and lowstand system tracts and generated by the interplay between tectonic uplift and global sea-level fluctuations. The Late Quaternary depositional packages appear folded up to the recentmost one, including the basal unconformity of the last glacial sequence. In addition, thick landslide bodies (already evidenced in the study of Rebescio et al., 2008) were imaged in great detail. The distinctive structural and stratigraphic features imaged by the sparker profiles are corroborated by high-resolution CHIRP profiles, which have locally evidenced offset of the near-bottom reflectors.

The pattern emerging from the integrated data analysis supports the contention that the Amendolara ridge is a composite fault-propagation fold limited to the south by a major south-displacing transpressional system. The ~60 km long system is arranged in at least four segments limiting as many morpho-bathymetric highs. In the central part of the system, a fault scarp rupture is mapped at the sea-bottom. Appraisal of publicly available multi-channel seismic reflection profiles indicate that the mapped structures are the shallow-crustal expression of steep transpressional faults, which emanate from underneath the Apulian platform and cut the thin-skin Apennine belt. Based on the size of fault segments and the modeled depth of micro-seismicity, we argue that the Amendolara deformation belt may incorporate the source of moderate-sized historical earthquakes (e.g. 1836). Active seismogenic and/or creep faulting and fold growth controls the near-sea bottom slumping and creeping and possibly prehistoric catastrophic landsliding.

Key terms: Himalayas; Main Central Thrust Zone; shear zone

The Main Central Thrust Zone (MCTZ) is one of the most intriguing and long-time discussed geological features of the Himalayas (e.g. Searle et al. 2008, for a discussion). It is a crustal scale shear zone several km-thick, extending along strike all along the Himalayas and marking the juxtaposition of the high-grade Greater Himalayan Sequence (GHS) over the low- to medium-grade Lesser Himalaya Sequence (LHS). In the geologic literature, a common definition, location and kinematic interpretation of the MCTZ is still lacking.

During autumn 2010, in the framework of a collaboration with Ev-K2-CNR and the Nepal Academy of Science and Technology, new structural and petrographic data were collected, and field mapping was performed, in the MCTZ along an east-west trending cross section in the Rolwaling and Khumbu Himal (east-central Nepal) from the villages of Lukla to Jiri, in an area still poorly known from the geological point of view.

At a regional scale, the structural setting of the investigated area is

dominated by north-dipping composite foliations, parallel to the lithological contacts or the compositional banding. The MCTZ has been identified as a several km-thick shear zone characterized by mylonites, mesoscopic shear zones and tectonic slices. These slivers comprise a number of different lithologies: augen-gneiss, two-micas paragneiss and micaschist, slate, quartzite, pure and impure marble, Ca-silicate fels. No sharp structural breaks can be clearly mapped at the boundaries of the MCTZ. However, the upper portions of the MCTZ can be roughly envisaged in the Poyan area, about 5 km south of Lukla, where mylonitic biotitic orthogneiss occurs structurally below the garnet + K-feldspar + kyanite + sillimanite Barun gneiss of the GHS. The lower portions of the MCTZ are underlined by strongly deformed two-micas augen-gneiss outcropping in the Karikhola area, about 10 km south of Lukla, above biotite-bearing phyllites of the LHS; these peculiar gneiss are reported in the literature as the Paphlu augen-gneiss (Maruo & Kizaki, 1981). In the MCTZ, the abundant kinematic indicators record a consistent top-to-south sense of shear.

The results of this study can be usefully compared with additional data collected further eastward (e.g. Goscombe et al., 2006; Searle, 2008; Mosca et al., 2010) and discussed in the regional tectonic scenario of the central-eastern Himalaya.

SEISMIC DAMAGE ZONES AND THEIR IMPACT ON DEEPWATER STRUCTURE CHARACTERIZATION

IACOPINI David¹, BUTLER Robert W.H.¹

- 1 - University of Aberdeen

Presenter e-mail: d.iacopini@abdn.ac.uk

Key terms: fold-thrust structures;; 3-D seismic interpretation; deformation localization; seismic imaging

In recent years the advent of 3D seismic data as a research tool has been a major factor in our understanding thrust faults, normal fault propagation and linkage. Thanks to the new 3D migration algorithms, extreme advances on describing the real 3D geometry and relationship between thrust fault and folds associated with gravity driven deformation has been done. The well accepted classes of structures (eg. fault bent folds, trishear faults and detachment folds;) mainly based on cross sectional geometry either derived by exposed section or from 2D seismic profiles resulted unsatisfactory on describing the full 3D geometry and the three dimensional evolution of thrust related folds. Measurements of growth sequence and detailed fault plane geometry from 3D seismic data illustrate a great variability along strike of the internal geometry that cannot be fully represented by any of the existing models. A direct consequence of those new 3D models is a better characterization of the toe-thrust traps geometry and more complicated constrain into sequential restoration of 3D thrust structures. However there is still poor understanding of the internal architecture of the thrust and fault zones especially within deep water environment, that even where seismic data are excellent they still are conventionally and routinely defined by breaks and apparent offsets of seismic reflectors. As clearly indicated by outcrops and by detailed seismic image processing these descriptions are not satisfactory and they miss to identify position of thrusts, their associated splay and the zones of damaged wall rocks. The main reasons were partly due to the poor seismic resolution failing to detail objects within the resolution of these complexities but also to a simplified geometrical assumption by the interpreter during the migration process that do not take into account the complexity systematically observed in analogue outcrop studies. This is specifically true when we are dealing with exceptionally good seismic datasets where details can be analyzed at different scale and complex fault or thrust geometry can be visualized. In order to improve our understanding of such complexities and investigate the geological meaning of that low signal to noise zones in different context, various images processing workflow using combination of seismic attributes has been recently proposed. Those studies highlight and extract potential geological information from the systematic signal distortion around fault, thrust, and steep fold limb. This disturbed area has been called fault seismic distortion zones or more generally seismic damage zones. Part of those disturbed zones is clearly associated to deformation complexities associated with fault thrust and fold, other to imaging problem due to the presence of geometrical complication around the fault and folds. We stress and show that in various situations the two different sources can be reasonably distinguished by developing specific workflows or seismic imaging surgery. At a larger scale the main faults thrust and damage imaged clearly shows a branched and dendritic architecture, with interconnected double verging thrusts. In both the time-dip and coherence map the main fault structures appear as bands defined by a patchwork of small curvilinear discontinuities and non rotated but disrupted reflections. Concluding, seismic damaged zones store more information than simple reflector disruption or incoherent noise. In those specific cases obtaining detailed information on the real geometrical properties of fault systems developing post stack signal processing (or attributes generation) to fine tune the imaging of the main structural features can be critical for the geometry prediction within scenario of hydrocarbon exploration as well as for reconnaissance of seismogenetic structures in submarine seismically active margin.

THE INVESTIGATION OF SEISMOGENIC SOURCES THROUGH ANALOGUE MODELING: INSIGHTS FROM THE 2009 L'AQUILA EARTHQUAKE (MW 6.3, ITALY)

Key terms: Seismogenic fault; sandbox modeling; Central Apennines

The 6 April 2009, L'Aquila earthquake (Mw 6.3) represents one of the best documented normal faulting sequences worldwide as it allows seismological, interferometric and geological data to be analyzed jointly. Nevertheless, an apparent discrepancy exists between deep and surface data. Integration of available instrumental data showed that the earthquake rupture developed on a 45° SW-dipping normal fault extending from 9-10 to 2-3 km depth (e.g. Chiarabba et al., 2009). On the one hand, field surveys highlighted surface breaks (fractures and small faults) after the earthquake near Paganica, named the Paganica Fault System (Emergeo Working Group, 2009). On the other hand, the overall pattern of coseismic deformation revealed by InSAR analyses showed an asymmetric subsiding basin with maximum vertical displacement (19-28 cm; Atzori et al., 2009) falling halfway between the city of L'Aquila and the village of Fossa, 5 km from the Paganica Fault. In order to identify a faulting process compatible with all these data, in particular with the dynamic rupture cut-off at 2-3 km depth and with the surface breaks (InSAR data and surface ruptures), we tested two different hypotheses using the sandbox modeling technique: 1) a seismogenic fault that reaches the surface (direct fault propagation model); 2) a blind seismogenic source extending between 2-3 and 9-10 km that does not reach the surface (blind seismogenic source model).

We selected a modeling technique commonly employed to simulate upper crustal rocks. All models are scaled 1:100,000. We used a new apparatus designed to reproduce the deformation associated with an earthquake occurring in the uppermost crust, and that occurs specifically above the seismicity cut-off. In the first model the master fault was free to propagate towards the surface from its seismological tip point. The experiment showed that a synthetic fault propagated upward from the upper tip of the modeled seismogenic source with a dip of 70°. In this case, the associated subsiding basin was asymmetric, its depocenter being located along the emerging fault plane. We therefore obtained a typical basin-bounding normal fault. In the second model we prevented the fault from propagating upward by introducing an artificial barrier to simulate the buried top of the master fault. This allowed us to evaluate if and how rocks located above the dynamic rupture can experience secondary brittle deformation. The results showed the formation of secondary extensional faults located on the fold that develops above the upper tip of the master fault, where horizontal tensile stress is maximum. These faults are not directly connected with the deeper master fault, and in this case the depocenter of the basin is located about 5 cm (i.e. 5 km in nature) away from the surface faults.

A comparison of our results with geological observations shows that, even though the causative fault of the 2009 L'Aquila earthquake did not reach the surface, for instance because according to seismological data dynamic rupture stopped at 2-3 km, motion on the Paganica Fault System may indeed occur, either on a pre-existing fault reactivated for its favorable orientation, or on secondary structures related to the fold above the upper tip of the master fault, which is in turn coseismically deformed. These two observations are consistent with the InSAR-detected coseismic deformation.

PROPAGATION OF THE IDRİJA STRIKE-SLIP FAULT SYSTEM IN FRIULI (WESTERN JULIAN ALPS AND CARNIA REGION, NE ITALY): PRELIMINARY REPORT.ZANFERRARI Adriano¹; POLI Eliana¹

1 - UNIVERSITY OF UDINE

Presenter e-mail: adriano.zanferrari@uniud.it**Key terms: Idrija fault system; strike-slips faulting; seismotectonics; eastern Southern Alps; NE Italy**

The NW-SE trending, dextral strike-slip Idrija fault system is a Neogene to Quaternary seismogenic structural network, extending from W-Slovenia to NE Italy. Its activation is linked to the N-directed motion of Africa vs. Europe, coupled with a counter-clockwise rotation of the Adria microplate. Structural characteristics, kinematics and seismogenic activity are well known in western Slovenia. On the contrary in the Friuli region the lack of updated geological and structural data, till now prevented a correct mapping of the fault trace. Detailed geological mapping (1:5,000) carried out in the framework of the 049 "Gemona del Friuli" geological sheet (Italian CARG Project), enabled to define the geometric and structural characteristics of the Idrija fault system in the Friuli-Carnia area too. The dextral strike-slip fault-system, (that here presents a WNW-ESE trending, and was mapped for about sixty kilometres), causes contractional and extensional bends, duplexes and positive and negative flowers. Both Paleogene Dinaric and Neogene-Quaternary Southalpine thrusts are cut by the Idrija strike-slip system. The neotectonic activity of the fault system is demonstrated by: 1) deformation of Pliocene to Middle Pleistocene continental successions; 2) morphotectonic evidence; 3) historical and instrumental seismicity that hit Carnia. Earthquakes recorded by the Friuli Venezia Giulia seismometric network, managed by the O.G.S.-Trieste (Seismological Research Dept.), show WNW-ESE dextral strike-slip focal mechanisms; 4) the coseismic deformations recorded by the topographic high precision survey performed after the M=6.4 and M=6.1, 1976 Friuli earthquakes, that may be now linked to the present activity of the Idrija fault system in the Tolmezzo-Venezzone area. On the basis of the new geological and structural mapping, and on the available morphotectonic data related to the surficial expressions of the active faults, we will afterwards try to define geometric and kinematic characteristics of the seismogenic faulting which affect this portion of the eastern Southern Alps, giving a new contribution for the definition of the seismic hazard of this region.

RELATIONSHIP BETWEEN NEOTECTONICS AND FLUID ESCAPING IN THE NORTHERN SICILIAN CONTINENTAL MARGINPENNINO Valentina¹; SULLI Attilio¹

1 - Dipartimento di Scienze della Terra e del Mare - Università di Palermo

Presenter e-mail: valentinapennino@unipa.it**Key terms: Neotectonics; Fluid escape; Pockmark; Mound; Seismicity**

New exploration in the marine environments has revealed that the fluid escape structures are often associated with neotectonic elements and are aligned along the same direction. Sometimes is observed the migration of fluid along fault planes to the sea floor as gas venting (Forrest et al., 2005).

This paper aims to recognize and to classify the different types of structures associated with fluid seepage, particularly those that develop along alignments coinciding with or parallel to the neotectonic lineaments, in order to assess the interactions between tectonics and fluid circulation. The study area extends, from west to east, from the Gulf of Castellammare to the Gulf of Termini (offshore northern Sicily), and belongs to the northern Sicily continental margin, in the transitional area between the Sicilian-Maghrebian Chain to the south and the southern Tyrrhenian Sea to the north.

Previous morphostructural studies identified a wide W-E trending right-lateral shear zone, mainly characterized by both a synthetic NW-SE/W-E trending, and antithetic left-lateral N-S/NE-SW fault systems, which affected the tectonic edifice, since the Pliocene (Giunta et al., 2009), while the current seismicity shows compressional focal mechanisms aligned to the NW-SE and ENE-WSW trends, in agreement with axis of maximum horizontal compression oriented NW-SE (Neri et al., 2003).

We used a dataset of seismic reflection profiles, both high and very high resolution single-channel and multi-channel profiles, acquired respectively with CHIRP, sparker and airgun sources, and high resolution morphobathymetric data acquired down to 2200 m, in relation to the MaGIC project (Marine Geohazards along the Italian Coasts).

The data allowed us to distinguish three different types of fluid escape structures by means of highly contrasting seismic and morphological signatures. In particular, mounds and buried mounds have been recognized in the continental shelf, while pockmarks occur in the continental slope; the latter are often found to be aligned in this area. Two fault systems have been recognized: a NW-SE trending extensional and/or transtensional system, which produces the recent articulation of the seabed, and an ENE-WSW trending compressive, which contributed to the formation of morphological relieves.

The seismicity of the area confirms the recent activity of both the systems, because the clusters of earthquakes of 1998, 2002 and the most recent until 2011 (<http://www.ingv.it>), are aligned with the recognized tectonic structures, and have focal mechanisms with major compression horizontal axis oriented NW-SE, compatible with the orientation of the tectonic lineaments.

The identification of fluid escape structures, aligned with the neotectonic lineaments and with the clusters of earthquakes, allows us to hypothesize the relationship between the circulation of fluids and faults, the latter being preferential pathways for the rapid ascent of the fluid towards the surface.

Moreover, the recent seismic activity indicates that the recognized neotectonic structures, respectively oriented NW-SE and ENE-WSW, are active and especially seismogenic structures.

TECTONIC DISCONTINUITIES IN THE GREATER HIMALAYAN SEQUENCE OF THE HIMALAYAN BELTCAROSI Rodolfo¹; MONTOMOLI Chiara¹; VISONÀ Dario²

1 - University of Pisa

2 - University of Padova

Presenter e-mail: carosi@dst.unipi.it**Key terms: Himalayan belt; shear zone; geochronology; exhumation**

The Himalayan belt has a spectacular continuity for more than 2000 km. In spite of the fact that the main tectonic units building up the chain can be recognized all along the belt, detailed structural analyses performed during the last years (CAROSI ET AL., 2006, 2007, 2010) pointed out that the Greater Himalayan Sequence (GHS) presents important tectonic discontinuities at the regional scale.

These shear zones, mainly located in the core of the crystalline units, triggered exhumation of the crystalline rocks during the collisional phase. A high-temperature contractional shear zone with a top-to-the SW sense of shear affects the core of the Greater Himalayan Sequence (GHS) in western Nepal. The shear zone developed during the decompression (sillimanite stability field) of rocks that previously underwent relatively high-pressure metamorphism (kyanite stability field). PT conditions indicate that the footwall experienced higher pressure than the hanging wall and similar temperatures. This indicates that the shear zone developed during contractional tectonics, allowing the upward movement of the hanging wall whereas the footwall continued to be underthrust. Monazite growth constrains the initial activity of the shear zone at 25.8±0.3 Ma, before the onset of the Main Central Thrust zone. The late intrusion of a cross-cutting granitic dyke limits its final activity (17±0.2). Monazites in kyanite-bearing gneisses from the footwall record prograde metamorphism in the Greater Himalayan Sequence from ~43 to 33 Ma. These data suggest that exhumation of the GHS started earlier in western Nepal than in other portions of the belt and before the activity of both the South Tibetan Detachment System (BURCHFIEL ET AL., 1992; CAROSI ET AL., 1998, 2002) and Main Central Thrust zone (SEARLE ET AL., 2008 and references therein).

As a consequence, western Nepal represents a key area where channel flow driven mechanism of exhumation, which is active from Bhutan to central-eastern Nepal, does terminate. In this area, exhumation of crystalline units likely occurred by foreland propagation of ductile, and subsequently, brittle deformation.

Since the shear zone started to move during the underthrusting of the GHS it changed the fate of the hanging wall rocks that were the first to be exhumed: they inverted their displacement starting to move upward and southward. It is worth noting that by activation of the shear zone and before MCT movement, the footwall rocks continued to be underthrust

reaching higher pressures with respect to hanging wall rocks. This stage was followed by the overall exhumation of the GHS. As a consequence different P-T-t paths are obtained for footwall and hanging wall rocks, being the main difference the maximum pressure reached. Considering only the P-T-t paths, without the exact deformation path of the rocks or, at least, the geometry and kinematic indicators in mylonites, we could erroneously interpret the shear zone as a normal sense shear zone (in contrast to the movement indicated by kinematic indicators in the mylonites). A main consequence, from this case study, is that interpreting the sense of movement of tectonic structures having only the P-T-t paths may lead to erroneous interpretations.

TRANSCURRENT TECTONICS IN THE NORTH-WESTERN SECTOR OF THE VOLTRI MASSIF: INSIGHT FROM FAULT-SLIP ANALYSIS

FEDERICO Laura¹, VIGO Andrea¹, CRISPINI Laura¹, CAPPONI Giovanni¹
 1 - Dip.Te.Ris - Università di Genova

Presenter e-mail: federico@dipster.unige.it

Key terms: fault-slip analysis; paleostress; fault zone; Voltri Massif; Western Alps

We studied the brittle structures occurring in the northwestern sector of the metaophiolitic Voltri Massif (Western Ligurian Alps), with the aim to characterise the kinematics and evolution of a poorly-known tectonic lineament, i.e. "Pra' Vallarino - Tiglieto" (Martinis & Pasquare, 1971) and its role in the tertiary evolution of the area.

This fault zone is largely developed inside HP serpentinite in its central-eastern part, whereas it represents the contact between bedrock and post-orogenic Oligocene deposits of the Tertiary Piedmont Basin (TPB) in its western part. Some of the studied faults crosscut basal deposits of the TPB, and therefore can be relatively dated to be post-Lower Oligocene. This study couples structural analysis of fault zones with analysis of tectonic lineaments from aerial photographs and paleostress determinations by means of inversion of fault-slip data.

Fieldwork revealed that this lineament is actually the sum of different fault segments, with a dominant transcurrent character but changing orientations. They are accompanied by the development of wide fault zones, (locally hundred meters wide) and huge amounts of fault rocks, (mostly crush breccia and cataclaste, according to Sibson, 1977). In the central part of the study area (between Pra' Vallarino and Acquabona) faults are dominantly E-W or WNW-ESE trending and steeply dipping, whereas they move to NE-SW trends at the western and eastern terminations (near the villages of Sassello and Tiglieto, respectively). According to field relationships, faults have been grouped into different Riedel systems (either left-hand or right-hand) that allow to obtain a first-order determination of orientation of paleostress axes. The reconstruction of paleostress tensors is then refined coupling field observations with different methods of inversion of fault-slip data and using different open-source computer programs (Faultkin 4.3.5 and Fsa), that calculate either P-B-T axes or resolved stress tensors. This approach is able to distinguish different superposed stress tensors and therefore is especially useful to unravel a polyphase deformation pattern like the one we studied.

We therefore identified strike-slip and oblique-slip stress tensors with σ_1 oriented either NW-SE or NE-SW, linked to left-hand or right-hand strike-slip systems.

Overprinting relationships between these two events are still under investigation, but regional studies (e.g. Capponi et al., 2009; Crispini et al., 2009) suggest a possible correlation of the stress field with

NE-SW-trending σ_1 with a Late Oligocene-Early Miocene tectonic phase, as defined by Mutti et al., 1995 ("Fase Ligure III") which displays NE-SW shortening.

THE "ÉCAILLES INTERMÉDIAIRES" OF THE RIO SECCO-CLARÉE VALLEY AND COL LONGET (WESTERN ALPS)

VALETTI Lorenzo¹, MOSCA Pietro²

1 - Via Circonvallazione 23/int.22, Strambino (Torino)

2 - CNR - Istituto di Geoscienze e Georisorse, Torino

Presenter e-mail: p.mosca@csg.to.cnr.it

Key terms: tectonic slices; Ultrabriançonnais; breccias

In the western Alps, a series of discontinuous tectonic slices reported in literature as "écaillies intermédiaires" (EI) locally outcrop along the contact between Piedmont and Briançonnais units. In general, these slices consist of pre-Tertiary basement rocks and/or thin Mesozoic cover sequences of Ultrabriançonnais (or Acegllo) affinity, showing then an almost complete erosion of Triassic platform carbonates by transgressive Upper Jurassic deposits (e.g. Lemoine, 1961).

This paper describes the structural-geological features of the EI outcropping in the Rio Secco-Clarée Valley (north of Montgenèvre, high Susa Valley) and Col Longet (high Ubaye Valley) areas. In the Rio Secco-Clarée Valley area, the Chaberton-Grand Hoche unit of Piedmont affinity is over a tectonic unit formed by a pre-Tertiary

basement and its Permo-Mesozoic cover along a major thrust plane, folded and cross-cut by N-S trending strike-slip faults. The basement consists of polymetamorphic quartz-micaschists, monometamorphic micaschists and orthogneisses showing a pervasive blueschist-greenschist facies metamorphic imprint of Alpine age. The lower portions of the metamorphic cover sequence are Permian to Lower Triassic quartzites with diffuse pink quartz pebbles and intercalated red shales (Pseudoverrucano facies), upward followed by Scythian quartzites and by rare platform carbonates considered Middle Triassic in age (Barfety et al., 1995). The upper portions of the cover sequence consist of heterogeneous detrital calcschists and marbles with intercalations of breccias, and a peculiar conglomeratic micaschist ("Permien reconstitué" of literature); clasts of these levels are made of Triassic carbonates, Permo-Triassic quartzites and basement rocks, and have sizes ranging from mm to cm. These chaotic deposits rest unconformably above both the basement rocks and the lower terms of the cover sequence and their age ranges from Late Jurassic to Cretaceous-Eocene? (Barfety et al., 1995).

In the investigated sectors near Col Longet, a few hundred meters-thick succession of megabreccias crops out between Piedmont and Briançonnais units. Breccias have sub-angular clasts and blocks up to dam-sized, made up of material dismantled from the adjacent Briançonnais units (micaschists, quartzites and carbonates) and deposited on marine environments (Lemoine, 1967). The megabreccias fade upwards into gray marbles, which are tentatively considered Late Cretaceous in age on the basis of regional correlations.

The most striking feature of the investigated tectonic units is therefore the occurrence of Upper Jurassic to Cretaceous levels dominated by huge breccias; the sub-angular aspect of clasts and blocks suggests rock fall processes with short distance transport. In addition, the EI exposed in the Rio Secco-Clarée Valley area show an almost complete erosion of Triassic platform deposits, conversely reaching several hundred-meters in the adjacent Briançonnais units. The tectono-depositional evolution of the investigated EI is presented and discussed within the regional tectonic scenario of the western Alps, pointing emphasis on the syn- and post-rift extension occurring along the continental margin.

Key terms: Dauphinois; Thrust; Ventimiglia

Since 2010, an extensive field-work has been performed north of Ventimiglia (IM) by the Pavia University surveyors of the Dipartimento di Scienze della Terra e dell'Ambiente for the Riskinat-Interreg project (Pavia Unit Resp. Prof. S. Senò) in collaboration with Regione Liguria (Resp. Dott. G. Gorziglia). The investigated area is constituted by a thick Dauphinois succession of sedimentary rocks. The post-Cretaceous Dauphinois units near the boundary between Italy and France are formed by a well-known succession: the "Priabonian trilogy". It is formed by rocks that deposited in the Alpine underfilled peripheral foreland basin. A thick succession of Cretaceous marly limestones (Calcari e calcari marmosi di Trucco) forms the pre-Cenozoic basement, top-bound by a regional unconformity (mostly an angular unconformity with rarer paraconcordance evidences) sealing up late Cretaceous and Paleocene deposits. The following transgression caused the deposition of marine-continental transitional deposits (conglomerates, sandstones and marls of the Microcodium Formation) during the Early Eocene. The vertical evolution of these deposits in the developing Alpine foreland basin is represented by the nummulitic limestones and calcarenites of the Calcareniti di Capo member, belonging to a shallow platform environment (about few to a hundred meters depth). The deepening trend bring to the sedimentation of marls and pelites of Marne di Olivetta San Michele Formation and finally to the turbidite sandstones of the Ventimiglia Flysch (corresponding to the Italian sub-basin deposit of the Gres d'Annot turbidite system).

The field mapping of the study area evidenced the presence of a kilometric thrust (Abellio thrust) that juxtaposes two tectonic elements made up by the same, above described Cretaceous-Eocene succession. The units has been informally named "M. Terca unit" (the upper) and "Rojà unit" (the lower). The thrust is roughly NNE-SSW oriented; the amount of west-transport of the M. Terca unit is probably limited but significantly diminishes toward the South. This assumption is supported by observing the amplitude and geometry of the associated drag folds. The thrust is interrupted by a lateral ramp located northward near the M. Gouta area and reaches the coast near Ventimiglia toward the South. The geometry of the thrust has been also reconstructed through digital modelling in order to understand the real implications of its anticlockwise rotation. The Abellio thrust has been tentatively dated as Late Oligocene-Early Miocene, when the north-west Alpine compressive thrust fronts propagated in the Helvetic-Dauphinois zone. Interesting implications may come from its position, as the Abellio thrust could be considered the southernmost onland structure affecting the Dauphinois succession. Its transport was probably also influenced by the interactions between the complex geometry of dispersal blocks that followed the rifting of Greater Iberia (causing the anticlockwise rotation of the Corsica-Sardinia) and the Alpine-Apennine orogens.

Key terms: uplift; Western Alps; interferometry; faults; tectonic activity

In this work we integrated and compared structural geology, geomorphology, quaternary geology with Permanent Scatterers data, in order to constrain the current tectonic activity of the central Western Alps, where evidences of superficial deformation are scarce.

The study area is characterized by low deformation rate, as attested by the low magnitude of the instrumental seismicity (Eva et al., 1997; Perrone et al., 2010; in press) and by the GPS data (Calais et al., 2002). Nevertheless some moderate historical seismic events, like those of the 1808 seismic sequence, struck this area.

Continuous velocity surface maps (Iso-Kinematic Maps: IKM; Morelli et al., 2011) obtained from geo-statistical and spatial cluster techniques (Hot Spot analysis) of PS were compared with geological model.

The comparison of the IKM with the fault pattern shows a rough correspondence with some of the regional brittle tectonic features that dissect this part of the Alpine chain. In particular isokinematic boundaries show a correspondence with the Lis-Trana Deformation Zone (Balestro et al., 2009; Perrone et al., 2010) and the southern prolongation of the Canavese Line, in the innermost part of the chain, and with the Longitudinal Fault system (Sue and Tricart, 2003) in the external sector. The correspondence between the trace of the brittle tectonic features and the isokinematic boundaries may represent a further constrain for the current activity of the regional fault systems dissecting this sector of the western Alpine Chain.

Key terms: Northern Apennines; structural analysis; gravity interpretation; subsurface geological mapping

Commonly complex structural settings characterize transition zones between basin and belt areas. In this scenario a multidisciplinary approach is the most suitable to reconstruct subsurface geological structures.

The case study concerns the Monsummano-Montecatini area, located in north-central Tuscany, where part of the Northern Apennines structural stacking (Tuscan Nappe and Ligurian Units) crops out at the margin with the Montecarlo basin.

In this contribution we present the results of a multidisciplinary study targeted to the definition of the overall outcropping and subsurface structures of the Monsummano-Montecatini area. Data from structural-geological survey, aerial photo interpretation and analysis of brittle structures have been integrated with the results of a gravimetry survey used to map the subsurface distribution of rock density.

In particular a structural analysis aimed to the definition of geometry and kinematics of the occurring brittle structures (faults and joints) has been performed in several measurement stations especially located in the Tuscan Nappe carbonate succession of Monsummano-Montecatini area and Marliana area, about 5 km north of Montecatini. The elaboration of the collected data allowed the identification of two main populations of high-angle discontinuities oriented respectively roughly NE-SW and NW-SE. The kinematic analysis indicates that brittle tectonics is characterized by a polyphase evolution with the superposition of normal and/or oblique-normal movements on strike-slip movements.

The gravimetric survey has been carried out in a 25 km² area including Monsummano and Montecatini ridges as well as the Monsummano plain. The Bouguer anomaly map is characterized by the occurrence of a positive gradient, trending from NE-SW in the eastern sector to N-S in the western sector of the map. The horizontal gradient-gravity map allows to identify some discontinuities whose trends correspond to major faults evidenced by the structural-geological study.

Modelling of gravity anomalies along three selected profiles, crossing NE-SW, N-S and WNW-ESE the investigated area, fit with height main gravimetric bodies characterized by weak density differences.

On the basis of the results of the structural-geological study and the gravimetric modelling, three geological cross-sections have been realized, allowing the interpretation of the subsurface geological structure of Monsummano plain and Monsummano-Montecatini ridge up to a depth of about 1-1,5 km. These cross-sections have been also constrained with available well data and other geophysical information.

The main structural feature is represented by a complex fault system formed by main faults oriented respectively NE-SW and NW-SE. This fault system affected the E-verging antiforms which deformed the Tuscan Nappe carbonate succession outcropping in Monsummano, Montecatini and Marliana areas, as well as the other geological units including the Neogene-Quaternary deposits filling the Monsummano plain. In particular the NE-SW directed faults cutting along the Nievole Valley determined the interposition of less permeable formations (Ligurian Units and Macigno and Scaglia formations) inside the Mesozoic carbonate succession, assuming importance for the relations between the hydrothermal systems of Monsummano and Montecatini.

In conclusion, this study allow to highlight how the integration of a detailed structural-geological analysis with a gravity survey, a not invasive geophysical method, can provide a better definition and understanding of the subsurface structure prefiguring a 3D geological model. This new insight in the structure of the Monsummano-Montecatini area will be a very useful document for planning the hydrogeological research to be undertaken in this thermal area.

ANALYSIS OF THE FAULT PATTERN IN THE LOWER LANZO VALLEY (ITALIAN WESTERN ALPS): A MULTI-SCALE INTEGRATED APPROACH

CADOPPI Paola¹, FUSETTI Ermes², MORELLI Michele³, PERRONE Gianluigi¹
 1 - Dipartimento di Scienze della Terra - Università di Torino
 2 - Regione Piemonte
 3 - ARPA Piemonte

Presenter e-mail: paola.cadoppi@unito.it

Key terms: Western Alps; fault pattern; structural analysis; Lanzo Valley

This work combines morpho-structural analysis, field mapping and detailed structural analysis for the study of the fault network in the Lower Lanzo valley (Italian Western Alps), where the Sesia-Lanzo Unit and the Lanzo Ultramafic Complex crop out. At the regional scale this area is bordered by two major post-Oligocene tectonic discontinuities: the Canavese Line and the Lis-Trana Deformation Zone (Balestro et al., 2009).

Morpho-structural analysis (carried out both on satellite, Landsat 5 TM and Aster, and aerial images) allows detecting three lineament systems: Ln1 (E-W), Ln2 (NE-SW), Ln3 (NW-SE).

Ln1 system is constituted by the longest lineaments (up to 2-3 kilometres long), usually arranged to form several, sub-parallel belts that cross the whole study area.

Ln2 system is widespread in the whole study area even if the highest density of distribution is mainly observed in the northern sector of the analysed area. These lineaments are characterized by a moderate variability in terms of strike and length. Ln2 lineaments often terminate against Ln1 lineaments or, in some cases, cut them.

Ln3 system is better shown on Aster image and it consists of fewer and shorter lineaments than the others, but is evident throughout the whole area. Its lineaments often define clusters of lineaments which form sub-parallel belts that can reach a multi-kilometre length (western sector).

Field mapping and structural analysis allowed distinguishing three main fault systems striking E-W, NE-SW and NW-SE.

The E-W fault system represents the major brittle structural feature and it is constituted by E-W striking steep faults, up to few kilometres long. Slip indicators show mostly right-lateral movements and rare normal movements; overprinting relations and the rheology of fault rocks indicate that strike-slip activity pre-date extensional ones. A dextral component of displacement is also suggested by the rotation of the main syn-metamorphic foliation and the lithological contacts in the correspondence of these faults.

The NE-SW fault system is constituted by few steep fault segments, ranging from the hectometre- to kilometre-scale, with right-lateral and reverse movements. At map-scale these faults tend to link the E-W major faults.

The NW-SE fault systems is constituted by rare steep fault segments, mostly concentrated in the western part of the area; these faults show right-lateral, left-lateral and extensional movements; overprinting relations between different striae generations show that strike-slip pre-date extensional ones.

On the basis of the geometry, the hierarchical relations between different fault systems, the rheology of fault rocks and the mineralisations on fault surfaces (mainly represented by antigorite and asbestos fibers), two main faulting stages were distinguished: the first one is related to the development of major E-W right-lateral faults, at times linked by minor NE-SW and NW-SE faults, whereas the second one could be related to the extensional reactivation of the pre-existing structures.

As the orientation, the geometry and the hierarchical relations of the lineaments are very similar to those of the geological discontinuities at different scales, it is then possible to attempt to extrapolate the structural model outlined in the mapped area to the adjoining sectors of the Lower Lanzo valley.

The right-lateral movements along E-W faults, consistent with a bulk NW-SE shortening direction with a NE-SW extension, do not seem to be consistent with the dextral activity along the adjoining Canavese Line and Lis-Trana Deformation Zone (see also Perrone et al., 2010). The occurrence of E-W dextral strike-slip faults in this area may therefore raise new questions about the post-Oligocene tectonic evolution of the innermost part of the chain.

Presenter e-mail: geo_fab@libero.it

Key terms: Georisorsa; Pietra di Finale; Beni Culturali

This article proposes the development of an integrated geological analysis methodology for characterizing and preserving the quarry sites of Pietra di

Finale, a sedimentary mass of long-standing importance for the production of dimensional stone, situated in an area of great cultural and natural value.

The rock mass of Pietra di Finale crops out near Finale Ligure in western Liguria and covers an area of about 20 km², in the hydrographic basins of the Pora, Aquila and Sciusa torrents and fronting the sea between Capo Noli and Caprazoppa. It had its genesis in a marine-shelf depositional environment that was then subjected to continental transgression.

Pietra di Finale is a miocenic biocalciuridite of medium compacted porosity that was used over the centuries as building material and for ornamentation, both in Italy and overseas, in all its diverse colors (Chiaro, Antico, Rosa and Verzezi), corresponding to its different facies. The preservation of such a rich and diverse cultural and archeological patrimony has been aided by the gradual diminution of mining activity in recent years, but this activity has left profound marks on the landscape as it adapted to the vagaries of commercial, industrial and financial oscillations over time.

The interdisciplinary approach proposed here provides for a census of all the quarry sites and the study of their state of preservation and current ore potential for the formulation of proposals for their possible use for environmental and tourist purposes, while furnishing information for the revival of mining activity, even if only from the point of view of its possible substitution and/or restoration.

A survey of the area under consideration has identified around thirty quarry sites that can be distinguished chronologically (historic and recent) and by the extraction technique used (underground and open-pit). The historic quarry sites have, for the most part, an optimal scenic setting and sufficient stability for their total exploitation, whereas the areas of more recent extraction have often interfered with sites of archeological interest (Rocca dell'Aquila quarry) or stability of the caric morphology, causing rock falls in open-citit quarries and instability and flooding in the underground rooms.

Even if these conditions do not pose an immediate risk for public safety, they highlight the need to carefully assess any risk in resuming mining activity at Pietra di Finale and preserving quarry areas no longer suitable for such activity for environmental and tourist use.

Key terms: Kaolinitic clay; Ethanol-gasoline blends; Soil contamination; Compression index; Liquid limit

Over the past four decades, a number of experimental studies have been carried out for relating engineering and hydrogeological properties of soils with pore fluid composition which can change as a consequence of chemical pollution. Special attention was paid on petrochemicals and hydrocarbon-based fluids, with particular regards to the effect of transport fuels (gasoline, diesel and kerosene), on Atterberg limit, compressibility and permeability of soils. Petrochemicals and transport fuel pollutants can alter the consolidation characteristics of clayey soil, increasing the total or differential settlements of the foundations of engineering structures resting on it, which may later undergo functional or structural failure. In the last years the energetic plans of many country in the world promote the using of gasoline added with bio-fuels, such as bio-ethanol, with the purpose to control air pollution emission. It is expected in the future for gasoline with high-ethanol content an increase of episodes of soil contamination, as occurred in the last decades for conventional transport fuels. The present work shows the results of different laboratory investigations (Atterberg limit and oedometer test) conducted on a remolded commercial kaolinitic clay contaminated by bioethanol-gasoline blends. Liquid limit was determined by using the fall cone test which is very simple to perform and it is less operator-dependent than the Casagrande percussion method. Some difficulties were encountered to perform oedometer tests with contaminated soils due to the high volatility of both gasoline and ethanol: to reduce the fluid evaporation during the test the entire consolidation cell was enclosed within a plastic bag. In addition to eliminate the micro and macro-cracks produced by ethanol-gasoline blends on the oedometer cell body, the perplex cylinder was replaced with a glass one. Samples were prepared mixing the kaolinitic soil with distilled water and with gasoline to which several fractions of bio-ethanol were added. Ethanol was added in the gasoline in weight fraction up to 85%: in order to prevent phase separation of the water and gasoline in the blend (de-mixing), anhydrous ethanol (high purity ethanol) was employed (water content is below 1%). Physicochemical properties of pore fluid influence the van der Waals attractive force of clay and its fabric. When water is used as pore fluid (dielectric constant of about 80), the structure of the kaolinite leads to a parallel-arrayed clay. On the contrary when bio-ethanol is added in the gasoline in weight fraction of 10% (E10, dielectric constant of about 2.8) the structure of the kaolinite leads to a more flocculated soil. These physicochemical effects influence both equivalent liquid limit and compression index values of soil which reach the highest values when E10 is used as pore fluid, respectively of 80% and 0.60. On the contrary when soil is mixed with water both properties decrease respectively of 28% and 43%. A relative minimum of compression index was observed for a dielectric constant between 6.2 and 15.7. The oedometer tests were also used to investigate indirectly changes in permeability during compression due to the different pore fluid composition. As observed for compressibility the presence of bioethanol and gasoline increases significantly the permeability. The results obtained may be useful to increase the knowledge on the modification of physical properties of low plasticity soils due to accidental contamination of bio-fuels.

3 - Environmental Protection Agency of Liguria - Italy (ARPAL)

Presenter e-mail: valerio.pucci@unige.it

Key terms: Geoindicators; environmental monitoring; sustainable development

Short time scale geologic changes have been suggested as efficient indicators of environmental evolution as they provide data over periods of 100 years or less. Geoindicators measure both catastrophic events and those that are more gradual but evident within a human lifespan (Berger & Iams 1996; Berger 2008). Moreover, some indicators can provide a record of natural events through time. In landscape, natural areas and environments in broad sense, they reflect both the development of intrinsic components and a passive or active lithosphere - anthroposphere interaction. The indicators measure parameters that can be used to assess changes in rates, frequencies, trends, and/or magnitudes in geological processes. Most indicators address non-biological components of the exogenous cycle as physical-chemical parameters of groundwater, erosion and deposition at different scale in different geological matrix and environments (e.g. coastline, slopes, river basins, caves). At present, the IUGS GEOIN checklist is actively applied in sensitive areas of the Earth planet in all continent such as Australia (<http://www.environment.gov.au/soe/2011/>), North America (United States in National Parks and Monuments, Canada), South America (Argentina, Brazil, Peru), Africa (Mozambique, Mauritania, Egypt, Zambia), Eastern Europe. Provided that geoinicator differs from the environmental monitoring of anomalies exceeding the threshold values or to catastrophic events, a preliminary study was addressed to verify and transfer the GEOIND checklist of 27 indicators to the Liguria territory. This choice intends to achieve a time - integrated acquisition of the environmental parameters beyond the observation needed to the "state of environment" report.

The following steps are carried out:

- 1) selection of sustainable indicators within the IUGS checklist. This list includes observation of: i) coral chemistry and their growth pattern ii) desert surface crust and fissures iii) dune morphology and activity iv) dust transport v) frozen ground activity vi) glacier fluctuation vii) groundwater quality viii) groundwater chemistry in the unsaturated zone ix) groundwater level x) karst activity xi) lake levels and salinity xii) landslides and avalanches xiii) relative sea level xiv) sediment sequence and composition xv) seismicity xvi) shoreline position xvii) soil and sediment erosion xviii) soil quality xix) stream channel morphology and position xx) streamflow xxi) stream sediment storage and load xii) subsurface temperature and regime xxiii) surface displacement xxiv) surface water quality xxv) volcanic unrest xxvii) wetland extent, structure and hydrology xxviii) wind erosion. Our selection was addressed to observation of significant features of the Liguria geology, both for environmental equilibria (coastal setting, slope equilibria, river basins) and for economic and social issues (water and soil resources).
- 2) analysis of the present monitoring network. The present geomonitoring in the region is in line with the national and EU normative (e.g., Italian D.Lgs. 152/06, Dir. 2000/60/CE, etc.). Excellence in high resolution and / or time integrated data acquisition is active along the Roja river; other advanced projects devoted to landslide monitoring and groundwater chemistry and levels cover most of the first rank occurrences.
- 3) elaboration from the present ARPAL, SIRAL and UNIGE databases.
- 4) selection of strategic sites, within regional parks, urban, karst areas and the coastline belt.
- 5) deployment of new recording tools
- 6) validation of acquired data
- 7) elaboration of new data in the perspective of global change and / or local triggers of geological processes.
- 8) design technical improvements to the present monitoring network. The GEOIN project is therefore i) a tool considered over a longer time scale than current State of the Environment (SOE) scale, and ii) environment monitoring beyond Civil Protection (emergencies) needs.

MODELLO DI RECUPERO AMBIENTALE DI DISCARICHE AD ALTO RISCHIO NELLA PROVINCIA DI SALTA (ARGENTINA)

COPPOLA Luigi¹, LAZZARI Silvestro², VISICH Maria Del Carmen³

1 - Università degli Studi della Basilicata (U.S.B.) - Italia

2 - Cedit Europa - Centro Dati e Servizi per l'Ambiente e il Territorio - Via Ancona 37, 85100 Potenza - Italia

3 - Universidad Nacional de Salta. Avda. Bolivia N° 5050. Salta (Capital)

Presenter e-mail: cedateuropa@virgilio.it

Key terms: Argentina; Discariche; Rischi; Recupero ambientale

In tutta la provincia di Salta i versanti collinari sono oggetto di depositi di R.S.U. in cave a cielo aperto abbandonate al termine della coltivazione senza alcuna copertura. Sono depositi, questi, che incidono fortemente sullo stato di inquinamento del sottosuolo nonché della falda freatica, in connessione con i corsi d'acqua superficiali da cui dipendono la tutela ambientale e lo sviluppo economico - sociale della Provincia. Attualmente più località, in provincia di Salta, hanno necessità di un recupero ambientale dovuto alla presenza di discariche di R.S.U. non protette e ad alto potenziale inquinante. Una di queste è ubicata nel municipio di Capital, a circa 3 km dalla città di Salta, nella depressione tettonica del Valle De Lerna, sul versante sinistro del tratto intermedio della pianura alluvionale del Rio Arias-Arenales. Quest'ultimo è altamente inquinato essendo il ricettore di una grande quantità di percolato. La discarica misura, in senso areale, 15.000 mq circa ed ha spessore dell'ordine di 15 m, ed è priva di compattazione e copertura. La stratigrafia locale è rappresentata da un orizzonte litologico composto da sabbia e limo in lenti interdigitate, relitto di una antica conoide Quaternaria. Lo spessore di questo deposito di superficie è di circa 20 m e poggia su argille caolimitiche della formazione Piquete di età terziaria. La permeabilità su tali argille è stata determinata con l'ausilio delle dissipazioni delle pressioni neutre registrate con la punta piezometrica C.P.T.U. e generate dall'infissione di un penetrometro dotato di cella di pressione. Le prove sono state effettuate in tre punti diversi (C.P.T.U. 1,2,3), sottostanti la discarica, a profondità compresa tra 22 m e 25 m dal suolo. La permeabilità dell'orizzonte argilloso caolimitico è piuttosto limitata e compresa tra 10-6 e 10-7 cm/s. Ne deriva che il substrato delle alluvioni si comporta come un sistema chiuso ed un livello impermeabile di protezione delle falde idriche profonde. Non è stato però considerato che la superficie di discontinuità è inclinata sia pure di pochi gradi (2°-3°) verso la pianura

alluvionale del Rio Arias-Arenales e pertanto funge da letto impermeabile del deflusso dei liquami della discarica.

L'impianto determina quindi vari effetti negativi tra cui:

a. contaminazione della falda freatica per infiltrazioni del percolato;
b. contaminazione delle acque fluviali da percolato e rifiuti solidi urbani (R.S.U.);

c. contaminazione dell'ecosistema circostante la discarica.

L'inquinamento si diffonde in luoghi piuttosto distanti dalla discarica per la migrazione sia del plume nel sottosuolo, che dei residui trasportati dalle acque fluviali.

Dopo un'analisi di rischio lo studio propone alcune possibili soluzioni al problema, attraverso due ipotesi di intervento.

La prima, economica ma non risolutiva, prevede un confinamento dei rifiuti con argille ben compatte e poco permeabili. La discarica sarà protetta mediante opere di difesa erosiva e lo smaltimento del percolato e dei gas prodotti dai rifiuti.

La seconda, costosa ma risolutiva, prevede il confinamento con materiali impermeabili artificiali di ultima generazione (geotessili) ed interventi a presidio dei R.S.U. e smaltimento dei gas.

In superficie la discarica sarà protetta con opere di recupero ambientale. Bibliografia essenziale

SLUDGE MANAGEMENT IN PIEDMONT DIMENSIONAL STONES INDUSTRY: NEW EXAMPLES OF RESIDUAL SLUDGE "RENATURATION"

DINO Giovanna Antonella¹, FORNARO Mauro¹, PASSARELLA Iride¹
1 - UNIVERSITA' DEGLI STUDI DI TORINO

Presenter e-mail: giovanna.dino@unito.it

Key terms: dimensional stone; residual sludge; bioremediation; secondary raw material; artificial loam

Residual sludge management is an aged problem, object of legislative changes and potential application developments. Such wastes (EWC code 010413) arise from the treatment of mud produced in dimensional stones working plants. The average production for the two largest quarry basins in Piedmont are: 70 Mt/Y for the VCO and 16 Mt/Y for Luserna Stone Basin. The main problems related to their management are: the size distribution (fine materials, potentially asphyxial), the presence of heavy metals (due to the treatment with gang saw with abrasive shot and diamond framsaw) and the presence of TPH (mainly due to losses of oil machines).

The residual sludge management, now considered according to the Legislative Decree 152/06, could have additional problems, related to the entry into force of L.13/09, which connotes them as "earth and rock removed (digging and mucking)" with unavoidable "interpretative" problems. They are used, as wastes, for environmental restoration (R10) or raw material for cement plants (R5). It is also possible to think about their systematic treatment in consortium plat for the production of secondary raw materials (filler, etc.) or "Products" (artificial loam). The paper will report the results of a recent experimentation, conducted at the plant of AFIB (Trino Vercellese), to recovery such wastes (composting of a mix of residual sludge, shredded green material, loam, compost and nutrients - specific microbial activators) for the production of "artificial loam" (Bioremediation treatments).

The components are designed to start up and accelerate the process of aerobic degradation, in order to transform the organic matter and obtain a structurally, chemically and biologically stable products. The final product acquires definite properties other than a mere blending of mineral and organic material (this is a loam with suitable characteristics to support a consortium vegetable, also once finished the organic fermentable components).

The individual materials were used in established quantities (see ACEA employment).

All materials were stored in lengthened piles, wet, mixed, homogenized using a wheel loader and arranged to form two stock piles, covered by semi-permeable sheets.

The trial lasted 8 weeks; during this period the piles were periodically turned (to aerate and mix the material and stimulate the growth of microbial colonies able to degrade and mineralize organic matter) and monitored (by means of systematic sampling and analysis: grain size distribution, moisture, pH, ash, total organic matter, N tot, C tot, index of humification, C/N, heavy metals, nutrients, TPH (C10-C40)).

In order to evaluate the quality of the loam, phytotoxicity tests were set up on different test plants.

It was also estimated the microbial load both on sludge as such and on produced artificial loam, to obtain an indication of the status of organic soils.

The results confirm that the developed protocol offers the chance of handling such a waste material to produce a loam potentially useful for land reclamation of industrial and residential areas. They also show a good performance of the process (reduction of the concentration of heavy metals and increasing of organic matter). The obtained loam respects the limits imposed by the D.Lgs 152/06 for commercial and industrial lands. In the experiments conducted at ACEA the obtained products were better (within the limits for residential land). That was because the material had a lower initial concentration of heavy metals. Lately, instead, the absence of turning machines, air insufflators and of closed hangars caused a decrease in the efficiency of the process. However, biological tests show that plant growth was excellent: 75% compared to the sand and peat witness, with microbial load improvement of about 3-4 orders of magnitude.

After all, it should be interesting to implement the experimentations of such applications, which are also interested by international patent (EU Patent No 1299265).

Key terms: Catena Costiera Calabria; DGPV; Terremoto 1783; Rotture a forbice

La porzione centro-meridionale della Catena Costiera compresa tra i territori compresi tra Paola-San Lucido ad Ovest e Rende-Cosenza ad Est è coinvolta da deformazioni gravitative a varia scala, che vanno dalle vere e proprie DGPV, alle grandi frane ed alle frane p.d..

Nelle unità alpine di alto grado metamorfico, costituenti l'ossatura della Catena Costiera di quel territorio, predominano le DGPV, lungo le rotture delle quali si impostano i corsi d'acqua, che non presentano, quindi, un'origine da soli fenomeni di erosione lineare. Essi, con andamenti prevalenti a ferro di cavallo delimitano ed evidenziano le morfologie da rotture gravitative, tra le quali sono pure comprese alte scarpate, trenches, deformazioni a ginocchio e rigonfiamenti nelle zone di massima compressione. Questi ultimi aspetti prevalgono nel versante tirrenico del tratto di Catena Costiera esaminato.

L'area di San Lucido-Paola costituisce un chiaro esempio di "continuum" tra le rotture da neotettonica, le deformazioni gravitative profonde, le grandi frane e le frane p.d..

Nel versante ricadente nella Valle del Crati, invece, emergono comportamenti differenziabili nei movimenti gravitativi, che comprendono strutture ad enclon e grandi frane, in corrispondenza delle principali linee tettoniche, che coinvolgono sia le metamorfite del basamento che i terreni plastici del Terziario e del Quaternario.

Tutto il restante corpo metamorfico della Catena Costiera è coinvolto da deformazioni attribuibili a tettonica gravitativa a forbice, con parziali rotazioni delle masse in senso orario. Ai suddetti movimenti va attribuita la notevole espansione laterale verso Est, e cioè verso la Valle del Crati, delle stesse masse metamorfiche, con il conseguente spostamento, per fenomeni gravitativi, delle sovrastanti formazioni sedimentarie del Terziario e del Quaternario.

Infine, si evidenzia come, a causa della diffusa presenza di rotture tettoniche e gravitative nelle metamorfite del basamento e nelle formazioni sedimentarie mioceniche e plio-pleistoceniche, il territorio esaminato sia da considerare ad alto rischio sia da frane che da terremoti, come testimoniato dalle profonde deformazioni gravitative prodottesi in occorrenza del terremoto del 1783.

Key terms: Lime stabilization; geotechnical; laboratory tests; clayey soils

The construction of road, railways and airport embankments requires the use of materials with good physical and mechanical properties, the supplying of which often requires the opening of quarries located far from the construction site; this makes arise evident problems both on the environmental and on the economical point of view. There is therefore a strong interest for the techniques able to improve soils characteristics and allowing to use materials which would otherwise be rejected, such as clayey soils. The most popular method to stabilize clayey soils is the lime stabilization, which is widely used due to its simplicity and cheapness. When lime is added to a clayey soil it first reacts by exchanging calcium ions with the interlayer cations of clay and inducing the formation of floccs; such a process is known as modification. The modification leads to a more open framework and reduces dry density and plasticity, making the soil more workable. Once the affinity for lime of the clayey part of a soil is satisfied, if a further amount of lime is available, and there are suitable conditions, the real stabilization occurs, improving the main geotechnical parameters of the soil and reducing compressibility and swelling phenomena. The reactions leading to stabilization are known as pozzolanic and the amount of lime necessary to induce them strongly depends on the cation exchange capacity of the treated soil.

Most of the methods normally used to estimate the amount of lime needed to pass from modification to stabilization are affected by uncertainty, since they establish such amount on the basis of the plasticity index, which is not always representative of cation exchange capacity. On the contrary a good estimation of the cation exchange capacity can be obtained by evaluating the specific surface. Thus, introducing in the preliminary analyses for lime treatment tests able to estimate the specific surface of clayey soils, can be useful to have a sound indication of the amount of lime necessary to pass from modification to stabilization. Furthermore, since the specific surface of clayey soils decreases with lime addition, the use of such tests can help in verifying the efficiency of modification. In this work the Methylene blue stain test was used to study the efficiency of lime treatment, in the field of modification, in soils with clayey fraction made by Kaolinite and Na-Montmorillonite, mixed in different proportions. The results have shown that this test is able to follow the evolution of clayey minerals in the lime-modification field, since it detects the gradual reduction of specific surface which takes place as lime is added, up to a lime weight% which satisfies the affinity of clayey minerals for lime, and which depends on the clay nature. The analysis showed that the higher the soil activity the higher the specific surface decrease and the higher the lime percentage above which specific surface does no longer reduces; such percentage corresponds to the lime quantity which separates the modification and stabilization fields. The Methylene blue test can therefore be used both to preliminary estimate how efficient is the modification process of a soil, and to define the lime quantity allowing to enter the stabilization field.

The mineralogical investigations (X-ray powder diffraction analysis of glycolated and untreated sample to evaluate the swelling properties evolution and thermal analysis) carried out on the soil more rich in montmorillonite strengthened the results obtained by the Methylene blue test. In this soil, the addition of about 4% of lime reduces interlayer distance, mass loss on ignition and swelling properties. Moreover this lime addition changes the microtexture of clay soils, increasing the pore index and the workability of the material, as evidenced from SEM analysis.

STATISTICAL APPROACH IN LANDSLIDE SUSCEPTIBILITY ASSESSMENT OF SLOW-MOVING EARTH FLOW

DONNARUMMA Angelo¹, REVELLINO Paola¹, GRELE Gerardo¹, GUADAGNO Francesco Maria¹

1 - University Of Sannio, Department Of Geological and Environmental Studies, Benevento, Italy

Presenter e-mail: angelo.donnarumma@unisannio.it

Key terms: Earth Flows; Probability of areal failure; Slope angle

Assessment of the landslide susceptibility and identification of potentially landslide-prone areas have experienced extensive advance in the scientific literature. A variety of methods have been developed including deterministic, probabilistic and statistical approaches. The statistical analysis is widely used mainly in large-scale provisional studies, as it allows for a better understanding of the relations between landslide phenomena and predisposing factors, guarantying a lower degree of subjectivity with respect to heuristic methods.

However, a key issue is represented by the definition of predictive models founded on rigorous statistical bases. The assumptions on which these models are based, are only partially satisfied when the statistical analysis deals with discrete variables such as for example the slope angle. In this case, methodologies adopted are usually based on the assumption that the landslide susceptibility monotonically increases with increasing slope angle. Nevertheless, even though in geomorphologic environments dominated by intermittent slow movements (such as earth flows) landslide evolution is mainly connected with the slope steepness, it has to be taken into account that high slope angles do not always produce earth flows. High gradients can be often due to the presence of stony layers within sequences, which influences the behavior of the masses.

Based on the above considerations, the paper introduces a methodology to estimate the susceptibility to develop intermittent earth flows, involving structurally and lithologically complex sequences and showing visco-plastic mechanisms of failure. In particular, a spatially distributed model to predict potential instable areas has been applied to a pilot area of the Benevento province in Southern Italy, with the aim to calculate the probability of areal failure.

The model applies statistical-mathematical algorithms to slope angle data obtained from a statistically significant landslide sample. Since the study area is characterized by a complex lithological setting, landslide distribution has been analyzed within four-groups of homogeneous litho-technical unities.

The analysis has shown an interval of slope angles ranging from 9° to 12° where the largest occurrence of landslides can be found. In addition, the low frequency of instabilities on steeper slopes can be explained by a deficit of susceptible and potentially involving materials, partially due to the presence of stony sequences. Consequently, the probability of areal failure has been calculated only on slope angle range already affected by existing landslide phenomena.

Results obtained show that the methodology applied is able to evaluate the landslide susceptibility of areas characterized by intermittent failure mechanisms. Moreover, since the methodology has been developed to analyze spatial domains which are homogeneous with respect to the set of variables that came into play, it could be applied in similar geomorphological environments.

HYDROGEOLOGICAL STUDY ABOUT THE CONSEQUENCES OF HYDROMETRIC FLUCTUATIONS ON THE RIVER BANKS

CREMONESI Daniele¹, COLOMBO Loris², FRANCANI Vincenzo³

1 - Università degli Studi - Milano Bicocca

2 - Libero professionista

3 - Politecnico di Milano

Presenter e-mail: vincenzo.francani@polimi.it

Key terms: Morphological evolution; Critical gradient; Liquefaction; Piping

The morphologic evolution of river banks is conditioned by the erosion effects due to the flow and liquefaction and piping phenomena, already studied for others Italian application cases.

This study, applied on the Pioverna river, located in the Prealps area in Lombardy (Italy), follows previous researches presented in geological literature, and it examines the effects of hydraulic head fluctuations of river beds due to floods, both in flood growth and in its decrease. In this context, critical conditions for river banks stability could occur. They can often generate situations of geological instability.

It is underlined that, during floods, abnormal hydraulic gradients, could be generated. These situations can cause velocity increases in groundwater flow circulation, which can generate piping, and slope liquefaction, as identified in literature equations.

In this note, it is also studied geological instability due to flood in the Pioverna river. The flood can cause, in any zones, hydrometric level growth about 3 meters respect to the previous conditions, in different hydrogeological situations.

It is observed that critically conditions for river banks befall when:

- The bedrock emerges near to the river; in this case instability interests the alluvial deposits which separate riverbed from the bedrock;
- There are fluvial islands that create a wedge shaped aquifer;
- A high - permeability layer, constituted by silty and sandy sediments with less permeability, flanks the bank river.

A further objective of the study, it has been to examine the causes of anomalous water - bearing stratum gradients. They may be generated especially during flood decrease, when groundwater flow runs towards the river, and when hydrometric river head comes back to the previous levels briefly (called "flash floods").

The situations described before facilitate the permanence of higher groundwater levels not so far away by the river, whereas only a small groundwater part lies to the hydrometric river head.

For this reason, important piezometric fluctuations are generated in closed areas; these oscillations are the principal cause of observed criticalities. Known models, partially modified in order to describe as well as possible all critical situations, are used to analyze the behavior of hydraulic heads. It is also observed that, with a detailed mathematical description, it is possible to improve the knowledge of critical phenomena, even if there are not usually enough data about permeability and hydrogeological structures, in order to apply a valid mathematical model.

However, this approach allows to simply identify any hydrogeological layers subjected to the critical situations described before. This is possible

also knowing permeability distribution, the most simple data which can be collected during geological surveys.

TERRITORIAL GRAVITATIONAL DEFORMATION ALONG CALABRIA IONIAN COAST AS HAZARD FACTOR FOR LARGE CIVIL ENGINEERING WORKS

GUERRICCHIO Alessandro¹, FORTUNATO Gerardo¹, GUGLIELMO Elena

Alessandra¹, PONTE Maurizio², SIMEONE Vincenzo³

1 - Università della Calabria - Dipartimento Difesa del Suolo

3 - Politecnico di Bari

Presenter e-mail: v.simeone@poliba.it

Key terms: Territorial gravitational deformation; Scaly clay; Tectonic and landslide; Large civil engineering works

Siderno area along the Ionian coast of Calabria region (Southern Italy) is affected by deep seated large geomorphological deformations and landslides, conditioned by the structural geological set up of the territory and by its ancient earthquake history. Pliocenic units rest transversely on the va-ricolored scaly clays, a geological unit strongly deformed in consequence of its tectonic history as gravitational thrust.

These deformations involve a so large area that can be qualified as "Territorial gravitational deformations".

The Pliocenic Unit (gravels, sands and clays) seems a huge block subject to a slow sliding movement toward the Ionian sea at ESE, at the contact between the below scaly clays that have a really low shear strength and stiffness. This large block is bordered by two wide torrents: fiumara Torbido at NE and fiumara Novito at SE. During this movement, in consequence of different mechanical behavior of the Pliocenic unit and the varicolored clays and of the severe seismic history of the study territory, the Plio-Pleistocenic units are dismembered in large blocks related to landslides. All these fractures have generated a lot of deep seated landslide and surficial landslides. The first one in consequence of the low shear strength of the varicolored clays, the second ones of the fractures in the Plio-Pleistocenic masses.

The evidence of all these fractures in the Plio-Pleistocenic unit are evident in a lot of scarps and in all the deformations and the anomalies of the stream network, that cannot be related to erosion phenomena, but mainly to large deep seated gravitation deformation. Also the curvature of the coastline just in front of Siderno Marina can be related to the movement of a large block, subject also to a counterclockwise deformation, of the block where Siderno itself is located. Such phenomena have been severely activated or reactivated during the disastrous earthquake of 1783, that destroyed large part of the Calabria Region and, at present, conditions the vulnerability and the risk of the whole territory.

On the bottom of large fractures, locally varicolored clays outcrop also in consequence of "camber valley" bulging phenomena. To recognize that all the morphological anomalies in the study area have to be related to these gravitative territorial deformations is really relevant for the hazard related to a large civil engineering work.

An earth dam, in fact, recently built up upstream to the town of Siderno Marina (RC), was founded on impermeable Pliocenic-Pleistocenic units, that are dismembered by large landslides. So the water can flow through clays toward the varicolored scaly clays favoring the plastic behavior and the loss of stiffness of this unit. So, it may be possible the generation of landslides and small earthquakes re-lated to water level variation. Therefore, in the management of water level in the dam it is necessary a particular attention and a monitoring system to limit risk connected to the reservoir.

GEO-ENGINEERING CRITERIA FOR A SUSTAINABLE ENHANCEMENT OF HISTORICAL DIMENSIONAL STONES

GIULIANI Andrea¹, FORNARO Mauro¹

1 - Università di Torino - Dipartimento di Scienze della Terra

Presenter e-mail: andrea.giuliani@unito.it

Key terms: Dismissed quarry site; Geomechanical survey; Giacimentological quality; Cultural heritage; Historical dimensional stone

Inside the framework of the mineral resources, the dimensional stone materials derived generally from a unicum ore-body, whose cultivation has been not only an economic activity, but also an opportunity for social employment. In this context, the rediscovery of dismissed quarries still offers the opportunity to recover limited volumes of stone that could be precious for the necessary restoration of important monuments, like the SS. Shroud Chapel inside the Turin Cathedral. According to the three pillars of sustainability (Environment, Society and Economy), it is also possible to transform these sites from negative elements into environmental resources for the mankind, making the best use of the giacimentological capability of natural material. Therefore, it was developed a method for the classification of rock mass that are interesting for the exploitation of an ornamental stone. This study is connected to the increasing demands that the Offices of Superintendence of Cultural Heritage are asking to the researchers for recovering of suitable materials useful in extraordinary restorations (due to fires, wars, earthquakes etc.) of the architectural monuments of Italy.

The first aim of this study was to increase the giacimentological knowledge on the historical ornamental stone of the "Monregalese", a geographical area of Southern Piedmont, achieved by a bibliographic census of the dismissed mine sites and a geological surveys of the most representative ones.

These quarry sites are concentrated in some geological formations ("San Pietro dei Monti Dolostones", "Rio di Nava Limestones" and "Val Tanarello Limestone") linked to some tectonic units of the Brianzonese Ligure Domain ("Ormea Unit", "Caprauna Armetta Unit" and "Klippen of Deviglia Unit"). This work of prospection was supported by a giacimentological characterization of stone materials. All lithotypes were investigated with repeated tests of Point Load, according to current technical standard; the results of this test (Uniaxial compressive strength: 64 ÷ 135 MPa) have shown that the historical ornamental studied rock are within the reference range proposed in literature.

All involved quarry faces of historical excavations were surveyed with geomechanical analysis, following the ISRM recommendations. Because of the minimal difference between the results in the investigated

quarry sites, it was proposed an original methodological approach designed ad hoc, called F.A., that analyze the relative influence of joint and the orientation of the quarry-fronts on productivity, in order to obtain another geomechanical parameter for a possible classification of quarry sites investigated.

The method developed was tested in the mining basin of the "Pietra di Luserna" (Bagnolo Piemonte - CN) through the survey of two thousand meters of quarry-faces. On this basis, the comparison of the parameter Jv and the index F.A. made it possible to classify all the dismissed sites, identifying three classes of giacimentological quality.

The practical applicability of the study was reached with the translation of each classes in a real measurable parameter (cube meters). This aim was developed with the evaluation of the mining yield in a quarry site (Rio Sbornina, Frabosa Soprana - CN), re-opened for the reconstruction of the SS. Shroud Chapel of Turin Cathedral. The volumetric calculation of stone blocks was made possible thanks to 3D modelling software (SketchUp Pro) that has also allowed the measurement of irregular solids. It was possible to highlight how a lower quality site provided a very limited amount of stone material, even in very large blocks, useful to achieve monolithic elements with structural functions (e.g. columns); the same quarry also has provided for some standard blocks for a commercial activity.

The project produced a possible method based on the identification and the comparative classification of historical quarry sites that could be applicable in other quarrying situations.

THE REALIZATION PROCESS OF THE HYDROGEOLOGICAL MAP OF THE CARG SHEET N.348 "ANTRODOCO" (CENTRAL ITALY)

AMANTI Marco¹, CONTE Giovanni¹, MARTARELLI Lucio¹, MONTI Gennaro Maria¹, MOTTERAN Guido¹, SCALISE Anna Rosa¹, SERAFINI Roberto¹, SILVI Angelantonio¹

1 - ISPRA - Geological Survey of Italy

Presenter e-mail: lucio.martarelli@isprambiente.it

Key terms: Hydrogeology; Hydrogeological mapping; CARG Project; Antrodoco; Central Italy

The Geological Survey of Italy (now Land Resources and Soil Protection Dept. of ISPRA) is realizing the new Geological Map of Italy at 1:50,000 scale (CARG Project). In this framework, the "N.348 Antrodoco Sheet" Project started. This project foresees, besides the basic geologic mapping, the realization of different informative layers, concerning hydrogeology, applied geology, geomorphology and geo-anthropogenic activities. The realization of the hydrogeological thematic level was assigned to the Applied Geology and Hydrogeology Unit of ISPRA.

The N.348 "Antrodoco" sheet map is located between Lazio and Abruzzo regions (Central Italy) and is characterized by a very complex structural asset, due to the occurrence of structural units deeply involved in the Apennine Orogeny. The four main units cropping out in the sheet map area are the M.Sibillini (carbonatic shelf, slope and basin environment), the Gran Sasso-Cittareale (carbonatic shelf, slope, basin and foredeep environment), the M.Giano-M.Gabbia (carbonatic shelf and slope environment) and the Acquisanta-Montagna dei Fiori (foredeep environment) units.

Concerning the hydrogeological aspects, the study has included research activities about water sources (springs, wells), streams and waterways, in order to characterize the hydrogeological asset. In particular a detailed screening of the springs (about 200 water points collected) has been carried out and about 70 of them have constituted a control network aimed to the measurement and characterization of groundwater flow rates and of some physical-chemical in situ parameters (temperature, pH and electric conductivity). These data have been uploaded in a specific Geographical Information System (GIS) to perform the cartographic elaborations showed in this work. They consist in a preliminary hydrogeological cartography composed of a main map illustrating a hydrogeological complex classification on the basis of their relative hydraulic conductivity, distinguished as follows (from bottom to top): (i) Calcareous complex (Lower Jurassic-Upper Cretaceous), showing a high relative permeability degree and including Calcare Massiccio, Corniola, Marne del Monte Serrone, Calcari e Marne a Posidonia, Calcari Diasprigni and Maiolica formations; (ii) Calcareous-marly complex (Middle Cretaceous-Middle Eocene), intermediate relative permeability, including Marne a Fucoidi, Scaglia Bianca and Scaglia Rossa formations; (iii) Marly-calcareous and marly complex (Upper Eocene-Upper Miocene p.p.), low relative permeability, including Bisciario, Marne con Cerrogna, Marne ad Orbulina formations; (iv) Flysch complex (Upper Miocene p.p.), low relative permeability, including the Laga Formation; (v) Conglomeratic-sandy and detritic complex (Upper Pliocene-Pleistocene), intermediate to low relative permeability; (vi) Alluvial complex (Quaternary), low relative permeability.

Other significant hydrogeological elements have been also reported in the main map and concern: (i) surface hydrology (boundaries of hydrographical basin and sub-basin, stream gauging stations, meteo-climatic stations, streamwater-groundwater exchange processes); (ii) groundwater hydrology (boundaries of hydrostructure, spring flow rates, groundwater flow directions).

Furthermore, complementary smaller-scale sketches at the margin of the main map have been realized (e.g., hydrogeological structure map, hydrogeological complex map based on effective infiltration information, hydrogeological cross-sections).

The aspects regarding the cartographical criteria and the realization process adopted for the best cartographical representation of all the cited hydrogeological elements derived from field surveys have been discussed.

HAZARD SPATIAL ANALYSIS IN RELATION TO STORM TRIGGERED SHALLOW LANDSLIDES IN A SECTOR OF THE SANNIO APENNINES.

SORIANO Marcella¹, GRELLE Gerardo¹, ESPOSITO Libera¹, REVELLINO Paola¹, GUADAGNO Francesco Maria¹

1 - UNISANNIO

Presenter e-mail: sorianomarcella@libero.it

Key terms: Gis; Shallows landslides; Storm-induced landslides; TRIGRS code

Storm-induced slope instability assumes a character which is recurrent both in time and space.

Therefore, for these phenomena hazard analysis must take into account

not only the morphological and mechanical-hydrological features of the slope, but also the multi-year storm regimes in the area.

Current spatial analysis of data, implemented in the GIS platform, provides reliable scenarios with regards to triggering susceptibility. Particularly, the TRIGRS code provides an infinite-slope analysis which can be associated with a simplified hydrological model based on Iversen's linearized solution of Richard's Equation. The forecasting model is water table time-dependent and acts in a rainfall-runoff system in relation to conditions of surface runoff in saturated soils.

The saturation condition suggests that the model is more suitable for hazard scenario analysis during previous storm periods in clay slopes. In a North-Eastern sector of the Sannio Apennines, the availability data on the outcropping lithology, landslide and rainfall history, has permitted a spatial stability analysis in relation to the alteration cover of the clayey Formation in hazard terms.

The DEM, regarding an area of about 500 Km², was obtained from a map with a 1:5000 scale. In addition, in this area, the storm history data, related to the village of San Giorgio La Molara, has permitted the definition of the time-dependent probability occurrence of storm-triggered landslides. In this regard, in relation to Gumbel's probabilistic regression method, the synthetic rain rate-time series were defined in order to define the hazard scenarios in different return probability periods of storms under an un-stationary pore pressure regime.

The results show a good correlation with past landslides that occurred under similar storm conditions. Hence, the method can be a useful tool-analysis in planning in landslide-prone areas.

4 - Department MECMAT, Reggio Calabria Mediterranean University, Reggio Calabria, Italy

5 - Regional River Basin Authority Calabria Region Catanzaro, Italy

Presenter e-mail: pinoman1@alice.it

Key terms: rock slope; landslide; vulnerability; risk mitigation.

The problem of the instabilities on the Scilla Rupe (RC, Italy), known for a long period, determines an hazard situation on the surrounding areas (existing historical buildings and downstream structures). The Rupe has been classified as a landslide risk area with from high to very high level inside the Hydrogeological Plan of the Calabria region (PAI, 2001) because several vulnerabilities, such as "Ruffo di Calabria" castle upstream and the homonymous strategic platform and the Chianalea village downstream, there are.

In order to analyze in detail the Rupe, a specific study on the safety measures and the risk mitigation by means of the structural works has been developed using a specific regional activity programming (OPCM 3734- General Plan of the works for the soil protection in Calabria, 2010). The applied methodology is based on detailed geological researches, on the geomorphologic and hydrogeological analyses, on the mineralogical and petrographic analyses, on physical-mechanical laboratory tests and on in situ investigations. In particular, laser scanning technologies have been used and a geostuctural relief has been performed in order to analyze spatially the geomechanics data.

The detailed study allowed to define a correct geological-technical model of slope and to define the likely evolution models in relation to intensity (in terms of size, velocity and type) of mass movements. The used multidisciplinary approach focused on the construction of geomechanical asset, at the mass scale, and on the individuation of the potentially unstable rock blocks. The proposed approach improves the traditional approaches based on the geometric reconstruction of the structural asset of rock slopes.

The developed investigations allowed to define a strongly diaclasato and fractured crystalline-metamorphic (especially granodioritic) rock mass. The larger litoclasti and fractures reduce strongly the spatial continuity of the rock along the Rupe. The safety measures, that will be performed, will aim to: reduce the detaching and shallow fall from the wall of the fissured rock blocks, stabilize the rock mass of bedrock (rock fall and rock slock slide), such as the large wedge retained by the barbacane- underpinning. In fact, in these cases, rock volumes can slope along preferential slip surfaces and further accelerations can be generated if earthquakes or water infiltrations occur.

Finally, the obtained data have been integrated with stability analyses of rock slopes, where the geological-technical model of slope has been divided in analytical failure models corresponding to the physical situation of the Rupe in order to demonstrate the effectiveness of the works (ante and post-operam analyses).

HEAVY METAL CONTAMINATION OF THE SACCA DI GORO AND VALLI DI COMACCHIO LAGOON AREAS (PO RIVER DELTA, NORTHERN ITALY)

RAPTI Dimitra¹

1 - University of Ferrara

Presenter e-mail: cpr@unife.it

Key terms: lagoon; heavy metal; water; sediments

The lagoon areas of the Sacca di Goro and Valli di Comacchio, within the Po River delta, are holds a major naturalistic interest as well as an economic one due to the aquaculture activities (mussels, clams and eels). In there lagoon systems, the quality of the sea-bottom sediments is crucial not only for the cultivated species, but also for the potential bio-accumulation problems in heavy metals. The definition of the qualitative status of the lagoon sediments is crucial for adopting the best management strategies and the protection of the environmental conditions.

We determined the concentration in SiO₂, TiO₂, Al₂O₃, Fe₂O₃, MgO, MnO, CaO, Na₂O, K₂O, P₂O₅, Ba, Ce, Co, Cr, La, Nb, Ni, Pb, Rb, Sr, Th, V, Y, Zn, Cu, Ga, Nd, S and Sr, of 70 samples homogeneously collected

over the lagoon areas. This large dataset allowed i) to define the environmental quality of the sediments, ii) to recognise the areas with the higher contamination risk; and iii) to emphasise the local occurrence of polluting phenomena associated to chromium, nickel, vanadium, cobalt, lead, zinc and copper.

Key terms: aggregate quarry lake; washing process; mud; water exchanges; environment and water hazard

The topic of the research is the management of the mud coming from aggregates washing process, which are commonly put into the quarry lakes.

Before focusing on the mud disposal in quarry lake, it should be good to understand the origin of such "scraps", which come from the sands and gravels washing.

After the digging out of the raw material (a mix of sands, gravels, silt and clay) the tout venant is sent to the treatment plant in order to obtain the different aggregates products (washing process).

After the size selection in the dressing plants we obtain the main products for aggregates industry and mud, characterized by: fine size distribution (silt-clay dimension), high water content, and sometimes TPH (total petroleum hydrocarbon), brought about by the working plants operations. The practice of disposal the muddy slurries into the quarry lakes will improve the silts deposition phenomenon that progressively can wrap the bottom and the walls of the excavation.

Silts deposition can also lead to some problems about the water flux and piezometric surface and about the hydrochemical features, limiting the water exchange between the aquifer and the lake, thus increasing its trophic state and foreclosing potential reuse at the end of quarrying activity.

Production data, provided by a sample of Piemonte pit lakes, allowed to estimate the average amount of silts in lakes in approximately 1 m/y. The size distribution analysis allowed to classify such muddy slurries as weak clayey silt.

A modeling approach was chosen in order to define the piezometric variations related to these backfilling, while chemical analysis of water were carried out in order to define the hydrochemical relationships between lakes and groundwater.

Thanks to researches and field surveys it is possible to observe that silts deposition in quarry lakes involves changes in groundwater level, particularly the wrapping of the excavation walls, instead it does not determine substantial changes in the case of sedimentation on the bottom of basins. In any case, the calculated piezometric variations were modest. In the investigated situations there were not found very thick sediments of silt and clay on the walls, since the slopes (about 30° and more steep during the excavation activities), due to the presence of gravelly-sandy material, do not allow the accumulation of excessive thickness of silts. In the case of resulting material, composed mainly by silt, the hydraulic conductivity allows, even if reduced, water exchanges with the groundwater, supported by a good correlation between the chemical composition of waters of the quarry lakes and the shallow groundwater intercepted by the excavation. In this way it is generally guaranteed water exchange in the lake, thus promoting reuse at the end of the mining activity. It is of course to avoid an immoderate lake refilling by muddy slurries in order to let a sufficient thickness for lateral water exchange. At the moment the habits of putting the mud in the lakes does not seem to be dangerous for environment and water. Nevertheless it is useful to underline that mud coming from the working plants could be considered as "waste" (D.Lgs. 152/06; D.Lgs. 117/08; L. 13/09). In this case the material have not to be deposited into the quarry lakes. A possible change to reuse these recovered material is the production of "artificial loam" (after a bioremediation treatment).

Land farming application of "mud as such" appear not feasible due to size distribution and to the possible contamination of TPH (to verify). The now proposed technical system - studied for residual sludge from dimensional stones industry - concerns the composting of a mix (mud, shredded green material, natural loam, compost and nutrients) which is deposited in covered piles, periodically aerated and monitored. At the end of the process it is possible to obtain "artificial loam", to use for quarry rehabilitation, civil works, etc.

MONITORING AND MAPPING OF RESIDUAL NITROGEN IN LOWLANDS. THE CASE STUDY OF FERRARA PROVINCE.

SALEMI Enzo¹, COLOMBANI Nicolò¹, MASTROICICCO Micòl¹, TESINI Enrico², CASTALDELLI Giuseppe³

1 - Università di Ferrara - Dipartimento di Scienze della Terra
2 - ENEA UTVALAMB - IDR - Bologna
3 - Università di Ferrara - Dipartimento di Biologia ed Evoluzione

Presenter e-mail: slmnze@unife.it

Key terms: soil nitrogen; groundwater; pollution; C/N ratio

After the growing seasons, the soil nitrogen that remains as inorganic phases (Nitrate and Ammonium), represents one of the most serious threat for cultivated land, determining eutrophication and groundwater nitrate contamination. This issue has recently become a priority within the European Community Framework Directive for water protection (WFD) which has established a list of measures and limitations to be applied in areas declared "vulnerable to nitrate from agricultural sources. The Ferrara Province (Northern Italy), is an intensively cultivated area since decades. The land is fertile and allows the cultivation of different crops, especially winter cereals, maize and energy plants which cover more than 65% of the land.

The Ferrara province is a flat area located on Po lowlands covering an area of 2.623 km². It is characterized by a flat topography and is fertilized by more than 91% with synthetic fertilizers, mainly urea. The minimal run-off and an homogeneous inorganic nitrogen load allow to simplify the

hydrological and nitrogen balance: excess nitrogen tend to move vertically through the unsaturated zone, becoming one of the most important causes of groundwater contamination.

A monitoring program was started in 2010, to estimate the readily available nitrogen before and after maize and wheat cropping cycles. 742 core samples (1 m long and 2.5 cm int. diam.) were taken in 67 different agricultural plots, fertilized in 2009 with synthetic urea, respectively with 240 kg/ha for plots cultivated with wheat and 160 kg/ha for plots cultivated with maize and with 700 - 900 kg/ha of chicken manure (only sandy soils along the coastal zone). Cores were splitted and analyzed into two halves, in order to investigate separately the upper soil layer stressed by tillage, roots growth and weathering (0 to 50 cm of depth) and the lower undisturbed one (50 to 100 cm of depth). Samples were colorimetrically analyzed for urea (CO(NH₂)₂), NH₄⁺, NO₂⁻ and NO₃⁻ using a double beam Jasco 550C spectrophotometer and a Technicon Autoanalyser II. C and N were obtained using an elemental analyzer Fisons Instruments.

Data were processed using Geographical Information System applications to obtain maps of the residual mineral nitrogen availability and C/N ratio, for each of considered soil. Results highlights the presence, at different concentration, of residual nitrogen as NH₄⁺ and NO₃⁻ mainly, in the whole territory. Distributions of NH₄⁺ and NO₃⁻ are correlated with C/N ratio values, which are prevalently dependent on the textural characteristics of soils and influenced by the type of fertilizer used. This information can be transferred to agro-technicians and farmers to accurately estimate the amount of fertilizer to be added in the next cropping season. The proposed procedure highlight the possibility to assess nitrogen needs in specific vulnerable zones and proceed with fertilization by avoiding to generate excess and risk of nitrate leaching to groundwater.

LARGE SCALE FACILITIES HIGH-PRESSURE EXPERIMENTS: THE GYPSUM CASE HISTORY

NAZZARENI Sabrina¹, COMODI Paola¹

1 - Dip. Scienze della Terra, Università di Perugia

Presenter e-mail: sabrina.nazzareni@unipg.it

Key terms: gypsum; X-ray synchrotron diffraction; neutron diffraction; high pressure

Recently, strong developments and improvements of high-pressure (HP) experiments at large scale facilities (both synchrotron and neutron facilities) opened new scenarios on the accurate determination of physical properties of minerals at very deep conditions. High-pressure single-crystal X-ray diffraction (SCXRD) synchrotron experiments allow to determine small structural variations with pressure due to increase of the quality of data collection. In HP experiments the angular limitation access to the Ewald sphere, due to the diamond anvil cell, can be partially encompassed by the high intensity of the synchrotron X-ray beam using small samples and multiple mounting into the DAC. At the same time, HP neutron powder diffraction experiments could determine the hydrogen position (and hydrogen bonds evolution) directly both on deuterated and natural materials.

We performed high-pressure single-crystal synchrotron and neutron diffraction experiments on gypsum (CaSO₄ 2H₂O) to study the HP behavior of this sulphate including the hydrogen bonds. Literature data [1-4] suggested a polymorphic transition at 4 GPa and the structure of the new polymorph, gypsum-II, was recently solved [5]. SCXRD studies [4-5] suggested that water molecules play a key role on the phase transition. We combined the HP neutron data with single-crystal and powder synchrotron diffraction data measured on gypsum up to 13 GPa at ESRF (Grenoble, France - ID09 and ID27 beamlines). We performed HP neutron powder diffraction up to 10 GPa at ILL (Grenoble- D20 beamline), loading a Paris-Edinburgh cell with NaCl as pressure calibrant and deuterated Ethanol/methanol as pressure transmitting medium and the same sample used in previous papers. Powder diffractions were collected with a radio oscillator collimator and each data collection was measured from 3 to 6 hours as P increased. The lattice parameters of gypsum at increasing P were obtained by refining the powder pattern by using the Fullprof software.

In the pressure range investigated we recognised two discontinuities in the a and b lattice parameters and beta monoclinic angle corresponding to the first phase transition at 4 GPa (already suggested [4-5]) and a second phase transition at around 7 GPa not clearly defined previously. A very good agreement was found between our XRD data set (SC-XRD in house, synchrotron SC- and powder XRD at ESRF, Grenoble) and the lattice parameters measured by neutron diffraction at D20 (ILL- Grenoble). We used the synchrotron XRD data to constrain the neutron refinement and decrease the refined variables, thus to focus in the H coordinates and occupancies.

Single-crystal XRD data [4] showed that the gypsum interlayer, where the water molecules are located, strongly decreases its thickness up to 3.94 GPa. The water molecule shares an oxygen with the Ca-polyhedron and hydrogen atoms (H1 and H2) form, at ambient pressure, weak hydrogen bonds with the oxygens belonging to S- and Ca-polyhedra. Neutron diffraction data suggest that increasing pressure the two hydrogens configuration changes: the coordinates of H1 move slightly from its position at ambient pressure whereas the y/b coordinate of H2 decrease significantly explaining the different compressibility of the two hydrogen bonds [4].

These new hydrogen bond configurations confirm that in the gypsum structure there is an increasing shift of the calcium-sulphate layer along a axis that lead to the phase transition and allow to retain water molecules at high pressure, namely to prevent the free movement of water molecules and should affect the dehydration condition.

TOBERMORITE 11 Å: ONE MINERAL SPECIES, SEVERAL THERMAL BEHAVIORSBIAGIONI Cristian¹, BONACCORSI Elena¹, MERLINO Stefano¹¹ - Università di Pisa, Dipartimento di Scienze della Terra

Presenter e-mail: biagioni@dst.unipi.it

Key terms: tobermorite 11 Å; tobermorite 10 Å; tobermorite 9 Å; thermal behavior

Tobermorite 11 Å, $\text{Ca}_{4-x}\text{Si}_6\text{O}_{15-2x}(\text{OH})_{2-2x}\cdot 5\text{H}_2\text{O}$, with $0 < x < 1$, is a calcium silicate hydrate characterized by a variable content of "zeolitic" calcium cations. Its crystal structure is formed by calcium polyhedra layers, continuous in the plane (001), connected to wollastonite-like chains on both sides. These structural elements form the so-called "complex module", common to all the phases of the tobermorite group. This module is C-centered, with cell parameter a 11.2, b 7.3, and width c_0 11.2 Å. Two kinds of complex module exist, due to the two different ways of placing the "bridging" tetrahedron with respect to the "paired" tetrahedra in wollastonite-like chains on the two sides of the calcium layer. The stacking of these two different complex modules forms clinotobbermorite and tobermorite 11 Å, with monoclinic and orthorhombic subcells, respectively [1]. The 11 Å phases, both monoclinic or orthorhombic, are characterized by double silicate chains, and their polyhedral framework shows cavities that may host "zeolitic" cations and water molecules.

Three kinds of thermal behavior were distinguished at 300°C [2]: "normal" (tobermorite 11 Å shrinks to a 9 Å phase at 300°C), "anomalous" (the 11 Å phase does not shrink at 300°C), and "mixed" (both the 11 and 9 Å phase coexist at 300°C). However, further investigations [3] indicated that the thermal behavior of tobermorites is more complex than that depicted by the previous authors.

In order to understand the involved processes during dehydration, several natural tobermorites were studied through a multi-technique approach. Tobermorites from N'Chwaning II mine (South Africa) and San Vito di Leguzzano (Italy) showed an "anomalous" behavior at 300°C but the former, shrunk to a 10 Å phase at 420°C, whereas the latter preserves its 11 Å basal spacing. TG curves showed different weight loss patterns; in particular, tobermorite from N'Chwaning II mine lost 10 wt.% at 300°C, corresponding to 4 water molecules, whereas the sample from San Vito Leguzzano showed a weight loss of 8 wt.% (3 H₂O pfu). Chemically, the only difference between the two specimens is related to the presence of 0.5 Al pfu in the Italian tobermorite; the introduction of Al in tobermorite

is possible through the substitution $\text{Si}^{4+} + \text{O}^{2-} \rightarrow \text{Al}^{3+} + \text{OH}^-$. The different amount of OH groups in the two studied specimens may give rise to different hydrogen bond schemes; the important role of "zeolitic" water molecules in stabilizing the position of H₂O and OH bonded to the calcium layers was hypothesized by [4]. The occurrence of additional hydrogen bonds, related to the introduction of Al in tobermorite, may contribute to the stabilization of the 11 Å phase. On the contrary, their absence may result in structural changes upon dehydration that can lead to the shrinking to 10 Å. The 10 Å phase was characterized through SC-XRD, ²⁹Si NMR and micro-Raman spectroscopies. It shows a orthorhombic (or pseudo-orthorhombic) subcell with a 11.2, b 3.67, c 20.4 Å; spectroscopic data point to the maintenance of double wollastonite-like chains. It is interesting to note that a clinotobbermorite-like phase appeared during the transition from the 11 to the 10 Å phase. "Normal" tobermorite from Montalto di Castro (Italy) was studied through in situ X-ray powder diffraction. At 300°C, tobermorite 9 Å appears. Also in this case, the diffraction patterns suggest the occurrence of a clinotobbermorite-like phase as an intermediate product between the 11 and the 9 Å phases.

THERMAL BEHAVIOR OF AFGHANITE, AN EIGHT-LAYERS MEMBER OF THE CANCRINITE GROUPBALLIRANO Paolo¹, BOSI Ferdinando¹¹ - Dip.to Scienze della Terra, Sapienza Università di Roma

Presenter e-mail: paolo.ballirano@uniroma1.it

Key terms: Afghanite; Cancrinite group; HT X-ray powder diffraction; Rietveld method

Thermal behaviour of afghanite, $(\text{Na}_{15}\text{K}_5\text{Ca}_{11})\Sigma_{21}[\text{Si}_{12}\text{Al}_{24}\text{O}_{96}](\text{SO}_4)_6\text{Cl}_6$, s.g. P 31c, $a = 12.7961(7)$ Å, $c = 21.4094(13)$ Å, an eight-layers member of the cancrinite group, has been investigated by combined electron microprobe analysis, X-ray single-crystal diffraction, and high-temperature X-ray powder diffraction. Non-ambient data were collected in the 323-1223 K thermal range on a specimen from Case Collina, Latium, Italy. RT structural data, from single-crystal work, provided improved details on cation partition with respect to reference data. The framework consists of columns of cancrinite cages ($[4^6\bar{1}]$ polyhedra following the IUPAC nomenclature) stacked along $[0\ 0\ z]$, and regularly alternating liottite ($[4^6\bar{6}^{17}]$ polyhedra) and cancrinite cages piled along $[2/3\ 1/3\ z]$ and $[1/3\ 2/3\ z]$. It has been observed that the cancrinite cages alternating with the liottite cages are more compressed along z than the remaining ones. As result the chlorine atom, located at the centre of the cages, is driven off-axis in order to obtain a favorable coordination with the neighboring calcium atoms. Repeated heating-RT-cooling cycles led to the partial afghanite structure disruption and the partial conversion, via an intermediate disordered phase, to hayingne. Thermal expansion shows a discontinuity at 448 K for both a and c cell parameters, a feature previously reported for other cancrinite-like minerals. In fact, up to 448 K the c cell parameter expands significantly and more than the a cell parameter. Above the discontinuity temperature T_d , the thermal expansion is reverted becoming greater for the a cell parameter. Afghanite shows a significant microstrain at RT that increases up to ca. 700 K and subsequently decreases as a function of T . Cooling to RT permits a significant release of ϵ microstrain and this process is coupled with a significant expansion of the c cell parameter as compared to the starting RT data. The expansion of the c axis has been prevalently attributed to the full expansion of the cancrinite cages alternating with the liottite cages. Upon reheating at 1173 K, the microstrain increases back to

approximately the same value calculated for the first heating process. Repeated heating/cooling cycles did not modify the ϵ values both at RT and at HT.

MINERALOGICAL APPLICATION OF NANOINDENTATION TESTINGBELLATRECCIA Fabio¹, SEBASTIANI Marco¹, DE FELICIS Daniele²¹ - Dipartimento Scienze Geologiche, Università Roma Tre² - Dipartimento di Ingegneria Meccanica e Industriale, Università Roma Tre

Presenter e-mail: bellatre@uniroma3.it

Key terms: Nanoindentation; Elasticity; Elastic modulus; Hardness; Minerals

The study of elastic properties of rocks and minerals had a significant development because these data are crucial for the interpretation of the propagation of seismic waves on which all models of Earth's internal structure are based. In addition, these properties are essential for determining the equation of state of geological materials [1,2]. Other physical properties related to elasticity, such as hardness, fracture toughness, contact stiffness, creep resistance, can be used to understand the mechanisms of ductile deformation of rocks at the level of the mantle or deep crust, and of the brittle behaviour of rocks at the level of upper crust. Finally, since the elastic properties are closely related to the crystal-chemistry of minerals, they can be used to probe the structural deformations induced by phase transitions and/or ionic substitutions [3,4]. The measurement of the elastic properties of minerals is essentially based on three methods: 1) direct mechanical methods; 2) sound wave velocity measurements and 3) electromagnetic wave scattering methods (Brillouin, inelastic X-ray/neutron). All of these methods are now well established, mature and widely used however they have an inherent limitation: they do not allow the measurement of elastic properties of materials at micro to nano scale [5].

Nanoindentation testing (introduced by Oliver and Pharr in 1992 [6]) has been widely adopted in the last two decades for the surface mechanical characterization of bulk materials and coatings. The method involves the controlled penetration of a diamond pyramidal indenter into the material: by measuring the load and displacement during the loading and unloading parts of the test, hardness (i.e. resistance to plastic deformation) and elastic modulus can be calculated [6-7]. In this way, a very accurate characterisation of the elastic properties at material's surface can be achieved, with a depth resolution and a lateral spatial resolution of the order of few nanometres. Three factors motivate the use of nanoindentation for the study of the mechanical properties of minerals. Firstly, in such tests the load and displacement of the indenter tip, are continuously monitored thus the method is ideal for probing local gradients and heterogeneities in samples. Second, no extensive sample preparation is required prior to mechanical testing. Third, most nanoindentation instruments provide experimental control that allows for a variety of different deformation modes. The data so far published are scarce and cover a limited number of minerals (some phyllosilicate, kyanite, K-feldspar, periclase, garnet, quartz and the first nine minerals of the Mohs scale) [8,9,10,11]. However, the results show the possibility of very interesting developments in the field of mineralogy, applied mineralogy and gemmology.

TRACE ELEMENT AND REE BEHAVIOR OF GEM-QUALITY GREEN ANDRADITE FROM VARIOUS LOCALITIESADAMO Iliaria¹, BOCCHIO Rosangela¹, DIELLA Valeria²¹ - Dipartimento di Scienze della Terra, Università degli Studi di Milano² - CNR, Istituto per la Dinamica dei Processi Ambientali, Milano

Presenter e-mail: iliaia.adamo@unimi.it

Key terms: andradite; major-element composition; trace-element composition; REE profile

Andradite, of ideal composition $\text{Ca}_3\text{Fe}_2\text{Si}_3\text{O}_{12}$ and space group Ia3d, is a rock-forming garnet typically found in metamorphic rocks (i.e. serpentinites and skarns). The structure consists of a framework of alternating SiO_4 tetrahedra and FeO_6 octahedra, with cavities containing Ca cations in eightfold coordination (Novak and Gibbs, 1971). Because relatively few studies are devoted to the trace-element composition, including REE profiles, of Ca-Fe^{3+} garnets (Gaspar et al., 2008), we have undertaken a study of andradite, in particular focusing on gem-quality green-colored crystals (variety "demantoid"). A suite of 28 andradite samples, occurring both in serpentinites and skarns, coming from the most notable localities worldwide (Italy, Russia, Iran, Pakistan, Madagascar, Namibia, and Romania) has been investigated by means of EMPA and LA-ICP-MS. More details about geology and garnet formation are reported by Bocchio et al. (2010) and Pezzotta et al. (2011). Our work aims to provide a chemical characterization of these stones and so contribute to a quantitative evaluation of the crystal chemistry of andradite.

The analyzed crystals cover a restricted range of composition, from almost pure andradite ($\text{Adr} \geq 98$ mol%) to members of andradite-uvarovite ($\text{Adr}_{81-96}\text{-Uv}_{3-18}$) or andradite-grossular ($\text{Adr}_{76-94}\text{-Gr}_{5-12}$) solid-solution series. They are homogeneous, with the only exception of a sample from the skarn deposit of Namibia, showing a composition varying from pure andradite up to almost pure grossular ($\text{Grs}_{89}\text{Adr}_{11}$), which frequently occurs

in garnets from skarn (Smith et al., 2004; Gaspar et al., 2008). The chondrite-normalized diagrams of selected trace elements (Sc, Ti, Cr, Co, Ni, Zn, Sr, Y, Zr) indicated that all the examined garnets, both associated with serpentinites and skarn deposits, display a comparable pattern of distribution. However, the garnets occurring in the skarn rocks (*i.e.* samples from Madagascar, Namibia, and Romania) contain minor amounts of the chromophore elements, in particular of chromium, which is almost absent. The chromium contents detected in specimens from serpentinites are instead very variable, ranging from a few ppm up to 1 wt%. With regard to the profile of REE, we observed that (i) all the samples showing a composition close to pure andradite, both associated with serpentinites and skarns, exhibit LREE-enriched and HREE-depleted patterns with a strong positive Eu anomaly, whereas (ii) the uvarovite-enriched samples show flatter patterns with a small positive Eu anomaly, and (iii) grossular rich samples are LREE-depleted with no Eu anomaly or negative one. These results indicate that the incorporation of REE in andradite is mainly controlled by the crystal chemistry. In particular, the substitution of Fe³⁺ (and Cr³⁺) for Al expands the framework and consequently favors the incorporation of the larger LREE. However, also the bulk composition of the host rocks and the physicochemical conditions occurring during the growth may contribute to the REE incorporation (Whitney and Olmsted, 1998; Smith et al., 2004; Gaspar et al., 2008).

SECONDARY MINERALS FORMED IN ACID MINE DRAINAGE ENVIRONMENT: THE CASE OF LIBIOLA MINE

CARBONE Cristina¹; MARESCOTTI Pietro¹; LUCCHETTI Gabriella¹; DINELLI Enrico²

1 - Dip. Te. Ris, Università di Genova, Italy

2 - Dip. di Scienze della Terra e Geologico-Ambientali, Alma Mater

Studiurum - Università di Bologna, Italy

Presenter e-mail: carbone@dipters.unige.it

Key terms: secondary minerals; acid sulphate waters; mine-waste; Libiola

The sulphide-ore of the Libiola mine (Sestri Levante, eastern Liguria, Italy) occurs as massive-, stockwork- and disseminated-mineralizations within pillow and brecciated basalts of the northern Apennine ophiolites [1]. They mainly consist of pyrite-chalcopyrite mineralizations with minor sphalerite and pyrrhotite. Gangue minerals are mainly represented by quartz with minor chlorite, magnetite, hematite, carbonate, and serpentine minerals. The Libiola mine represent one of the most important Italian exploited sulphide-ore, already known in the Bronze Age [2]. Nowadays, the mining area is completely abandoned. Underground and superficial waters are mostly Acid Sulfate Waters [3, 4], due to active Acid Mine Drainage processes triggered by oxidation of pyrite-chalcopyrite mineralizations. Mine wastes are acid generating because they contain a high amounts of partially altered sulphide-rich mineralizations [5]. Secondary minerals directly formed within dumps, streams, and outcropping mineralized bodies through precipitation from contaminated solutions. They are within stream sediments of the creek and stream of the area or on and within waste-rock dumps. In this last setting, they occur as cement waste-rock fragments and as coating on rock surfaces or between the mineralized clasts, where they partially or completely replace both ore and gangue minerals. They are mainly represented by iron oxyhydroxides and oxyhydroxysulphate (such as goethite, ferrihydrites, lepidocrocite, hematite, and schwertmannite), sulphates (such as jarosite, brochantite, gypsum, epsomite, bieberite, bonattite, siderotil, halotrichite, chalcantite, pickeringite, melanterite, copiapite, hydroxoodwardite, and basaluminite) and Cu-carbonates (such as malachite and azurite). Locally, native copper, chrysocolla, and alunogen are abundant as fracture fillings or as coating and occur in both superficial and underground settings. The presence of these minerals and the evaluation of their stability fields are of environmental concerns because they can play an important role in attenuating the contaminant load of mine effluents [6, 7]. The goal of this study is a comprehensive overview of the mineralogy and geochemistry of secondary minerals that formed in the Libiola mine, owing to acquire a detailed mineralogical knowledge about the genesis and the evolution of the authigenic secondary phases. The knowledge about the types of mineral phases allow to understand the short and long-term fate of the ecotoxic metals. All these information are paramount parameters for any predictive models and also to define effective remediation strategies.

Key terms: Pyroxenes; Thermo-elastic properties; Ab initio Calculations

Recent developments of (i) sophisticated codes for quantum-mechanical calculations on crystalline materials [1]; (ii) effective hybrid HF/DFT Hamiltonians [2]; (iii) algorithms from the calculation of thermo-elastic properties of crystals [3] starting from ab initio calculated static equations of state (no zero point and thermal effect included) and frequencies of the vibrational mode, together with the increased availability of computational resources at a relatively low cost, allows for the determination of compressibility of minerals with accuracies and reliabilities which parallels those reachable experimentally, at room temperature. At high temperatures, in general, while the accuracy of the experimentally measured compressibility decreases dramatically, that of the ab initio calculation remains high, so that the theoretical approach can reliably be used to produce data which are crucial for the development of models of

the Earth's interior.

Examples of applications of the whole first principle procedure will be shown with reference to pyroxenes (in particular diopside, jadeite and ordered omphacite). In the case of diopside, the calculated bulk modulus (K_0) and its first pressure derivative, at room temperature, are 106 GPa and 5.5 respectively, to be compared with the correspondent experimental values of 107(1) GPa and 5.8 [4]. The calculated dK/dT is -0.011 GPa/K, and the thermal expansion coefficient at 300K is 2.12×10^{-6} K⁻¹.

Presenter e-mail: isacco.scanavino@libero.it

Key terms: Periclase; Ferropericlase; Lower mantle; ab-initio calculations; thermodynamic properties

The thermodynamic properties of periclase and ferropericlase, at pressures and temperatures typical of the Earth's lower mantle, have been studied through ab-initio calculations carried out at the hybrid HF/DFT level. The correlated thermodynamic properties were calculated by following a standard statistical-thermodynamics approach, within the limit of the quasi-harmonic approximation. The dependence of the calculated parameters by temperature/pressure/composition in iron has been shown, paying particular attention to the effects on bulk modulus and on thermal expansion. About the former, at environmental conditions an adding of 3% of iron in the chemical composition increases the bulk modulus from 160.14 GPa to 167.41 GPa; the same percentage at the P/T deepest lower mantle conditions (135.8 GPa and 4000 K) reduces the bulk modulus from 563 GPa to 558 GPa. About the thermal expansion, the same percentage in iron at environmental conditions reduces this parameter from 2.79E-05 1/K to 2.60E-05 1/K; at the deepest lower mantle conditions the decrease is less pronounced and the coefficient goes from 1.191E-05 1/K to 1.186E-05 1/K.

Features and evolution of many geological processes, such as fluid-rock interaction, CO₂ sequestration, fault weakening and dolomite stability under subduction conditions, significantly depend on the physical-chemical properties of dolomite. Our attention was focused on the study of cation distribution over crystallographic sites since it is one of the main factor impacting physics and thermodynamic properties of the mineral. *In-situ* [1] and *ex-situ* [2] experiments attributed a T range of about 1200-1400K to the intra-layered-type disordering where Ca and Mg are randomly distributed over cationic sites. Such structures, however, have not been found in nature probably due to the non-quenchability of thermally treated systems [2]. However, there is a possibility of domain disorder that could be stable at lower temperatures and is not investigated in sufficient detail. In order to study various types of disorder in dolomite as well as the thermodynamic stability of disordered dolomite structures, we have used both theoretical and experimental approaches. First principle total-energy calculations were performed at the hybrid Hartree-Fock/Density-Functional-Theory level [3] using a development version of CRYSTAL software [4]. Calculations were carried out by using the WC1LYP Hamiltonian [5], which includes a non local exact Hartree-Fock exchange contribution. Different stoichiometric disordered dolomite structures were simulated and they appeared to be due to both intra- and inter-layered-type defects. Starting from theoretically calculated energies, a quantum-statistical calculation approach was used in order to obtain the probability of specific disordered configurations at a given temperature. A very low degree of disorder was observed for temperatures below 750K. As T increases, a disordered configuration becomes gradually the most stable one. Such observations allowed us to preliminarily state that disorder in the cation distribution in dolomite seems energetically stable at lower temperatures than expected from previous results. In the experimental part, dolomite crystals were thermally treated by using a piston cylinder apparatus under P of 3GPa and T of about 1270K, 1370K and 1470K. Products were studied by using powder and single crystal X-ray diffraction. The former analysis evidenced an increase of the intensity ratio of 006/015 reflections by increasing T as a marker for disordering [6]. Moreover, data refinement showed mixed Ca and Mg cationic site occupancies. It shows that the disorder is produced by the heat treatment. On the contrary, three dimensional refinement by using single crystal X-ray diffraction analysis showed evidences of twinned structures, following the {11-20} twin law, consisting of twin domains with a high internal crystallographic order. So even if the theoretical modelling suggests the intra-layered-type disordering as the main mechanism affecting Ca-Mg distribution in dolomite during heat treatment also at relative low T, single crystal X-ray

diffraction suggests presence of highly ordered domains at all temperatures and a localisation of disorder to twin boundaries and defects in the structure. We can speculate that the twinning could be driven by either a dis-ordering process during thermal treatment or a re-ordering process during the quench. *In-situ* single crystal X-ray diffraction analysis under HT and HP conditions are in progress at the ESRF synchrotron facility (Grenoble) in order to clarify the kinetic effects.

Key terms: *serpentinite; metabasite; asbestos minerals; characterization*

The study concerns the investigation of asbestos and other fibrous minerals carrying out on 32 natural rock samples collected in the metabasite sequence belonging to the Gimigliano-Mount Reventino Unit (GMRU).

The GMRU consists of serpentinites, metabasalts, metagabbros/metadolerites with a sedimentary cover made up of marble alternating with calceschists and quartzites. Opicalcites are found in close association with serpentinites and show brecciated fabric. Owing to possible presence of asbestos and other fibrous minerals in these kinds of lithologies, the aim of this investigation is to evaluate their presence and in detail to characterize them. Previous studies are not detailed and above all referred to quarries, because some of these lithologies are quarrying for using as building and ornamental stones and road bed. Besides in these rocks, road yards have often opened.

The univocal distinction among asbestos and other fibrous minerals is very important in so-called "green rocks" as regulated by the Italian law (DM 14/06/1996) which demands the asbestos presence identification and quantification. Besides the Italian law (DM 18/03/2003) established to make a map of the asbestos presence in Italian outcropping rocks.

Moreover, the interaction between natural water and serpentinitic rocks can also cause in former an enrichment in heavy metals in particular Cr which is potentially dangerous for human health.

To reach the target a detailed characterization of the main lithologies (serpentinites, metabasites) are being conducting by MOLP, XRPD, SEM/EDS, TEM/EDS, TG/DSC, XRF and micro-Raman investigations.

The most abundant minerals in serpentinitic rocks are serpentine minerals, chlorite and clay minerals. Serpentinites show pseudomorph mesh texture and bastite replacing olivine and pyroxene respectively with some rare relicts of these silicates. Intergrowths of fibrous chrysotile with bastite are frequently recovered. TEM/EDS investigations show that serpentine minerals are represented by chrysotile, asbestiform and massive antigorite, fibrous polygonal serpentine, fibrous proto-chrysotile, asbestos tremolite-actinolite and lizardite as main phases. Metabasites consist of amphiboles (dominated by asbestos tremolite-actinolite), epidote, albite, muscovite, chlorite, titanite, calcite, magnetite and nimite.

These new knowledges could be used i) as markers of specific environmental conditions during asbestos mineral formation, ii) to identify eventually health hazard areas owing to asbestos fiber presence, iii) to provide data for compulsory Italian mapping.

Key terms: *thallium; sulfosalts; Monte Arsiccio mine; Apuan Alps; Tuscany*

Together with the magmatic hydrothermal system of La Fossa Crater (Vulcano, Eolie Islands, Sicily, Italy; Camprostrini *et al.*, 2011), the Monte Arsiccio mine is the second Italian locality showing the presence of thallium-bearing mineral assemblages. In particular, it is an interesting locality for the study of thallium sulfosalts in metamorphic environment. Notwithstanding over two centuries of mineralogical studies on the Apuan Alps ores, only recently the first thallium mineral, chabournéite, was identified from the Monte Arsiccio mine (Bonaccorsi *et al.*, 2010); at the same time, Moëlo *et al.* (in press) detected the presence of minor Tl in Sb-rich sterrite from Pollone mine, confirming the geochemical complexity of the hydrothermal paragenesis of the ore deposits from Apuan Alps. Successively, boscardinite and routhierite were also discovered. These minerals have been identified by X-ray diffraction and chemical analyses. These sulfosalts are associated with baryte, calcite, cymrite, dolomite, pyrite, quartz, realgar, sphalerite, stibnite, and zinkenite in Triassic dolostones of the Sant'Olga level.

Chabournéite occurs as black metallic veins; chemically, it agrees with the general formula $Tl_{5-2x}Pb_{2x}(Sb,As)_{2-2x}S_{3+2x}$, with x in the range 1.2 and 1.5 in the two analyzed samples. Therefore it is one of the Pb-richest chabournéites ever described; in addition, this new occurrence shows the lowest As contents, with $As/(As+Sb)$ equal to 0.20 and 0.10 in the two samples. The crystal structure of chabournéite from Monte Arsiccio has been determined in the space group $P-1$; it confirms the general features given by Nagl (1979) but on the basis of a simpler and more symmetrical unit cell, without any visible superstructure, that may be due to the higher Sb contents of

chabournéite from Monte Arsiccio.

This mine is the type locality of boscardinite (IMA 2010-079), a recently approved new mineral that occurs as lead-grey masses in quartz veins or in dolostones. Its simplified chemical formula is $TlPb_2(Sb,As)_2S_{11}$; minor Ag is also present. Boscardinite is the Tl-Sb homeotype of baumhauserite. Its crystal structure was determined and refined to $R = 4.5\%$ for 4319 observed reflections, in a cell with a 8.0929(4), b 8.7610(5), c

22.4497(11) Å, α 90.868(4), β 97.247(4), γ 90.793(4)°, space group $P-1$. The crystal structure of boscardinite can be described in the sartorite homologous series, as formed by the 1:1 alternation of sartorite type and dufrénoysite type layers.

Finally, routhierite was identified on the basis of X-ray powder diffraction and qualitative chemical analysis. It occurs strictly associated with chabournéite, boscardinite, and stibnite, as small cinnabar red anhedral crystals, up to 1 mm. A full characterization of this new occurrence is planned.

The occurrence of a thallium-rich sulfide ore in the Apuan Alps constitutes a very interesting topic according to two points of view. First, it is a new field of exploration of the crystal chemistry of thallium sulfosalts, whose occurrences are extremely rare in the world. Secondly, the geochemistry of this ore, with (Sb,As, Pb, Zn, Tl, Cu, Hg)-sulfides and sulfosalts associated with pyrite is very similar to that described at Jas Roux (French Alps - Johan & Mantiene, 1974), and may be related to the same type of metallogenic process related to Alpine orogeny.

Key terms: *sulfosalt; new minerals; chemical composition; crystal structure; Peru*

Menchettiite was found at the Nivel 890, Uchucchacua polymetallic deposit, Oyon district, Catajumbo, Lima Department, Peru, that is the same type locality for three other Mn-bearing sulfosalts, uchucchacuaite, $Pb_2AgMnSb_2S_{12}$ [1], benavidesite, $Pb_2MnSb_2S_{12}$ [2], and the newly approved manganoadratite, $AgMnAsS_3$ [3]. The new mineral has been named after Silvio Menchetti, full professor in mineralogy and crystallography at the University of Florence.

Menchettiite occurs in a calcite matrix associated with orpiment, minerals of the tennantite-tetrahedrite series, and other, still unnamed, minerals of the system $Pb-Ag-Sb-Mn-As-S$. Electron microprobe analyses carried out on the same crystal used for the structural investigation led to the following empirical chemical formula: $[Pb_{4.81}Mn_{3.20}Ag_{1.95}Cu_{0.01}Fe_{0.02}Zn_{0.01}Sb_{6.09}As_{3.94}Bi_{0.01}]_{\Sigma=28.04}[S_{23.95}Se_{0.01}]_{\Sigma=24.96}$.

Menchettiite is monoclinic, space group $P2_1/n$, with $a = 19.233(2)$, $b =$

$12.633(3)$, $c = 8.476(2)$ Å, $\beta = 90.08(2)^\circ$ and $V = 2059.4(8)$ Å³; and it is ubiquitously twinned on $\{100\}$. Its crystal structure [$R = 0.0903$ for 2365

reflections with $F_o > 4\sigma(F_o)$] is based on Pb-S like slabs of four-octahedra thickness and appears topologically identical to that of ramdohrite, $Pb_2Sb_{11}Ag_2S_{24}$ [4]. The main difference is related to the atomic species occupying the different structural sites. In detail, in menchettiite: (i) the M1 site appears occupied by a mixture of Pb and Mn whereas it is fully occupied by Sb in ramdohrite; (ii) the M5 site is dominated by Sb whereas it is fully occupied by Pb in ramdohrite; (iii) M9 is fully occupied by Mn whereas it is $Sb_{0.50}Ag_{0.50}$ in ramdohrite; and (iv) variable amounts of As are hosted in M2, M7 and M10 which are fully occupied by Sb in ramdohrite. The geometrical parameters of the coordination polyhedra change accordingly. Menchettiite can be classified among the Sb-rich members of the lillianite homeotypic series which are described with the general formula $Ag.Pb_{3-2x}Sb_{2+5x}Se$ [5]. Besides the heterovalent substitution $2Pb^{2+} \rightarrow Ag^+ + Sb^{3+}$ taken into consideration by the above formula, however, two isovalent substitutions relate menchettiite to the others lillianite homeotypes, i.e.

$Mn^{2+} \rightarrow Pb^{2+}$ (also working in uchucchacuaite [1]) and $As^{3+} \rightarrow Sb^{3+}$. Thus, the general formula of menchettiite can be written as follows: $Ag.Pb_{3-2x-y}Mn_xSb_{2+5x-z}As_ySe$ with $x = 0.5$, $y = 0.8$ and $z = 1.0$. This formalism makes evident the close similarity of the new mineral with uchucchacuaite ($x = 0.5$, $y = 0.5$, $z = 0.0$), the only member of the series to have the same ratio between metallic and semi-metallic elements. In its appearance and physical properties menchettiite is indeed quite similar to uchucchacuaite; as expected on the basis of its higher Mn/Pb and As/Sb ratios, however, menchettiite exhibits a reflectivity lower than that of uchucchacuaite.

IN SITU STUDY OF THE THERMAL BEHAVIOR OF PLOMBIÈRITE

BIAGIONI Cristian¹, BONACCORSI Elena¹, MERLINO Stefano¹, BERSANI Danilo²

1 - Dipartimento di Scienze della Terra - Università di Pisa

2 - Dipartimento di Fisica - Università di Parma

Presenter e-mail: elena@dst.unipi.it

Key terms: *tobermorite group; plombièrite; thermal behavior*

Plombièrite is the most hydrated phase belonging to the tobermorite group; it is characterized by a basal spacing of 14 Å. The structure solution and refinement by Bonaccorsi *et al.* (2005) indicated that the

chemical formula of plombièrite is $\text{Ca}_2(\text{Si}_2\text{O}_7)(\text{OH})_2 \cdot 9\text{H}_2\text{O}$. Similarly to other members of the tobermorite group, its structure is composed by the stacking along *c* of a complex module, which is formed by a calcium layer, decorated on both sides by wollastonite-like single silicate chains. The modules are shifted each other of *b*/2 and are separated by a layer of additional calcium cations and H_2O molecules.

The thermal behavior of plombièrite is apparently simple: at 110°C plombièrite shrinks to a 11 Å phase, which transforms into tobermorite 9 Å upon heating up to 300°C. However, some authors (Farmer *et al.*, 1966; Mitsuda & Taylor, 1978) describe a more complex behavior, with the appearance of a new phase at higher temperature, with basal distance of ≈ 10 Å. Another matter of discussion is represented by the polymerization of the silicate chains in the 11 Å tobermorite formed through the dehydration of plombièrite: all the so far studied samples of natural tobermorite 11 Å show double wollastonite-like chains, whereas the 11 Å phase obtained upon heating might show single chains (Wieker *et al.*, 1982; Yu & Kirkpatrick, 1999).

Specimens of plombièrite from Crestmore (California, USA) and Zeilberg (Bavaria, Germany) were studied *in situ* through the experimental apparatus described by Meneghini *et al.* (2001) at the GILDA beamline of ESRF (Grenoble, France). The results obtained by the two specimens confirmed that at 110°C plombièrite shrinks to a 11 Å phase; the refinement of the cell parameters showed clearly the decreasing of the *c* parameter, whereas *a* and *b* maintain their values. These data pointed to the approaching along *c* of unmodified complex modules.

At the beginning, the so-formed 11 Å phase presented a basal spacing of nearly 11.7 Å, in accordance with the results of a previous study by Yu & Kirkpatrick (1999); this value progressively decreased down to 11.3 Å at about 250°C. At 300°C, the 11 Å phase is replaced by a 9 Å phase. As already observed by previous authors, the higher the temperature, the longer is the basal spacing of the 9 Å phase, which shifts toward 10 Å. To investigate the condensation degree of the silicate chains in the 11 Å phase formed by dehydration of plombièrite, either double or single, we collected the micro-Raman spectra of the heating product of plombièrite from Crestmore, and compare them with those of other phases with known structure. Our results point to the occurrence of single silicate chains, in agreement with that reported by Yu & Kirkpatrick (1999). In principle, it is possible to hypothesize that 11 Å phases characterized by single chains occur also in nature, due to the possible dehydration of plombièrite under mild metamorphic conditions. However, up to now this kind of phase was not yet discovered in natural samples.

Key terms: sulfosalt; new mineral; chemical composition; crystal structure; Peru

A new manganese bearing sulfosalt was found at the Nivel 890, Uchucachaca polymetallic deposit, Lima Department, Peru, that is the same type locality for three other Mn-bearing sulfosalts, i.e. uchucachacuite [1], benavidesite [2], and the just approved menchettiite, Pb-Mn-Ag-Sb-As-S₂ [3]. Associated minerals are Mn-rich calcite, alabandite, Mn-rich sphalerite, proustite, pyrite, argentotennantite, stannite and other unnamed minerals of the system Pb-Ag-Sb-Mn-As-S. Electron microprobe data, lead to the following empirical formula: $(\text{Ag}_{0.95}\text{Cu}_{0.05})(\text{Mn}_{0.95}\text{Pb}_{0.05})(\text{As}_{0.87}\text{Sb}_{0.13})\text{S}_{2.99}$. Single-crystal X-ray data were collected with a CCD diffractometer, using MoK α radiation. Unit-cell parameters (*a* = *a* = 5.4496(5), *c* = 32.949(1) Å; $\alpha = \beta = \gamma = 90^\circ$) and analysis of intensity data indicated the Laue group *4/mmm* and E-statistic strongly indicated the structure to be centrosymmetric. However, systematic absences gave contradictory information and first attempts to solve the structure by a standard way (Patterson and direct methods) were unsuccessful.

Due to the strong subcell *a*_{sub} = *a*, *c*_{sub} = 1/3 *c*, a first model of the average structure was obtained by refining a chalcopyrite-like model (I4-2*d*). The obtained atom coordinates were then transformed for a 3-fold unit-cell and the model slowly achieved convergence in the P1 space group (*R*1 = 0.093 for 1622 *F*_o > 4 σ (*F*_o) and 0.15 for all 2939 data). At this stage, an analysis of the structure with the ADDSYM routine of the PLATON program [4] revealed the real symmetry to be P4-22; in this space group the structure was refined up *R*1 = 0.086 for 907 reflections with *F*_o > 4 σ (*F*_o) and 0.14 for all 1532 independent data). The structure consists of a stacking sequence along [001] of square-net layers of O atoms (O-O = 2^{1/2}*a*/2 = 3.85 Å) each one shifted of 1/2*a* with respect to the adjacent one, with the cations located in the center of the O₄ squared nets. In the sequence, one Mn-S₂ layer is stacked by two AsAgS₂ layers, thus determining the 3-fold translation along [001]. The layers containing Mn²⁺, located at *z* = 1/8, 3/8, 5/8 and 7/8, are the most regular. Layers containing As³⁺ and Ag⁺ are more irregular, mostly due to the lone-pair bearing As³⁺ cation which is asymmetrically located within the O₄ squared nets. Couples of AsAgS₂ layers are interconnected to each other by both As³⁺-S and Ag-S bonds which complete the coordination polyhedra forming AS₂ and AgS₂ pyramids, respectively. In turn, the sulfur atoms of the AsAgS₂ layers complete the octahedral coordination of Mn²⁺.

Due to the analogy of the chemical formula and the unit cell parameters with those of quadratite (AgCdAs₂, *a* = 5.499(5), *c* = 33.91(4) Å; [5]) the new mineral here described was supposed to be the Mn-analogue of quadratite and therefore named manganoquadratite. The crystal structure of quadratite (supposed to crystallize in the I4₁/amd space group) however, is still unknown and whether these two minerals are strictly isostructural or not remain to be ascertained.

KAZANSKYITE, BA Na₃Ti₂Nb (Si₂O₇)₂O₂(OH)₂(H₂O)₄, A NEW TITANIUM DISILICATE MINERAL WITH THE TS BLOCK FROM KIROVSKII MINE, KOLA PENINSULA, RUSSIA.

CAMARA Fernando¹, SOKOLOVA Elena², HAWTHORNE Frank C.²

¹ - Università di Torino

² - University of Manitoba

Presenter e-mail: fernando.camaraartigas@unito.it

Key terms: new mineral; titanium disilicate; crystal structure; Kola Peninsula

Kazanskyite, ideally BaNa₃Ti₂Nb(Si₂O₇)₂O₂(OH)₂(H₂O)₄, triclinic:

a 5.4260(9), *b* 7.135(1), *c* 25.514(4) Å, α 98.172(4), β 90.916(4), γ 89.964(3)°, *V* 977.61(5) Å³, *Z* = 2, is a new representative of titanium disilicate minerals with the TS (titanium silicate) block[1]. It occurs at Kirovskii mine, Mt. Kukisvumchorr, the Khibiny alkaline massif, Kola Peninsula (Russia), associated to natrolite, barytolamprophyllite, nechelyustovite, hydroxylapatite, belovite-(La), belovite-(Ce), gaidonnayite, nenadkevichite, epididymite, apophyllite-(KF), sphalerite. The crystal structure of kazanskyite is a new structure type and does not have any analogues. It is a combination of a TS block and an I (intermediate) block. The TS block consists of HOH sheets (H = heteropolyhedral, O = octahedral).

The TS block exhibits linkage and stereochemistry typical for Group III (Ti-Nb = 3 a.p.f.u.) of the Ti-disilicate minerals: two H sheets connect to the O sheet such that two (Si₂O₇) groups link to the trans edges of a Ti octahedron of the O sheet [1]. In the O sheet, there are four M² sites. The M²(1) and M²(2), M²(3), M²(4) sites are occupied by Ti_{0.74}Mn_{0.26} and Na, Na_{0.77}Mn_{0.15}Ca_{0.07}Fe²⁺_{0.01}, Na_{0.77}Mn_{0.15}Ca_{0.07}Fe²⁺_{0.01}, respectively. The cation composition of the O sheet is ideally Na₃Ti₂p.f.u. (per formula unit). The TS block has two H sheets, H1 and H2, which differ in coordination number and dominant cation at the M² site, [6]-coordinated Nb and [5]-coordinated Ti, respectively. In the H sheets, there are four Si sites occupied solely by Si and tetrahedrally coordinated by O atoms, with <Si-O> = 1.62 Å. In the H sheet, (Si₂O₇) groups link to M² polyhedra. The chemical formulae of the H sheets is ideally NbTi(Si₂O₇)(H₂O) and of the TS block is Na₃Ti₂Nb(Si₂O₇)₂O₂(OH)₂(H₂O). There are two peripheral sites, A¹

(1) and A²(2), occupied by Ba_{0.91}Sr_{0.28}K_{0.21} and Ba_{0.19}^{0.81}, respectively.

There are two I blocks: the I1 block is a layer of A¹(1) atoms with ideal composition Ba a.p.f.u.; the I2 block consists of A²(2) atoms and H₂O groups, ideally (H₂O)₂. TS blocks and I blocks alternate along [001]. We write the chemical formula of kazanskyite as two TS and two I blocks divided by two: Na₃Ti₂Nb(Si₂O₇)₂O₂(OH)₂(H₂O) + Ba + (H₂O)₂ = BaNa₃Ti₂Nb(Si₂O₇)₂O₂(OH)₂(H₂O)₄, *Z* = 2. The I1 and I2 blocks of kazanskyite are topologically and chemically identical to the I1 and I2 blocks in nechelyustovite [2]. The layer of Ba atoms (I1 block) also occurs in barytolamprophyllite [3] and bornemanite [4].

IMPROVEMENT OF THE CRYSTAL STRUCTURAL MODEL OF TINAKSITE

KANEVA Ekaterina¹, MESTO Ernesto¹, SCORDARI Fernando¹, VLADYKIN Nikolai²

¹ - Dipartimento Geomineralogico, Università degli Studi di Bari, Bari, Italia

² - Institute of Geochemistry, Irkutsk, Russia

Presenter e-mail: kev604@mail.ru

Key terms: Tinaksite; crystal structure refinement; structural disorder

Tinaksite from ultralkaline apgaitic Murun massif (Russia) has been investigated. The name reflects its composition: titanium (Ti), sodium (Na), potassium (K) and silicon (Si). Its structure was reported for the first time in 1971 by Petrunina [1]. To the best of author's knowledge,

tinaksite is the only silicate based on {**hb**, 2 **oo**} [Si₂O₇(SiO₂)] hybrid anion [2]. The structural model of Tinaksite proposed by Petrunina [1] was validated and improved by von Bissert [3] in 1980, who observed a more regular tetrahedra conformation. The tinaksite investigated by von Bissert [3] is triclinic with chemical composition: Na₂Ca₂Ti₂[Si₂O₇](OH). The compound here investigated has chemistry more complex, ((Na_{0.855}K_{1.993}Ca_{2.008}Ti_{0.792}Mg_{0.083}Fe³⁺_{0.096}Mn_{0.106}Zr_{0.027}Sr_{0.012}Zr_{0.027}Zr_{0.008}Ni_{0.007}Cr_{0.005})[Si₂O₇](OH), compared with Petrunina's [1] and von Bissert's [3] ones. It has been refined in P1, using the following lattice parameters: *a* = 7.0565(1) Å, *b* =

10.3750(1) Å, *c* = 12.1885(2) Å, $\alpha = 92.802(1)^\circ$, $\beta = 90.763(1)^\circ$, $\gamma = 99.241(1)^\circ$.

In this work, the cation partition derived from SCXRD and EPMA data, is presented. The structure has been anisotropically refined up to a *R*(*F*) = 0.025 (for 5238 observed reflections with *F*_o > σ (*F*_o)). Tinaksite exhibits straight channels parallel to [001] direction, formed by double chains of silicate. The channels are stretched approximately along [110] direction, with maximum dimension 10.972(2) Å.

The highest peak in the Fourier difference map is related to some structural disorder inside the Ti octahedron. This disorder likely can be ascribed to the entrance of the large K substituting the six-fold coordinated Na atom. As a matter of fact, the replacing of Na for K changes the coordination number of the polyhedron from 6 to 7, which seems to influence the neighbouring Ti atom position.

Another point concerns the K1 and K2 atoms located inside the channels. According to von Bissert [3], the higher K1 thermal parameter with respect to the K2 one indicates the site filled by K1 is disorder. The

structural refinement shows that K1 atom is located over at least three different positions. A charge distribution analysis, performed by means of the Chardi-It software [4], has returned an EON number [5] of 11 and 9 for the K1 and K2, respectively. The bond distances for the three K atoms, related to K1, show these atoms are not always bonded to the same oxygens. Indeed, K1 can move inside a cage formed by 14 oxygen atoms with a volume of about 90 Å³. This volume results to be much larger even than the one of the ideal twelve-fold coordinated K atom (~18 Å³).

CRYSTALCHEMISTRY OF CR-SPINELS FROM THE SHETLAND OPHIOLITE COMPLEX (SCOTLAND)

LENAZ Davide¹, DERBYSHIRE Elizabeth Jane², O'DRISCOLL Brian²
 1 - Dipartimento di Geoscienze, Università di Trieste, Trieste, Italy
 2 - School of Physical and Geographical Sciences, Keele University, Keele, United Kingdom

Presenter e-mail: lenaz@units.it

Key terms: crystal chemistry; Cr-spinel; ophiolites; Shetland Island

Cr-spinels are typical accessory minerals in a wide variety of ultrabasic rocks such as dunites, harzburgites and lherzolites, occurring in various geological settings and belonging to different depth-zone facies. In the present study, ten Cr-spinel crystals from four localities in the ~492 Ma Shetland ophiolite (NW Scotland) have been studied using single-crystal XRD to assess their petrogenesis and cooling history. The mantle section of the Shetland Ophiolite dominantly outcrops on the Isle of Unst and preserves a heavily serpentinized, two kilometre-thick section of layered dunites and harzburgites (Spray and Dunning, 1991; Flinn, 2001). Numerous podiform chromitites (defined as >60% vol. Cr-spinel) enclosed in dunite lenses are frequently found close to the petrological Moho (Flinn, 2001). Cr-spinel seams are between 10 cm-1 m in thickness and laterally discontinuous over the scale of several meters. Previous work reveals that the Cr# [Cr/(Cr+Al)] of the seams vary in different chromitite locations; 0.63-0.81, 0.60-0.67, 0.60-0.65, and 0.65-0.67 respectively (Derbyshire et al., unpublished data).

In the study of spinels the most important structural parameters are cell edge and oxygen coordinate. These parameters are influenced both by chemistry and the cooling history inferred by the host rocks. In particular, oxygen coordinate is sensitive of this last "condition" being influenced by the cation-exchange between T and M sites. For single-crystal XRD analyses, synthetic spinels were mounted on an automated KUMA-KM4 (K-geometry) diffractometer, using MoK α radiation monochromatized by a flat graphite crystal. The unit cell (a0) was determined by 24 equivalent reflections of (12 8 4) or (8 4 4) (about 90° and 50° of 2theta), according to the size of the crystal accurately centred at both sides of 2theta. Data collection was made according to Della Giusta et al. (1996) up to 2theta = 55°. The analyzed Cr-spinels show cell edges and oxygen coordinate parameters ranging from 8.2580 (6) to 8.3134 (6) Å and 0.2623 (1) to 0.2631 (1), respectively.

One of the most peculiar features of the analysed Cr-spinels is that, despite their occurrence in ophiolitic samples, their structural parameters resemble those of Cr-spinels occurring in layered mafic complexes such as the Bushveld (Lenaz et al. 2007) and Stillwater (Lenaz et al. 2011) intrusions, rather than those of Cr-spinels in typical ophiolitic samples (cf. Bosi et al. 2004). In fact, the spinels from ophiolitic complexes usually show similar cell edges, but very different u parameters ranging between 0.2616 (1) and 0.26267 (8), where low values derived by cation vacancies due to Fe²⁺ oxidation to Fe³⁺.

BENTONITES AND BENTONITIZED ROCKS OF MARCHE REGION (CENTRAL, ITALY) (UMBRO - MARCHEAN APENNINES)

MATTIAS Pierpaolo¹

1 - University of Camerino

Presenter e-mail: pierpaolo.mattias@unicam.it

Key terms: Bentonites; Bentonitic Earth; Mines; Underground; Marche Region (Italy)

The presence of bentonites and bentonitized rocks inside the sedimentary sequences of the Umbro - Marche Apennines (Central Italy) is poorly known, even though several careful studies have been devoted to these rocks owing to their industrial importance. The above rocks form beds, levels or lenses, spanning from Cretaceous to Miocene in age. They are found inside terrains belonging to several lithostratigraphic units, from the Bisciaro Fm until the Laga Fm. Complex lying of bentonitic deposits is the result of several and successive dislocations caused by orogenic pulses. In the Pesaro-Urbino province (northern Marche), under particularly favourable conditions, bentonite levels and / or lenses, 40 to 200 cm - thick, originated between marine sediments such as marly limestones and marls. In the past, bentonitic materials have long been known and used as pietra saponaria (soap stones), argille da bianca (fuller's earth), or argille

smettiche (smectitic clays). In the late century, from the end of 30's to the whole 70's, these rocks have been the object of several researches also of regional extent. Afterwards, national and foreign chemical industries provided to open some mines in the most promising sites. Purity of such bentonitic materials, as well as their excellent suitability for technological uses, pushed excavation further down until a 275-m depth was reached, corresponding to a digging level of the 9th order, in the Lama - Mondaino mine.

Other important mines were located in the Montefotogno - I Pianacci area (where an exploitation of small extent is still carried on), at Montefabbi (Talacchio - Colbordolo), S. Martino (Case Cecchini - Belvedere Fogliense), and S. Maria (Val di Loto - Sassocorvaro), plus minor occurrences. Mineralogical analyses revealed that the smectitic term is composed mainly by montmorillonite, montmorillonite - beidellite, and rarely by nontronite. Negligible amounts of calcite, quartz, illite, kaolinite, and dolomite are recognized. The genesis of bentonitic rocks has been widely discussed in the past. Nowadays, it is linked to emplacement of volcanic ashes coming from westerly volcanoes. The age, and mainly the chemistry, of such volcanic materials allow to ascribing them to huge eruptive cycles of the Western Sardinia volcanic district. At the moment, all the bentonite mines are covered by a natural vegetation, which obliterated them almost completely.

DOES HOLLANDITE CONTAIN WATER? PHASE TRANSITIONS IN HOLLANDITE INDUCED BY TEMPERATURE

BIAGIONI Cristian¹, CAPALBO Carmen¹, LEZZERINI Marco¹, PASERO Marco¹
 1 - Università di Pisa

Presenter e-mail: pasero@dst.unipi.it

Key terms: hollandite; thermal behavior; phase transitions

As a part of an ongoing study on the crystal-chemistry of the so-called "tunnel oxides", we aimed at clarifying the possible presence of water in hollandite and in the other minerals of the cryptomelane group, whose general formula is $(A^+, A^{2+}_{0.5})(M^{2+}_{x-1}M^{3+})O_{16}$ ($x \approx 2$). Due to the microporous nature of these minerals, it cannot be excluded that the tunnels may host water molecules, together with the A exchangeable cations (K⁺, Na⁺, Ba²⁺, Pb²⁺, Sr²⁺). So far specimens of Fe-rich hollandite from Vagli were studied.

Their chemical formula can be expressed as $(Ba_{0.79}Sr_{0.22}Na_{0.02}K_{0.01})_{\Sigma=1.04}(Mn^{4+}_{5.70}Ti_{0.32}Fe^{3+}_{1.05}Mn^{2+}_{0.79}Al_{0.13})_{\Sigma=7.99}O_{16}$. As almost all members of the cryptomelane (all but manganite), hollandite is nominally anhydrous. The ideal topological symmetry of hollandite is tetragonal, space group $I4/m$, with $a \approx 10$, $c \approx 2.9$ Å. A single-crystal X-ray diffraction study of hollandite from Vagli carried out with a conventional Siemens P4 four-circle diffractometer proved that its c axis is doubled and the actual symmetry is monoclinic. The observed cell parameters are a 10.152(4), b

9.938(4), c 5.828(2) Å, β 90.71(3)°, space group $P2_1/n$. The doubling of the c parameter has been related to the ordering of Ba cations between two split positions within the tunnels. The crystal structure of anhydrous hollandite has been refined to $R = 5.01\%$ for 1641 observed reflections. Assuming an actual electron density equal to $[Ba_{0.8}Sr_{0.2}]$, as indicated by EPMA data, we tried to include water molecules, alternating with Ba along the tunnels. This would result in a better coordination of barium and would avoid unlikely Ba...Ba interactions between neighbor cations. Notwithstanding the difficulty in accurately refining the occupancy of water molecules sharing the same sites with heavy cations (also because of the high mobility of both), a plausible and self-consistent crystal-chemical model has been depicted; in addition, the refinement converged to $R = 4.97\%$.

In order to confirm the presence of water in hollandite, TG/DSC runs have been carried out with powdered samples (ca. 25 mg), using a Netzsch STA 449C equipment in N₂ atmosphere, from room temperature up to 1200°C, with a thermal gradient of 10°C/min. After each run, the products were identified through powder X-ray diffraction using a Philips PW1050/25 diffractometer. The collected data suggest the presence of three steps of weight loss: i) at T \approx 730°C, a small endothermic hump related to a weight loss of 1.2 wt.%, maybe due to molecular water loss; ii) at T \approx 895°C, a broad endothermic peak, probably related to the appearance of bixbyite and minor hausmannite in the heated products, as indicated by PXRD pattern; finally, iii) at T \approx 950°C, a marked endothermic peak is observed. The final product consists of hausmannite and, maybe, of a new-formed Ba-bearing Mn phase. The total final weight loss is approximately 9 wt.%.

Further thermo-gravimetric data on other specimens of hollandite from different localities are planned to verify the extent of the weight loss observed for the sample from Vagli. Preliminary data seems to confirm the above-described trend.

Key terms: adsorption; epitaxy; enantioselectivity; calcite; surfaces

The mechanisms of biologically driven crystal growth are usually limited to the stereochemistry of the adsorption of biologically interesting molecules. Hence, the theoretical approach is confined to the study of the interaction between specific sites of crystal surfaces (substrate) and the isolated molecule (adsorbate). This is, of course, a necessary step to evaluate the adsorption energy of an isolated molecule on a given substrate. Nevertheless, more information is needed to understand the "cooperative effect" when the adsorbate is not made by a randomly distributed molecular population but is localized either in 2D nuclei or in monolayers making epitaxy with the substrate.

The results of the researches we carried out in the last decade clearly show that several morphological changes, already attributed to the random adsorption of impurity on specific crystal surfaces, can be correctly interpreted in the light of 2D epitaxially adsorbed phases. This is the case of the 2D epitaxies of: i) - Li₂CO₃ on Calcite growing from Li-doped

solutions [1]; ii)- SiO₂ (α-quartz) on Witherite growing from Na-metasilicate doped solutions [2]; iii)- formamide on NaCl crystals growing from aqueous solutions [3]. Moreover, it has been shown, in i) and iii), that the 2D adsorption is a preliminary step for selective adsorption in the growing substrates followed by the formation of "anomalous mixed crystals" in the sense of Johnsen [4]. In this work, we deal with the changes induced in the morphology of calcite crystals when variable amounts of L- and D/L- Aspartic Acid are added to the growth solution. It is worth remembering that the mother solution, supersaturated with respect to calcite, is unsaturated with respect to both the impurities we used, in order to verify:

-the occurrence of 2D adsorbed phase on the crystal surfaces
-the enantioselectivity of the calcite {21.4} scalenohedron surfaces with respect to the L- enantiomer and to the racemic phase of the Aspartic Acid.

Concerning the theoretical aspects, the Hartman-Perdok analysis [5] on the <441> zone of calcite has been carried out and the calculation of the surface (γ_{hkl}) and attachment energies was performed, on both unrelaxed and relaxed surfaces. The flat (F) character of the {10.4} and {11.0} forms and the stepped (S) one of the {01.8} and {21.4} forms contradicts the observed occurrence frequency of natural crystals:

{21.4} > {01.8} > {10.4} > {11.0}. A minor reduction of the relaxed γ_{hkl} values of both {01.8} and {21.4} forms, could be sufficient to make the theoretical equilibrium shape of the crystal composed by the {10.4}, {01.2}, {10.0}, {00.1}, {01.8} and {21.4} forms, which explains the richness of the growth morphology of calcite, even if water adsorption is not considered. Our analysis is focused on the {21.4} scalenohedron. Epitaxy models are described: i)- between D and L {21.4} surfaces and the adsorbed 2D layers of polar {010} and {0-10} L-Aspartic acid; ii) - between the {10.4} surface and the adsorbed 1D rows and 2D Aspartic layers. Hence, the adsorption enantiospecificity is better explained through a "cooperative molecular" approach, instead of searching for the best interaction of a single molecule on specific surface sites.

Presenter e-mail: ventruti@geomin.uniba.it

Key terms: Ferric sulphate hydrates; sideronatrite; HT-FTIR spectroscopy; phase transition

Sideronatrite - Na-Fe³⁺(SO₄)₂(OH)³(H₂O) - is a secondary iron-bearing, hydrous sulfate formed during oxidation of pre-existing sulfides. It is a typical sedimentary product in some soils and evaporitic deposits. Sideronatrite is formed in acid, sulfate-rich environments, and plays an important role in the acid drainage mobilization of metals and in the monitoring of water quality. The dehydration behavior of sideronatrite from Sierra Gorda (Chile) was investigated by *in situ* high-T FTIR spectroscopy. The structural variations induced by thermal treatment were monitored by FTIR using the bending mode of the water molecule around 1650 cm⁻¹, the stretching modes around 3500 cm⁻¹, and the corresponding combinations modes in the wavenumber region 4000-6000 cm⁻¹. A succession of three structural phase transitions have been observed in the range RT - 400°C. In the first and second phase transition (sideronatrite

→ metasideronatrite I, [Na-Fe³⁺(SO₄)₂(OH)³(H₂O)] [1] and

metasideronatrite I → metasideronatrite II, [Na₂Fe³⁺(SO₄)₂(OH)]² and one interstitial water molecules, coordinated by the Na atoms, are lost respectively, while the backbone of the structure present in sideronatrite, i.e. the [Fe³⁺(SO₄)₂(OH)]³ chain, keeps unchanged. The loss of OH-group corner-sharing between two adjacent Fe³⁺-octahedra in sideronatrite chain, involves the break down of the [Fe³⁺(SO₄)₂(OH)]³ chain and the subsequent formation of an intermediate amorphous transition phase from which the Na-Fe(SO₄)₂ compound [2] will form later. Thermogravimetry combined with mass spectroscopy of evolved gases confirm furtherly the dehydration and dehydroxylation processes observed.

THE DUAL BEHAVIOUR OF THE β-AS₂S₃ ALTERED BY LIGHT

ZOPPI Matteo¹, PRATESI Giovanni²

1 - Museo di Storia Naturale - Università di Firenze

2 - Dipartimento di Scienze della Terra - Università di Firenze

Presenter e-mail: g.pratesi@unifi.it

Key terms: beta-As₂S₃; realgar; pararealgar; alacranite; light

The mineral realgar (alpha-As₂S₃), and the polymorph of high temperature, beta-As₂S₃ (stable over 252 °C) undergo a peculiar process of alteration induced by light. Both the phases alter to pararealgar (Bonazzi et al., 1995), as a result of the exposure to natural or artificial light (Douglass et al., 1992; Bonazzi et al., 1996) and this causes an anisotropic increase of the unit-cell volume (up to 2.6%) of both the polymorphs. During the process of alteration, starting from both realgar or the beta-phase, arsenolite occurs along with a metastable phase, named

chi-phase, which is the precursor of pararealgar. As Bonazzi et al. (2006) shown remarkable work has been done to understand the nature of the transformation and the authors relate the unit-cell expansion to the substitution of As₂S₃ units by As₂S₂ uzonite-type molecules according to

the reaction 5As₂S₃ + 3O₂ → 4As₂S₂ + 2As₂O₃ and the following removal of the additional sulfur atom to produce the molecule of pararealgar. Thus, the untied S atom would be ready to enter another realgar molecule and continue the cyclic mechanism. To better understand the role of the oxygen and if the unit-cell expansion of the beta-phase is really due to the presence of uzonite-type molecules, some powdered beta-phase has been altered by the light with and without the presence of the air, XRPD data were collected in transmission geometry, and structural refinements along with quantitative phase analysis were carried out using the Rietveld method. The alteration induced with the presence of the air caused the formation of pararealgar, arsenolite and an amorphous phase, while from the powder not in contact with the air only pararealgar was obtained. The second part of the experiment was aimed to detect if the two types of pararealgar, so obtained, could transform into the beta-phase through the action of the heat in a closed environment, and within the stability field of realgar. The powder made by pararealgar, arsenolite and amorphous phase yielded crystalline arsenolite and alacranite. Differently, the powder made of only pararealgar turned into the chi-phase, and slowly into the beta-phase only, the unit cell exhibiting a contraction. This points out that the beta-phase altered by the light shows a dual behaviour whether or not that occurs with the presence of the air, that is the oxygen. In the first case the transformation is not reversible and follows a mechanism above mentioned, while in the second case the transformation is reversible. With these evidences it is difficult to make the hypothesis that some As₂S₂ molecules form during the alteration under the light, since neither arsenolite nor amorphous phase occurs, and the whole material turns into pararealgar. It is also difficult to invoke the proposed mechanism to explain both the expansion of the unit cell of the beta-phase and the contraction of the unit cell of the chi-phase. In this case the transformation must be due to a different mechanism, such for instance the direct transformation of the As₂S₃ molecule, of alpha and beta polymorphs, to that of pararealgar with the simple breaking of the As-As and AsS bonds and the sudden reconstruction.

Key terms: Gruppo Mineralogico Geologico Napoletano; Minerals of Somma-Vesuvius; Minerals of Campi Flegrei; Discovery Minerals; Collaboration with Institute of Research

Gruppo Mineralogico Geologico Napoletano (GMGN) is a non-profit organization founded in Naples in 1980 by three mineralogy fan: Massimo Russo, Giovanni Coslovich and Claudio Lombardo (the latter two left the group over time).

Over the years GMGN has built up a remarkable experience in the field, so that it has substantially contributed to a better knowledge of the mineralogy of the Neapolitan area, especially Somma-Vesuvius and Campi Flegrei areas.

Over the years it has enjoyed the collaboration of several major national and foreign research institutes: universities of Bari, Napoli, Milano, Pisa, Roma, the British Museum of London, and the Muséum National d'Histoire Naturelle of Paris. At the present GMGN cooperates with Istituto Nazionale di Geofisica e Vulcanologia sezione di Napoli | Osservatorio Vesuviano, Dipartimento di Chimica Strutturale e Stereochimica Inorganica, University of Milano and Associazione Micromineralogica Italiana.

The research carried out by GMGN has led to the discovery of 34 species new to Somma-Vesuvius (one Type Locality: fluoro-potassichrichterite), two now discredited (one Type Locality: caratite now pyrite), two to be reviewed according to the new IMA definitions: pyroclorite and betafite, and two in which GMGN has contributed to a better knowledge of the species: euchlorine and quadridavvne. Similarly, for Campi Flegrei GMGN has contributed with 13 species new to the area and one be reviewed according to the new IMA definitions: pyroclorite.

In these thirty years of activity GMGN has published a significant number of scientific and specialized articles in the following bulletins: Notiziario del GMGN, GMGN Notizie, GMGN News, Rivista Mineralogica Italiana, MICRO, and on the web. The collaboration with the Associazione Micromineralogica Italiana led to the realization of a book very popular among scientists and collectors: Russo, M. and Punzo, I. (2004): I Minerali del Somma-Vesuvio, edited by Associazione Micromineralogica Italiana.

The GMGN meets regularly to discuss topics related to the Campania territory, to organize geological and mineralogical excursions and lectures and to give specialized advices about Campania minerals. More information: www.gmgcn.it.

Key terms: mineral collections; assessment; standardization

The recovery of the mineralogical heritage by public institutions, with a

view to increasing musealization, can lead to the purchase of entire private collections or any part of them.

However, in the practice, the evaluation is influenced by factors and "interests" that are not always clearly defined. Instead, the increasing transparency of public administrative acts, requires the adequacy of evaluations, whose methods need to be more reproducible and less attackable.

In this work the authors focus on a series of reproducible parameters, which, starting from the values prevailing in the period, tend to make a final assessment more transparent.

MINERALOGICAL TRANSFORMATIONS IN SERPENTINITES FROM THE MT. CAPANNE THERMOMETAMORPHIC AUREOLE (ELBA ISLAND, ITALY)

FERRARI Marco¹

¹ - Dipartimento di Scienze Applicate Università degli Studi di Napoli "Parthenope" Centro Direzionale, Isola C4 80413 Napoli

Presenter e-mail: marco.ferrari@uniparthenope.it

Key terms: serpentinite; olivine; thermal metamorphism; reaction mechanism; TEM

The Mt. Capanne intrusion (Elba Island, Italy) induced thermal metamorphic reactions within pseudomorphic lizardite (liz) + chrysotile (chr) serpentinites, giving rise to prograde minerals crystallization. This research is aimed at characterizing the thermally induced mineralogical and micro/nanostructural transformations in serpentinites, showing four main prograde reactions.

The first prograde reaction takes place both in bastites and mesh cores and leads to the formation of antigorite. Antigorite grows in the form of lamellae, longer than 50 µm, with random orientation; it develops at the expense of low-crystallinity liz + chr serpentine. The TEM study showed that antigorite has a highly defective structure with variable superperiodicity, modulation dislocations and polysynthetic twinings. The second prograde reaction leads to a fine intergrowth of talc and chlorite starting from the low-crystallinity liz + chr serpentine of the bastites. TEM images show that talc within bastites grows in the form of very long and rather thin lamellae (typical thickness of 30 - 60 nm), which are finely intercalated to low-crystallinity serpentine. Talc is always associated with lesser amount of chlorite. The lamellae of chlorite show a rather variable width, but they are always wider than the talc lamellae. High-resolution images and SAED patterns showed that also chlorite is often affected by structural defects, generally concentrated in specific crystal portions rather than homogeneously distributed.

The third prograde reaction causes the formation of anthophyllite and/or tremolite amphiboles. Prograde amphiboles can nucleate both in bastites and mesh textures. Within bastite, they may grow as tiny acicular crystals with size around 100 µm in length, developing in random orientation, and evolving to a fine-grained interpenetrating felt. Alternatively, they may progressively replace the bastitic serpentine from the outer toward the inner portions, producing a large pseudomorphic single crystal. In mesh textures, amphiboles typically occur as elongated crystals, with an acicular-fibrous habit in random orientation. In some cases anthophyllite and tremolite coexist within meshes. High-resolution TEM images and SAED patterns showed that anthophyllite is typically affected by polytypic disorder with random stacking of anthophyllite, protoanthophyllite and cummingtonite; conversely, tremolite is very ordered and defect-free. The fourth prograde reaction leads to the formation of forsteritic olivine, replacing mesh serpentine and never occurring within bastites. TEM observations suggest that all prograde transformations take place through amorphization and subsequent recrystallization processes; low crystallinity sites tend to react easily evolving to higher temperature paragenesis, while high crystallinity sites tend to persist in samples of higher metamorphic grade.

In most cases, the retrograde association (lizardite + chrysotile) tends to transform directly into prograde associations (talc + chlorite, amphibole and olivine). The formation of prograde antigorite in interpenetrating textures, found in a single outcrop, may have been favored by an intense deformation.

Serpentinite outcrops show a variable metamorphic grade. It could be due to the complex sequence of the intrusion emplacement, to a non-uniform movement of hydrothermal fluids and to a variable deformation induced by pluton on the wall rocks.

MG-METASOMATISM OF METAGRANITOIDS FROM THE ALPS: GENESIS AND POSSIBLE TECTONIC SCENARIOS

FERRANDO Simona¹, FREZZOTTI Maria Luce², COMPAGNONI Roberto¹, CASTELLI Daniele¹

¹ - University of Torino

² - University of Siena

Presenter e-mail: simona.ferrando@unito.it

Key terms: metasomatism; ultramafic rocks; seawater

The genetic process and the possible tectonic scenarios responsible for the origin of continental Mg-metasomatic rocks in the Alps are proposed by integration of field, petrological, geochemical (bulk-rock chemistry and stable isotope compositions) and fluid inclusion data previously reported for Mg-metasomatic rocks derived from post-Variscan granitoids (e.g., whiteschists, leucophyllites).

Despite the heterogeneous data, the large range of peak metamorphic conditions (from the lowermost greenschists-facies to the ultrahigh-pressure medium-temperature eclogite facies) and the distinct time of metasomatism (from rifting to exhumation), some common features have been recognized in all of the continental Mg-metasomatic rocks belonging to the palaeogeographic realms of both Europe and Adria: i) they occur along shear zones within the metagranitoids; ii) they display a simple MgO-Al₂O₃-SiO₂-H₂O±K₂O-silicate mineralogy; iii) based on major-

and trace-element compositions, they can be grouped in four homogeneous Classes, representative for a progressive increase in Mg-metasomatism from the host rock to the centre of the shear zone; iv) from Class 0 (protolith) to Class 3 (Mg-richer rocks) the lithologies show an increase in Mg, Ni, H₂O, Fe, Cr, and a decrease in Na, Ca, Sr, P, K, Rb, Si; v) fluid inclusion data, coupled with bulk-rock chemical compositions, indicate that the metasomatic fluid was a Ni-Mg-rich brine, containing also

Fe and Cr, and possibly undersaturated in Si; vi) δ¹⁸O and δD data are indicative for seawater, locally mixed with meteoric water, as source of the metasomatic fluid.

All the data indicate that the genetic process responsible for the Mg-metasomatic rocks is most likely the same all along the entire range of the Alps. The proposed process assumes highly channelized fluids (derived from ultramafics that has previously interacted with seawater) that infiltrated the continental crust along high strain zones and produced chromatographic fractionation of major and trace elements. Distinct petrological data and timing of metasomatism from each locality suggest at least three possible tectonic scenarios for this genetic process: rift-related ocean-continent transition, oceanic-continent subduction, and continent-continent collision.

TEMPERATURE DEPENDENCE OF YTTRIUM PARTITIONING BETWEEN GARNET AND XENOTIME: AN EXPERIMENTAL STUDY

DI ROCCO Tommaso¹, FUMAGALLI Patrizia², MAZZOLI Claudio¹, NESTOLA Fabrizio¹

¹ - Dipartimento di Geoscienze, Università di Padova

² - Dipartimento di Scienze della Terra, Università degli Studi di Milano

Presenter e-mail: tommaso.dirocco@uniroma1.it

Key terms: garnet; xenotime; yttrium

Yttrium is a notable trace element particularly compatible with garnet. Lanzitrotti (1995) provided evidences that, among major metapelite minerals, yttrium preferentially partitions into garnet and that the mode of major metapelite phases besides garnet have little effect on its fractionation. On the contrary trace elements are extremely sensitive to changes in accessory mineral assemblage (e.g. Ganguly, 2010). Xenotime (YPO₄) is a common accessory mineral in metapelites and arguments for garnet growth in equilibrium with xenotime are presented in several papers (e.g. Martin, 2009). Pyle & Spear (1999) described a relevant temperature control on the solubility of yttrium in garnet in xenotime-bearing metapelites from New England (USA). On the basis of a strong negative correlation between Y concentration and temperature they derived an empirical calibration to be used as geothermometer. However, no experimental studies do exist to date on the temperature dependence of Y partitioning between garnet and xenotime. In order to unravel this relation, high pressure (up to 2.0 GPa) xenotime - saturated synthesis of garnet have been performed in an end-loaded piston cylinder. The simple model system MgO-FeO-Al₂O₃-SiO₂ has been investigated at temperature between 800 and 1000°C with running compositions falling along the join almandine-pyrope + 5 wt% YPO₄. Gels have been prepared as starting materials using tetraethylorthosilicate (TEOS) as silica source, pure Mg-, Al-, Ca-, Y-nitric solutions, ferric benzoate and ammonium dihydrogen phosphate (NH₄H₂PO₄) digested in deionised water. Gels were fired in a gas-mixing furnace at fO₂ conditions approaching the IW (iron-wustite) buffer at 1 atm for 3 hours. The powder was tightly packed into a gold capsule with an internal graphite sleeve to keep the oxygen fugacity low. Run products were preliminary identified by X-ray powder diffraction, carefully inspected on back-scattered electron images and by X ray element maps, and analysed by electron microprobe and particle-induced X-ray emission (micro-PIXE). The use of the proton microprobe stems from its higher spatial resolution and lower X-ray background with respect to electron microprobe. This allows to measure trace element

concentrations down to levels of ~ 1 ppm on a 1 µm beam spot (Fraser, 1990). Preliminary results will be discussed.

Key terms: Fe3+/sum(Fe) ratio; garnet; dehydration-redox reactions; micro-XANES; flank method

Although it is accepted that the mantle wedge above subduction zones is oxidized, the exact processes of relative oxidation are still controversial

(e.g. Parkinson & Arculus, 1999). It is widely recognized that oxidized components are transferred to the overlying mantle wedge by fluid phases coming from the subducting slab (e.g. Parkinson & Arculus, 1999; Peslier et al., 2002; Malaspina et al., 2009; Rowe et al., 2009; Hirschmann, 2009); however, the study of the redox reactions occurring at the interface between the subducting slab and the mantle wedge, is often hampered by the difficulties in accurately determining the oxidation state of phase assemblages involved in these redox reactions.

In this contribution we report the results of a micro-XANES study (performed at ESRF ID22) on strongly-zoned garnet crystals from an eclogitic FeTi-oxide gabbro (Monviso meta-ophiolites, western Alps), aimed to the determination of the $Fe^{3+}/\Sigma Fe$ variation across the crystals. The studied sample extraordinarily well preserves evidence of its prograde evolution during subduction down to a depth of ca. 80 km (Gropo &

Castelli, 2010). Because in the studied garnet the $Fe^{3+}/\Sigma Fe$ variations are small and occur on a micrometric scale, the challenge of this study was twofold: (i) the spatial resolution must be of the order of microns, and (ii) the spectral resolution must be as small as possible in order to appreciate the differences in the oxidation state of garnet. The results of the XANES

spectra, acquired with a spatial resolution of $1.7 \mu m \times 5.3 \mu m$, show that the $Fe^{3+}/\Sigma Fe$ ratio decreases from a maximum of 0.14 in the garnet core to a minimum of 0.00 in the garnet rim.

These results are in excellent agreement with those previously obtained using the "flank method" at the electron microprobe. Comparing the results obtained with the two techniques, it can be concluded that

micro-XANES can be successfully used to estimate $Fe^{3+}/\Sigma Fe$ variations in

natural garnets at a high spatial resolution ($< 5 \mu m$), provided that the differences in $Fe^{3+}/\Sigma Fe$ are higher than ca. 5%. The "flank method" is the only method which has demonstrated, so far, to be sensitive to smaller variations (i.e. $< 5\%$) of the $Fe^{3+}/\Sigma Fe$ ratio in garnet, for $\Sigma Fe > 8 \text{ wt}\%$.

The measured $Fe^{3+}/\Sigma Fe$ zoning in garnet, combined with the already estimated P-T conditions of its growth, provides qualitative information about the redox equilibria occurring during subduction of the studied FeTi-oxide metagabbro. Dehydration-redox equilibria involving the breakdown of lawsonite and chlorite (i.e. $Qtz + Lws + Chl + Omp1 + Grt1 = Grt2 + Omp2 + H_2O + O_2$) are responsible for a significant chemical re-equilibration of garnet (and omphacite), resulting in a progressive

decrease of its $Fe^{3+}/\Sigma Fe$ ratio toward the rim and, consequently, in the release of oxygen. Dehydration-redox reactions of this type, occurring at least locally during subduction of the oceanic crust, may be likely involved in the oxidation of the mantle wedge.

FE3+ DISTRIBUTION BETWEEN GARNET AND PYROXENES IN METASOMATISED MANTLE WEDGE GARNET PERIDOTITES

MALASPINA Nadia¹, LANGENHORST Falko², FUMAGALLI Patrizia³, TUMIATI Simone³, POLI Stefano³

1 - Università degli Studi di Milano Bicocca

2 - Friedrich Schiller Universität Jena

3 - Università degli Studi di Milano

Presenter e-mail: nadia.malaspina@unimib.it

Key terms: *Fe3+ partitioning; clinopyroxene; oxygen fugacity; mantle wedge; subduction zone*

The determination of the oxidation state of most metasomatized garnet peridotites is a demanding task because a large number of phases incorporate both ferric and ferrous iron (e.g. garnet and clinopyroxene), and may show zonations. Oxygen fugacity in high pressure peridotites is traditionally determined from the Fe^{2+} and Fe^{3+} contents of garnet in equilibrium with olivine and orthopyroxene. However, the low Fe^{3+} contents in orthopyroxene as well as the Fe^{3+} partitioning into further peridotite mineral phases are often neglected. Previous studies demonstrated that the increase of Fe^{3+} in garnet with increasing temperature does not depend on the whole-rock Fe_2O_3 , but is rather the consequence of the redistribution of Fe^{3+} from clinopyroxene into garnet. This implies that the Fe^{3+} content of all the mineral phases and their possible Fe^{3+} zonations must be considered to obtain reliable quantifications of the oxidation state of the whole rock.

This study presents new measurements of Fe^{3+} in garnet, olivine, clinopyroxene and orthopyroxene of a mantle-derived garnet peridotite from Donghai County, the southeastern end of the Sulu ultrahigh pressure terrane. These rocks correspond to a slice of supra-subduction lithospheric mantle wedge, tectonically emplaced into the crust. They record a multistage metasomatism by an alkali-rich silicate melt at high temperature, and a subsequent influx of a slab-derived incompatible element and silicate-rich fluid during the Triassic UHP metamorphism. We employed two

"unconventional" techniques to measure the $Fe^{3+}/\Sigma Fe$ content of mineral phases with high spatial resolution: (i) the Flank Method electron microprobe analyses for garnet, performing for the first time quantitative Fe_2O_3 map analyses on zoned garnets at the University of Milano, and (ii) the electron energy loss spectroscopy (EELS) for garnet, olivine and pyroxenes, at the Bayerisches Geoinstitut.

The results indicate that the pyrope-rich metasomatic garnets present a chemical zoning, with the complementary decrease in Al_2O_3 from ~26 to ~21 wt%, relative to the increase of Fe_2O_3 from ~0.8 to ~2.5 wt%. Such a trend is likely related to the Fe^{3+} -Al substitution in the garnet octahedral site, which is sensitive to the garnet oxidation state.

Clinopyroxenes are diopside in composition, whereas olivine and orthopyroxene have ~92 mol% of forsterite and enstatite, respectively. The EELS measurements show that clinopyroxene contains relatively high

$Fe^{3+}/\Sigma Fe$ ratios and Na contents, ranging from 0.48 to 0.51 and from 0.13 to 0.17 a.p.f.u., respectively. Interestingly, also orthopyroxene may

contain $Fe^{3+}/\Sigma Fe$ up to 0.10 (± 0.05), a percentage comparable to that of garnet, with important consequences in the study of redox processes in mantle rocks and in the application of many geothermometers.

Garnet/clinopyroxene and orthopyroxene/clinopyroxene qualitative partitioning indicates a minimum partitioning of Fe^{3+} from clinopyroxene to garnet. The enrichment in Fe^{3+} of Ca-clinopyroxene requires the incorporation of a $NaFe_3Si_2O_6$ (aegerine) component, particularly in garnet peridotites where the Al content of clinopyroxene is buffered by its coexistence with garnet. The coupled Na- Fe^{3+} enrichment of our clinopyroxene likely suggests a corresponding enrichment in the whole rock. The Fe^{3+} substitution mechanism into clinopyroxene as aegerine component could be therefore favoured by the influx of alkali-rich metasomatic fluid phases. This suggests that a possible net bulk oxidation and the redistribution of Fe^{3+} between garnet and pyroxenes could depend on additional variables besides temperature and pressure. Such mechanisms open new possibilities to unravel the redox processes occurring in the portion of mantle wedge interfacing the subducting slab, which is a key location where the mantle redox reactions likely occur.

SUBSOLIDUS PHASE RELATIONS IN K-BEARING PERIDOTITE SATURATED WITH COH FLUIDS

TUMIATI Simone¹, POLI Stefano¹, FUMAGALLI Patrizia¹

1 - Dip. Sc. Terra, Università di Milano, via Botticelli 23, Milano

Presenter e-mail: simone.tumiati@unimi.it

Key terms: *COH fluids; carbonates; high pressure; experimental petrology*

The mantle wedge overlying a subducting slab in the sub-arc region is fluxed by aqueous fluids originating from the dehydration of the downgoing oceanic lithosphere, previously hydrated, and its sedimentary cover. These fluids, enriched in large ion lithophile, can promote the crystallization of hydrous minerals in mantle-wedge peridotite, especially amphibole and phlogopite. Several authors stressed the importance of carbon, released from the subducting slab (e.g., carbonate-bearing sediments, ophiocarbonates), which can modify the composition of the slab-related fluid and thus its capability of transferring masses to the mantle wedge. In particular, COH fluids obviously influence the coexistence of hydrous minerals, carbonates and elemental carbon (graphite/diamond) in the mantle wedge. However, experimental data concerning relatively complex peridotite compositions are restricted to date to the two studies of Olafsson & Eggler (1983) and Wallace & Green (1988), who described subsolidus phase relations that are profoundly mismatched.

We carried out experiments in the system KNCMAS+COH at $P=1.6-3.2 \text{ GPa}$, $T=900-1050^\circ\text{C}$, $fO_2=NNO$, under fluid saturated conditions. The starting bulk composition is that of a spinel lherzolite -30% olivine (ol) + 5% phlogopite (phl) (cf. Konzett & Ulmer, 1999), which represents a metasomatized peridotite. Seeded gels were loaded in a piston-cylinder apparatus using conventional double capsule technique. GCOH fluids have been generated by addition of 10 wt.% oxalic acid dihydrate and excess graphite. Following thermodynamic modeling, we expect binary H₂O-CO₂ fluids characterized by intermediate XCO₂ and X(O).

Phlogopite is ubiquitous. The stable carbonates are dolomite (dol) at low P (1.6 GPa at 950°C), magnesite (mag) at high-P conditions (2.6 GPa at 900°C). We observe in between a region where both mag and dol are stable. In this region, an increase in T up to 1060°C at 2.6 GPa induces the melting of the system, producing magnesite-carbonates. Carbonate-out occurs for $P < 1.8 \text{ GPa}$ and T around 1000°C, leaving an assemblage composed of ol + orthopyroxene (opx) + clinopyroxene (cpx) + garnet (grt) + amphibole (amph) + phl. In this region, melting occurs at 1075°C producing trachyandesite.

Amph stability field extends up to 3 GPa at 900°C and 2.6 GPa at 1040°C. By increasing P, mass-balance calculations suggest that amph-breakdown reaction produces cpx and grt. Despite amph breakdown, the COH fluid phase decreases its abundance with increasing P, because fluid at fh2 NNO changes its composition from XCO₂=0.65 at 1.6 GPa, 1000°C to XCO₂=0.1 at 3.2 GPa, 900°C.

Cpx does not occur in equilibrium with amph+dol for $P < 2.3$. Chemographic analysis suggests that the absence of cpx in dol-bearing, low-P lherzolite is expected at COH-fluid saturation, i.e. at fluid-present conditions. In mag-bearing, high-P lherzolites, ol can be consumed entirely by COH fluids, through the reaction $ol + CO_2 = en + mag$, leaving an assemblage composed of opx + mag + cpx + amph + grt + phl. Indeed, we observe a marked decrease in ol abundance, especially in experiments where both dol + mag occur.

In conclusion, the presented experimental data constrain the mineral assemblages expected at different P-T conditions in mantle-wedge lherzolites fluxed by K-bearing H₂O-CO₂ fluids. From the slab at around 100 km depth upwards the inner mantle wedge at about 50 km depth, we expect first mag+amph, followed by mag+dol+amph, then dol+amph and finally fluid+amph assemblages

Key terms: *mantle peridotites; MORB mantle heterogeneity; pyroxenites; isotope geochemistry; melt-peridotite interaction*

The occurrence of mafic layers in peridotites constitutes an important compositional heterogeneity in the mantle, and their role in mantle melting and basalt generation is currently debated (e.g. Hirschmann &

Stolper, 1996; Salters & Dick, 2002). Pyroxene-rich lithologies are commonly documented in subcontinental lithospheric mantle, from both tectonically-emplaced ultramafic massifs and mantle xenoliths (e.g. Downes, 2007), and rarely sampled in abyssal peridotites (e.g. Warren et al., 2009). They are mostly interpreted as high-pressure magmatic products and rarely as remnants of recycled oceanic crust. However, the origin and composition of such lithologies, and their potential role in creating small-scale heterogeneities in the MORB mantle remain still poorly constrained. In this study, we present field, chemical and isotopic data on pyroxenites and host peridotites from some peridotite massifs of the External Liguride ophiolitic Units (Northern Apennines, Italy) with the aim to widen the knowledge on the origin of pyroxenites in MORB-type settings and discuss the occurrence and extent of chemical and isotopic heterogeneities in the MORB mantle related to the pyroxenitic component. At this latter purpose, pyroxenites and host peridotites have been accurately sampled from single dm-scale profiles, in order to test whether the existence of lithologic heterogeneities in the mantle in turn reflects the occurrence of isotopic contrasts at the small scale. Pyroxenites occur as cm-thick bands (up to 12 cm) parallel to the tectonite mantle foliation and vary from spinel-bearing websterite to clinopyroxenite. As the host peridotites, they are partially recrystallized at plagioclase-facies conditions. The occurrence of orthopyroxene-rich rim between pyroxenite and peridotite and large poikilitic orthopyroxene in the wall-rock peridotites indicate that host peridotites have interacted with melts related to pyroxenite intrusion. These latter display very heterogeneous whole-rock chemistry, almost covering the entire compositional range defined by worldwide lithospheric pyroxenites ($X_{\text{Mg}} = 74-88$, $\text{Al}_2\text{O}_3 = 10-17$ wt%, $\text{CaO} = 7-20$ wt%). The pyroxenite chemistry reflects high-pressure magma segregation of tholeiitic melts dominated by clinopyroxene crystallization. Both mineral and bulk-rock compositions from peridotite-pyroxenite traverses reveal that the host peridotites have been significantly modified in terms of major (e.g. X_{Mg} , Al_2O_3 , CaO) and trace element (e.g. the LREE) composition by the interaction with pyroxenite component. A multi-step, sequential leaching procedure on clinopyroxene separates enables us to remove partial contamination and provides reliable Sr isotope data. The Sr and Nd compositions of clinopyroxenes from pyroxenites and peridotites fall in the typical range of normal MORB ($^{87}\text{Sr}/^{86}\text{Sr} = 0.7023-0.7029$; $^{143}\text{Nd}/^{142}\text{Nd} = 0.5134-0.5128$). Internal Sm-Nd isochrons based on plagioclase, clinopyroxene and whole-rock from several pyroxenite samples yield ages ranging from 174 to 183 Ma (with errors between $\pm 11-25$) for the low-P mantle exhumation. On a slightly larger spatial scale, isotopic profiles through the pyroxenite-peridotite boundaries indicate cm-scale modification of the wall-rock peridotite, presumably related to emplacement of the pyroxenites. This suggests that deep melt intrusion can locally modify the host peridotites and introduce small scale compositional heterogeneity in a MORB mantle.

EVIDENCES OF MELT-ROCK INTERACTION ON THE PETROGENESIS OF WEHLITES FROM SORKHBAND ULTRAMAFIC COMPLEX, SOUTHERN KERMAN, IRAN: CONSTRAINTS ON MINERAL AND WHOLE ROCK CHEMISTRY

NAJAFZADEH Alireza¹, ARVIN Mohsen², AHMADIPOUR Hamid², PAN Yuanming³

Presenter e-mail: najafar@yahoo.com

Key terms: petrogenesis; wehrlites; melt-rock interaction; Sorkhband ultramafic complex; Iran

The Ordovician Sorkhband ultramafic complex lies in the southern Kerman Province of Iran. The wedge shape complex covers an area of more than 100 km² and is divided into lower and upper parts. The former comprises of dunite, podiform chromitite deposits (Faryab mine, largest in Iran), massive and dyke like olivine clinopyroxenite, wehrlite (as bands with width of 0.5-5m and a few meters long) and olivine websterite dykes. The upper part consist of foliated porphyroclastic diopside harzburgite with subordinate lenses and dykes of dunite, massive and dyke like olivine clinopyroxenite and minor orthopyroxenite dykes with no significant chromitite mineralization.

According to petrographical studies, wehrlites show granular textures with variable modal composition which consist mainly of 40-70% olivine (Fo90-91), 20-50% diopside clinopyroxene, 1-10% bronzitic orthopyroxene and <1% chromite (Cr# = 65-67, Mg# = 44-46). Some olivine minerals show evidences of recrystallization as triple junction with other minerals, deformation lamellae along its slip planes, mini kinking and irregular extinction band configurations, whereas clinopyroxene minerals are deformed and often exhibit exsolution lamellae of orthopyroxene.

Mineral chemistry of olivine, clinopyroxene, orthopyroxene, and chromites in wehrlites are similar to olivine clinopyroxenites and reveal a mantle origin for the Sorkhband ultramafic complex. Moreover, chondrite normalized rare-earth element (REE) patterns of wehrlites show flat medium REE (MREE) and heavy REE (HREE) patterns, [(Gd/Yb)N ~ 1], and highly light REE (LREE) depletions similar to olivine clinopyroxenite patterns. Furthermore, platinum group element (PGE) show highly differentiated pattern in wehrlites with a positive slope (similar to olivine clinopyroxenites) and high Pd/Ir ratio (36-59).

According to Nicolas and Prinzhofer (1983), wehrlite may be formed by the passage of a melt through dunite bodies where by the process of impregnation and melt-rock interaction clinopyroxene crystallize in dunite. Such impregnated clinopyroxenes are allotriomorphic and interstitially filled between olivine crystals and due to poikilitic crystallization may contain spinel and olivine inclusions. Other evidences of melt-rock interaction in the Sorkhband ultramafic complex have been reported before (Najafzadeh et al., 2009, 2010).

So, regarding the mineral chemistry; REE, PGE and transition elements (TE) patterns similarity in between wehrlites and olivine clinopyroxenites in the Sorkhband ultramafic complex it can be concluded that wehrlites are most likely formed by interaction of pyroxenite melt with dunites as a result of impregnation and melt-rock interaction.

Key terms: Melt-peridotite reaction; Igneous sapphirine; Finero complex

Sapphirine is generally interpreted to be of metamorphic origin in high Mg-Al rocks. Igneous sapphirine, i.e. sapphirine crystallized from melt, is very rare. We examined sapphirine-bearing rocks in the Finero Phlogopite-Peridotite Massif, Western Italian Alps, to investigate a possible igneous origin for sapphirine in a melt modified via melt-peridotite interaction. Sapphirine locally occurs in a melanocratic zone between a leucogabbroic vein and the host peridotite. The leucogabbroic vein cuts the foliation and lithologic layering of the peridotite massif, which is defined by alternating phlogopite-rich harzburgites and pyroxenites, indicating that its emplacement occurred after the main metasomatic events in the massif. Melanocratic seams are observed on both sides of the leucogabbroic vein. These mainly consist of orthopyroxene and amphibole, and show a marked zoning in modal compositions: an orthopyroxene-rich zone overgrown on the host peridotite side (OPX zone), whereas an amphibole-rich zone occurs on the leucogabbroic vein side (AMPH zone). Sapphirine precipitated in the AMPH zone as independent interstitial grains (up to 3 mm long), as independent grains within large amphibole grains or as overgrowth on spinel. The amphiboles with sapphirine inclusions can also enclose spinel crystals that do not have sapphirine envelopes. Amphibole in the sapphirine-free melanocratic zone is more abundant in incompatible elements, such as TiO₂ and K₂O, than that in the gabbroic veins and the OPX zone, excluding the development of diffusion-controlled subsolidus reaction. A pronounced enrichment in Al₂O₃ of the parent hydrous melts is indicated by the composition of the amphiboles and phlogopites of this study that show higher Al₂O₃ than those crystallized by basaltic melts. Mineral assemblages and chemistry in both the melanocratic zone and the host peridotite can be explained by melt-peridotite interactions, which resulted in replacement of peridotite olivine by secondary orthopyroxene in the OPX zone, and by Al₂O₃, TiO₂, FeO enrichments in the host peridotite beyond the recrystallization front. Interactions between peridotite and a hydrous, high Al₂O₃, orthopyroxene-oversaturated, mafic melt related to the formation of the leucogabbroic vein caused the formation of orthopyroxene at the expense of peridotite olivine. This resulted in high MgO/FeO and high Al₂O₃/SiO₂ ratios in a modified melt, allowing for precipitation of igneous sapphirine.

ESTIMATION OF OVERPRESSURE IN ASTHENOSPHERE BASED ON THE THEORY OF THERMOELASTICITY OF SOLIDS

FEDORYSHYN Oleksandr¹

1 - Carpatian Branch of Subbotin Institute of Geophysics of National Academy of Ukraine

Presenter e-mail: ofedoryshyn@mail.lviv.ua

Key terms: thermo-elasticity; fluctuations of strains; partial melting

The substance of the Earth mantle is inhomogeneous. It consists of a lot of components with various properties. Mathematical modelling of such medium is difficult and in order to obtain a complete solution we should be restricted by simple mathematical models. Abnormal properties of mantle substance in the depths of 60-100 km, where asthenosphere is located, are explained by presence of partial melt in it. This work deals with investigation of thermo-elastic properties of a two-phase material of the Earth mantle. Presence of the internal strains caused by partial melting is shown.

The two-phase statistically inhomogeneous thermoelastic medium consisting of a solid phase and melt is considered. Effective thermoelastic constants for such medium can be found by averaging of the common system of the equations of movement and balance of warm [Shermergor T.D. 1977]. For any mediums the resolving of such problem is impossible, therefore it is necessary to be limited to correlation approach, that is to accept that physical parameters of phases not so strongly differ among themselves. Formulas for effective modules of elasticity, temperature factor of strains and heat conductivity can be defined. We know that when there is no external loading and at uniform heating of the homogeneous medium there is no strain. In this case average strains in the heterogeneous medium equals to zero. However, fluctuations of strains will not be equal to zero, because the thermal stress coefficients in phases are various. That is why it is interesting to find the mean-square fluctuations of deformations and strains. These fluctuations will be equal

$$\langle \sigma'^2 \rangle = 9K^2 \langle \epsilon'^2 \rangle; \langle \epsilon'^2 \rangle = M_\beta (T - T_0)^2.$$

Here σ' and ϵ' are fluctuations of strains and deformations accordingly, K is the effective bulk module, M is average quadratic fluctuation of thermal expansions coefficient, T_0 is the initial temperature. Angular brackets indicate averaging on ensemble.

The substance of the Earth's mantle does not have a definite temperature of melting. According to the experimental data there is a region of melting. At T_{sol} temperature it starts melting (solidus), and at T_{liq} temperature it melts completely (liquidus). Temperatures of solidus and

liquidus are not constants and depend on pressure and thus on depth too (Magnitskiy V. A. 1965). We shall accept for simplicity linear dependence of quantity of the melted material on temperature, that is $c_m = (T - T_{m0}) / (T_{m1} - T_{m0})$, $c_{li} = (T - T_{m0}) / (T_{m1} - T_{m0})$, c_{cr} and c_{sol} are volumetric concentrations of liquid and solid phase in partial melt ($c_{cr} + c_{sol} = 1$). Melt is a phase transform of the first sort. At phase transforms of the first sort the first derivative of internal energy varies step-like. Thus, process of melting can be modelled as step-like variation of the elasticity modules and the heat expansion coefficient caused by temperature changes. Now we can define strains which result in partial melt by means of resulted above formulas. In order to analyse the dependence of magmatism on deformations it is of interest to estimate the appearance of internal strains as a result of partial melting. Dependence of internal strain on temperature will be in the following form

$$\langle \sigma \rangle = 3K \sqrt{M\beta} (T - T_0).$$

As we can see the rise of temperature of the medium by a few degrees leads to appearance of additional strain which is comparable to geostatic pressure.

Key terms: cathodoluminescence; UHP; impure marbles; SEM-EDS; microraman

Impure calcite-dolomite marbles from the ultra-high pressure (UHP) Brossasco-Isasca Unit (BIU) of the Dora-Maira Massif (Western Alps) are studied under cathodoluminescence (CL), petrographic microscope, and SEM-EDS. Most of the polymetamorphic (Variscan and Alpine) evolution of these marbles has been already reconstructed mainly by silicate minerals, whereas the local variability in microstructure and mineral assemblages of carbonate minerals are still unconstrained.

Under petrographic microscope, the studied impure calcite-dolomite marbles are medium- to coarse-grained, locally with a weak foliation defined by: i) phengite or Mg-chlorite wrapping around both porphyroclastic dolomite and clinopyroxene; ii) alignment of neoblastic clinopyroxene and garnet; iii) silicate-rich layers. Different relative amounts, kinds and compositions of silicate minerals are present. Early mineral assemblages include garnet, clinopyroxene, phengite, olivine, talc, and rutile, and late mineral assemblages include epidote s.l., Ca-amphibole, phlogopite, chlorite, serpentine, talc and titanite. Rare quartz and accessory zircon are also observed.

Dolomite is strongly zoned under CL and SEM, mainly because of variations in Ca, Mg and Fe contents. The locally zoned dolomite core is most likely a Variscan relic which may include garnet, diopside and rare ilmenite. The locally zoned dolomite rim, which partly corrodes the pre-Alpine core, is interpreted as a product of the Alpine metamorphism. In some samples, the outermost rim locally includes Ca-amphibole, phlogopite and titanite. In one sample, late dolomite, in equilibrium with serpentine, partly overgrows olivine.

The rock matrix is constituted by weakly-deformed medium-grained Mg-calcite that partly corrodes dolomite. In rare samples, exsolved dolomite is present within Mg-calcite. CL observations reveal that Mg-calcite is usually zoned with a rim composition variable from sample to sample. Rare, undeformed and fine-grained (Mg)-calcite is locally present at the grain boundaries.

In conclusion, microstructures in carbonates from the BIU marbles are complex such as that shown in the associated silicate minerals. Because in impure marbles both carbonate and silicate minerals record the same growth history under CL, this is a simple but powerful tool to correlate the evolution of the two groups of minerals. Therefore, the use of CL in studies on metacarbonate rocks allows to better constrain their PTX metamorphic conditions because it is suitable for a more detailed evaluation of the equilibrium mineral assemblages.

BORON ISOTOPE STUDY OF MAGMATIC-HYDROTHERMAL TOURMALINES FROM BIELLA AND TRAVERSSELLA PLUTONIC COMPLEXES (PERIADRIATIC IGNEOUS PROVINCE, WESTERN ITALIAN ALPS)

CASTELLI Daniele¹, DINI Andrea², ROSSETTI Piergiorgio¹

Key terms: Boron isotopes; Tourmaline; Periadriatic Igneous Province; Western Alps

The Biella pluton is part of an Oligocene volcano-plutonic complex emplaced at shallow crustal levels within the eclogite-facies rocks of the Austroalpine Sesia-Lanzo Zone. It is a composite stock of calc-alkaline to shoshonitic affinity ranging in composition from monzogranite-granodiorite to syenite and monzonite. Volcanic to volcanoclastic sequences coeval to the Biella stock occur as a steeply dipping belt truncated, to the southeast, by the Insubric Lineament; they range in composition from basaltic andesite and andesite of high-K calc-alkaline affinity to trachyandesite and trachydacite of shoshonitic affinity. Palaeomagnetic, geological and petrological data show that both the Oligocene igneous rocks and the Sesia-Lanzo country-rocks suffered a clockwise (towards southeast) tilting, along a NE-SW trending subhorizontal axis, during late Tertiary; as a consequence, along both the Cervo and Sessera valleys

crustal sections, from deeper (to the NW) to shallower (to the SE) levels are exposed (Bernardelli et al., 2000; Callegari et al., 2004; with refs.). The Traversella stock, coeval with the Biella complex, is also intruded in the Sesia-Lanzo Zone and is mostly composed of diorite to quartz-diorite and monzonite of high-K calc-alkaline affinity, with some mafic cumulates showing shoshonitic affinity (Vander Auwera & Andre, 1991, with refs.). Both plutons record a complex history of magmatic-related fluid circulation that often involves boron-rich fluids as shown by the occurrence of abundant tourmaline.

Within and around the Biella pluton tourmaline occurs (Bernardelli et al., 2000; Rossetti et al., 2007):

- as a late-magmatic phase in aplitic dykes in the monzosyenite and as Pl + Qtz + Tr + Tur orbicules in satellite magmatic bodies;
- in early Kfs + Qtz + Tur hydrothermal veins;
- as Tur ± Qtz ± Ru clasts, locally surrounded by Qtz + Tur, embedded by Qtz ± carbonate matrix in brecciated veins and breccias;
- as very fine-grained tourmalinite (Tur ± Qtz ± Py) clasts in a Qtz + Py + Cpy hydrothermal matrix in brecciated veins;
- as radial aggregates of cm-long, acicular crystals in the matrix of a large hydrothermal breccia body at roof of the pluton;
- as a product of metasomatic replacement of phengite and garnet in metapelites from the Sesia-Lanzo Zone in hydrothermal breccias close to the pluton contact.

At Traversella, the occurrence of dolomite marble lenses in the host rock favored the development of complex skarn bodies (mined for magnetite: Vander Auwera & Andre, 1991, with refs.). Tourmaline occurs:

- as a late-magmatic phase in aplitic dykes crosscutting quartz-diorite;
- within the skarn bodies (which locally contain abundant boron-bearing phases other than tourmaline: e.g., ludwigite, szaibelyite and low-T, secondary phases, like canavesite).

Boron isotopes represent a powerful systematic in tracing the origin of volatile elements in magmatic-hydrothermal systems and the extent of water/rock interactions occurred (e.g. Palmer & Swihart, 1996). In this study, boron isotope compositions of tourmaline from magmatic to hydrothermal/metasomatic settings have been determined. The new boron isotope data coupled with chemical features of tourmalines (Rossetti et al., 2007) provide new constraints on the evolution of fluid chemistry during the magmatic-hydrothermal transition at the interface between pluton and host rocks. Availability of couples of minerals from similar settings in Biella and Traversella intrusions as well as the occurrence of different boron-bearing minerals (tourmaline and ludwigite) allow the discussion of boron isotope fractionation behaviour in a high temperature setting.

Key terms: rhyolite; hydrothermal weathering; kaolin deposit; Roccastrada

Roccastrada rhyolites are pliocene volcanic weathering of crustal anatectic origin; they represent the most acid product of the Toscan Magmatic Province. A kaolin deposit, derived from hydrothermal weathering of the Roccastrada rhyolites, formed near Piloni di Torriella (GR, southern Tuscany). The raw material is currently mined for the ceramic industry. Hydrothermal fluids caused significant changes of the mineralogical and textural properties of the primary rock as well as changes of the bulk rock composition. The deposit is heterogeneous due to different weathering extents of the rhyolites so that lithologies ranging from poorly weathered to strongly weathered rhyolites and kaolin outcrop in the mining area. The aim of this work is to classify the different materials outcropping in the deposit and to show their location on a map. Samples have been analyzed by XRF, polarised light optical microscope and SEM-EDS techniques so that field observations can be sustained and correlated with laboratory test, in order to show the effects of different extents of weathering on rhyolites at both macroscopic and microscopic scale. XRF tests show that different lithologies have different bulk rock compositions: as a consequence of kaolinization, Al₂O₃ contents and LOI values (wt.%) increase with the weathering extent, while SiO₂, K₂O, CaO and Na₂O (Wt.%) decrease, often giving rise to nearly pure kaolinitic materials of great interest for exploitation. Locally, high S concentration are found, especially in strongly weathered rocks: S is unwelcome in ceramics and the definition of the location of S-enriched materials in the deposit is fundamental during exploitation.

Investigations by optical and electronic microscope show how weathering affects both the texture and the mineralogy of the primary rocks and allows the reconstruction of a weathering sequence: primary plagioclase is substituted by kaolinitic aggregates, amorphous silica and, locally, alunite in poorly weathered rhyolites. In weathered and strongly weathered rocks also glass and alkali-feldspar are substituted by these pseudomorphic assemblages. Biotite can occur either preserved or totally substituted by pseudomorphic aggregates similar to those described above. Weathering of biotite consists of progressive leaching of Fe, Mg and Ti which, due to low mobility in water solutions, form hydroxides and oxides in the neighbouring groundmass.

The extent of weathering and the amount of kaolinite and alunite are extremely variable all over the deposit: hydrothermal fluids with different compositions circulated through the deposit, causing different weathering products to form.

GEOCHEMICAL FEATURES OF TWO ROCK TYPES IN THE LOWER BASIC CRUST OF THE SERRE (CALABRIA): A PRELIMINARY

STUDY.

MUSCHITIELLO Annalisa¹, FORNELLI Annamaria¹, MICHELETTI Francesca¹
 1 - Dipartimento Geomineralogico, Bari University
 Presenter e-mail: annalisa.muschitiello@uniba.it

Key terms: Calabria; basic rocks; lower crust; geochemistry

In the Serre massif (southern Calabria, Italy) a Variscan crust section crops out consisting of: i) a middle- to low-grade metamorphic rocks in the upper segment, ii) an about 13 km thick "layer" of granitoids and iii) 7-8 km thick lower crust. The deep crust forms the lower part of the section and includes from the bottom to the top: a) layered metagabbros including meta-peridotites; b) felsic and mafic granulites with interleaved metapelites; c) migmatitic metapelites with interleaved metabasites, rare marbles and felsic orthogneisses.

The aim of this study is to characterize the geochemistry and the evolution of the Neoproterozoic to Early Cambrian basic magmatism represented by metagabbros and metabasites.

The reconstruction of the geodynamic setting in which the basic magmas were emplacement could allow a better understanding of the tectonic evolution of the peri-Gondwana terranes having memory of the West African craton.

The effects of the Hercynian metamorphism have modified the mineralogical assemblage and, in some case, have induced partial melting modifying the original compositions.

Petrographic and geochemical (major and trace elements) analyses have been performed on ~20 samples collected at the base of the deep crust in the gabbroic portion. Two groups of basic rocks have been defined on the basis of the petrographic features. The first group characterized by coarse grained and isotropic texture, consists of gabbros and Qtz-gabbro containing Pl+Opx+Cpx+Amph±Qtz±Grt, rare crystals of biotite can be also present. Frequently, amphibolites with green or brown hornblende form thick layers. On the other hand leucocratic portions showing trondhjemitic composition are interspersed within the main gabbroic body. The second group is characterized by a medium grained and anisotropic texture formed by Pl+Opx+Bt+k-feld±Cpx±Qtz±Grt. Peculiar characteristics of this rock-type are the abundance of biotite and the presence of pockets of granitic melts having eutectic composition. In both groups, few porphyroblastic garnet crystals occur including amphibole, pyroxene, plagioclase, ± biotite and ± quartz. Frequently, garnet crystals are rimmed by Opx+Pl+Amph or Amph+Pl symplectitic corona in biotite free-rock types or by Bt+Pl±Qtz symplectitic corona in biotite bearing-rock types.

The two groups of rocks have variable chemical compositions owing to the variability of their components. The former are subalkaline rocks (Na₂O+K₂O=1.17-4.84%) with a content of K₂O around 0.47%, whereas the latter are alkaline rocks (Na₂O+K₂O=4.88-6.77%) with a content of K₂O around 3.9%.

The metagabbros show lower Rb, Sr and Nb contents (Rb=0-12 ppm; Sr=68-592 ppm; Nb=0.5-13 ppm) than the Bt-bearing metabasites (Rb=10-210 ppm; Sr=389-1044 ppm; Nb=8-25 ppm).

The contents of the other major elements are quite similar despite varying in a large range (SiO₂=41.53-60.38% vs. 45.75-51.16%; Al₂O₃=14.71-20.75% vs. 14.72-19.48%; FeO=6.29-13.99% vs. 8.13-12.54%; MgO= 2.59-9.84% vs. 4.72-7.99%; CaO=6.82-15.49% vs. 5.73-8.96%) for the presence of cumulitic portions and of differentiated rock type, in addition the Variscan partial melting events complicate the chemical variability. The first data (ACF and A'KF diagrams) indicate a common origin from basic magmas for the two rock types so the alkali enrichment for biotite bearing-rocks can be connected with host rock interaction or due to permeation of melts derived from wall rocks in Variscan times.

Different hypotheses about the origin and evolution of metabasic rocks of the Serre, can be proposed.

Presenter e-mail: daifmenana@yahoo.fr

Key terms: Algeria; Miocene; Petrology; genesis

Miocene andesites are part of an igneous series that outcrops in the Northeast of Algeria and that belongs to Maghreb's magmatic margin belt. This series includes volcanic, subvolcanic and plutonic rocks. On the basis of their nature and their field relationship, rocks have been divided into four main groups: andesites, microgranites, rhyolites and diorites.

Andesitic-group covers around 25 Km² and presents a wide range of colour, texture and structure. Four facies are distinguished: andesites (stricto-sensu), dacites, discrete amounts of rhyolites and strongly rare basalts. Pyroclastic andesites are widespread and characterized by their poor sorting producing various breccias. Massive andesites are essentially composed of flow, and some pillow-lavas. In spite of this huge heterogeneity, andesites are intimately related to each other in time, space, mineralogy and chemical nature. They have a constant and particular paragenesis: olivine is lacking, orthopyroxene is restricted to basic andesites which are less common whereas plagioclases, clinopyroxenes and hydrous minerals are abundant; titanomagnetite, ilmenite and sphene are also present in small quantities.

The salient geochemical characteristics of these rocks are high SiO₂, K₂O, Rb and low FeO, MgO, CaO, Ba and Sr. They also show enrichment in light Rare Earth Elements (REE) and depletion in heavy REE. Whole rock 87Sr/86Sr ratios are high and unequal (from 0.707 to 0.710). All these characteristics testify that investigated andesites are mostly acid, medium to strongly potassic and are typical of calc-alkaline suites of continental margins.

The genesis of this series, previously considered as complex because difficult to explain according to an usual subduction process, has been partly resolved late years by some models as that proposed by Maury et al. (2000). The main purpose of this contribution is to point out particular geological features dealing with this genesis.

MODELING VOLCANIC ASH TRANSPORT AND DEPOSITION

MACEDONIO Giovanni¹

1 - Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Vesuviano, Napoli, Italy

Presenter e-mail: macedonio@ov.ingv.it

Key terms: volcanic ash fallout; numerical modeling; volcanic hazard

Volcanic ash fallout can be responsible for severe damages to buildings, infrastructures, viability, agriculture, livestock and air traffic. Numerical models are available for the simulation of transport and deposition of volcanic ash emitted during explosive eruptions, allowing short-term forecasts. Actual models are able to capture the main processes related to the transport of volcanic plumes, including advection by the wind, spreading due to atmospheric turbulence, particles settling and aggregation. Moreover, statistical analysis based on meteorological records, field observations and modeling allows the estimation of the probability of occurrence of different fallout scenarios in a given area, to be used for long-term analysis.

In this talk, both methods for forecasting the evolution of volcanic plumes and for producing hazard maps for ash fallout are presented. In the former case, the forecast wind field and other meteorological parameters, coupled with observations and measurements of the volcanic plume or pre-defined eruption scenarios, are used for forecasting the evolution of the concentration of ash in the atmosphere and the thickness of the deposit. In the latter, a large dataset of daily wind velocity averages (typically 10-50 years) is used to simulate the ash dispersal under different wind and volcanic conditions. The obtained maps show different frequencies of occurrence of ash deposition in different zones and allow the estimation of the probability maps (hazard maps) for volcanic ash fallout. Typically, these procedures start with the reconstruction of the eruption parameters able to reproduce past deposits (total mass, grain size distribution, column height, wind velocity, etc.). This task is performed through a best fit of the model parameters with field measurements and leads to the definition of one or more eruption scenarios. This procedure needs the simulation of the ash fall deposit under different input and environmental conditions and is typically very time consuming. For this, simplified ash dispersal models were used in the past for best-fits and statistical analysis. The use of powerful computers may circumvent this difficulty.

LIDAR MONITORING OF VOLCANIC CLOUDS

FIORANI Luca¹, COLAO Francesco¹, PALUCCI Antonio¹

1 - ENEA, UTAPRAD-DIM

Presenter e-mail: luca.fiorani@enea.it

Key terms: laser remote sensing; environmental monitoring; backscattering lidar; volcanic ashes; air transportation

The threat to air transportation represented by volcanic ashes has been recognized after the dramatic events of British Airways Flight 9 on 24 June 1982. More recently, the Eyjafjallajökull's eruption caused substantial disruption to air traffic across Europe. This problem is also present in Italy where the Catania airport undergoes frequent stops due to Etna's plume.

In the last decade the Diagnostics and Metrology Laboratory (UTAPRAD-DIM) of the Italian National Agency for New Technologies, Energy and Sustainable Economic Development (ENEA) developed the Agile Tuner Lidar for Atmospheric Sensing (ATLAS), mounted on the Environmental Laboratory (ENVILAB) hosted in a small truck. ATLAS can be decomposed in four subsystems: transmitter, receiver, detector and ADC (Analog-to-Digital Converter). The main parts of the transmitter are a tunable TEA (Transverse Excited Atmospheric) CO₂ laser and an off-axis reflective beam expander consisting of two OFHC (Oxygen-Free High Conductivity) copper mirrors manufactured in our laboratory. The laser is tunable thanks to the agile tuner consisting of a diffraction grating and a scanning mirror actuated by a computer-controlled galvo motor. The receiver is based on a Newton telescope. A liquid-nitrogen-cooled mercury-cadmium-telluride photodiode, coupled with a pre-amplifier designed to complement it, has been chosen as detector. The ADC is embedded in a PCI (Peripheral Component Interconnect) card mounted in the personal computer that controls the experiment.

In this paper, the monitoring capabilities of ATLAS in the frame of air safety will be discussed. ATLAS already characterized the Etna and Stromboli volcanic plumes. At Etna, the extinction coefficient inside the volcanic plume was retrieved, while at Stromboli also water vapor concentration in cross sections of the plume and wind speed at the crater were measured. Water vapor concentration and wind speed were retrieved by differential absorption lidar and correlation technique, respectively. Lidar returns were obtained up to a range of 5 km. The spatial resolution was 15 m and the temporal resolution was 20 s. By combining these measurements, the water vapor flux in the Stromboli volcano plume was found. To our knowledge, it is the first time that a CO₂ laser-based lidar is used to profile a volcanic plume and a lidar retrieves water vapor concentrations in a volcanic plume.

UNRAVELLING RADON EMISSION FROM ROCK DAMAGE MECHANISMS: NEW LABORATORY INSIGHTS

TUCCIMEI Paola¹, SOLIGO Michele¹, CASTELLUCCIO Mauro¹, SCARLATO Piergiorgio², MOLLO Silvio², PIZZINO Luca², VINCIGUERRA Sergio²

1 - Università "Roma Tre"

2 - Istituto Nazionale di Geofisica e Vulcanologia, Roma

Presenter e-mail: tuccimei@uniroma3.it

Key terms: radon emission; toron; rock deformation; seismic surveillance; laboratory experiments

Positive radon anomalies are commonly used as a tool to predict dynamic failure in the crust, as stated by the widely-used dilatancy model for earthquake prediction. The model foresees that the formation and propagation of cracks prior to rupture will serve to create new surface area and hence increase radon emanation. However, this simplified picture is not only occasionally contradicted by negative radon anomalies, but sometimes negative anomalies are measured at the seismic source, whilst contemporaneous positive anomalies are recorded at monitoring stations located hundreds of kilometres away. Mysteriously, alternating increases and decreases or no significant variations have also been recorded. Hence, despite early promise, radon emanation does not appear to be a very compelling warning signal and many questions remain unresolved. Although numerous studies have investigated field radon emanation from rocks under natural stress conditions, only few have attempted to experimentally relate rock deformation with radon change. Here we present, for the first time to our knowledge, an original experimental set-up consisting of a new accumulation chamber made of a drypack material, a polyester-aluminum-polyethylene bag, containing the rock specimen and connected in a closed-loop configuration to the RAD 7. The drypack-chamber is loaded under a uniaxial press, without being damaged during rock deformation. Radon gas concentration emitted from the samples is simultaneously and continuously monitored by the system; therefore, the originality of the experiments consists in a real time monitoring of radon emission changes during the whole process of rock deformation. Additionally, the drypack-chamber is surrounded by a heating belt that allows us to investigate the effect of high temperature conditions (up to 90 °C) on radon emission. It needs to be stressed that the radonometer is alpha-spectrometry based and is able to measure simultaneously ²²²Rn (radon) and ²²⁰Rn (thoron) activity concentrations. The great advantage of determining thoron is the possibility of recording any activity change in the closed system within the length of a single run cycle (30 minutes), due to the short half-life of ²²⁰Rn (55.6 seconds) that reaches any new equilibrium conditions in about 5 minutes. Results demonstrate that radon exhalation from the rock specimen drastically increases with increasing the experimental temperature. This finding allows us to discriminate low variations in radon emissions when rock samples are uniaxially loaded under the press. Uniaxial compressive tests performed on highly porous (47 %) volcanic tuff from Vico Volcanic District (central Italy) shows that the radon emission decreases with increasing load. Such a variation is proportional to a reduction of porosity associated with the compaction of the tuff sample. When the specimen fails, a drastic increase of emission is verified. Moreover, long-term experiments (in the order of weeks) performed by maintaining a constant load on the tuff specimen show that the deformation increases with time. The radon signal coherently continues to decrease up to the complete closure of pores. At that point, a further increase of load does not induce any additional compaction and any radon emission change, with a constant exhalation up to the failure. This has strong implications in the field of radon anomalies prior to earthquakes, showing that the seismic event can be preceded by no significant radon anomalies, as already documented in literature. Our experimental investigation sheds light on several apparently contradictory signals recorded by radon monitoring stations near active faults and volcanoes. Results demonstrate that emanation rate is governed by the prevalent deformation mechanism. In terms of seismic and volcanic hazard, the deformation mechanism of rocks under stresses should be carefully considered to properly interpret data from geochemical field monitoring.

Key terms: Last Interglacial; Speleothems; Stable isotopes; Paleoclimatology; U/Th dating

The last interglacial is the most obvious analogue for understanding the climate variability of interglacial conditions when human impact was virtually absent (even if orbital configuration was not exactly that of the current interglacial). However, few well radiometrically dated records exist for this period (e.g. Bar-Matthews et al., 2000) worldwide. Corchia cave (Apuan Alps, Central Italy) shows a continuous phase of speleothem growth during the period between ca 140 to 90 ka allowing a systematic replication of proxy records from several stalagmites. Stable isotopes (carbon and oxygen) on speleothems calcite from 3 different speleothems obtained with high resolution show very consistent variations and the time series (anchored by more than 100 U/Th dates on exceptionally pure calcite, allowing a mean resolution of less than 50 yr) replicate in detail the most obvious climatic phases recorded in GNIP ice core and marine records (Drysdale et al., 2006, 2009), with the main advantage of an independent, radiometrically-supported chronology. U and Mg trace element records show a consistent anti-correlation, with variation

substantially in phase with the 180 time series, supporting the interpretation that changes in oxygen isotopic composition were mostly driven by changes in the amount of precipitation and trace element variations were driven by prior calcite precipitation linked to changes in residence time of the water within the fractures, as also supported by the geochemical data obtained from different water monitored in different parts of the cave (Piccini et al., 2008). Speleothem growth was severely reduced for most of the late marine isotope stage 5 (MIS5) and MIS3 and 2 (as also supported by several drill cores on flowstone), with significant resumption of speleothem growth at ca 12-13 ka. We suggest that this phase of discontinuous and extremely reduced growth was due to glaciated conditions in the catchment of Corchia cave.

ADSORPTION OF HCL GAS ONTO VOLCANIC ASH

SCHIAVI Federica¹, HUBER Julia², GOLLNER Gertrud², KEPLER Hans²

1 - Università di Pavia

2 - Bayerisches Geoinstitut, University of Bayreuth

Presenter e-mail: federica.schiavi@unipv.it

Key terms: HCl; adsorption; experimental approach; volcanic ash; volcanic eruption

During volcanic activity large quantities of gases and ashes are injected into the troposphere and, in case of major explosive eruptions, into the stratosphere. The injections of considerable amounts of gases (e.g., SO₂ and HCl) into the stratosphere may disturb its chemical equilibrium and affect Earth's climate. In particular, chlorine free radicals, which form by breakdown of gaseous HCl molecules via heterogeneous chemical reactions and photolysis, contributes to the destruction of the ozone layer. However, before reaching the stratosphere a significant fraction of gases may be removed from the eruption column by adsorption onto volcanic ash surface. Thus, experimental investigations of the adsorption process of volcanic gases on ashes at conditions relevant for volcanic plumes become important to estimate the removal of HCl from the atmosphere during eruptive events.

We performed adsorption experiments on a synthetic glass with rhyolitic composition and on natural obsidian collected on Vulcano island (Aeolian Islands, southern Italy). Both synthetic and natural glasses were ground to sub-micrometer sized particles using a planetary mill under dry conditions. The glass powder was stored in a simple volumetric vacuum device, which was purged with pure HCl gas to a desired pressure. Pressure dropping caused by adsorption was recorded by a vacuum gauge until an equilibrium pressure was reached within hours or days. The pressure was increased in six steps from 32 to 932 mbar and from 87 to 957 mbar in the experiments on rhyolitic and obsidian glasses, respectively. The amount of HCl adsorbed on ash surface during each step was then calculated from the recorded pressure drop applying both the ideal gas law and the van-der-Waals equation.

Preliminary results from two experimental runs performed at room temperature on rhyolitic and obsidian glasses, respectively, indicate that adsorption on the order of 1.4 mg/m² and 0.5 mg/m² occurs even at low partial pressures of HCl. The amount of adsorbed HCl appears to depend on the glass composition, and increases rapidly in the first two pressure steps (P ≤ 200 mbar) in both experimental runs. At higher pressures, HCl adsorption on obsidian ashes continues to increase but less rapidly, whereas the adsorption isotherm for the rhyolitic sample reaches a plateau and exhibits a very slight increase at the highest pressure. The forms of the adsorption isotherms provide evidence for both chemical and physical adsorption mechanisms. No significant desorption and a slight desorption are observed in the experiments on rhyolitic and obsidian ashes, respectively. This suggests that the adsorption process of HCl on ash particles is a partially irreversible mechanism that contributes to the removal of volcanic HCl from the atmosphere.

NEW SEISMO-STRATIGRAPHIC DATA ON BURIED VOLCANIC STRUCTURES IN THE SOUTH-EASTERN OFFSHORE OF THE ISCHIA ISLAND (NAPLES BAY, SOUTHERN TYRRHENIAN SEA): IMPLICATIONS FOR THE CAMPANIA VOLCANISM

AIELLO Gemma¹, MARSELLA Ennio¹

1 - Istituto per l'Ambiente Marino Costiero Consiglio Nazionale delle Ricerche Napoli

Presenter e-mail: gemma.aiello@iamc.cnr.it

Key terms: volcanic structures; seismic stratigraphy; Ischia island; Naples Bay; Tyrrhenian sea

Some new seismo-stratigraphic data on buried volcanic structures and Quaternary deposits in the south-eastern offshore of Ischia island (Naples Bay) are here presented. In particular, we focus our presentation on southern continental slope of Ischia island and eastern Ischia offshore, surveyed during the realization of geological maps at the scales 1:25.000 and 1:10.000 (Geological Map n. 464 "Ischia"; Aiello et al. 2009. Explanatory Notes to the Geological Map - Marine Geology, in press.). The geological bodies recognized through seismic interpretation are the volcanic seismic units, acoustically transparent, representing the rocky acoustic basement and the systems tracts of the Late Quaternary depositional sequence. The prevailing volcanic activity, which controlled the stratigraphic setting of the Naples Bay, has prevented the application of a classical stratigraphic approach, taking into account the associations of depositional systems and the interstratified volcanic bodies (volcanites and volcanoclastites). The sequence stratigraphic approach permits recognition and mapping of depositional bodies defined as three-dimensional objects, consequently to their relative stratigraphic position. Complementary stratigraphic information about the nature of the individuated depositional bodies and the geological processes controlling their deposition and preservation is furnished.

Volcanic deposits resulting from effusive and explosive eruptions extensively crop out in the Ischia Island, constructing volcanic edifices; some of them are still well preserved, other ones are completely dismantled or buried. The main geo-volcanologic event is represented by the eruption of the Green Tuff of the Epomeo Mt, conditioning a complex calderic resurgence. It allowed for the gradual uplift and emersion of the calderic rocks with a rate of about 800-1100 m. Corresponding volcanic products crop out along the southern coasts of the island at Mt. Vico, S.

Angelo and Scarrupata di Barano. In the Ischia island the occurrence of intrusions, volcanic domes and necks and tabular seismic units makes more complex the sequence stratigraphic approach in the geological interpretation of seismic profiles. The marine sedimentation includes both the contribution of siliciclastic sediments, alluvial or marine in origin and that of volcanites and volcanoclastites erupted by Ischia and Procida volcanic complexes. While the volcanic bodies are deaf to the acoustic energy, the pyroclastic edifices and/or deposits may be acoustically observed. As a consequence, the seismic stratigraphy offshore the Phlegrean Fields is more complex and difficult to interpret with respect to that one of the eastern sector of the Naples Bay, where sedimentary seismic units prevail, apart from the Dohrn canyon morpho-structural lineament. The sub-actual terrace of the Maronti offshore, coincident with a progradational wedge deposited during the last 5-6 ky should coincide, in terms of geological times, with the Holocene highstand wedge. This is not confirmed neither by the thickness of the Holocene sequence, anomalously high, due to the high sedimentary rates coming from the Serrara Fontana basin neither by its internal geometries. A geologic section has been constructed along the south-eastern Ischia offshore. It documents the stratigraphic relationships between the volcanic units of the acoustic basement and the Quaternary deposits. The section is located along the volcanic structure of the Ischia Bank through the Ischia Channel. Here it crosses the relic volcanic edifice "Il Pertuso" and arrives up to the continental shelf of Procida Island (Punta Solchiaro).

Key terms: LA-ICP-MS analyses; Aeolian Islands magmatism; Lipari-Vulcano magmatic system; volcanoclastic provenance

Paola Basin, in the Eastern Tyrrhenian margin, is an elongate trough bounded by the Calabrian Arc terranes to the east. Its western margin is represented by the Aeolian Volcanic Arc, which separates it from the Tyrrhenian bathyal plane. The shoreline of the basin is about 150 km long, from Cape Bonifati to Briatico. It represents the submerged part of the Calabrian Coastal range Province, consisting of Mesozoic ophiolites and Paleozoic basement nappes (phyllite, schist, gneiss and plutonics) thrust over the Triassic to Paleogene Apenninic sedimentary units (dolostone, limestone and clastics) [1, 2, 3]. It has been estimated that during Quaternary the uplift rates of the Calabrian Coastal Range have been of 1 +/- 0.1 mm/yr [4]; this quick uplift determined high sedimentation rates in the shelf area [5]. The Paola Basin filling sequence can be divided into two portions: the pre-12ka is characterized by sandy-turbidites and mass-failure deposits, while in the post 12ka pelagic and hemipelagic sediments dominated [6]. In the upper portion, at 20 cm of depth, a tephra layer attributed to the 79 AD eruption of Vesuvius [6] has been found. This tephra consists of pumices fragments with stretched and flattened vesicles containing abundant microphenocrysts of leucite and diopside and minor feldspar. Loose crystals of biotite are common. Glass composition is phonolitic with K₂O content higher than 7wt%. Compositional and textural studies of the lower sandy-turbidites at 372 cm of depth evidenced the occurrence of a second distinctive sandy-gray crystal-rich bed containing fragments of vesiculated glass and porphyritic, non vesiculated, volcanic clasts. Micromorphoscopic observation by SEM showed that glass fragments are characterized by rounded and sub-rounded outlines with stretched vesicles. Glass has a dacitic-rhyolitic composition and K₂O content around 5wt%.

The absence of non-volcanic detritus suggests that both tephra layers deposited sin-ruptively. A provenance of the post 12ka tephra layer from the 79 AD plinian eruption of Vesuvius seems to be confirmed whereas the calcalkaline affinity of the pre 12ka tephra layer suggests an origin from the Aeolian Arc volcanic system.

THE MT. ARCI OBSIDIANS (SARDINIA IS.- ITALY)

MATTIAS Pierpaolo¹, LINI Massimo², URRACI Elio³, BELLATRECCIA Fabio⁴

1 - Univ. Camerino

2 - Gruppo Mineral. Romano

3 - Naturalista

4 - Univ. Roma 3

Presenter e-mail: pierpaolo.mattias@unicam.it

Key terms: Obsidians; Genesis; Mt. Arci; Sardinia; Italy

The Mt. Arci obsidian is an important, well known geo-resource, as it has been subjected to an intense exploitation since the Neolithic, i.e. 9,000 to 8,000 years ago.

The Mt. Arci volcanic relief lays in the central - western region of Sardinia, almost 16 - 18 Km SE of Oristano. The central part of the igneous body is

a N-S trending ridge, more than 25-30 Km long and less than 5-6 Km wide. The massif has a thick morphology, reaching 812 m above sea level at Punta Trebinalonga. The Mt. Arci is included in the sheet no 217 (Quadrants I and II) of the 1:100,000 IGM topographical map. It has to be noted that the massif has a strongly asymmetric shape, also due to intense faulting.

The succession of the eruptive events that built up the massif is particularly complex, as it covers wide chemical spectrum (salic and femic magmas coexist) and time span (from 18-15 My to 3.5-3 My). The later igneous activity is thought to have given origin to the obsidians. Field surveys found obsidian occurrences in the eastern sector, next to the Pau village (just renowned for the obsidian, and in the southern sector, mainly along the basal belt of the massif. Obsidians form numerous outcrops, twenty-nine of which were inferred to have a primary origin (Fanti and Lugliè, 2010). Some other occurrences, presently hidden by the morphological arrangement or by the vegetation cover, cannot be excluded.

Generally, obsidian outcrops at the Mt. Arci have little thickness.

Nevertheless, some of them (S. Maria Zuarbara-Marrubiu, Roia Cannas, Perdus Urias, Conca Su'Ollastu, Canale Perdara, Riu Solacera) underwent to extraction of perlite, in which obsidian is frequently included.

On the basis of their colors and textures, the obsidians can be subdivided in the following types: monochromatic black and "coda di pavone" (fan-like), reddish, brown, and gray; stratified; breached with heterogeneous polychromatic elements; "fiocco di neve" (snowflake-like); "cariate" (decayed) or crenulated.

In most of cases, the genesis of the Mt. Arci obsidians can be ascribed to assimilation of preexisting volcanic rocks, like tuffites, ignimbrites, volcanic breaches, by the high-temperature primary magma. The decayed and crenulated obsidians, in particular, were originated from marine deposits rich in remains of siliceous organisms (sponges, echinoderms, etc.), before the relief emerged of 380 - 400 m at least.

These studies allowed to classify the glassy products into four types: SA, SB1, SB2, and SC, respectively (cfr. mainly Tykot, 1992, 1996, after Puxeddu, 1958).

The whole Mt. Arci massif represents the area no 1 of the Parco Geominerario Storico-Ambientale della Sardegna (Geomineral Historic and Environmental Park of Sardinia), because of its morphological and petrological peculiarities. Moreover, it has been included in the World Heritage list of the UNESCO, owing to the cultural aspects connected with exploitation and use of the obsidian.

After all, the obsidian can be considered as the object of the first exploitation activity having a significant economical impact in the history of Europe.

Key terms: geochemistry; Atlantic Patagonia; marine shell

Late Quaternary raised coarse-beaches from the Gulf of S. Jorge (Atlantic Patagonia, Argentina) preserve rich parautochthonous shell beds potentially useful for the paleoenvironmental reconstructions (Aguirre, 2003). Petrographic, XRD and geochemical analyses (in particular Mn and Fe content and Mn/Sr ratio) along with the comparison of living and fossil shells of the bivalves *Prototacha antiqua*, *Mytilus edulis* and *Aulacomya atra* indicate that fossil shells sufficiently preserved pristine structure. Also, Strontium radiogenic isotope data suggest a well-preserved state since the studied samples have retained their original seawater isotopic signatures. Therefore, their isotopic and geochemical composition can be used as proxy for the reconstruction of the past sea conditions (e.g. Dodd, 1965; Mook, 1971; Klein et al., 1996). The oxygen stable isotopes record suggest significant changes in the Gulf circulation and salinity, possibly related to the shift of the frontal position of the superficial Falkland (Malvinas) and Brazilian currents during time. Trace elements content (Mg, Ba, Sr, U) appears more difficult to be interpreted, particularly for the high variability observed in living specimens. However, high U content on some set of fossil shells is interpreted as evidence of subtle diagenesis and/or adsorption of this very mobile element making currently particularly arduous, as well known in literature (Kaufman et al., 1971; 1996), the application of the U/Th dating method.

RELATIONSHIP BETWEEN EXCHANGEABLE LEAD AND TEMPERATURE TREATMENT IN A Pb-CLINOPTILOLITE

BRUNDU Antonio¹, CERRI Guido¹, CALIA Massimo¹, DE' GENNARO Maurizio²
 1 - Dipartimento di Scienze Botaniche, Ecologiche e Geologiche - Università degli Studi di Sassari
 2 - Dipartimento di Scienze della Terra - Università degli Studi di Napoli "Federico II"

Presenter e-mail: abrundu@uniss.it

Key terms: cation exchanges; clinoptilolite; lead; thermal treatments; zeolite

The technological characterization of a Pb-clinoptilolite can contribute to the evaluation of the problems presented by zeolite-based exchangers used to treat lead contaminated wastewaters, since the zeolite itself become a potential source of pollution. Thermal treatments could represent a way to achieve the inactivation of exhausted Pb-exchangers. Heating can affect the structure and, consequently, the properties of a zeolite, so a thorough study of the heating effects on Pb-clinoptilolite has been started. This work shows the relationship between temperature treatment and exchangeable lead in a Pb-clinoptilolite.

A Sardinian epicalcite, containing 66% of clinoptilolite (along with glass, feldspars, quartz, opal-CT and biotite), was processed through autogenous comminution followed by dry and wet sieving, obtaining a powder 125-64

µm in size with 87% of zeolite grade (Siemens D5000 diffractometer; Rietveld QXRPD, Topas 4.2 software). This material was split in two aliquots (BZ and CZ) conducted in Pb-form in different times. Initially, these were contacted with a 1 M NaCH₃COO solution (10 cycles, 2 h each; solid/liquid = 30 g/l; T = 65°C; continuous stirring). The Na-forms (BZ2 and CZ2) were then brought to Pb-forms (BZ3 and CZ3) by 3 further exchange cycles in a 0.5 M Pb(CH₃COO)₂ solution (2 h/cycle; solid/liquid = 30 g/l; T = 65°C; continuous stirring). Lead release from Pb-clinoptilolite was tested at 20°C in 0.5 M KCH₃COO (BZ3) and NaCH₃COO (CZ3) solutions (10 cycles, 2 h each; solid/liquid = 30 g/l; continuous stirring). The results were compared with the lead releases, measured in the same solutions and conditions, from different aliquots of BZ3 and CZ3 previously heated for 2 h at 200, 300, 400, 500, 600, 700, 800, and 900°C. White solutions and eluates resulting from all exchange processes were analyzed by AAS.

Chemical analyses showed that both BZ3 and CZ3 substantially contain Pb-clinoptilolite end-members. With respect to their initial Pb²⁺ contents, lead releases from unheated materials were incomplete: 47% in K- and 54% in Na-solution. Regardless of the solution used, heated powders presented the same decreasing relationship between percentage of lead released vs. temperature treatment. Heating up to 400°C brought to a weak decrease of exchanged Pb²⁺ (≈ 43% at 400°C), that became pronounced from 500 (≈ 35%) to 700°C (< 2%). Materials heated at temperature ≥ 800°C did not evidence lead release.

EXTREME CHROMITE ALTERATION IN ANTANIMBARY CHROMITITES FROM THE MAEVATANANA BELT, TSARATANANA SHEET (NORTHERN MADAGASCAR)

PEDROTTI Maria¹, GRIECO Giovanni¹, FRANCHI Michele², RANDRIANJA Roger²

1 - Università degli Studi di Milano

2 - Ecole Supérieure Polytechnique. Université d'Antananarivo

Presenter e-mail: maria.pedrotti@unimi.it

Key terms: chromite alteration; Antanimbary chromitites; ferritchromites; Madagascar

The Maevatanana Belt, located in the north-central Madagascar, is the westernmost of three belts (Andriamena, Beforona and Maevatanana) belonging to the Tsaratanana Sheet. This tectonic unit, individuated by Collins (2006), is composed of mafic gneisses, tonalites, chromite-bearing ultramafic rocks and meta-pelites, some of which were metamorphosed to ultra-high temperatures at 2.5 Ga (Goncalves et al., 2004).

Chromitites were found close to the village of Antanimbary in the northern part of Maevatanana Belt, but unlike nearby chromitites, hosted within ultramafic bodies of Andriamena belt, they have never been studied. Seven separate chromitite lenses, forming a 3 km long, NE to SW trending, alignment, outcrop close to the Ikopa river bank. They are included within a metamorphic unit, known in literature as orthoamphibolite, composed of sodic plagioclase, hornblende-like amphibole and minor biotite and quartz.

All chromitites are massive with more than 70 and up to 90 modal % chromite and have a cumulus texture where the cumulus phase is always chromite with intercumulus silicates. Chromite grains, completely altered in ferritchromite, ranging from 0.5 to 0.1 mm in size, are euhedral, with fractured cores and porous rims, and enclosed in an anhedral silicate gangue. The most common silicate mineral is chlorite, whose composition falls in the fields of sheridanite and clinochlore and shows detectable Cr₂O₃ contents (1-2 wt%), which are anyway low if compared to kammererite usually associated to ferritchromite. Tremolitic to actinolitic amphibole and orthopyroxene also occur, often in intergrowth. Serpentine and titanite are present as accessory silicate phases. Ilmenite, as tiny inclusions in chromite grains, is the most common non silicate gangue mineral, followed by rutile, monazite, magnetite and rarely pyrrhotite. Chromite crystals (isolated or in aggregates) preserve the original shape even if they are completely altered in ferritchromite. A slight core to rim zonation occurs with broken and porous ferritchromite cores surrounded by a more porous corona showing a stronger alteration. Grains never preserve composition of primary chromite. Generally ferritchromites are

very low in Cr₂O₃, never exceeding 43 Cr₂O₃ wt%. FeO is high, ranging between 29.23 and 32.81 wt%, calculated Fe₂O₃ is never below 6.60 wt% and reaches very high values, up to 28 wt%, in more altered ferritchromite grains. MgO is extremely low, systematically below 2.14 wt%. Al₂O₃ content is strongly variable, with the lowest and highest limits at 3.33 and 21.96 wt%.

Ferritchromite composition, plotted in XFe vs XCr and XFe vs XFe₃₊ "fried egg diagrams", shows a best fit with layered mafic-ultramafic intrusions (Barnes and Roeder, 2001), confirmed by composition of chromite alteration rims from Bird River Sill (Ohnenstetter et al., 1986). Quite constant high values of XFe, ranging between 0.89 and 0.94, together with variable XCr evidence that alteration of primary chromite is complete and occurred firstly at reducing conditions with a primary substitution of Fe²⁺ on Mg. Only after almost complete loss of Mg iron is oxidized to Fe³⁺ and substitutes for Al and Cr.

Key terms: Micro X-ray Fluorescence Spectrometer; Mediterranean Marbles; Trace elements; Provenance determination; Archaeometry

In the last few decades marble provenance identification has represented a focal concern for archaeometric researches, leading to the creation of extensive databases based on the combined results of different geological and physico-chemical methods. Even though isotope geochemistry seemed to give the most discriminant results, the progressive increasing of the database and the consequent overlapping of the characteristic fields pointed out the need of developing multi-method strategies.

The methodological approach presented here combines petrographic and micro-XRF geochemical data acquired on a set of 320 reference samples from 20 different Mediterranean quarrying sites.

Main goal of the research was to evaluate the effective discriminant capability of a new micro-analytical approach based on trace element quantification with micro-XRF Eagle III-XPL (Röntgenanalytik Messtechnik GmbH, Germany) non-destructive instrument. Poly-capillary lenses (30 µm) were used to collimate the microbeam at the sample surface. Single spot analyses on calcite grains gave reproducible results and allowed overcoming the problem of the considerable variations of solution-based ICP-MS analyses.

Preliminary results on Alpine and Apuan Italian marbles encouraged the creation of a wider database which took advantage of the availability of different collections coming from the University of Turin, Genoa and Florence and from the Regional Museum of Natural Science of Turin. The whole set of samples led to the acquisition of original data and allowed quantitative testing the discriminant power of the chosen variables though different samples of the same quarry and in different quarries of the same district. Moreover, it contributed to the scientific valorization of valuable Cultural Heritage.

The choice of the varieties to be included in the database was determined by the historic and economic importance of each specific quarrying site over time. They correspond to the well-known Greek marbles from Aegean Islands and Attica, Turkish islands, Aegean coast and Western Anatolia. Spain was represented by Macael marble, while Italian Apuan varieties were analyzed together with some of the best known Alpine white marbles.

Calcite compositional data were acquired optimizing analytical conditions for different energetic intervals and the statistical error was evaluated by amorphous and crystalline standards (NIST SRM 610 - 612, Standard Carrara Marble M43). The referred averages for NIST SRM trace elements standards (SRM 610 - SRM612), were used for µ-XRF calibration. Applying 40kV, 1 mA, a Ti primary filter (25 µm thick), the statistical intensity error percentage from Mn to Nb was < 5% at 50 ppm nominal concentration (live time of 1000 s) and < 3% at 500 ppm (live time 1000 s). Mg concentration was acquired for 1000 s using 10 kV, 1 mA on unfiltered primary beam. Statistical intensity error, in this case, was below 2% at 500 ppm nominal concentration.

Calcite compositional data were cross-checked and critically compared to SEM-EDS, ICP-AES and ICP-MS independent analyses on the same samples.

Factor and principal component statistical analysis drove the selection of the experimental variables, taking into account petrographic and geochemical evidences. Continuous variables matched micro-XRF calcite composition, expressed as ppm of the most discriminant minor and trace elements: Mg, Mn, Fe, Zn and Sr. Petrographic parameters as maximum grain size, grain boundary shape, texture and shape of the crystals were considered as categorical variables.

Chemometric methods were used for data processing and development of proper grouping procedures. The final cross-validated models were successfully used in different case-studies, including byzantine ancient marble artifacts from Liguria and medieval coat of arms from the Raconigi (CN, Italy) residence of the Royal House of Savoy.

MAGNETIC SEPARATION TESTS ON A BRAUNITE-RICH MANGANESE ORE, ESKISEHIR, TURKEY

KASTRATI Shpetim¹, GRIECO Giovanni¹, PEDROTTI Maria¹, CAZZANIGA Alberto¹

¹ - Università degli Studi di Milano

Presenter e-mail: shpetim.kastrati@unimi.it

Key terms: manganese ore; braunite; metal recovery; Turkey

Turkey is an important manganese ore producer and exploration for new manganese deposits is ongoing. One of the prospected areas is the melange zone of the Eskisehir ophiolite. Some samples from the Tayclar deposits, located in the Eskisehir ophiolite melange, were used in this study to assess the feasibility of magnetic enrichment of manganese ore. The Eskisehir ophiolite is located in the western part of the Izmir-Ankara-Erzincan Suture Zone (IAESZ) that crosses Turkey from the west (Izmir area) to the east (border with Georgia) (Uysal et al., 2009). Manganese deposits within the IAESZ are classified by Ozturk (1997) as radiolarian chert-hosted deposits. They are related to Neo-Tethyan suture and form the epi-ophiolite sediment succession together with associated radiolarite, radiolarian chert, siliceous shale and brown claystone. The deposits show high Mn, Si variable and low Al contents. The most important of these deposits is the Cayirli Mn deposit in central Anatolia. The Tayclar deposit has never been mined and the local geology is not well known due to paucity of outcrops and absence of investigation. Mn-rich rocks are mainly strongly deformed braunite-rich quartzites, with NW-SE trend of layering. As a whole the Tayclar deposit belongs to the IAESZ Mn deposits but it is characterized by a strong metamorphic overprint that changed its mineralogy and texture.

Mineralogy and texture of the Tayclar deposit show conditions that can favour magnetic enrichment of ore at relatively fine grain size, providing the opportunity to produce a high grade final product. Magnetic properties of Mn ore have been assessed in magnetic prospecting (Bhimasankaram and Rao, 1957). Braunite shows a paramagnetic behaviour that is strongly affected by incorporation of elements, like Mg and Fe, substituting Mn. In addition the Tayclar deposit shows a metamorphic re-crystallization with grain size increase that allows good separation of Mn-rich phases and quartz at relatively fine grain size of crushed ore.

For the experiment samples, about 25 kg each, were taken from two outcrops (ESK1 and ESK2) and mixed in equal proportion. Ore was crushed at grain size < 4mm.

Magnetic separation tests were carried out with a Permroll dry magnetic separator at University of Eskisehir, using constant roll speed and magnetic field.

First test, on the whole sample, crushed at < 4 mm, shows that separation of a Mn-rich sand is possible with a high metal recovery. Efficiency is higher for the finest fraction (< 1 mm), with an MnO content increase from 15 to 30 wt% at a very high metal recovery of more than 96 wt%. For coarser grain sizes, without any change of setting, metal recovery decreases due to stronger effect of gravity (78 wt% at > 2 mm) but MnO enrichment increases up to 35 wt%.

A second test was carried out dividing beforehand the feeding sand in three grain size classes, in order to study the effect of sorting on separation. Results show that metal recovery does not change meaningfully and hence previous separation of feeding sand in different grain size classes is useless.

In conclusion tests show that braunite-rich metamorphic manganese deposits can be successfully enriched magnetically, with a metal recovery that is inversely correlated to grain size. Minimum grain size is hence chosen on the basis of crushing costs and market demand. Bhimasankaram V. L. S. and Rao B. S. R. Manganese ore of South-India and its magnetic properties. Geoph. Prosp. 1957, 6(1), 11-24. Ozturk H. Manganese deposits in Turkey: distribution, types and tectonic setting. Ore Geol. Rev. 1997, 12, 187-203.

BIOGENIC AND ABIOTIC HYDROCARBONS AND OROGENIC BELTS

SCALERA Giancarlo¹

¹ - Istituto Nazionale di Geofisica e Vulcanologia

Presenter e-mail: giancarlo.scalera@ingv.it

Key terms: Hydrocarbons origin; Abiogenic hydrocarbons; Fold belts building; Expanding Earth

Oil and associated phenomena can be found preferentially along old fold-belts and margins. A fold belt building model proposed in preceding papers by SCALERA (2005, 2007, 2008) can be used to judge if the difficulties encountered by the different biogenic/abiogenic conceptions can be solved. The main characteristics of the model are:

- The tectonic overpressures (MANCKTELOW, 1995, 2008), and the higher temperatures at shallower depth in the model of SCALERA (2005, 2007, 2008), can bear a relation with the synthesis of biogenic and abiogenic hydrocarbons.
- Higher thermal gradients - produced by the isostatic uplift of very deep materials - together with uplifted contents of mantle metals (catalysts) and hydrogen, can favour the occurrence of the conditions leading to the development of the Fischer-Tropsch reaction.
- The underthrust carbonate slabs can interact at proper high temperature with hydrogen and catalytic metals.
- Pressure range can be very wide both because the nonlithostatic overpressures (MANCKTELOW, 1995, 2008) at the boundary between uplifting material and adjacent stable or underthrust lithosphere and occasionally because the inevitable occurrence of strong earthquakes during the thrust-fold belts building.
- Laboratory experiments (MARTINELLI & PLESCIA, 2005) have ascertained that calcareous-marly rocks to which friction is applied produce an emission of CO₂ and methane of inorganic origin.
- The compressional state of the gravity-driven nappes, together with the general rifting environment of the proposed model and the aperiodic activation of deep change of phase with extrusion of material below the fold belt, can be facilitating factors in HCs migration towards the surface and its accumulation under impermeable layers.

The lack of reducing conditions in the upper part of the upper mantle to be possible the Fischer-Tropsch reaction (GLASBY, 2006), is overcome in this model by the upward isostatic transport of the reducing under-lithospheric mantle environment. The criticism of Kenney that suitable TP conditions to produce HCs can be found only at depth greater than 100 km is overcome by the transport of such conditions toward the surface. In my framework a high-temperature reducing environment of undepleted mantle rises up and come in contact with the relatively cold oxidizing lithospheric environment. In the interposed region of thermal gradient, and of hydraulic gradient due to nonlithostatic overpressures - all at depths not overcoming few tens of km - a continuum of very different physicochemical conditions come in existence.

A number of chemical reaction are then favoured in this sort of tectonic oxidizing-reducing pile, leading to a multiple origin of hydrocarbons. In addition, near to the surface - in the first few tens of kilometres - a considerable amount of fluids (FYFE, 1978) and of organic biogenic material of various provenance is present in the underthrust sedimentary layers, which can participate in a passive way (contaminant) or active way (transmuting materials, kerogens) to the HCs forming.

In Italy, a comparison of the petroleum and gas fields (data from PIERI, 2001) with the maximum felt intensity (VIII, XI, X and XI MCS degrees; fig. 2) shows a good agreement between the model and the highest seismic energy release. The earthquakes enclose an elongated area of tectonic working in which hydrocarbons can be produced in the depths, and then expelled laterally toward the cold side of the region. The 'warm side' can be considered the region where the volcanic rocks are located. On this side oil cannot migrate without be decomposed. More deep geochemical investigations and analyses need in determining the real nature (biogenic or abiogenic or mixing of them) of the Italian hydrocarbons.

DIFFERENT FINE POTTERY CLASSES FROM THE ARCHAEOLOGICAL SITE OF "TIMPONE DELLA MOTTA" IN THE SIBARITIDE AREA (CS) - CALABRIA

ANDALORO Eliana¹, DE FRANCESCO Anna Maria¹, JACOBSEN Jan K.²

¹ - Dipartimento di Scienze della Terra, Università della Calabria

² - Groningen Institute of Archaeology

Presenter e-mail: eliana.andaloro@unical.it

Key terms: Archaeometry; Fine pottery; Characterization; Provenance; Technology

In this work, we focus on the archaeometric characterisation of some pottery remains dated to the 8th and early 7th centuries BC. The examined sherds come from the excavations carried out by the Groningen Institute of Archaeology (GIA) on the acropolis of the Timpone della Motta archaeological site, located near the well-known Greek colony of Sybaris (Calabria, southern Italy).

We focus here on four ceramic classes frequently found in the sanctuary: a) matt-painted pottery ("Undulating band", "Fringe" and "Messapian" styles); b) Oinotrian-Euboean style; c) colonial ware (hydriskai); d) Sub-Thapsos pottery.

All the sherds were examined by means of an integrated analytical approach, including petrographic, mineralogical, chemical and micro-morphological investigations and also clay sediments from the area around Timpone della Motta, representing the potential raw materials used for local pottery production, were sampled for comparison with the pottery. To establish pottery firing temperatures, firing tests (950°C) on the collected clay samples and on each test thin section and diffractometric analysis were carried out.

The results demonstrated that the groups of Matt-painted ("Undulating band" and "Fringe" styles), Oinotrian-euboean, colonial-ware and Sub-Thapsos pottery from Timpone della Motta are characterised by similar features. Although they are very similar, thin-section observations and the chemical data (such as their higher Fe₂O₃ and MgO contents) did highlight some small differences only between the Colonial-ware and Sub-Thapsos group respect to the other two classes. The "Messapian" matt-painted pottery instead show very different characteristics, compared to the other ceramic groups.

The similarity between the chemical compositions of the matt-painted pottery (local styles) and Oinotrian-euboean ceramics could implies their production with the same raw materials. The local styles matt-painted and Oinotrian-Euboean groups, are compositionally similar to both the Pliocene and alluvial clay sediments outcropping near Timpone della Motta, but the comparison between the fine ceramics and the thin sections of firing tests showed the greater similarity with the Pliocene clay tests. The extensive outcrop of Pliocene clay sediments near the archaeological site may explain the large-scale production of pottery ware in this area testified by the great numbers of matt-painted and Oinotrian-Euboean specimens brought to light during excavations.

The composition of "Messapian" matt-painted pottery is completely different from the collected clayey materials, so very probably, they were not locally produced.

The chemical data for the hydriskoi and Sub-Thapsos showed some small differences with respect to the other two groups and to the local clays. This could suggest that this ceramic type was not locally produced or, alternatively, that Fe- and Mg-enriched clay layers, possibly occurring in Pliocene outcrops nearby the archaeological site, were used to produce this type of pottery; otherwise could be supposed that the amorphous nodules were intentionally added, therefore local production might also be hypothesised for this groups.

As regards technological features, the combined information of XRD data and micro-morphological observations by SEM indicated a rough estimate of firing temperatures. Temperatures higher than 850° C are inferred for almost all examined samples, instead observations allow to estimate a firing temperature higher than 1050°C for the over-fired hydriskai.

INFLUENCE OF RAW MATERIALS ON THE QUALITY OF TRADITIONAL LIME BINDERS.

CANTISANI Emma¹, CAMAITI Mara¹, FALABELLA Ambra¹, FRATINI Fabio¹, PECCHIONI Elena²

¹ - CNR Istituto per la Conservazione e Valorizzazione dei Beni Culturali

² - Dipartimento Scienze della Terra Università di Firenze

Presenter e-mail: e.cantisani@icvbc.cnr.it

Key terms: Traditional binders; Limestones; Quality of lime

This contribution presents the preliminary results of a research project named Calci DOC, included in the activities of Forum Italiano Calce. The aim of this project is to realise a database of the raw materials used in the Italian regions for the production of traditional lime. The project was born in Tuscany with the collection of different stones that from Middle Age up to the last century have been utilized for the production of lime and natural hydraulic lime. The project has two purposes: from one side to identify the carbonate rocks, usually outcropping in the neighbourhood of the furnaces, and to fit them into the geology of each region. On the other side we want to assess the relationship among the chemical, mineralogical and physical properties of these carbonate materials and the type and quality of lime that was produced.

Concerning Tuscany, pure Apuan calcitic marbles with different microstructures, pure limestones, marly limestones and other carbonate lithotypes have been utilised in the past centuries and were considered within this study. A standardised processing of the carbonatic stone materials was followed: burning temperature, burning time, slaking, aging of the lime putty, time of setting of the lime putty.

All samples were preliminarily characterised from the chemical (X ray fluorescence), mineralogical (X ray diffraction, thermogravimetric analyses TGA), petrographical and physical (optical microscopy and porosimetry techniques) point of view. The colorimetric coordinates expressed in CIELab system were measured with a Minolta colorimeter on the rock samples and on the hardened binder samples. After the setting of the lime putties, during carbonation, at time intervals, mineralogical controls (XRD) and SEM EDS morphological observations on polished and fractured surfaces were performed. The hardness of the binder samples was measured with a Drilling Resistance Measurement System (DRMS). The obtained drilling resistance was put in relation to the compressive strength of material.

In particular for the Alberese marly limestone, the stone used in the Florentine area for the production of lime, the role of structure, porosity and different amount of clay minerals in controlling the development of calcium silico aluminate, has been investigated. A comparison with the characteristics of the marly limestone from the Chartreuse Massif used in France for the production of the Roman cement (or Prompt Natural Cement) is proposed.

Presenter e-mail: rossella.arletti@unito.it

Key terms: Glass; EMPA; XRD; Unguentaria

In this work a series of glass fragments of Egyptian unguentaria were characterized from the chemical and physical point of view. The studied samples were produced in the first period of the Egyptian glass production, during the new Kingdom of Egypt. The glass production in Egypt started under Thutmose III kingdom and reached its maximum during the kingdom of Amenhotep III (XVIII dynasty, 1390-1352 BC.) e Amenhotep IV/Akhenaton (XVIII dynasty, 1352-1338 BC). In this period, different glass shapes and typologies appeared with a large variety of decorations and colours. The aim of this work is to compare these samples, never analysed before, with the data relative to coeval Egyptian productions in order to identify a common origin.

The analysed fragments pertain to six vessels (amphoriskoi and krateriskoi) coming from Thebes area and stored at the Egyptian Museum of Turin (Italy) after the excavation carried out at the Valley of the Queens. All these vessels, are blue with yellow, white and turquoise decorations and produced with the core forming technique.

The chemical analyses of major and minor elements were performed by Electron Microprobe (EMPA). The nature of the opacifying and colouring agents was determined by X-ray powder diffraction. Since only micro volumes were sampled from the artefacts (less than 1 mm³), the diffraction experiments were carried out using a single crystal diffractometer equipped with a CCD camera.

The chemical data show that all the samples contain high levels of Na₂O. However, along with a number of glass containing rather high levels of both MgO and K₂O - thus classified as plant ash based glass - some show rather low levels of K₂O along with high MgO amount. Most of these low-potassium high-magnesium samples are Al-rich Co-bearing blue glass: this seems to indicate the possible coloration with Co-bearing alum. This is also consistent with the high level of MnO present in these samples.

These data suggest the use of two different kinds of flux for the production of these glass: an organic source (for the production of most of yellow, white and turquoise items and an inorganic one leading to lower levels of K and Mg-) used for the production of the Co-bearing samples. Yellow opaque decorations are rich in Pb and Sb, while only Sb is present in the white and light blue ones. This is consistent with the results of the X-ray powder diffraction analyses, that confirmed the presence of lead antimonates in the yellow decorations and of calcium antimonates in white and light blue ones. No crystalline phases were detected in dark blue, black and violet bulk glass.

replicas

Campania is known as one of the Italian regions with the largest number of archaeological sites, and pottery was widespread in the whole region since prehistoric times, with many workshops operating in the territory. Aim of this research is to achieve new data on raw materials for ceramics (clay and additives) from Campania region (Italy), with particular attention to those most likely exploited for archaeological pottery. Samples were chosen taking into account their proximity to the ancient archaeological sites and to the ancient ways of communication; further information was gathered through the personal communication of potters that still today are using local clays.

Minero-petrological and physical investigations on ceramic raw materials are valuable tools to better define the provenance of pottery and the technological potential of clays.

Clayey raw materials from Campania region mainly consist of basinal sediments; the others are represented by alluvial sediments and strongly weathered pyroclastics.

From a chemical point of view basinal and alluvial sediments can be distinguished in calcareous (CaO > 6%) and non-calcareous (CaO < 6%); pyroclastics are only non-calcareous, a parameter strongly influencing the technological features of ceramic products. Because of their good thermal shock resistance, non-calcareous clays are more suitable for cooking ware, whereas calcareous clays are generally used to produce common ware or pottery for liquid storage, due to their higher sintering degree achieved at relatively low firing temperatures.

A moderate to high plasticity characterizes both basinal and alluvial sediments, due to the abundance of different clay mineral phases (e.g. illite-smectite, kaolinite, chlorite) and finer fraction; kaolinite/halloysite bearing weathered pyroclastics show worse plastic features and a higher abundance of coarser fraction.

Liquid and plastic limits as well as shrinkage are other physical features that strongly affect the technological attitude, such as moldability of clayey raw materials whereas grain size distribution influences the physical-mechanical properties of ceramic products. For this reason ancient potters used to modify the grain size of clays either depurating or adding temper. For example, temper improves the toughness of pottery, enhancing the thermal shock resistance of cooking wares or the impact resistance of amphorae.

Sands of the Bay of Naples coastline were analyzed for comparison with the additive observed in the ceramic findings of this area. Those tempers reflect the petrographic composition of the volcano-sedimentary neighboring lithologies, thus they can be used as provenance tracers for the Bay of Naples pottery.

Two different clayey samples from the Bay of Naples area were chosen to make ceramic replicas fired at different temperatures, in order to simulate the technological process as is assumed to be made originally. A calcareous clay from the Island of Ischia (historically known as production center and raw materials supplier) was mixed with different proportions of temper from Campi Flegrei to reproduce the main features of common wares (e.g., fine ware, table ware, amphorae, bricks); a non-calcareous weathered pyroclastic from Sorrento was used to simulate the characteristics of cooking ware.

Petrophysical investigation showed that higher strength and lower water absorptions were achieved at relatively low firing temperatures (850 °C) for the calcareous ceramics of Ischia. Temper addition improves the mechanical stress resistance, due to the formation of a secondary pore system (discontinuities at the ceramic matrix/temper grains interface), which dissipates the mechanical energy. Such a feature is particularly suitable for the production of objects such as amphorae. Pottery made with weathered pyroclastics show better refractory features, which make these materials appropriate for the production of cooking ware.

Key terms: tuff; ignimbrite; building materials; ageing tests; weathering

The volcanoclastic rocks are undoubtedly an outstanding material widely employed in historic buildings of some relevant cities in southern Italy. In particular, the Neapolitan Yellow Tuff and Campanian Ignimbrite (the yellow facies, with prevailing zeolites and the gray facies, almost exclusively constituted by feldspars), have been extensively used in the architecture of the city of Naples and of Campania region, both as a building material and as ornamental stone when used facciavista.

These materials definitely represent an historical-cultural heritage which deserves appropriate protection; however, any conservative operation cannot disregard a deep knowledge of the lithotypes as well as the environment in which they are used as building material.

As a rule, the correct understanding of all the technical features (origin, formation mechanisms, mineralogical and chemical features, geomechanical properties, accurate interpretation of the weathering phenomena, etc.) represents a prerequisite necessary to plan the appropriate restoration and/or preservation interventions, including the use of consolidating and waterproofing products.

The present work aims at evaluating the influence of some parameters such as temperature, humidity and crystallization of soluble salts on some physical features of the stone.

On this account, some new parameters have been measured so far, such as the dimensional changes induced by increasing heating and by water saturation. Tests carried out on high zeolite-bearing rocks (TGN; ICgi), showed sensible shrinkages under increasing temperatures, likely due to dehydration of these hydrous phases, and a likewise significant volume increase after water immersion (swelling test). By contrast, feldspar-bearing rocks (ICgr) evidenced slight or no variation of these parameters under the same experimental conditions.

A possible explanation to this unusual behavior should be that the zeolitized rocks subjected to changes in temperature or humidity, undergo deformations that may lead to loss of cohesion of the constituent elements and thus to the decay of the physical properties of the rock; moreover, the combination of two effects such as water that penetrates the pores

and the dimensional changes upon heating may represent the main weathering agent (Weiss et al., 2004; Benavente et al., 2008). Artificial ageing tests (wet-dry and freeze-thaw) providing cyclic variations in temperature and humidity also highlighted the different behaviour of the two zeolite facies (TGN and ICg) if compared to the ICgr. To better understand the decay mechanisms of volcanoclastic materials, soluble salts crystallization tests were also carried out. Actually, salt crystallization definitely represents a major cause of physical deterioration of macroporous materials exposed to marine aerosol. This test enabled to appreciate the substantial different behavior of the investigated rocks. In particular, TGN quickly achieved a substantial deterioration (total disintegration) of the specimens already after few treatment cycles. Another relevant aspect of this research is that the changes of many petrophysical parameters (water absorption by capillarity or by total immersion, ultrasonic velocity, uniaxial compressive strength, etc.) induced by accelerated ageing tests are not to be linked to the absolute porosity values of the different materials (these values are almost similar for the three investigated lithotypes), but mainly to the different porous system and a different pore size distribution.

MONITORING OF COLOR CHANGE AT BUILDING SURFACES: POTENTIALITIES FOR EVALUATING POLLUTION IMPACT ON CULTURAL HERITAGE

BONAZZA Alessandra¹, OZGA Izabela Joanna¹, TITTARELLI Francesca¹, FAVONI Orlando², GHEDINI Nadia³, SABBIONI Cristina¹

1 - Institute of Atmospheric Sciences and Climate, National Research Council, Bologna

2 - Department of Materials and Environmental Engineering and Physics, Ancona

Presenter e-mail: A.Bonazza@isac.cnr.it

Key terms: Monitoring; Color; Cultural Heritage; Pollution Change; Impact

The majority of the monuments and archaeological sites constituting our cultural heritage is located in urban areas. Thus buildings and remains of cultural/artistic interest undergo the impact of different climate and pollution parameters, which act synergistically, but at the same time need to be addressed separately. It is important to consider local-scale variations of the urban environment, such as changes in pollutants, temperature and relative humidity cycles, wind field, urban heat island effect, etc. In conservation field, nowadays one of the most important challenge is to understand the impact caused by environmental changes on cultural heritage.

The available scenarios of multi-pollutants trends in Europe indicate a shift in modern urban atmospheres from and SO₂ dominated situation to a multi-pollutant situation, linked to the driven role played by traffic in determining the overall pollution in urban centres. In view of the proven overwhelming influence of mobile combustion sources in determining the future urban atmosphere, "modern" soiling on built heritage will be likely to contain primarily organic carbon (OC). This will imply a change in composition of damage layers, which will presumably assume a yellow-brown coloration.

The EC TeACH project (Technologies and tools to prioritize assessment and diagnosis of air pollution impact on immovable and movable cultural heritage) sets out to understand the different types of damage on cultural heritage that can be expected in the future, due to changes in pollutants, both in terms of typology and concentration.

To accomplish this goal, from the technological point of view the project aims to develop a non invasive device for the continuous monitoring of the damage caused on monuments located outdoor by changing pollution impact, based on the change of colour of the architectural surface. A prototype is currently under testing at 5 monuments located in urban sites in Europe and one in the Mediterranean area, characterized by different environmental and climate conditions: Cologne Cathedral (Germany), S. Maria del Fiore Cathedral in Florence (Italy), the National Gallery in Oslo (Norway), the Arriaga Theatre in Bilbao (Spain), the National Museum in Cracow (Poland), the historic walls of Salé (Morocco). At each target site samples of surface deposits and damage layers have been collected and analysed by:

° Ion chromatography to measure soluble ions, including water soluble organic anions (e.g. formate, acetate and oxalate).

° Chemical-thermal methodology for carbon fraction speciation and measurement, including organic and elemental carbon (OC and EC).

° Colorimetric analyses directly at the building surface for blackening/colour change characterisation using a portable spectrophotometer.

Results achieved within this still running project on the composition of damage layers will be presented and discussed. Elaboration of carbon fractions data will be liked in particular to colorimetric parameters (L*, a*, b*), with the aim of exploring the application of monitoring of color change of architectural surfaces as potential strategy for preventive conservation.

Presenter e-mail: mabvenuti@unifi.it

Key terms: silver, copper and lead; archaeometallurgy; Colline Metallifere; Montieri; Tuscany

Tuscany has been for centuries one of the most important mining regions of Italy. Among the many districts, the "Colline Metallifere" hosts a number of base and precious metal deposits which fed a long-lived mining and metallurgical industry, possibly dating back to the onset of the Etruscan domination (IX-VIII cent BC). The whole district is now included within the "Technological and Archaeological Park of the Colline Metallifere", established in 2002.

Base and precious metal deposits of the Colline Metallifere district are mostly constituted by Cu-Pb-Zn(Ag) vein bodies associated with late-Apenninic tectonic lineaments and emplaced by magmatic-meteoric hydrothermal fluids in the late stages of the Apenninic orogeny (Lattanzi et al., 1994). Ore mineralogy includes mainly chalcopyrite, galena, tetrahedrite, pyrite and sphalerite. The former three minerals are the most important silver-carriers, particularly the Ag-rich variety of tetrahedrite (Tanelli, 1983).

The ancient town of Montieri played a major role in the exploitation and metallurgical treatment of base and precious metal ores (mainly Pb, Ag and Cu) at least since the X-XI cent AD, when the castle of Montieri and its mines came into possession of the Bishop of Volterra (Bruttini & Grassi, 2010). According to some scholars, the first issues of the mint of Volterra, known as 'old Volterrani' and consisting of an imitation of coins ("lucenses") minted at Lucca in the 12th-13th century, were coined just at Montieri, possibly in the Palazzo delle Fonderie, a still-standing old edifice in the centre of the town.

In order to better ascertain type and evolution of smelting and metalworking industry at Montieri, a cooperation project was established between the Dip.to Scienze della Terra (Univ. of Florence) and the Dip.to di Archeologia e Storia delle Arti (Univ. of Siena). We started to analyze several kinds of archaeometallurgical material unearthed during recent excavations in the Palazzo delle Fonderie di Montieri (slags), at the nearby S. Niccolò Rectory (slags) and Montemassi Castle (coins).

The otherwise scanty traces of metallurgical activity found during excavations at Le Fonderie are referable to metalworking activity for lead, copper and iron; the employed ore charges were presumably constituted by sulfidic ore assemblages. Nothing can be said about the possibility that the edifice actually served as a mint in the Middle Age.

From the Montemassi Castle we analyzed for textural, chemical and Pb-isotope composition four coins ("denari"), two typical "lucenses" (minted at Lucca) and two showing somehow distinctive stylistic features, which could be ascribed to a different mint (i.e., "old Volterrani" coined at Montieri?). Based on their mineralogical, textural, chemical and Pb-isotope composition, the two pairs of currencies appeared similar to each other. All the coins are made of a Cu (85 wt%) - Ag (15 wt%) alloy and show evidence of intentional surface silvering through the blanching method. The similarity between the four coins does not necessarily imply, however, that all of them have been produced in the same mint. Pb-isotope compositions of all coins fall within the compositional field of polymetallic sulfide deposits of southern Tuscany and far apart from the corresponding field of the Apuane Alps district (cf. Lattanzi et al., 1997), another important base and precious metal district of northern Tuscany, very close to the town of Lucca. This seems to indicate that, independently from where coins were minted, metals for coinage came from southern Tuscany, and possibly from the Colline Metallifere.

Key terms: hyperspectral sensor; gypsum; cleaning procedure; marble surface

Hyperspectral image analysis (HIA) is a potential tool for obtaining many spectral information in the visible and near infrared region with a series of narrow and contiguous wavelength bands, permitting to discriminate materials on the basis of their different patterns of absorption at specific wavelengths. This technique, widely used for determining the characteristics and properties of soils, air and water in a rapid, simultaneous and non-destructive way, has been recently proposed as a non-invasive method for in situ analyses of artworks (Vettori et al 2008, Camaiti et al. in press).

A portable high-resolution spectroradiometer (a special kind of spectrometer that can measure radiant energy), ASD FieldSpec FR Pro, is a compact, field portable and precision instrument designed to acquire Visible and Near-Infrared (VNIR: 350-1000 nm) and Short-Wave Infrared (SWIR: 1000-2500 nm) punctual reflectance spectra with a rapid data collection time (about 0.1 s for each spectrum). The ASD-FieldSpec FR Pro spectroradiometer can acquire spectra using the contact reflectance probe employing an artificial internal light source with a spot analysis of about 1.5 cm².

Since the spectral fingerprints of a number of mineralogical phases fall within the spectral range covered by ASD-FieldSpec FR Pro, like calcite and gypsum.

In collaboration with Opificio delle Pietre Dure of Florence, the spectroradiometer has been employed for selecting the best cleaning procedure on a marble column belonging to the Loggia di Baccio D'Agnoletti of Florence Cathedral. The column was originally heavily affected by sulphation and the superficial gypsum layer showed a good adhesion to the underlying patina; in this situation a not controlled gypsum removal may cause the damage of the original surface (over cleaning). Our results on the marble column indicate differences in the cleaning efficacy depending on the methodology adopted.

These results point out that portable hyperspectral instruments may be powerful tools for characterizing historical surfaces in a non-destructive and non-invasive way.

Presenter e-mail: cbelfio@unicit.it

Key terms: Shipwreck; Dressel 1 amphorae; Volcanic inclusions; Production area; Trade routes

This work deals with the petrographic and chemical study of Dressel 1 amphorae from the cargo of a shipwreck discovered in the "Secca dei mattoni" shallows, between the islands of Ponza and Palmarola (Italy). The presence of this shipwreck has been firstly signalled in 1986 by some skin-divers of the Archaeological Superintendence of Latium. This was followed with an immediate inspection and some emergency recovery. The ship, resting on the sea bed at a depth of thirty metres, had two differentiated cargos made up of Brindisi amphorae, in the lower layer, and Dressel 1 and Lamboglia 2 types (the most frequent), in the upper layer. The entire cargo would seem to form a well determined typology, already known thanks to the discovery of other wrecks, above all along the Iberian Peninsula and the French coast of the Mediterranean. Everything seems to coincide with a very precise trade route along which wine and ceramics were carried from Southern Italy (probably with departure from the Apulian coasts, due to the layout of the cargo, with a stop over in Campania, probably at Pozzuoli, where she took on board the Dressel 1 and the Lamboglia 2 items) as far as Gaul or Spain, in the chronological period between the end of the 2nd century and the early part of the 1st century BC.

The research carried out on Dressel 1 amphorae aims to confirm or reject the hypothesis of a production of such a ceramic type in the Campanian area. With this aim, mineralogical-petrographic (POM and SEM-EDS) and geochemical investigations (XRF) have been performed. Microscopic observations highlighted homogeneous textural and compositional features for all examined Dressel 1 amphorae, thus suggesting a common provenance area. This hypothesis was also confirmed by XRF results, since the bulk chemical composition of all artefacts resulted to be quite similar. In addition, in order to obtain more precise information on their production area, punctual microchemical analyses have been performed on single crystals of clinopyroxene (largely represented among the volcanic temper occurring within the pastes), according to a volcanic inclusions based approach for provenance studies, recently proposed by Barone et al. (2010). The data obtained have been then compared with compositions of clinopyroxenes occurring within volcanic rocks from different South Italian magmatic provinces. The data are still being processed, even if the first observations seem to indicate a magmatic affinity between the ceramic clinopyroxenes and those from volcanic rocks of the Campanian area, thus confirming the provenance area hypothesized for the examined artefacts.

Key terms: Glass mosaic tesserae; Rome; SEM-EDS; LA-ICP-MS

Variouly coloured vitreous mosaic tesserae have been brought to light during the numerous archaeological excavations of the Roman site "Villa dei Quintili" (Rome, Italy). The architectonic complex, dating back to the 2nd century AD, is considered to be one of the largest in the roman suburb, extending between the Appia Antica and the Appia Nuova. The mosaic tesserae studied here have been taken out from the thermal area of the villa, in the southwest wall of Calidarium, embedded in the bedding mortars.

A double analytical approach has been used in order to obtain a complete chemical characterization of all examined tesserae. Specifically, analyses by scanning electron microscopy coupled with energy dispersive x-ray spectrometry (SEM-EDS) have been carried out for the determination of major elements, whereas laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) for trace elements, including REE. Data obtained highlight that all tesserae mainly consist of SiO₂ (55-72 wt%), Na₂O (8-20 wt%) and CaO (5-7 wt%), and subordinate amounts of K₂O and MgO. For this, they can be defined as soda-lime-silica glasses. The concentration of alkali indicates that samples have been produced using natron as flux.

The high Sb₂O₃ content in all samples is imputable to the deliberate addition of antimony to the batch as a decolorant, while Cu and Cr, also present, were probably used as colorant substances.

Presenter e-mail: abrundu@uniss.it

Key terms: local raw materials; Nuragic pottery; technology; Sant'Imbenia Amphorae; Sardinia

The Nuragic Village of Sant'Imbenia is located in North-West Sardinia (Alghero, SS). It was inhabited from approximately the XIV to VII century BC by natives and, during the last period of life, also by foreign people. It is obvious that as well as goods and raw materials they exchanged ideas, knowledge and technologies.

The aim of the work is identify the trades and contacts of this settlement through the provenance of clays and the technology of ceramic. Particularly, the study takes into account the results of the archaeometric analyses of the so-called Sant'Imbenia Amphorae found in the Village during the excavations carried out in 1990 and 2008. Sant'Imbenia Amphorae, in fact, are considered "an open question" by the archaeologists either for production area or chronology.

80 selected ceramic samples were studied by X-ray fluorescence, X-ray powder diffraction and optical microscopy to analyze their chemical, mineralogical and textural features and compare clays with local raw materials.

Analytical results reveal that the Amphorae are characterized by two different typologies. The first, more abundant, is compatible with a local production which results relevant and specialized, the second suggest an import from different sites.

Presenter e-mail: elisa.conz@gmail.com

Key terms: earthenware; technological features; Aosta Valley; polarized light optical microscope

Some archaeological investigations, promoted by Regione Autonoma Valle d'Aosta, Assessorato alla Cultura and Servizio Beni Archeologici, have been carried out in 2005, just in front of the Aosta Cathedral. The excavation revealed the workshop and the kiln where architectural earthenware, used for the Cathedral façade decoration, was produced and fired.

The construction of the new Cathedral façade was started in the second half of XV century and finished in 1526. The polychrome earthenware Renaissance Apostle statues are located in the arch entrance, which is decorated with flowers tiles.

Flower tile sherds, clay mixtures, raw clay bricks and firing scraps have been found in the excavation. These findings suggest that only the tiles for the Cathedral decoration were fired in the kiln, as scraps from the sculptures weren't excavated and the small size of the kiln suggests that the statues were made in another workshop. Evidence from the clay materials suggest two possible provenances: a local deposit, probably known by Romans, and/or a deposit in the Eorediese (Ivrea region).

In this work the manufacture process and the firing conditions are reconstructed through the petrographical and mineralogical study of the archaeological findings. Thin sections of tile sherds have been studied to determine their textures and components. Moreover firing tests have been run on mixtures obtained using the original clay materials from the excavation in order to locate the clay provenance area and to compare them with the actual tiles and to reconstruct the technological features of the craftsmen.

The observation under polarizing light optical microscope allows to correlate the clay mixtures with the scraps. The yellowish clay found in the excavation has been fired at 850°C and compared with three tiles fragments found in the same spot. The fired yellow clay mixture is texturally characterized by alternating bands consisting of layers, with a high temper percentage content, and layers with high percentage of matrix. The same texture is observed in the tile sherds from the excavation, supporting that tiles were produced using these raw materials. Future development of this work is the examination of the clays, tiles, scraps and mixture firing tests by Scanning Electron Microscopy (SEM) and X-Ray Fluorescence.

PRELIMINARY MINERO-PETROGRAPHICAL ANALYSES OF STONES AND MORTARS IN A ROMAN BRIDGE (THE "PONT'EUZZU" OF ILLORAI-SARDINIA)

CUCCURU Stefano¹, MAMELI Paola¹, PINTUS Laura²

1 - DISBEG - Università di Sassari
2 - Comune di Illorai

Presenter e-mail: scuccuru@uniss.it

Key terms: roman bridge; ashlars; mortars; crusts

The preliminary results of archaeometrical investigations performed on the building materials of the Pont'Ezzu Roman Bridge of Illorai (Sardinia), with the aim of a future restoration, are reported.

The monument, built in Roman times is characterized by an original portion consisting of squared ashlars (about 70 x 30 x 30 cm) and a portion rebuilt in medieval times, located at the top of the bridge, which

consists of shapeless blocks of about 30 cm in diameter. Mineropetrographical analyses carried out in optical microscopy (OM) evidenced that the ashlar is made of a welded ignimbrite, rhyolitic in composition, with eutaxitic texture and xenoliths mainly of metamorphic origin. The irregular blocks instead are made with different lithotypes representative of several rocks outcropping nearby where, beyond tertiary ignimbrites, Silurian marble, granites and metavolcanic rocks are the most suitable for artifact building. Ashlar interstices are also filled with three different mortars, apparently of different ages.

In order to support restoration, a detailed evaluation of alteration processes has been carried out. Macroscopic analyses evidenced lichens, white crusts and, in some ashlar of the basal portion, alveolization and scaling (Normal 1 /88). As for the crusts, they are more evident on the arcades, particularly in the volts, where they completely coat the masonries. Such crusts are made of calcium carbonate and in places assume the consistence of true concretions reaching thicknesses of 2 cm. Taking into account their relevance, it is necessary to assume a source of calcium carbonate different from the pyroclastite ashlar. At the current state of observations, stones (e.g. marbles) employed in the restoration of the summital portion as well as lime mortars could be hypothesized as the principal source of calcium carbonate. Moreover, SEM observations on sampled crusts permitted to better appreciate the different coating films and EDS analyses do not evidenced the presence of nitrogen, typical of biological crusts (e.g. due to birds dropping). Finally, optical microscopy analysis of the mortars have shown different characteristics among the three different types. These concern the nature of the binder and aggregate as well the binder/aggregate relationships. From this characterization, that is in progress, the age and the composition of the mortars, as possible Ca source for the concretions, is expected.

Key terms: glass; archaeometry; chemical characterization; LA ICP MS

The archaeological excavation of Piazza Bovio in Naples, has yielded a large deposit, characterized by exceptional findings related to the production of a glass workshop built on site or nearby, around the mid to late sixth century AD.

The workshop features, coupled with the presence of numerous broken glass for recycling and glass scraps, lead to identify the area, as part of a secondary workshop.

Samples of residues of glass melting activities, selected finished objects and glass scraps, dated to VI century AD and IX-X century AD, were analysed by SEM/EDS associated to LA-ICP-MS analysis. The study aims to highlight the technological and compositional differences of the studied glass fragments and to verify the hypothesis of a secondary production in Naples, using raw materials from Levant area, which seems to continue until the eighth century in the southern Italy.

The composition of sixth century glass fragments of Piazza Bovio, indicates the use of natron-based glass and supports the hypothesis of the technological, cultural and commercial continuity in the glass production from the Roman to early medieval period.

The analysis carried out on the medieval finished vessels, dated to the IX-X century, demonstrate the widespread recourse of recycled soda-lime cullet and/or glass tesserae, rather than the direct use of sand and natron or plant ash. The plant ash technology that becomes apparent in glass compositions, in both the Islamic world and the West after the ninth century, probably in Naples was a limited process.

The comparison of the Piazza Bovio glass fragments with Medieval glass of the Italian area (Mirti et al., 2000 and Silvestri et al., 2005) revealed a compositional similarity that probably, confirms the existence of few workshops for primary glass production in the Mediterranean Area.

A MULTIANALYTICAL APPROACH FOR THE STUDY OF HISTORICAL MORTARS FROM THE ROMAN "VILLA DEI QUINTILI" (ROME, ITALY)

Presenter e-mail: giusjficiera@hotmail.it

Key terms: historical mortars; Rome; hydraulic properties; construction phases; provenance of materials

The present contribution focuses on the study of historical mortars taken from the Roman archaeological site "Villa dei Quintili", dating back to the 2nd century AD. It's one of the largest architectural complexes in the south-eastern part of Rome, extending between the Appia Antica and the Appia Nuova.

The complex was in use until the 6th century. After that, it gradually decayed and in 1986 became property of the State.

The study regarded several types of mortars, taken out from different edifices within the monumental complex, such as the thermal area (Calidarium and Frigidarium), the Viridarium, some residential areas and the Nymphaeum.

All samples underwent an integrated analytical program including: a) a mineralogical-petrographic characterization through polarizing optical microscopy (POM), which allowed to define the nature and grain size of

binder and aggregate and the ratio between the two components; b) the study of hydraulic properties through mineralogical investigations (XRD and FTIR), aiming to the identification of CSH phases, and microchemical analyses (SEM-EDS) in order to get compositional profiles along the reaction rims between binder and aggregate; c) punctual analyses by SEM-EDS and La-ICP-MS of lumps as well as of clinopyroxene crystals and pozzolana fragments, abundantly occurring among the aggregate fraction. Investigations have been carried out with the aim to discriminate diverse types of binder, to possibly identify different construction phases within the architectural complex and to restrict the source area of the raw materials used for the preparation of mortars. For the latter purpose, the obtained results have been also compared with literature data referring to the chemical composition of clinopyroxenes occurring within volcanic rocks from the Roman magmatic province and pozzolana samples from the Alban Hills area, thus allowing to better constrain the provenance area.

Key terms: andesites; archaeometry; provenance; Eolide; Kyme

The present study focuses on the provenance of volcanic stones (andesites) sampled in the archaeological site of Kyme (Turkey), the major city of the Aeolia was founded in the middle of the XI century BC by populations coming from the North of Greece. The work is part of a wider project aims to supply the first compositional data on the stone materials of Kyme. However, despite the archaeological importance of Kyme, there are few archaeometric studies on this city (Ciminale, 2003, Miriello et al., 2011). Previous and preliminary studies have suggested that the provenance of volcanic blocks could be from the Burunçuk quarry (La Marca, 2006) located near the ancient city of Larisa (a few kilometers from the archaeological site of Kyme). In this work were performed new and exhaustive compositional analysis, comparing the composition of the stones from the Burunçuk quarry with that of archaeological samples. The samples were studied by chemical (SEM-EDS, XRF), mineralogical (XRPD) and petrographic (polarised optical microscopy) analysis. The comparison between the archaeological samples and the quarry materials definitively confirmed the provenance from the Burunçuk quarry.

Key terms: pigments; rock paintings; Uganda; mineralogy; geochemistry

Rock painting samples from the archaeological sites of Nyero, Kakoro and Mukongoro (Teso District, Uganda) were collected in the framework of a collaboration between the Universities of Tuscia and Florence (Italy) and the National Museum of Uganda. The main goals of this project are those to provide a mineralogical and geochemical characterization of the pigments with which these rock paintings were made.

The Nyero rock-paintings sites are consisting of primitive drawings of unknown age, although they are commonly attributed to the Later Iron Age. These paintings are main set on the surfaces of large rounded blocks of Precambrian granites and granodiorites, the latter rising above the surrounding areas of about 30 to 50 m outlining a typical Inselberg landscape related to the long-lasting weathering of such acidic rocks.

The rock paintings mainly represent concentric circles, flowers, vegetables, ships and other figures not well defined. Two colors are dominating the Nyero paintings: white or reddish-orange.

The sampling collection was carried out in order to preserve the most significant drawings, consequently, only small flakes or fragments also containing the bedrock were removed. This has posed some difficulties in separating the drawing material and has allowed to collect only small quantities of the pigments. Thus, not destructive mineralogical and geochemical analyses were performed. In particular x-ray diffraction (XRD) and chemical analyses by FT-IR and micro-Raman spectroscopy were carried out.

Preliminary results indicate the presence of different pigments that were used to draw the rock: the reddish-orange color is certainly characterized by iron oxides, while for the white could assume the use of a mixture of kaolin based. Moreover, several organic compounds were recognized, e.g. calcium oxalates: whewellite [Ca(C2O4)·(H2O)] and weddellite [Ca(C2O4)2·(H2O)], in the pigment samples that were used to date the drawings by 14C radiometric method with the technique of accelerator mass spectrometry, at CEDAD (Centre of Dating and Diagnosis) of the University of Salento (Italy) and whose analysis is currently in progress.

Presenter e-mail: natalia.rovella@unical.it

Key terms: red-figured vases; archeometry; provenance

Three red-figured vases, kindly provided by the Carabinieri Corps for Protection of Cultural Heritage, Cosenza Unit (Calabria, Italy), were subjected to archeometric investigation.

The primary fine of the study was to establish the definite origin and source area of archaeological artefacts. For this reason the samples were characterized from petrographical, morphological, mineralogical, and chemical viewpoints with the aim of identifying technological features and defining the nature of coatings.

The results obtained highlighted common technological features: fine texture of the ceramic body, and black gloss painted directly on it.

A study of their composition excluded the possibility that they are of Greek production. Inductively coupled plasma mass spectrometry (ICP-MS) data revealed that they come exclusively from the Locride area in Calabria, South Italy.

Key terms: Mortars; Isola Capo Rizzuto; Characterization

In this work different samples of mortars taken from Aragonese Castle, located in Isola Capo Rizzuto (Crotone, Italy) were analyzed.

It was built in 204 BC and represents one of the most important monuments of Calabria.

With the aim of finding a complete characterization of the used mortars, different and complementary analytical techniques were carried out on the samples.

In particular samples were studied by optical microscopy and analyzed by SEM-EDS, LA-ICP-MS and XRPD analysis.

The results obtained identified different construction phases involved in building the Aragonese Castle. Precisely, data provide information on several important technological aspects: ratio binder/aggregate, porosity, presence of lumps.

In addition, mineralogical and petrographic characteristics of the aggregate were determined and found to be compatible with local geological deposits from the Crotona area.

Key terms: Pompeii; Common wares; LA-ICP-MS; archeometry

We present the preliminary results of an archeometric study performed on different pottery classes found in the archaeological site of Pompeii, during the I.E. 1980-81 excavations. The selected ceramic group, coming from the western side of the Forum of Pompeii, is the principal evidence of the commercial and cultural development of the ancient Pompeii town and it is ideal for an archaeological and archeometric study.

In the following work, we considered the common wares, both cooking wares and plain wares, dated in a large time span between the end of the fourth century B.C. and 79 AD. On the basis of the morpho-typological analysis, most of these vessels can be considered of local production, instead an extra-regional provenance is supposed for a small group.

The strong morphological and technological changes in the pottery production is an evidence of a large socio-cultural revolution that characterizes the considered period (IV B.C.-I AD. In particular from the II century B.C., but especially from the first century B.C., the Campanian town has highlighted the opening of new extra-regional common ware trade, in the Bay of Naples.

Optical microscopy (OM), X-ray diffraction (XRD), X-ray fluorescence (XRF), scanning electron microscopy (SEM/EDS) and Laser Ablation Inductively-Coupled Plasma Mass Spectrometry (LA-ICP-MS) were performed on the vessels in order to obtain information regarding provenance and technological change in the ceramic production (firing temperature and raw material source area) during the studied period of time.

Petrographic and chemical characterization verified the archaeological hypothesis about the presence of extra-regional productions. The identification of the provenance areas will provide important information on the complex trade mechanisms in the Bay of Naples.

Key terms: Islamic glass weights; Fatimid age; micro-XRF; coin reference

Analysis of glass objects in the field of Cultural Heritage primarily aims at determining chemical composition in order to obtain information on production techniques and geographical provenance. In fact, chemical composition may allow one to shed light on the raw materials used, and in some cases, the provenance of these may be ascertained; all this may provide useful data for a chronological assessment of the studied objects. In order to achieve such information the detection of major, minor and trace elements is strongly recommended.

This paper reports the results of an analytical approach for a non-destructive study of glass finds by the μ -XRF technique, which is suitable for quantitative analysis of small sized solid samples, showing lower limits of detection than electron microprobe analysis.

The Brandani-Rava collection consists of 62 Islamic glass weights from Egypt, mainly belonging to the Fatimid age (952-1170 a. D.), used as reference weights for coin production. Due to the legends impressed on the samples, that may contribute to their chronological classification, a non-destructive analytical technique had to be used, with the aim of determining whether the samples had been produced by recourse to evaporites or sodic ash as a source for the introduction of the network modifier in the glass batch. Forty four glass weights were analysed in this study; out of these, 37 may be assigned to the Fatimid age thanks to the legend impressed, reporting the name of the caliph ruling at the time of their production, three may be tentatively assigned to the later Mameluk age thanks to the symbol impressed on them, while the last four are of unknown allocation.

Major and minor (Na, Mg, Al, Si, S, K, Ca, Ti, Mn, Fe), as well as trace elements (Cr, Ni, Cu, Zn, Sr, Zr e Pb) were determined and quantified. The obtained results show that the composition of the analysed samples is consistent with a production based on the use of sodic plant ash, due to the relatively high contents of K₂O and MgO; in addition, the lack of correlation between the contents of Al and Ca, as well as the Sr contents, suggest the use of a non-calcareous sand, in agreement with the use of plant ash. Two opaque samples of late Fatimid age feature a high lead content together with the occurrence of Sn, related to the use of SnO₂ as an opacifier.

In conclusions, micro-XRF proved to be a well suited technique of elemental analysis for the non-destructive study of glass finds. The homogeneous composition of the analysed samples, while confirming the use of ash as a flux in Fatimid age, further suggests that comparable quantities of similar raw materials were employed in the course of several centuries; this further points to a consolidated tradition of glass production, appropriate for obtaining reference coin weights with matching features.

Presenter e-mail: e.cantisani@icvbc.cnr.it

Key terms: Florentine sandstones; Chromatic alteration; Valdese Church

The stone materials mainly used in Florentine architecture are two sandstones: Pietraforte, mostly used during the Middle Ages as building structures and during the Renaissance as facing, and Pietra Serena used for ornamental purposes. The first one is found in abundance in the hills at south of the city, whereas Pietra Serena is outcropping out in the hills near Fiesole (north of the city).

Pietraforte is a sandstone belonging to the turbiditic formation present in the allochthonous complex of the External Liguridi superposed on the Tuscan Series; Pietra Serena, instead, belongs to the sandstones of the Macigno Formation which consists of beds of turbiditic sandstones separated by pelitic levels which are the finest components of single turbidity current.

Petrographically, Pietraforte is a fine-grained lithic sandstone made in the same proportion by silicatic grains (quartz, feldspars and magmatic fragments) and carbonatic grains (dolostones). The grains are bounded by a mainly calcitic matrix that makes the rock particularly strong. Pietra Serena can be defined as a medium coarse-grained greywacke made by quartz, feldspars, micas, fragments of metamorphic and magmatic rocks. The matrix is quite abundant and is made by illite, kaolinite and chlorite-vermiculite (present only in some outcropping areas).

It is well known that the processes of decay of the sandstones are related to the type of matrix, the amount of cement, the kind of clay minerals present and to the distribution of porosity, which lead to water infiltrations, resulting in swelling and peeling.

The sandstones have a bluish-grey color in fresh cut, but is easily oxidized acquiring an ochraceous - reddish brown color on buildings. Such changes in color, appear to be due in part to the oxidation of iron, proceeding very quickly from the surface to the inside, without cohesion decrease. Indeed the chromatic changes not necessarily implies a deterioration of characteristics of the material, but they often seem to represent a natural patina acquired with the time. However, in some cases the thickness of oxidized layer and its hardness could also be the result of treatments performed in the past.

In Florence, several monuments and buildings are affected by such phenomenon, in particular it is possible to note an intense and diffuse reddish coloring on bell tower of Valdese Church entirely constituted by Pietra Serena sandstone, in the exterior columns of the Church Santissima Annunziata and in the historical building of Santa Croce square etc. About the origin of the color change, the hypothesis most reliable is a natural decay of stone, due to iron oxidation. On the other hand the presence of an intense and homogeneous distribution of the red color could be due to the application of conservative treatments, as a possible consequence of a recent restoration.

This study intends to verify the real and more probable causes of this frequent chromatic alteration and the processes which determine it.

Key terms: Neapolitan Yellow Tuff; Durability; Weathering; Consolidation
Cultural heritage represented by buildings, monuments and archaeological finds must be considered an asset of inestimable value as outlines the historical and cultural evolution of a country.

The use of the stone as building and decoration material has ancient origin and Italy offers several example of stone used over the centuries in sculpture, decoration, building pavement, etc.

The Neapolitan Yellow Tuff (NYT) is the oldest building material in the Naples area and the most represented in monuments and buildings of its historical centre. In some case tuff is coated by plaster but in the case of monumental buildings it was frequently used facciavista.

NYT is the most important volcanic product in the Neapolitan area. The factor which promoted the use of NYT for building is the local availability but also its physical and mechanical properties. However its mineralogical composition with the abundant presence of zeolites (>50%) and the high porosity make it extremely vulnerable to deterioration caused by weathering.

The interest in the protection of building made up of NYT is increased by its utilization in important monument such as the gothic churches (S. Chiara, S. Domenico Maggiore), Castel dell'Ovo and Castel Sant'Elmo. In this monuments the risk for deterioration is increase by sea-salt aerosol. In the recent years the awareness of having an architectural heritage, rich but "fragile", has produced a greater effort to preserve the stone and/or improve resistance to weathering.

In fact during the past intervention, replacing damaged blocks was a cheap solution thanks to good availability of NYT; at this time the closure of many quarries requires the preservation of this stone.

More recently however many efforts have been made to search products able to consolidate and stabilize weathered material and to reduce stone decay, without isolating it from the environment but protecting it from the causes of degradation.

The aim of this research is the testing two commercial product: an anti-hygro, a protective product which reduces the swelling ability of clay and zeolitic minerals and a polymeric consolidant (ethyl silicate) applied to the NYT.

Moreover in order to better evaluate the mechanisms of stone consolidation, it was selected, for comparison, a porous sedimentary rock, Pietra di Vicenza, with a pore radii distribution similar to TGN.

The two stones were saturated by immersion under laboratory conditions. The specimens were divided into test group: untreated, treated with consolidant and treated with antihygro and consolidant.

Investigations were conducted before and after consolidation and included mineralogical and petrographic analyses (XRD, XRF, SEM), and physical and mechanical determinations (porosity, pore radii distribution, capillary water uptake, water absorption, ultrasonic wave velocity measurements, compressive strength, colorimetric measurements).

The consolidated samples were subjected to ageing tests, weathering simulations such as wet-dry and freeze-thaw cycles, salt crystallization tests and salt spray.

This has made for measuring the effectiveness of consolidation and to study the changes in stone properties.

The products modify the physical properties of consolidated tuff and change the behaviour of weathering: all the treated samples show a decrease in porosity and water absorption, a color variations and an increase in durability against weathering.

GENESIS AND OCCURRENCE OF JADEITITE FROM THE MONVISO META-OPHIOLITE, WESTERN ALPS

COMPAGNONI Roberto¹, ROLFO Franco¹, CASTELLI Daniele¹

- 1 - University of Torino

Presenter e-mail: daniele.castelli@unito.it

Key terms: jadeitite; plagiogranite; Monviso meta-ophiolite; Cultural Heritage; stone axeheads

A composite boudin is exposed in the antigorite serpentinite of Vallone Bulè, within the Basal Serpentinite Unit of the Monviso massif (Piemonte zone of calcschists with meta-ophiolites). The boudin consists of a quartz-jadeite rock core and a jadeite rim, very similar to the lithologies used by prehistoric men to make stone axeheads (e.g. Ricq-de Bouard & Fedele, 1993; Compagnoni et al., 1996).

In spite of their different bulk-rock compositions, both core and rim show the same trace and REE patterns suggesting a common protolith. The quartz-jadeite rock exhibits a major, trace and REE composition consistent with that of oceanic plagiogranite, most likely a dyke cutting across upper mantle peridotites, later hydrated to serpentinites (e.g. Castelli & Lombardo, 2007, with refs.). Conversely, the jadeitite, which consists mainly of zoned jadeite crystals progressively enriched in the diopside component from core to rim, is significantly depleted in Si but enriched in Mg and Ca with respect to the quartz-jadeite rock. The trace and REE similarities and the ubiquitous presence of small zircons suggest that the jadeitite derives from an original plagiogranite -the present quartz-jadeite rock- through a metasomatic process involving a significant desilication and Mg- and Ca-enrichment connected to the peridotite serpentinization. The process, responsible for the transformation of the plagiogranite into a jadeitite, should have occurred during prograde Alpine high-pressure (eclogite-facies) metamorphism, since the first Na-pyroxene formed is a jadeite, corroded and partly replaced during the metasomatic process by a progressively more omphacitic pyroxene.

Because similar rocks -mostly jadeitites, but even meta-plagiogranites- are reported from other localities from the Western and Maritime Alps, it is likely that the raw materials of most jadeitites used to make stone axeheads, which are spread all over the Western Europe, have a similar genesis and derive from the Western Alps as long since suggested (Damour, 1881).

FAMOUS MINERAL LOCALITIES: THE RE-OPENING OF TREPÇA MINE, KOSOVO

GRIECO Giovanni¹, KASTRATI Shpetim¹, ZEQRIRI Izet², SHALA Ferat³

- 1 - Università degli Studi di Milano

- 2 - University of Pristina

- 3 - Trepça Enterprise under PAK Administration

Presenter e-mail: giovanni.grieco@unimi.it

Key terms: Trepça Mine; Kosovo; lead-zinc ore; hydrothermal; skarn

The Trepça mine, whose full name was in past Trepça Stari Trg and has now been changed to Trepça Stan Terq, is one of the most famous mineral localities in the world, but also the most valuable mining site of former Yugoslavia, that produced lead, zinc, silver and minor cadmium and bismuth. The mine underwent in the nineties of last century a rapid decline in production and suffered a forced closure due to the Kosovo war in 1999.

The mine is located in the Vardar Zone of the Dinarides Alpine Belt and is related to the intrusion of Tertiary post-tectonic magmas into a sequence of Paleozoic basement and Mesozoic sedimentary cover and ophiolite nappes. The Trepça ore deposit consists of a series of mantle orebodies and mineralized skarns within the sedimentary pile. The main orebodies are intercalated between thick marbled limestones at the bottom and thick schists at the top. The distribution of mineralization was controlled by a trachite and dacite volcanic chimney surrounded by an explosion breccia. Deposit formation is due to a hydrothermal plume of magmatic origin mineralizing carbonate host rocks, similar to the Kipushi model (Feraud et al., 2007).

Mineralogical paragenesis of Trepça Mine is extremely rich, with more than 60 different mineral species reported. Several of these minerals form valuable aggregates of bright metallic sulphides and well grown crystals of quartz, dolomite, calcite and rhodocrosite of collector interest. Moreover tens of specific studies were devoted to particularly interesting phases such as phosphates (e.g. childrenite, crandallite and ludlamite) and sulphides (e.g. galena, bournonite and cosalite).

Mining at Trepça is documented since the late Middle Ages when the most valuable metal extracted was silver. Mining continued under Turkish rule, but after 17th century declined rapidly till closure in the 19th century.

Modern mining at Trepça was begun in 1930 by the British owned Trepça Mine Ltd at the site of the open pit Middle Ages mine and went on in underground. During the following 60 years Trepça Mine, together with other nearby mines, was the most important mining district of Yugoslavia and one of the largest in the world for lead-zinc production, with a total production of about 3 millions tons of lead and 2 millions tons of zinc. Decline, that had already begun in the '70th, accelerated under Serbian rule in the '90th and culminated with closure of the mine during the Kosovo war of 1998-99. The two smelters were destroyed and the mine completely flooded.

Trepça Stan Terq Mine was reopened thanks to the efforts of the mine management and workers in 2005 with a production, in its first year, of 15.000 ton of lead-zinc ore. Since then production has increased each year, reaching 128.000 tons in 2010.

Reserves are still huge and could be enlarged by further exploration as the ore bodies have not yet been bounded. Assessed resources total about 40 millions tons at 4.02 % Pb, 3.25 % Zn and 76 g/t Ag.

Future development plans comprise: new exploration in the Trepça mineralized belt, increase of production from known resources construction of a new flotation plant, a standard procedure for control of mine production and, eventually, construction of lead and zinc foundries at Mitrovica Industrial Park.

A preliminary agreement between University of Milan, University of Pristina and Mine management led to a visit of the mine in April 2011. During a short survey of the exploitation front at level XI, 640 m below surface, several samples of collector interest were taken. The preliminary agreement is being improved in order to open Trepça Mine to scientific study, comprising collection and study of mineralogical samples, geological interpretation of ore deposit and characterization of huge tailing dumps.

Key terms: chromium; spinel; lherzolite; dike

The Balmuccia peridotite massif is one of the subcontinental mantle peridotite bodies intruded in the mafic-ultramafic Ivrea-Verbano complex in the Western Alps, Northern Italy. The Balmuccia body consists of dominant foliated lherzolites crosscut by several generations of pyroxenite dikes, approximately belonging to an earlier "Cr-diopside suite" and a later "Al-augite suite". These dike suites are interpreted as mineral segregations from melts which percolated into the lherzolite, refertilized it and caused focused dunitization of the host peridotite. Our study is focused on some thin, cm- to dm-thick pale grey-violet dikes presumably belonging to the late-stage Al-augite suite and intersecting the lherzolite mass at its eastern margin, near the intrusive contact with the Ivrea-Verbano complex. These dikes often show a spotted texture due to the segregation of abundant coarse vitreous black spinel phenocrysts. The mineral assemblage is both Al- and sulphide-rich. The silicate-oxide assemblage includes dominant clinopyroxene (diopside-augite) and blue-green, transparent Al-rich spinel, with minor Ti-rich Na-K pargasite amphibole, Al-bearing orthopyroxene (enstatite), accessory Ti-rich phlogopite and plagioclase and rare olivine (intergrown with spinel droplets). Abundant Fe-Ni-Cu sulphides (pentlandite, pyrrhotite, chalcopyrite and bornite) are widely disseminated across the dikes both as mm-sized polyphase nodules interstitial to the silicate-spinel matrix and as tiny, locally extremely abundant drop-like inclusions in spinel.

Assemblages containing bornite exclusively occur as inclusions in spinels, which host a redox-dependant equilibrium pentlandite-chalcopyrite-bornite association. The richness in Ni sulphides copes with the scarcity of olivine in this association and is one of the interesting features of these dikes. Another curious feature involves the margins of the dikes. The contacts

with the host lherzolite are sharp but not tectonic and are characterized by lateral passage from dike-related undeformed to lherzolite-related, variably foliated assemblages (olivine, ortho- and clino-pyroxenes, fine-grained dark brown spinel and rare amphibole). A visual inspection of the host lherzolite/grey dike contact zones showed a peculiar, progressive change in colour of the spinel from dark brown, in "distal" position, to green transparent near the dike margin. That was the most visible evidence of the interaction between lherzolite and intruding dikes, as an actual reaction zone is not easy to recognize texturally. Analytical transects across these mm- to cm-sized "contact zones" by means of microprobe showed that there may be a cryptic reaction zone. The lherzolite phases do record some changes in major element composition, and in particular spinel, pyroxenes and amphibole show variations in Chromium concentration, among others. Across the reaction zones lherzolite spinel vary their Cr content from about 19 wt% Cr₂O₃ to <1%. They also decrease their Fe²⁺ content whereas Al and Mg are enriched. Clinopyroxene shows a variable "response" to this reaction zone as it shows a tendency to Cr depletion coupled with Ti enrichment and fluctuations in alkalis. Accessory amphibole crystals in lherzolite show a trend of Cr depletion and Ti enrichment as well as a variability in Al and Na contents towards the dike margin. Cr is rather low in lherzolite orthopyroxene, however it shows a tendency to Cr and Mg depletion (and Fe enrichment) towards the dike contact. Olivine tends to be more forsteritic in a distal position. Ongoing and future analytical investigations are aimed to characterize and verify the meaning and the extent of this Cr-depleting Al-enriching and dike-lherzolite metasomatic interaction. Of particular interest is the fate of Cr, one of the economic elements enriched (after mobilization from a source) in relation to metasomatic processes, e.g., dunitization, affecting peridotites.

Presenter e-mail: gianmarco.rapisardo@unina.it

Key terms: Zeolites; genesis; Latium; minerogenetic aspect

Many ignimbritic deposits of Central and Southern Italy are deeply affected by minerogenetic process leading to the zeolitization of the volcanic products.

Zeolitization processes in volcanoclastic formations, develop by interaction between alkaline solutions and a precursor represented by a volcanic glass. This interaction mainly depends on the temperature conditions of the deposits, the glass composition, the cationic content of the interacting solution and its pH (Hall, 1998).

Phillipsite and Chabazite are the main zeolites occurring within the volcanoclastic deposits of central-southern Italy, such as the Neapolitan Yellow Tuff and the Campanian Ignimbrite from Campania region, and the *Rivieto-Bagnoregio* Ignimbrite (*Tufo rosso a scorie nere*), the *Sorano* formation (Sorano Yellow tuff) from Vulsini district, the *Tufo Giallo della Via Tiberina* from Sabatini volcanic district and the *Lionato* tuff from Albani Hills volcanic complex (Lazio and Toscana regions) (de Gennaro et al., 1995).

The present research reports the preliminary results of a detailed mineralogical characterization of the *Tufo Giallo della Via Tiberina* (TGV), Sabatini volcanic district (Nappi and Mattioli, 2003). The main goal of the study was to correlate the volcanological features (eruptive styles, emplacement mechanism, etc.) with the post-depositional minerogenetic processes (type of zeolite, areal and stratigraphical variations of authigenic phases, etc.) in order to propose a suitable minerogenetic model.

The investigated samples come from four quarries (*Cannetaccio*, *Perina*, *SICAT*, *Fantini*), located close to Riano (Rome). Optical microscopy (OM) on thin section and scanning electron microscopy (SEM) allowed to identify the major phases and their relationships. Quantitative mineralogical analyses were performed by X-ray powder diffraction (XRPD) using RIR-Rietveld (Bish and Post, 1993) methods. Chemical analyses were carried out by XRF for bulk rocks and by EDS for crystal phases.

The main zeolitic phases are chabazite and phillipsite (total content ranging between 25% and 55%). Analcime, was only occurring in samples from "*Cannetaccio*" quarry. Primary constituents are sanidine, calcite, pyroxene and an amorphous matter.

OM revealed that the occurrence of calcite, identified by XRPD, is related to the calcareous clasts from the underlying sedimentary basement. Further analyses are in progress to establish whether a carbonatic cement is present too, linked to post depositional carbonatic water circulation. EDS data shows that chabazite always display Ca as main extra-framework cation, followed by K, and vice versa for phillipsite. Analcime is probably related to the alteration of leucite. SEM observations show the presence of low-temperature K-feldspar (adularia).

EL CRESTON PORPHYRY-MO DEPOSIT (SONORA STATE, MEXICO): MINERALIZATION, ALTERATION PATTERN AND FIRST FLUID

INCLUSIONS DATA

ROSSETTI Piergiorgio¹, AQUÉ Riccardo², COLOMBO Fabrizio³, STRA Michel⁴

- 1 - Dipartimento di Scienze Mineralogiche e Petrologiche, Università di Torino
- 2 - Dipartimento di Scienze della Terra, Università di Siena
- 3 - Totem Pole Geological Consulting Ltd., Vancouver
- 4 - SEA Consulting Srl, Torino

Presenter e-mail: piergiorgio.rossetti@unito.it

Key terms: polyphase hydrothermal evolution; hydrothermal alteration; deep porphyry-Mo deposit

El Creston is a porphyry-moly deposit with proven and probable mineral reserve of 146,705,000 tonnes grading 0.077% Mo (+ Cu±Zn±Ag as byproducts). It is located in the Mexican part of the Basin and Range Province, where a metamorphosed Proterozoic basement, mainly composed of a metagranite body (Creston metagranite) intruded in a sequence of phyllites, quartzites, gneisses and metavolcanics, rests as a roof pendant on the Tertiary Sonoran batholith, which includes several intrusions mostly ranging in composition from granite-granodiorite to quartz monzonite. The deposit is related to the emplacement of porphyry stocks in the basement (particularly, the Creston metagranite). The mineralized system underwent a complex tectonic history, the most relevant structures being low-angle normal faults (dipping N35/30°) with horizontal displacement.

A polyphasic hydrothermal evolution is testified by several types of hydrothermal veins and breccias. The following main veins types have been recognized (older to younger, even if some reversals surely occur):

- Qtz + Kfs ± Ab ± Mlb (molybdenite) ± Phl (phlogopite) ± Ms ± Py ± Rt veins (QTZ-KF).
- Qtz + Kfs + Phl ± Mlb veins (QTZ-PHL).
- Bt + Mgt veins (BT-MT).
- Qtz + Ms + Rt ± Py ± Sp ± Ccp ± Td-Tn (tetrahedrite-tennantite s.s.) veins (QTZ-MU).

- Zn-Sd (zincian-siderite) ± Ms ± Sp ± Ccp ± Td-Tn veins (ZN-SID). Different types of breccia occur, including pre-mineralization intrusive breccias and hydrothermal breccias.

Among the 7 alteration facies identified, the most significant are:

- Qtz + Kfs + Ab ± Ph ± Zrn ± Py (KF), connected with the QTZ-KF veins;
- Bt + Mgt ± Ms ± Zrn ± Ep (MT);
- Qtz + Mu + Py ± Ccp ± Rt (MU), related to the QTZ-MU veins.

Apart from an early (relict) albittization stage, the KF and (often overprinting) MU are the strongest alteration facies; the envelope of MT alteration around the KF alteration likely represents its slightly lower T equivalent. Mineralization is mostly connected with the KF veins and related alteration. At least locally, however, molybdenite enrichments are found in Py-Ms-bearing assemblages and at the contact between the two alteration facies.

Strong enrichments also occur in the quartz (+ Kfs ± Phl) matrix of hydrothermal breccias.

A reconnaissance fluid inclusion study performed in quartz from the QTZ-KF and MU veins led to identification of the following populations:

- L+V+several solid phases (Phl, Ms, Cal, Mgt, Tur, Ccp...): these are the earliest inclusions, only occurring in QTZ-KF veins;
- L+V±Ccp: these are the most abundant inclusions, connected with the MU alteration;

- L+V+HI±Hem: rarely occurring in QTZ-MU veins, or QTZ-KF veins with MU overprinting;

- V+L±Ccp: VLC inclusions surely not due to necking are rare. Often in samples containing the halite-bearing inclusions, they may be coeval with them.

A striking feature of the fluid inclusions picture is the paucity of hypersaline inclusions. This observation and microthermometry/Raman preliminary data suggest that in the QTZ-KF veins fluids with low salinity and moderate CO₂ content, of likely magmatic derivation, were trapped above the solvus in the H₂O-NaCl-CO₂ system, thus implying a great depth of formation for the deposit. Also during cooling the fluid remained above the solvus, and only episodically unmixed: cooling and, probably, water-rock reaction, more than fluid immiscibility, played an important role for molybdenite precipitation at El Creston.

UNIDIRECTIONAL SOLIDIFICATION TEXTURES AND MINERALIZATION: THE KULE PORPHYRY-MOLYBDENUM SYSTEM (XINJIANG UYGUR, CHINA)

ROSSETTI Piergiorgio¹, COLOMBO Fabrizio²

- 1 - Dipartimento di Scienze Mineralogiche e Petrologiche, Università di Torino
- 2 - Totem Pole Geological Consulting Ltd., Vancouver

Presenter e-mail: piergiorgio.rossetti@unito.it

Key terms: magnetite-bearing UST; high volatile content; porphyry-Mo deposit; Variscan calc-alkaline magmatism

The Kule valley is located close to the western end of Xinjiang Uygur Autonomous Region, 100 km southeast of Yining. The area belongs to the western sector of the > 2500 km long, east-west trending Tian Shan mountain range. In this part of range (central Tien Shan) the Yili Terrane, a wedge-shaped Precambrian craton, is exposed, and bound by the North and South Tien Shan ranges. Variscan calc-alkaline granite and granodiorite bodies (dated 400-250 Ma) crop out over much of the Yili block, representing a still poorly understood magmatic arc derived from orogenic events on both sides of the block.

The Kule area is composed of a suite of magmatic rocks of inferred upper Carboniferous to Permian age. Based on field relations and petrographic features, the following units are recognized:

- Granite Unit, composed of: a) medium-grained, equigranular to porphyritic granite, affected by a pervasive "propylitic" alteration; b) microphyritic granite, made of plagioclase, K-feldspar and quartz phenocrysts in a micrographic matrix; c) microphyritic leucocratic granite, showing peculiar (UST) textures which are described below.
- Rhyolite Unit: it is a mixture of rhyolite lava and volcanoclastic rocks with the same composition. It includes massive rhyolite bodies related to emplacement of rhyolitic magma under hypobassal conditions.
- Tuff Unit: shows the same composition of the Rhyolite Unit, but displays features typical of pyroclastic (to epiclastic) deposition. Its primary bedding shows a NNE-SSW trending subvertical attitude, suggesting (in agreement with other evidences) that the Kule sequence suffered a tilting towards WNW.

- Andesite Unit: intrudes the Tuff Unit and is composed of porphyritic andesite affected by propylitic alteration. Dykes related to the Andesite Unit intrude the Rhyolite Unit.

The sequence is affected by veining, alteration and Mo mineralization. The following main veins types occur (older to younger):

- Qtz - Kfs ± Mgt (magnetite) veins: they crosscut the microporphyritic granite and rhyolitic rocks, producing a strong "potassic-type" alteration given by brown Bt + Qtz + Mgt ± Kfs;
- Qtz - Ms + Py ± Mib (molybdenite) veins and breccias: crosscutting the microporphyritic granite, rhyolitic rocks and Tuff Unit, they produce a mild to very strong alteration given by the same assemblage.
- Qtz ± Chl ± Ep ± Cc veinlets: they only occur in the medium-grained granite and Andesite Unit, where produce a pervasive Chl - Ep - Ab - Ttn ± green Bt ("propylitic") alteration.

When restored to its primary position, the Kule sequence shows features (e.g., calc-alkaline volcano-plutonic setting; multiple veining and alteration, with a "potassic" core surrounded and in part overprinted by a "phyllitic" envelope; hydrothermal breccias; molybdenite) typical of a (low-F) porphyry-Mo system.

The microgranite porphyry, that in the restored setting lies below the potassic core, shows a "layered texture", given by cm-thick coarse-grained, crenulated quartz - magnetite layers separated by leucocratic granite. Both quartz and magnetite crystals within the layers grow in the same direction, thus representing Unidirectional Solidification Textures, like those firstly recognized in the Henderson porphyry-Mo deposit (Shannon et al., 1982). Peculiar of the Kule microgranite is the occurrence of coarse-grained magnetite within the layers. However, the absence of hydrous magmatic phases in the microgranite (the only mafic mineral being fine-grained magnetite) strongly suggests, as proposed for other UST occurrences, release of (ore) fluid to the time of crystallization and solidification of the apex of a stock.

The occurrence of Unidirectional Solidification Textures at the Kule porphyry-Mo system further emphasizes their importance, as features indicative of high primary volatile content and ore fluid release in magmatic-hydrothermal systems.

TRACKING STRAIN IN DEEPWATER RESERVOIR USING SEISMIC ATTRIBUTES

IACOPINI David¹, BUTLER Robert W.H.¹, PURVES S.²

- 1 - Geology and Petroleum Geology, University of Aberdeen
- 2 - ffa, Newcastle

Presenter e-mail: d.iacopini@abdn.ac.uk

Key terms: exploration geophysics; reservoir characterization; fault imaging; post stack processing; seismic attributes

Nowadays most the interpretation models proposed within basin and reservoir system assume and simplify the seismic structures as simple line or surface strands. Faults are commonly picked as single plane or sharp discontinuity through the center of the fault.

Similarly, in compression system, deep-water toe thrust anticlines have been interpreted using traditional simplistic models such as fault-propagation folds, detachment folds, and both simple- and pure-shear fault bend folds. High quality 3D seismic data show that the deep-water anticlines typically display extreme variations in along-strike fold morphology which are not accounted for by any individual one of the above models; multiple conflicting kinematic models would have to be applied to explain different parts of a single structure (Higgins et al., 2009). Even in very high quality 3D seismic lines the thrust anticline structures are often represented by wipe out zones that are critical to determining the trap elements in compression thrust system (Kostenko et al., 2007). Drilling in such a zones disclosed a much more complicate picture of the thrust and zones system. Exploration success in the offshore fold belts depends on understanding and visualizing their architecture and those low signal/noise zones using specific seismic attributes. A detailed and correct 3D visualization of their architecture represents necessary steps toward a correct conduit-reservoir -cap rocks characterization. A specific studies focusing on the seismic image processing and mapping of fault distortion zone within thrust fault system is still lacking in the literature (Iacopini & Butler, 2011; Iacopini et al., 2011). In this contribution we describe specifically the main image processing workflow and underline the potentiality of combining seismic attributes through volume visualization techniques to describe, map and highlight some deformation properties of the seismic disturbance zones (SDZ) at the seismic resolution (10 to 100 m). As a result of the post stack seismic image processing we investigated discontinuities using semblance attributes (that quantify and delineate the short-range anomalies on the intensity of reflector amplitudes), collecting these into so-called "disturbance geobodies" and proposed a possible workflow to detect deformation in low signal/noise zones bounding the thrust and main forelimb. Disturbance geobodies (fig 1b) define tracts of closely spaced, small-offset reflector discontinuities, interpreted here as subsidiary thrust faults adjacent to the main thrust breaks identified in conventional amplitude displays.

We thank Steve Toothill and colleagues from CGGVeritas for permission to work and publish on the 3D dataset from the Niger Delta. We also thank ffa for provision of their SVI Pro software to the University of Aberdeen.

GPR MEASUREMENTS FOR STRENGTH CHARACTERIZATION OF CONCRETE

CAPIZZI Patrizia¹, COSENTINO Pietro¹, SCHIAVONE Salvatore¹

- 1 - DISTEM department University of Palermo, Italy

Presenter e-mail: patrizia.capizzi@unipa.it

Key terms: GPR; ultrasonic measurements; concrete; characteristic resistance

Ultrasonic survey for both non-destructive test and characterization of concrete artefacts is a rather established methodology (Blitz and Simpson, 1995), whereas GPR measurements, even though widely used for non-destructive investigations, are not sufficiently used for material characterization. In this paper we present an attempt of correlation between the mechanical properties of concrete and the material permittivity. GPR measurements on a set of concrete specimens (physical models) were acquired and US measurements had been carried out for results comparison.

The possibility of material characterization through the GPR measurements, taking into account the integration with the ultrasonic technique, has been studied and possible relationships between the permittivity of materials and their bulk density are discussed. A series of samples of concrete, characterized by different material properties, were used for georadar and ultrasonic measures, seeking correlations among experimental data.

GPR data were acquired using an IDS K2 GPR system with an IDS Aladdin Full Polar antenna (2000 MHz), whereas US measurements were obtained using a Boviari TDAS 16 system with probes characterized by a resonant frequency of 55 kHz. The concrete cubic specimens (edge of 15 ± 0.1 cm) have been used for detecting their permittivity (GPR reflection measures) and their mechanical strength (US measures). The US measures allow to calculate Young modules, E, by means of the US velocity, VUS, and density, d:
 $E = d \cdot VUS^2$.

Once every measure was completed, samples were subjected to the uniaxial compression tests to estimate their compressive strength. The apparent conductivity values achieved by GPR measurements were used to estimate seismic velocity V modifying empirical relationship (Wyllie et al., 1956), obtaining:

$$\frac{1}{V} = \frac{\phi - S\phi}{V_{air}} + \frac{S\phi}{V_{fl}} + \frac{1 - \phi - A}{V_{cement}} + \frac{A}{V_{aggregate}}$$

where ϕ is the concrete porosity, S is the porosity saturation, A is the aggregate fraction and V_{fl} , V_{cement} , V_{air} and $V_{aggregate}$ are, respectively, the seismic velocity in the fluid, in the cement, in the air and in the aggregate.

The values of characteristic resistance calculated using the relations (Italian law, D.M. 9/01/1996):

$$Rck = (E/5700)^2$$

were compared (Fig. 1). The Rck values estimated by GPR measurements show a poor correlation with the Rck values measured and calculated by US measurements, also because the permittivity increases with both the bulk density (increasing with the Rck) and water content (decreasing with Rck).

10.1474/Epitome.04.1264.Geoitalia2011

NEAR-SURFACE GEOPHYSICAL PROSPECTION TO REVEAL THE HIDDEN STRUCTURE OF THE TERRAMARA SANTA ROSA, POVIGLIO (ITALY)

MELE Mauro¹, CREMASCHI Mauro¹, GIUDICI Mauro¹, BASSI Agnese², PIZZI Chiara¹, LOZEJ Alfredo¹

- 1 - Dipartimento di Scienze della Terra "Ardito Desio" - Università degli Studi di Milano
- 2 - Dipartimento di Scienze della Terra - Università degli Studi di Parma

Presenter e-mail: mauro.mele@unimi.it

Key terms: Archaeogeophysics; Terramara Santa Rosa; Bronze age; Electrical resistivity imaging; Electromagnetic induction

The Terramara Santa Rosa (Poviglio, northern Italy) is an archaeological site which developed between Middle and Recent Bronze age, constituted by two settlements and delimited, as seen by aerial photograph, by earth rampart. The smaller settlement (Villaggio Piccolo; VP) to the North is the oldest part, founded during the Middle Bronze age. To South, a U-shaped rampart delimits the larger part of the younger site (Villaggio Grande; VG), which mostly dates to the Recent Bronze age.

The archaeological excavation has revealed that the settlements was surrounded by wide moats, running parallel to the villages fences and being part of a complex hydraulic system. The latter was built not for defensive purposes but to redistribute water toward the surrounding fields. The moat was fed by surface water probably taken form an adjoining Bronze Age Po palaeochannel and by groundwater drained by water wells dug inside the loamy clay ground to reach shallow and thin sand aquifers.

The Bronze landscape is today sealed by alluvial clay accumulated by Po river floods, 3-4 m thick, which fill depressions (moats and external areas) and hide the archaeological features.

Stratigraphic excavation was performed within the VP, at the transition between the VG and the hydraulic system, to the South. A large-scale geophysical survey (2008-2010) was carried out to provide an improved map of the buried structure and useful information to plan future archaeological excavations. Direct Current Electrical Resistivity Imaging (ERI) and Electro-Magnetic Induction (EMI) methods were applied to reveal the lateral and vertical heterogeneities between the near-surface, fine-grained sediments and the buried archaeological targets in order to improve the likelihood of locating the villages, the moats and other hidden targets in the surroundings.

70 ERI profiles, with Wenner and Wenner-Schlumberger array, were used to investigate the transition between the villages, the moats and the adjoining areas. Data were collected with roll-along technique and electrode spacing ranging from 1 m to 3 m, for an exploration depth of 15

m below the ground surface and a total length greater than 9000 m. EMI survey was conducted over a 16 ha wide area in order to map shallow heterogeneities at the site scale. Data acquisition was conducted with a ground conductivity meter, simultaneously transmitting at 5 kHz and 15 kHz frequencies, and using a vertical magnetic dipole configuration with 1.2 m distance between the coils. Measures were acquired in continuous mode (data sampling 1 Hz) with a snaked pattern of parallel profiles with 5 m separation.

ERI and EMI data revealed consistent apparent resistivity anomalies, supported by the results of the DC ERI data inversion. Since the electric and electromagnetic response of the site is strongly controlled by the presence of very fine, and therefore electrically conductive, loamy-clay sediments for which the presence of coarser textures (fine sand) increases the electrical resistivity, the geophysical survey highlights in a very neat and definite way i) the location of the villages, characterized by the highest values of electrical resistivity due to the increase of sandy textures that build up the point-bar complex where the villages were built on, ii) the moats that surrounds the villages, which appear as a conductive structure and iii) several local anomalies in the surroundings, some of which can represent possible archaeological targets.

Presenter e-mail: mariateresa.perri@unipd.it

Key terms: ERT; electrical resistivity tomography; tracer test; hydrogeology

During the last decade, hydrogeophysics has emerged as a discipline that, by using geophysical techniques, can complement the traditional hydrogeological data. Geophysical measurements are non-invasive, cost effective and can be performed with high spatial and temporal sampling. The most commonly applied technique is electrical resistivity tomography (ERT), both from the ground surface and in cross-borehole configurations. To infer reliable results from such a hydrogeophysical application, however, the uncertainty related to the data inversion has to be taken into account and specific attention must be paid to the experimental set-up and design, especially when the main target of the study is expected to be a quantitative estimation of the relevant hydrological quantities. The sensitivity and resolving power of ERT depend in fact on the type of acquisition methodology; operating from the ground surface only, for example, could lead to severe limitations in terms of resolution, and the corresponding results can be viewed only in qualitative terms. In this work, we present the results of a saline tracer test experiment performed in the saturated zone at the water works facility at Valdobbiadene (Treviso, North-East Italy), where an alluvial phreatic aquifer is heavily exploited for irrigation and drinking water supply. The experiment was monitored by time-lapse ERT acquisitions, using both surface and cross-borehole configurations. We compared the results of the two approaches and concluded that in general ERT can provide fundamental information on hydraulic characteristics as derived from tracer tests, but we also evidenced the strong limitations inherent in using surface electrode configurations only.

Key terms: Shallow gas; Eastern Lago Fagnano; Seismic analysis

Lago Fagnano, the southernmost ice-free reservoir of water in the world, occupies a deep tectonic depression developed along the E-W-trending Magallanes-Fagnano transform fault in Tierra del Fuego. It is 105-km-long, 7-km-wide in average, and has a maximum depth of 206 m. In the frame of an Italian-Argentinean scientific project funded by the Italian Ministry of Foreign Affairs, and jointly coordinated by the Istituto Nazionale di Oceanografia e di Geofisica Sperimentale (OGS) of Trieste and the Instituto de Geofísica "D. Valencio" of the Universidad de Buenos Aires, a series of high-resolution single-channel seismic reflection profiles were acquired on November 2009 and March 2010. These seismic data, collected by a Boomer source (150 kJoule) and a 10-hydrophones solid-state, single-channel streamer, complement and complete the seismic surveys carried out in the past in the Lago Fagnano. Ten gravity piston cores (with recovered sediment samples lengths variable from 80 cm to 170 cm) have been also collected to analyze the stratigraphy of the most recent (Middle to Late Holocene) sedimentary cover in the eastern sector of the basin.

Along some high-resolution seismic profiles the actual presence of shallow gas layers has been inferred because the typical very strong reflection and multiple reflections and acoustic blanking characterizing the seismic signal. The gas-related features observed on the seismic profiles include an amplitude phase reversal on top that creates multiple reflections. The gas abundance is well detected in seismic section because the sediment/gassy sediment interface (SGI) has a characteristic reflector with strong amplitude and reversed phase with respect to the bottom. The gassy sediments exhibit high attenuation (blanking) that hide geological sub-surface structures. The lake-floor morphology does not reveal any evidence of clear gas escape from the floor. The top of the acoustically high-amplitude layer is located between 0.3 and 1.7 m below the lake-floor. Seismic characteristics and velocity data

seem to suggest a low concentration of gas, most likely less than 1%. We assume that the main origin of gas could to some extent be linked to the presence of a shallow, thin peat-rich layer of Middle-Late Holocene age. In fact, the mapped gassy zone occurs in correspondence of the outlet of the Rio Turbio, the principal input of eastern Lago Fagnano, which discharges the waters coming from a relatively small sag pond located immediately to the east of the eastern shore of the lake, one of the numerous peatlands that characterize most of the Tierra del Fuego lowlands.

SHORT-TERM VARIATIONS IN RADON CONCENTRATION IN A DEAD-END MINING GALLERY

BOCHIOLLO Massimo¹, VERDOYA Massimo¹, PASQUALE Vincenzo¹

1 - Dipartimento Territorio e Risorse - Università di Genova

Presenter e-mail: massimo.bochiolo@gmail.com

Key terms: radon flow; natural hazard; underground environment;

time-series analysis; stress change

Radon is the densest gas known under normal conditions and the only noble gas to present a natural radioactivity. Because of such properties, it is considered a health hazard. Although radon dissipates rapidly into the air, in poorly ventilated underground environments it concentrates and can contribute to ionizing radiation exposure. For these reasons, a better knowledge of the several factors controlling the radon migration can be of crucial importance for the hazard assessment as well as the concern over the health risk in underground environments.

The radon escape from a rock is rather complex process which depends on a number of chemical, physical and mechanical properties of the rock, such as uranium content and distribution in the mineral grain, size and specific surface area of grains, degree of fracturing and fissuring, presence of water in cracks, and effective permeability. Concerning the bulk rock properties, the presence of discontinuities (fractures, thrust/shear planes, etc.) provides potential pathways for radon migration and favors air and water circulation resulting in higher radon exhalation. Besides, atmospheric pressure and temperature variations can control the radon flow. In this paper, we present the results of an analysis of time-series of radon concentration and environmental parameters recorded in a dead-end mining gallery, located in the Maritime Alps.

The mine is composed by a main tunnel, with a rather regular (roughly circular) section, which ends in two short dead-end branches. Near the entrance, a side shaft with slightly larger dimensions departs perpendicularly from the main tunnel. The mine was bored in metarhyolites and porphyric schists mainly composed by quartz, feldspar, sericite and fluorite. U-bearing minerals are generally concentrated in veins heterogeneously spaced and made of thin laminated yellowish crystals of metaautunite and of greenish tabular crystals of metatorbernite.

Radon air concentration monitoring was performed with an ionization chamber which was placed in different times at the bottom of each branch. During the monitoring, hourly mean values of temperature, pressure, and relative humidity as well as radon air concentration were measured. External data logs of atmospheric temperature, pressure and rainfall data were also available from a meteorological station located nearby, at a similar altitude of the mine.

Measurements have shown several unexpected results. The observed radon concentration very clearly exhibits daily and half-daily periods. Besides interaction and mass transfer with the external atmospheric environment, a detailed analysis confirms that these variations are also related to lunar-solar tides. Moreover, the amplitude of the anomalies is surprisingly large. This can be explained by the fact that the mine is close to the Ligurian Sea coast. When the sea tides change the water level at the shore, this produces additional pressure which increases the deformations (this phenomenon is called sea loading). Searching for radon concentration changes and monitoring their amplitude as a function of time can provide important clues on the complex emanation process. During this process, radon reaches the air- and water-filled interstices by recoil and diffusion, where its migration is directed towards lower concentration regions, following the local gradient. The radon emanation from the rock matrix could also be controlled by stress changes acting on the rate of migration of radon from the solid and the fluid phase to pore, fissures, and fractures. This yields emanation boosts due to rock extension and the consequent crack broadening, and emanation decrease when joints between cracks close.

A NONLINEAR THEORY OF THE KUROSHIO EXTENSION LOW-FREQUENCY VARIABILITY

PIERINI Stefano¹

1 - Dipartimento di Scienze per l'Ambiente, Università di Napoli

"Parthenope"

Presenter e-mail: stefano.pierini@uniparthenope.it

Key terms: Kuroshio Extension; low-frequency variability; oceanographic modeling; dynamical systems theory

The Kuroshio Extension (KE) is a highly stratified, eastward-flowing free inertial meandering jet formed by the confluence of the Kuroshio and Oyashio western boundary currents; it constitutes, therefore, a front separating the warm subtropical and cold subpolar waters of the North Pacific Ocean [1]. The KE displays a decadal variability of bimodal character connecting a zonally elongated, fairly stable, energetic meandering jet and a much weaker, highly variable and convoluted jet with a reduced zonal penetration [2]. Understanding the mechanisms that produce such low-frequency variability is relevant not only from a purely oceanographic point of view but also from a more general climatic perspective, as KE fluctuations are associated with vigorous air-sea heat exchanges known to be able to affect considerably the variability of the midlatitude coupled ocean-atmosphere system in the North Pacific region. In this context, modeling results of an ocean circulation model suggest

that the KE low-frequency variability may be basically due to nonlinear intrinsic oceanic mechanisms. A double-gyre reduced-gravity shallow water model of the KE [3], forced by a time-independent climatological wind and whose domain of integration is bounded to the west by a schematic coastline, exhibits a fairly realistic mean jet and a decadal chaotic bimodal variability whose characteristic period (of around 10 years), flow patterns and relevant transition details are found to be in significant agreement with altimeter data [4]. A complex dynamical mechanism supporting such internal oscillations, and involving the bimodal behavior of the Kuroshio south of Japan, is proposed in [3]. Moreover, the same variability is interpreted in [3-4] in the framework of dynamical systems theory as a homoclinic orbit in phase space resulting from a global bifurcation associated with the reconnection of the stable and unstable manifolds of the saddle fixed point corresponding to the weak -contracted- jet state [5]. Further extensions of these results are outlined. This theory and the one according to which wind-induced Rossby waves and the effect of mesoscale eddies are crucial in determining the variability are critically compared in [6]. The role played by the basin geometry in the double-gyre modeling approach discussed above is found to be absolutely crucial in [7]. The mechanism of coherence resonance is shown in [8] to occur for the modeled KE in a parameter range that precedes the global bifurcation responsible for the bimodal variability, provided the wind forcing is perturbed by an appropriate red noise. The same conclusions are drawn in [9] by using a spectral quasigeostrophic model that retains only the first four modes in a Galerkin projection. Finally, sequential importance sampling is used in [10] to assess the impact of observations on an ensemble prediction for the KE low-frequency variability based on an identical twin experiment using model [3]. This particle filtering approach gives access to the probability density of the state vector, which, in turn, allows us to determine the predictive power (an entropy based measure) of the ensemble.

THE NEW PROBLEMS AND PROSPECTS ON THE THERMOHALINE CIRCULATION STUDY WITH PARTICULAR EMPHASIS ON THE MEDITERRANEAN CIRCULATION.

ARTALE Vincenzo¹

1 - ENEA

Presenter e-mail: vincenzo.artale@enea.it

Key terms: THERMOHALINE CIRCULATION; DYNAMICAL SYSTEM; MEDITERRANEAN CIRCULATION

Since of the '50s Stommel's pioneering works, the dominant paradigm of the ocean conveyor belt is based on the concept that the horizontal pressure forces resulting from the hydrostatically balanced horizontal density differences drive the ocean flow.

More recently, many studies have revitalized the role of the ocean's eddy and wind field in establishing the characteristic and variability of the global thermohaline circulation. These recent finding reconcile Stommel theory with the modeling results of '70 regarding the effect of eddies on the deep flow, still an important component of the THC.

Moreover, due to the intrinsic heterogeneity and nonlinearity of the ocean circulation, describable by many variables that vary significantly over space and time scale covering many order of magnitude, if only due to the dominance of advective fluxes within the ocean water 3-D domains, but also to the many complex feedback between the domains. As consequence positive (negative) feedback can lead to instability that drives the system to new modes of behaviour that bear little resemblance to the external forcing, if such destabilising processes are not properly represented, the ocean circulation, for example simulated in the OGCM, may not be able to display important observed modes of ocean internal variability.

In this talk we review those studies, which collectively, are changing the classical view of the global conveyor belt; in particular we discuss how these results have had an influence on some recent theoretical and numerical results on the Mediterranean thermohaline circulation and on its future development.

Key terms: Finite Size Lyapunov Exponent; Adriatic Sea; Lagrangian transport; sea surface currents; coastal radar

In two-dimensional flows, a simple time dependence in the velocity field is enough to induce turbulent structures and consequently chaotic advection in particles trajectories.

Analysing these fields in the context of dynamical systems, an Eulerian approach would provide the configuration of the eddies at a given scale and time, while the application of a Lagrangian technique will show the

spatio-temporal variability of these eddies.

The fundamental assumption of chaotic advection is the sensibility of trajectories to initial conditions, meaning that fluid elements initially very close would follow diverging trajectories.

The exponential rate of separation between two particles is defined by the Lyapunov exponent λ .

The classical definition of Lyapunov exponent refers to the exponential rate of divergence, over infinite time, of infinitesimally closed initial points. The FSLE technique keeps the original idea of capturing the rate of divergence between trajectories, but its new formulation overcomes the limit operations dealing with real data:

$$\lambda_T(\mathbf{x}_i, \delta_i, t, r) = \frac{1}{T} \ln r$$

Since the choice of δ and r depends mainly on currents characteristics and length scale of the structures of interest, there is not a parameters choice suitable for any velocity field.

FSLE technique shows how portions of fluid initially compact can be stretched and/or folded as time goes by, producing a "cascade" of inhomogeneities from large to smaller scales. This allows to identify dynamical structures within scales far below the finest resolution achievable by the classical Eulerian analyses, without any assumption on the sub-grid velocity field.

In the previous years, the FSLE technique was applied in the Adriatic Sea dealing with dispersion studies based on drifters experiments or on velocity data produced by NCOM model. These analyses, involving different areas and times, led to the identification of the whole basin mixing scales (Lacorata et al., 2001; Haza et al., 2008) and to the characterization of an hyperbolic point located in the South Adriatic (Haza et al., 2007).

The new analysis proposed involves the northernmost part of the Adriatic Sea and it is based on high resolution measurements of the velocity field coming from a radars system placed along Italian and Croatian coasts.

Data, belonging to NASCUM project - North Adriatic Surface Current Mapping, are available for the period 2007-2008 and cover a regular grid with the following dimensions and resolution: 50km x 50km with 2km spatial resolution and 1h temporal resolution.

Since Adriatic Sea is strongly affected by Bora and Sirocco winds the aim is to find a correlation between wind forcing over the basin and surface dispersion.

Typical wind events have been already identified in the wind forecast maps available from ALADIN Numerical Weather Prediction Model. During these episodes, a FSLE analysis has been done on the sea currents field, identifying peculiar filamental structures developing (such as hyperbolic points or barriers to transport). Preliminary results will be shown in this work.

2 - Autorità di Bacino Regionale del Friuli-Venezia Giulia

3 - Dipartimento di Geoscienze, University of Trieste

Presenter e-mail: imancero@ogs.trieste.it

Key terms: lagoon; inlets; water flow; tidal channel

The lagoon system Grado-Marano is connected to the open sea by three inlets, Grado, Lignano and Porto Buso. They are about 400-500 m wide and less than 12 m deep. The aim of the research project led by the Autorità di Bacino Regionale del Friuli-Venezia Giulia, in collaboration with the Department of Geosciences at the University of Trieste and the Istituto Nazionale di Oceanografia e di Geofisica Sperimentale, is to monitor the water flow, water volume and sediment mass transport and exchange through the inlets. For this purpose, two bottom-mounted Acoustic Doppler Current Profilers (ADCPs) have been placed in the inlets of Grado and Lignano. Measurements started on the 6th and 7th July of 2010, respectively, with 0.5 m of the vertical resolution, and 10 minutes sampling interval, yielding a 3-components vector time series. Preliminary results, based on a six months long time, series show that the flow is highly polarized along the channel axes. The along-channel Principal Component (PC1) has more than 99% of the total energy. The first EOF (Empirical Orthogonal Function) mode of the PC1, representing the barotropic flow, accounts for about 99% of the variance in the Grado inlet and 98% in the Lignano inlet. Hence, vertically averaged time series are produced and a PC1 time series computed for further analysis. Average currents appear to be out flowing with magnitudes about 14 cm/s, while variability is about 60 cm/s (standard deviation). Current speeds can reach 1.3 m/s during the maximum inflow and outflow in both inlets. More than 90% of this variability corresponds to the astronomical forcing: the semi-diurnal constituents M2, S2 and the diurnal K1 make up also over 90% of the tidal energy in both records. Provisional estimates show that the K1 signal in Grado is out of phase with that of Lignano by about 10 hours, while M2 and S2 are almost in phase with 2 minutes and 20 minutes difference respectively, Lignano leading Grado. A comparison between the Lignano current velocity series and the sea level at the nearby Tre Canai station, inside the lagoon, shows a leading tidal signal at Lignano, with the maximum sea level recorded at Tre Canai 3 hours after the maximum inflowing through Lignano. In addition, measurements from the bottom mounted ADCPs have been compared to vessel-mounted ADCPs measurements carried out in the Grado and Lignano inlets. Linear relationship has been found between the vertically averaged current PC1 and the total volume transport following the model $Q = aV + b$; V is the current velocity in m/s and Q is the transport in m³/s. The parameter "a"

is 1768.2 and 2748.9, while "b" is 15.6 and 306.2 for Grado and Lignano respectively. Judging by the RMS values (0.6 m/s in the Grado and 0.53 m/s in the Lignano inlets); the transport can easily surpass 1000 m³/s in the former and 1900 m³/s in the latter inlet. An out flowing peak of 1.3 m/s detected on October 6th, 2010, can produce a water transport of over 2300 m³/s in the Grado inlet and 3800 m³/s in the Lignano inlet.

During the last decades there have been many efforts to collect marine environmental data collected in Europe. In the Mediterranean Sea between programs that have helped build the data base for studies on the variability and climate change, there were: Mediterranean Oceanographic Data Base (MODB), Mediterranean Data Archeology and Rescue (Medar-MedAtlas) SeaSearch, SEADATANET. Many data are available and accessible through information systems developed by various Italian institutions. A single portal is offered by www.seadatanet.org.

A careful analysis of these data have been done to see the consistency of these and associated errors. This has been done on the basis of knowledge of various instruments used to collect data and the different technologies used. Were then made estimates of errors and data are now assessed on the basis of criteria based on possible instrumental errors, and variability observed in the past.

Presenter e-mail: rmosetti@ogs.trieste.it

Key terms: *long time series analysis; climate change; Gulf of Trieste*

The times series of mean monthly values of air and sea temperature and total rainfall, recorded at the CNR station of Trieste from 1921 to 2010, are analysed by means of a new filtering method. The method selects the time intervals in which the considered parameters significantly increase or decrease in a much more accurate way than any trend analysis. This leads to single out typical fluctuations on scales of climatic relevance. Then, on the filtered data a regime-shift analysis has been applied in order to test the statistical significance of the fluctuations above. The main result is the evidence of a marked anomaly with respect to the behaviour ascribed to the green house effect, as commonly assumed, both in the past and in very recent years.

THE GULF OF TRIESTE: A LONG TERM ECOLOGICAL RESEARCH (LTER) SITE

CATALETTO Bruno¹

1 - Istituto Nazionale di Oceanografia e di Geofisica Sperimentale

Presenter e-mail: bcataletto@inogs.it

Key terms: *LTER; Gulf of Trieste; Planktonic communities*

The investigation of the planktonic communities of the Gulf of Trieste boasts an important tradition that, as far as some of its components, dates back to the beginning of the Seventies of the last Century. The analysis of the populations' fluctuations has called for the need to follow their temporal evolution with respect to the modifications of environmental parameters. For this reason we have spotted a steady location where to collect a series of subsequent temporal information. The site (called C1) is located close to the Riserva Naturale Marina di Miramare (45° 42'03"N, 13°42'36"E) and represents the study area where most ecological planktonic investigations in the North Adriatic were concentrated. To the zooplanktonic component, which from a historical point of view was the major part of the local Gulf investigations, other observations have been added, such as those on the dimensional plemto-, pico-, nano- and micro- fractions, both autotrophic and heterotrophic. Today, the Biological Oceanography Department (Bio) of OGS, continues to collect information at the C1 site, proceeding with ecological investigations on the plankton, with the aim of understanding the mechanisms that underlie the observed fluctuations of the populations subjected to natural (climate change) and human influences (impact). As much important it is, in parallel, the assembly of information aimed at understanding the ecology of the species (life cycle, intra- and interspecific interactions) that represent the foundations to appreciate structure, function, hence, the temporal evolution of the biological communities.

The relevance of historical studies and the progression and implementation of the research allowed the Gulf of Trieste to be included in the LTER Italia network, whose aim is to promote long-term ecological studies and investigations in all the environments, but especially in the marine one.

2 - Department of Life Sciences - University of Trieste

Presenter e-mail: mlipizer@ogs.trieste.it

Key terms: *bloom dynamics; long term ecosystem research; chlorophyll a; nutrients*

The Gulf of Trieste is a very dynamic system due to the concurrence of severe meteorological and hydrological forcing factors which determine pronounced inter-annual, seasonal and shorter term variability in hydrological and biogeochemical properties, as well as in biological processes.

Bloom temporal evolution shows pronounced inter-annual variability considering both the total autotrophic biomass in terms of chlorophyll-a and the relative importance of different size-classes.

This study aims at evaluating the temporal scales of variability in phytoplankton bloom evolution, taking into consideration in particular the role of continental inputs and nutrient availability on bloom development using monthly, bi-weekly and weekly data from a Long Term Ecosystem Research station in the Gulf of Trieste, North Adriatic. The short term dynamic of bloom evolution has been investigated with particular attention on the possible environmental factors triggering the onset and then determining bloom exhaustion.

The typical seasonal evolution of phytoplankton biomass is characterized by a late winter - spring bloom (February - May), with the largest chlorophyll-a concentrations generally measured in February, and a second autumn bloom occurring in October - November. The late winter-spring blooms are usually due to micro- and nano-plankton size fractions, while the autumn bloom is mostly due to picoplankton. However, episodic meteorological events, alterations in continental runoff and in nutrient inputs may significantly alter this seasonal pattern, changing the timing of bloom development, modifying the contribution of the different size classes and determining the rapid exhaustion of phytoplankton biomass.

THE LATEST DEVELOPMENTS OF OGS NODC INFRASTRUCTURE: EASY MANAGEMENT OF META-DATA DIRECTORIES AND REAL-TIME COLLECTION, VALIDATION AND STORING OF MARINE DATA.

PARTESCANO Elena¹, ALTENBURGER Alessandro¹, BROSIK Alberto¹, GIORGETTI Alessandra¹, VINCI Matteo¹

1 - OGS - Istituto Nazionale di Oceanografia e di Geofisica Sperimentale

Presenter e-mail: epartescano@ogs.trieste.it

Key terms: *relational database; meta-data; XML; real-time; oceanography*

The OGS NODC information system is completely integrated within the European distributed network of oceanographic data centers and is able to answer to the requests of information through the network by means of a standardized interface and making use of the XML technology to exchange and qualify information. The oceanographic database archives more than 200 millions of measurements of physical and biogeochemical parameters, of current, wave motion, sea level and meteorological data. The information in the data archiving system are fully validated, continuously updated and accessible through a dedicated Web Portal, available on Internet. All the metadata are public while the access to archived data is subjected to a Data Policy, defined in agreement with the data providers. All the data and metadata are contained in an Oracle relational database and all the metadata are managed using the XML format, in agreement with the European projects standards. The XML formats and exchange schema's are based on ISO 19115 content model that have been defined for the metadata services.

The latest developments of OGS NODC infrastructure concern:

- the management of CSR (Cruise Summary Report) metadata: in detail, a new interface has been developed, to insert the information related to CSR. This functionality gives us the possibility to insert new CSRs and to update the old ones. To realize this interface we used some forms developed with Open Office, connected to the database using the Oracle JDBC Driver;
- the management of EDMERP (European Directory of Marine

Environmental Research Projects) and EDMED (European Directory of Marine Environmental Datasets) metadata, with the direct storage of XML file into the database, using the Oracle XML DB. This set of technologies, is supported by the W3C and it gives the possibility to store, query, update, and transform XML data while accessing it using SQL. The XML files inserted directly on the database give us the possibility to manage the information associated with EDMERP and EDMED metadata directories. It is possible to access text node and attribute values using SQL/XML. In addition, we developed a RESTful Web Service, to manage these XML files, decoupling the applications from the database. In this way, we can use any application capable to handle http URLs, like Mikado (a tool developed into SeaDataNet project);

- the realization of a real-time data management system with the automation of the entire data handling process: from the measurement of raw data to the end-users use. This solution allows to cut down the time needed to the harvesting of multiple data formats, the conversion in a standard format, the structuring in a database and the validation. The real-time data management system is related to the real-time collection of several marine data types by automatic population of a relational database, granting interoperability and resilience. This prototype is produced for the management of the local meteo-marine network for the Civil Protection of Friuli Venezia Giulia. The interoperability is guaranteed using XML and OGC standard schemata for data transport and representation. The java library "ServingXML" is the core of that system, that allows to convert textual data, this conversion generates a new XML file which schema we have defined. The resilience of the application is obtained adopting a new approach using "Apache Camel" as rule-based routing and mediation engine operating in an event driven way, decoupling software services, in a Java environment.

In the NODC, except for the Oracle database, we use only Open Source software. Inspired by its European working experience the NODC is building, in collaboration with other OGS groups, this technological infrastructure. At the moment the data come from a wide range of instruments like: meteo-oceanographic buoys, CTD profiler, current profilers and directional wave; but in the future we will increase the types of data covered.
