Abstract

Glycerol dibiphytanyl glycerol tetraether (GDGT) lipids are part of the cellular membranes of Thaumarchaeota, an archaeal phylum composed of aerobic ammonia oxidizers, and are used in the paleotemperature proxy TEX86. GDGTs in live cells possess polar head groups and are called intact polar lipids (IPL-GDGTs). Their transformation to core lipids (CL) by cleavage of the head group was assumed to proceed rapidly after cell death but it has been suggested that some of these IPL-GDGTs can, just like the CL-GDGTs, be preserved over geological timescales. Here, we examined IPL-GDGTs in deeply buried (0.2-186 mbsf, ~2.5 Myr) sediments from the Peru Margin. Direct measurements of the most abundant IPL-GDGT, IPL-crenarchaeol, specific for Thaumarchaeota, revealed depth profiles which differed per head group. Shallow sediments (<1 mbsf) contained IPL-crenarchaeol with both glycosidic- and phosphate headgroups, as also observed in thaumarchaeal enrichment cultures, marine suspended particulate matter and marine surface sediments. However, hexose, phosphohexose-crenarchaeol is not detected anymore below 6 mbsf (~7 kyr), suggesting a high lability. In contrast, IPL-crenarchaeol with glycosidic head groups is preserved over time scales of Myr. This agrees with previous analyses of deeply buried (>1 m) marine sediments, which only reported glycosidic and no phosphate-containing IPL-GDGTs. TEX86 values of CL-GDGTs did not markedly change with depth, and the TEX86 of IPL-derived GDGTs decreased only when the proportions of monohexose- to dihexose-GDGTs changed, likely due to the enhanced preservation of the monohexose GDGTs. Our results support the hypothesis that in situ GDGT production and differential IPL degradation in sediments is not substantially affecting TEX86 paleotemperature estimations based on CL GDGTs and indicate that likely only a small amount of IPL-GDGTs present in deeply buried sediments is part of cell membranes of active Archaea. The amount of archaeal biomass in the deep biosphere based on these IPLs may have been substantially overestimated.

1. INTRODUCTION

Archaea form the third domain of life, as classified by Woese & Fox (1977). One of the characteristics that distinguish them from bacteria and eukaryotes is their membrane lipid composition, consisting of isoprenoid chains linked to glycerol moieties via ether bonds. Many archaea produce glycerol dibiphytanyl glycerol tetraether lipids (GDGTs; Langworthy, 1977; Koga & Nakano, 2008). These include a GDGT containing two acyclic biphytane moieties (GDGT-0; see Fig. 1 for structures), and GDGTs in which the biphytanes contain cyclopentane moieties formed by internal cyclization (e.g. GDGT-1 to -3). Crenarchaeol, which contains a cyclohexane moiety, and the crenarchaeol regio-isomer (Fig. 1) are GDGTs produced exclusively by Thaumarchaeota (Sinninghe Damsté et al., 2002b; 2012). In live cells, GDGTs are present as intact polar lipids (IPLs), i.e. with polar head groups such as hexose- or/and phosphate groups (Fig. 1b; e.g. Koga & Morii, 2005 and references therein). These IPLs are, upon cell death, presumably transformed by cleavage of the head group into recalcitrant core lipids (CLs) GDGTs (Schouten et al., 2013 and references cited therein), whose relative abundances are used in the temperature proxy TEX86 (Schouten et al., 2002). In enrichment cultures of Thaumarchaeota, IPL-GDGTs mainly occur as monohexose (MH)-, dihexose (DH)-, phospho- and hexose, phosphohexose (HPH)-GDGTs (Pitcher et al., 2010; 2011a; Schouten et al., 2008; Sinninghe Damsté et al., 2012). These IPLs are also observed in suspended particulate matter in the water column (Pitcher et al., 2011b; Schouten et al., 2012; Schubotz et al., 2009) and in marine sediments (Lengger et al., 2012a; Schubotz et al., 2009).

IPLs have been used as biomarkers for live microbes in studies of deeply buried sediments, the so-called “deep biosphere” (Biddle et al., 2006; Lipp et al., 2008; Lipp & Hinrichs, 2009). These studies have shown, in general, that archaeal IPLs dominate over bacterial IPLs (the latter representing generally <10% of total IPLs) in marine sediments at depths >1 mbsf. However, the IPL-GDGTs reported in these sediments consisted only of glycolipids, and several studies indicate that these are less suitable for use as biomarkers for live archaea. Experiments conducted by Harvey et al. (1986) have shown that archaeal ether lipids with a glycosidic head group are not degraded as rapidly as eukaryotic phosphoester lipids. Schouten et al. (2012) showed that water column profiles of crenarchaeol with a MH-head group in the Arabian Sea were...
However, Schouten et al. (2008; Sinninghe Damsté et al. 2012a) showed that the sphingolipid-GDGTs in the sediments they analyzed did not report phospholipid-GDGTs in the sediments they analyzed. Indeed, Lengger et al. (2010) predicted that the supposedly more labile IPLs containing a phosphate head group (e.g. hexose, phosphohexose (HPH)-GDGTs) would disappear rapidly with a large depth (186 mbsf) and time (2.5 Myr) interval. The results are interpreted to reflect preferential degradation of certain IPL-species originally present in the surface sediments. We also discuss the consequence of these findings for TEX$_{298}$ palaeothermometry.

2. Materials and methods

2.1. Site description

The sediments were recovered during ODP Leg 201 from the Peru Margin at site 1229, a leg specifically designed for microbial investigations (D'Hondt et al., 2003). The samples were from holes A, D and C at depths from 0 to 186 m (Table 1). The samples were directly frozen after recovery and stored at -20°C. The ages of the sediments were estimated based on reported sedimentation rates of 32.3 cm . kyr$^{-1}$ for the top 0-20 cm, 98.1 cm . kyr$^{-1}$ for 21-230 cmbsf and 5.1 cm . kyr$^{-1}$ for 231 to 270 cmbsf, which is interpreted as the base of the Holocene (D'Hondt et al., 2003). Below, an average sedimentation rate of 7.98 cm . kyr$^{-1}$ was calculated using the Pleistocene/Pliocene transition as stratigraphic marker (2,588 kyr), located at 190 mbsf (D'Hondt et al., 2003). Freeze-dried sediments were analyzed for organic carbon concentrations (C$_{org}$). The freeze-dried sediment...
was acidified overnight with 2N HCl, subsequently washed with bidistilled H₂O, and the water was removed by freeze-drying. The decalcified sediments were measured on a Flash EA 1112 Series (Thermo Scientific) analyzer coupled via a Conflo II interface to a Finnigan Deltaplus mass spectrometer. Standard deviations from three measurements ranged from 0.01 to 0.2 % TOC.

2.2. Sediment extraction and IPL-CL-GDGT separation

Aliquots (1-2 g) of freeze-dried sediment were extracted with a modified Bligh and Dyer procedure as described by Lengger et al. (2012b). The extracts were stored at -20°C. One aliquot of extract was directly analyzed by HPLC/ESI-MS for intact polar lipids (IPLs) containing crenarchaeol, while another aliquot was fractionated over a silica column in order to separate the IPLs from the core lipids (CL) following the procedure of Oba et al. (2009) and Lengger et al. (2012b). The core lipid fractions were dried and hydrolyzed to release CL-GDGTs according to Kim et al. (2010). This yielded the IPL-derived GDGTs, which are used in the TEX86). Ranging from 0.05 to 3.2 μg . g sed dw⁻¹ for GDGT-0, 0.03 to 2.2 μg . g sed dw⁻¹ for crenarchaeol, and 0.01 to 2.8 μg . g sed dw⁻¹ for the IPL-derived minor iGDGTs, with a tendency to decrease with depth, but again with large scatter (Fig. 2a). When concentrations were normalized to Corg, only minor changes in concentrations were observed: they ranged between <0.1 and 0.5 μg . g C org⁻¹ for the minor iGDGTs, 0.2 and 1.3 for GDGT-0 and <0.1 and 2.1 for crenarchaeol regio-isomer, which are used in the TEX86, ranging from <0.01 to 0.012 for the minor iGDGTs and crenarchaeol, and from 0.01 to 0.2 for GDGT-0 (Fig. S1b).

2.3. HPLC/ACPI-MS, HPLC/ESI-MS² and data analysis

Analysis of CL-GDGTs and IPL-derived GDGTs by HPLC/ACPI-MS and calculation of TEX86 was carried out as described previously (Schouten et al., 2012). Reproducibility for TEX86 values is typically < 0.02, corresponding to errors of < 1 °C. Temperatures were calculated using the calibrations according to Kim et al. (2010) for TEX86. Intact polar lipids with a crenarchaeol core (Fig. 1c) were directly analyzed by HPLC/ESI-MS² using a specific selected reaction monitoring method (SRM; Pitcher et al., 2011b). No direct absolute quantification of IPL was possible due to a lack of standards. Therefore, response areas per g sediment are reported. The method has been reported to detect amounts as low as 0.01 ng/g sediment dw, equating to ~ 7 pg injected on the column (Lengger et al., 2013). Performance of the ESI-MS² was monitored by repeat injections of an extract of Arabian Sea sediment (obtained from Lengger et al., 2012b), typically after each 8 sample runs. Duplicate injections yielded relative standard deviations of the areas (on average 2%). A principal component analysis was conducted on the concentrations of organic carbon, CL- and IPL-derived GDGTs and abundances of IPL-crenarchaeol species, using the software PAST (Hammer et al., 2001).

3. Results

Organic carbon concentrations ranged from 0.2 to 6.9 %, with a tendency to decrease with depth, but with large scatter (Table 1). This was also observed for concentrations of CL-GDGT-0, which ranged from 0.1 to 21 μg . g sed dw⁻¹, of CL-crenarchaeol, ranging from 0.2 to 55 μg . g sed dw⁻¹, and of the minor isoprenoid GDGTs (minor iGDGTs, the sum of GDGT-1, -2, -3 and crenarchaeol regio-isomer, which are used in the TEX86, ranging from 0.04 to 6 μg . g sed dw⁻¹ (Fig. 2a). When concentrations were normalized to Corg, only minor changes in concentrations were observed: they ranged between <0.1 and 0.5 μg . g C org⁻¹ for the minor iGDGTs, 0.2 and 1.3 for GDGT-0 and <0.1 and 2.1 for crenarchaeol (Fig. S1a). When the relative distribution is considered, CL-GDGT-0 slightly increased proportionally with depth (from 27 to 41 %), while crenarchaeol decreased (from 61 to 47 %) (Fig. 2a; right panel). IPL-derived GDGT concentrations, i.e. GDGTs in the IPL-fraction released by hydrolytic cleavage of head groups, were consistently lower than the CL-GDGT concentrations. Concentrations ranged from 0.05 to 3.2 μg . g sed dw⁻¹ for GDGT-0, 0.03 to 2.2 μg . g sed dw⁻¹ for crenarchaeol, and 0.01 to 2.8 μg . g sed dw⁻¹ for the IPL-derived minor iGDGTs, with a tendency to decrease with depth, but again with large scatter (Fig. 2b). The proportion of GDGT-0 in the IPL-GDGTs was higher than in the CL-GDGTs (38 %), and increased with depth to 52 %, while the minor iGDGTs decreased from 26 to 14 % and crenarchaeol from 36 to 33 % (Fig. 2b). When concentrations were normalized on TOC, no particular depth trend was observed, and concentrations ranged from <0.01 to 0.012 for the minor iGDGTs and crenarchaeol, and from 0.01 to 0.2 for GDGT-0 (Fig. S1b).

Table 1. Sample details, absolute depths, sedimentation rates, age and organic carbon content at station 1229 (Leg 201). Sedimentation rates used taken from Skilbeck & Fink (2006) and D’Hondt et al. (2003). Interval denotes the part of the core section that was used for analysis.
Figure 2. Concentrations vs. depth (mbsf) of (a) CL-GDGTs in $\mu g \cdot g$ sed $dw^{-1}$, (b) IPL-derived GDGTs in $\mu g \cdot g$ sed $dw^{-1}$, (c) IPL-crenarchaeol with MH-, DH- and HPH-headgroups (in area $\cdot g$ sed $dw^{-1}$). Coloured area graphs show GDGT distributions as a percentage of the total sum.
The MH- and DH-crenarchaeol directly measured by HPLC-ESI-MS\(^2\), showed a general decrease in concentration with depth, from 108 down to almost 106 area \(\cdot\) g sed dw\(^{-1}\) for both IPL-crenarchaeol species, though again with large scatter (Fig. 2c), while abundances of HPH-crenarchaeol decreased rapidly with depth and were below detection limit under 6 mbsf. The proportion of DH crenarchaeol compared to MH-crenarchaeol decreased with depth (Fig. 2c). Normalized on TOC, MH- and DH-crenarchaeol ranged between 104 and 107 area \(\cdot\) g\(^{-1}\) and HPH-crenarchaeol decreased from 103 area \(\cdot\) g\(^{-1}\) to below the detection limit (Fig. S1c).

Principal component analysis (Fig. S2) revealed that the first component (PC1) explained 81% of the variance in GDGT distributions, with the second component (PC2) explaining 9% of the variance. The samples from all depths varied only over PC1, except for 0.2 and 0.8 mbsf which were different from all the other depths on PC2. The loadings of all variables on PC1 were plotting similar to \(C_{org}\) suggesting their covariance with \(C_{org}\) while PC2 was defined by the concentration of HPH-crenarchaeol relative to MH- and DH-crenarchaeol (Fig. S2b).

The TEX\(_{668}\) of the CL-GDGTs ranged from 0.51 to 0.62 with no specific depth trend, while the TEX\(_{668}\) of IPL-derived GDGTs was slightly higher and ranged from 0.62 to 0.74 with a sharp decline below 102 mbsf (Fig. 3a).

4. Discussion

4.1 Degradation of IPL-GDGTs

Our results show that both CL- and IPL-derived GDGT-concentrations as well as TOC were decreasing with depth, although with large scatter. The large scatter is mostly due to the variations in depositional environment, due to the large timescales investigated (Myr). The Peru Margin is characterized by high productivity, controlled by coastal upwelling, and possesses a pronounced oxygen minimum zone (OMZ), which has varied over time (cf. Gutiérrez et al., 2011; Powell et al., 1990), leading to changes in organic matter fluxes, oxygen concentrations, oxygen exposure time and, consequently, organic carbon and biomarker preservation efficiency (cf. Hartnett et al., 1998; Hedges & Keil, 1995; Sminghne Damsté et al., 2002a). These different degrees of oxygen exposure time (OET) can potentially have a large effect on both the TOC and the concentration of biomarker lipids. Indeed, the principal component analysis (Fig. S2) suggests a covariance of the concentrations of CL- and IPL-GDGTs with \(C_{org}\). This suggests that preservation of CL- and IPL-GDGTs is determined by similar factors as \(C_{org}\).

Direct measurements of IPL-crenarchaeol with different head groups allowed us to investigate the prediction of Schouten et al. (2010) on the different degradation behavior of phospholipids versus glycolipids. At depths > 6 mbsf only glycosidic crenarchaeol was detected (MH- and DH-crenarchaeol), in agreement with the results obtained by Lipp and Hinrichs (2009). However, at shallow depths also HPH-crenarchaeol was present, a phospholipid which shows a rapid decrease with depth and is undetectable below 6 mbsf, i.e. within <7 kyrs. This confirms the prediction of Schouten et al. (2010) that HPH-GDGTs are degraded faster than IPLs with glycosidic head groups, and the observations of Lengger et al. (2012a) who observed a fast decrease of HPH-crenarchaeol over the upper 30 cm of surface sediments in the Arabian Sea. The depth profile of HPH-crenarchaeol is in strong contrast to that of the glycosidic crenarchaeol-IPLs, which show a depth trend similar to that of TOC and CL-GDGTs (Fig. 2e, Fig. S2). The apparent persistence of glycosidic GDGTs compared to HPH-GDGTs could either be due to archaea at depth producing only glycosidic GDGTs and no HPH-GDGTs, or be due to their better preservation. Several arguments are in disfavor of a significant contribution of in situ production to sedimentary MH- and DH-GDGTs: Firstly, crenarchaeol has, until now, only been found in Thaumarchaeota performing the aerobic oxidation of ammonia and not in anaerobic archaea, which would be expected in anoxic, deeper sediments. Secondly, calculations conducted by Schouten et al. (2010) showed that IPL-abundance clearly exceeded the amount expected from the number of archaeal cells present in these sediments by two orders of magnitude, indicating a substantial fossil contribution. Xie et al. (2013) recently showed that growth rates of archaea in subsurface sediments were extraordinarily low, thus rendering a substantial contribution of in situ production highly unlikely. Additionally, production of IPL-crenarchaeol and other IPL-GDGTs in the sediment would likely alter the distribution of GDGTs in the sediment, especially at depths where a strong archaean contribution would be expected, i.e. in the sulfate-methane transition zones (SMTZs) reported at this site at 30 and 88 mbsf (Biddle et al., 2006). According to Weijers et al. (2011), a strong increase in GDGT-2 / crenarchaeol would be expected in association with the presence of archaeal methanotrophic (i.e. ANME-1) communities. However, this is not the case in the SMTZ here (Fig. 3b), except for a small increase at 80 m depth, which is, however, only observed in the IPL-fraction and not in the CL-fraction. In any case, this imprint was not transferred to the underlying zones, in agreement with the observations of Weijers et al. (2011). This all suggests a relatively low contribution of in situ production to the sedimentary pool of GDGTs.

One observation is that MH-crenarchaeol concentrations increase with depth relative to DH-crenarchaeol (Fig. 2c), possibly due to a better preservation of the MH-crenarchaeol. The deeper sediments are also those containing the lowest amounts of organic carbon and were likely deposited in times of lower OMZ intensity and thus subjected to longer OET. It has been shown that DH-crenarchaeol is more labile under oxic conditions than MH-crenarchaeol (Lengger et al., 2013), and this may be the reason for its decrease in proportion. However, another possibility is a past change in pelagic Thaumarchaeota communities producing relatively more MH-crenarchaeol.

Our findings have implications for the use of IPL-GDGTs as biomarkers for live Archaea, especially for the use of glycosidic IPL-GDGTs in deeply buried sediments. According to our results, a large amount of these glycosidic IPLs is most probably fossil in nature and is not representative of the actual amount of live and active archaeal cells. Rather, it is advisable to focus on IPLs with more labile headgroups such as phospholipids as markers for living archaea and bacteria.

4.2 Impact of IPL-GDGT degradation on TEX\(_{668}\)

IPL-GDGTs in sediments are of interest because their production or differential degradation can affect GDGT-based proxies. While, as previously shown, the TEX\(_{668}\) is not affected by sedimentary processes over short time scales (<10 yrs, Lengger et al., 2012a, 2013), this has not yet been investigated over larger timescales. The TEX\(_{668}\) of the CL-GDGTs varied from 0.51 to 0.62 (Fig. 3a), likely reflecting the substantial changes in sea surface temperature (Schouten et al., 2002) over a time period stretching...
Figure 3. (a) CL- and IPL-derived $\text{TEX}_{86}$ values plotted against depth in mbsf, (b) GDGT-2/crenarchaeol ratio of IPL-derived and CL-GDGTS and (c) IPL-derived $\text{TEX}_{86}$ as a function of % DH-crenarchaeol.
to the late Pliocene (D’Hondt et al., 2003) which includes glacial-interglacial cycles (the dating/sampling of this core is not extensive enough to locate such cycles; cf. Skilbeck & Fink, 2006). IPL-derived GDGTs have TEX\textsubscript{86} values higher than the CL-GDGTs and ranged from 0.62 to 0.74 (Fig. 3a). This is similar to what was observed previously in deeply buried sediments analyzed by Liu et al. (2011) who reported a correlation between TEX\textsubscript{86} values obtained from IPL-derived GDGTs and CL-GDGTs, and Lengger et al. (2012a) in Arabian Sea surface sediments. However, we did not find such a correlation (R\textsuperscript{2}=0.013; P=0.62; Fig. S3). The reason for this might be the limited range of TEX\textsubscript{86} values (0.1 units compared to 0.4 units in the data presented by Liu et al., 2011), and scatter may have masked the correlation. The higher TEX\textsubscript{86} values of IPL-derived GDGTs may be due to the fact that core lipids are not distributed evenly over the IPLs. Lengger et al. (2012a) suggested that the higher TEX\textsubscript{86} of IPL-GDGTs versus CL-GDGTs is due to preferential degradation of HPH-GDGTs, which generally have lower TEX\textsubscript{86} values, leaving mainly GDGTs with higher TEX\textsubscript{86} values, such as DH-GDGTs, in the IPL-fraction. This is probably also the case here, as only glycosidic GDGTs remain in the deeper sediment (Fig. 2c), in agreement with Lipp et al. (2008b), Lipp & Hinrichs (2009) and Liu et al. (2011) who also found only glycosidic GDGTs at depth. Indeed, a trend to lower TEX\textsubscript{86} values from 0.2 to 6.5 m depth is accompanied by the disappearance of the HPH-crenarchaeol. However, the change is relatively small, which is possibly due to the HPH-GDGTs being present in low amounts compared to the MH- and DH-GDGTs even in the shallow sediment at 0.2 mbsf. This would be consistent with the reported rapid decline of the HPH-crenarchaeol abundance in the surface sediments (0.24 cmbsf) of the Arabian Sea (Lengger et al., 2012a).

A strong decrease in TEX\textsubscript{86} from 0.71 to 0.62 was observed for the IPL-derived GDGTs but not for the CL-GDGTs between 102 and 158 mbsf (Fig. 3a). In this interval, the DH-crenarchaeol concentrations decreased faster than the MH-crenarchaeol concentrations (Fig. 2c). In fact, the proportion of DH-crenarchaeol to summed IPL-crenarchaeol changed between these sediments from 58 to 31% and then decreased further to 7% in the deepest sediment (IPL-TEX\textsubscript{86} values; Fig. 2c). It is likely that this degradation pattern is more dependent on the head group than on the core lipid (cf. Lengger et al., 2013), and thus this proportional change in MH- versus DH-head group was likely occurring in all IPL-GDGTs. DH-GDGTs have a higher TEX\textsubscript{86} value than MH-GDGTs in all settings and organisms where this has been investigated (Lengger et al., 2012a; 2013; Pitcher et al., 2010; 2011a; Schouten et al., 2008; 2012; Schubotz et al., 2009; Sinninghe Damsté et al., 2012; Zhu et al., 2013). Thus, it may well be that the change in TEX\textsubscript{86} was due to the proportional change in DH-GDGTs versus MH-GDGTs. Indeed, a significant correlation (R\textsuperscript{2}=0.47; P=0.006) was observed between TEX\textsubscript{86} of IPL-GDGT and the % DH crenarchaeol (Fig. 3e). It is thus likely that the IPL-derived TEX\textsubscript{86} value depends, apart from the original pelagic signature, also on the relative degradation rates of types of IPL present. Schouten et al. (2012) found a similar correlation in suspended particulate matter in the Arabian Sea water column, although with a much more gradual slope (IPL-TEX\textsubscript{86}=0.628+0.0035×%DH; R\textsuperscript{2}=0.40). A similar phenomenon was observed in the post-depositional oxidation of marine sediment from the Madeira Abyssal Plain, i.e. the TEX\textsubscript{86} value changed with a changing proportion of DH-crenarchaeol (Lengger et al., 2013). As stated above, though, the CL-GDGT TEX\textsubscript{86} does not seem to be impacted by this effect, agreeing with previous observations. It is thus likely that the IPL-derived TEX\textsubscript{86} value depends, in addition to the original signature, also on the relative degradation rates of types of IPL present.

5. Conclusions

The analysis of deeply buried sediments retrieved from the Peru Margin showed that HPH-crenarchaeol was rapidly degraded in contrast to other IPL-crenarchaeol species, indicating its labile nature compared to glycosidic crenarchaeol-IPL-GDGTs, and was reduced to amounts below detection limits within less than 7 ky. This higher degradability makes it a suitable biomarker for living organisms in contrast to glycosidic IPL-GDGTs. TEX\textsubscript{86} values of CL-GDGTs did not show any obvious depth/age trends, however, IPL-derived GDGTs showed a strong decrease of TEX\textsubscript{86} in the deepest/oldest sediments coinciding with low TOC values. In agreement with previous studies, this could be due to the faster degradation of DH-crenarchaeol compared to the MH-crenarchaeol. Indeed, DH-crenarchaeol percentages showed a correlation with IPL-derived TEX\textsubscript{86}. Differential degradation, however, in spite of affecting IPL-derived TEX\textsubscript{86} values, does not have an impact on CL-TEX\textsubscript{86}.

Acknowledgements. We thank Dr. Ann Pearson and two anonymous reviewers for constructive comments which substantially improved the manuscript. We thank D. J. Rush and A. Mets for analytical assistance. This research used samples from the Ocean Drilling Program (ODP). The ODP was sponsored by the U.S. National Science Foundation and participating countries under management of Joint Oceanographic Institutions (JOI) Inc. S. K. L. was partly funded by a studentship granted to S. S. by the Darwin Institute for Biogeosciences. This is publication nr. DW-2014-1001 of the Darwin Institute for Biogeosciences.
