The structure of mangrove ecosystems is affected by various abiotic factors (temperature, salinity, nutrient availability, tidal range, topography, etc) and biotic factors (intra and inter-specific competition, fauna, anthropogenic pressure etc.) (Lee, 1999b). Faunal impact is largely due to the crab activities (Cannicci et al., 2008). Some authors refer to ‘crabs’ as mangrove ecosystem keystone species (Smith III et al., 1991; Schories et al., 2003). They contribute actively to the forest structure through two activities: ‘engineering’ activity (Bartolini et al., 2010) and herbivory behaviour (Schories et al., 2003). Burrows and galleries in hypoxic or anoxic soils allow a better soil oxygenation and increase the bioavailability of nutrients such as nitrogen and phosphorus (Smith III et al., 1991). In addition, some families of herbivorous crabs are known to be a threat to natural and artificial mangrove regeneration (Dahdouh-Guebas et al., 1998) and a regulator of competition in high stand density areas (Bosire et al., 2005), both through consumption of mangrove propagules and juveniles. We focus this ongoing study on the impact of herbivorous (Sesarmidae) and detritivorous crabs (Ocypodidae) on mangrove propagule establishment and growth in Gazi Bay, Kenya. To estimate this impact, we will first measure the correlation between floristic data (tree density, strata (canopy height) number, individual sylvimetric characteristics and specific composition), faunistic data (specific composition and density) and abiotic data (soil texture, oxygen level, acidity, nutrients bioavailability, organic matter and salinity) in contrasted areas.
