Affiliation Index	720

This book compiles the abstracts from the 32nd annual meeting of the Society of Environmental Toxicology and Chemistry – Europe (SETAC Europe), conducted from 15–19 May 2022 in Copenhagen, Denmark, and online.

The abstracts are reproduced as submitted by the author and accepted by the scientific Committee. They appear in order of abstract code and alphabetical order per presentation type. The poster spotlight abstracts are included in the list of poster abstracts. The presenting author of each abstract is highlighted in bold.

No part of this publication may be reproduced, stored in a retrieval system, or transmitted in any form or by any means, electronic, electrostatic, magnetic tape, mechanical, photocopying, recording, or otherwise, without permission in writing from the copyright holder. SETAC Europe's consent does not extend to copying for general distribution, for promotion, for creating new works, or for resale. Specific permission must be obtained in writing from SETAC for such copying. Direct all inquiries to SETAC Europe.

Society of Environmental Toxicology and Chemistry Europe (SETAC Europe)

About SETAC

In the 1970s, no forum existed for interdisciplinary communication among environmental scientists, biologists, chemists, toxicologists, managers, engineers or others interested in environmental issues. The Society of Environmental Toxicology and Chemistry (SETAC) was founded in North America in 1979 to fill the void and quickly saw dynamic growth in the Society's membership, meeting attendance and publications.

A unique strength of SETAC is its commitment to balance the scientific interests of government, academia and business. The Society by-laws mandate equal representation from these three sectors for officers of the World Council and Geographic Unit Boards of Directors and Councils, and in the composition of committees and other society activities. The proportion of members from each of the three sectors has remained nearly equal over the years.

The Society is concerned about global environmental issues. Its members are committed to Environmental Quality Through Science®, timely and effective communication of research, and interactions among professionals so that enhanced knowledge and increased personal exchanges occur. Therefore, SETAC publishes two globally esteemed scientific journals and convenes annual meetings around the world, showcasing cutting-edge science in poster and platform presentations. Because of its multidisciplinary approach, the scope of the science of SETAC is broader in concept and application than that of many other societies.

SETAC's growth is reflected in the founding of Geographic Units around the world. SETAC Europe was established in 1989 as an independent organisation, followed by SETAC Asia-Pacific in 1997 and SETAC Latin America in 1999. In 2002, the four existing organisations joined together under the governance of the SETAC World Council. SETAC Africa is the most recent Geographic Unit, which was adopted in 2012. As evidence of international acceptance of the SETAC model and of the great interest at the local level, regional chapters and branches have emerged in a number of countries.

SETAC publishes two journals, *Environmental Toxicology and Chemistry* (ET&C) and *Integrated Environmental Assessment and Management* (IEAM). ET&C is dedicated to furthering scientific knowledge and disseminating information on environmental toxicology and chemistry, including the application of these sciences to risk assessment. Integrated Environmental Assessment and Management focuses on the application of science in environmental decision-making, regulation and management, including aspects of policy and law, and the development of scientifically sound approaches to environmental problem solving. Together, these journals provide a forum for professionals in academia, business, government and other segments of society involved in the use, protection and management of the environment for the enhancement of ecological health and human welfare.

SETAC books provide timely in-depth reviews and critical appraisals on scientific subjects relevant to understanding a wide range of contemporary topics pertaining to the environment. These include any aspect of environmental chemistry, toxicology, risk assessment, risk management or environmental policy.

SETAC has two administrative offices, in Pensacola, Florida, USA, established in 1992, and in Brussels, Belgium, established in 1993.

Environmental Quality Through Science®

Track 1: Ecotoxicology and human toxicology: From molecules to organisms, from omics to in vivo

1.01 Advantages of using lab and field collected invertebrates in ecotoxicology: Challenges and opportunities for Environmental Risk Assessment (Part I)

1.01.T-01 Protein Binding on Acutely Toxic and Non-Toxic Polystyrene Nanoparticles During Filtration by *Daphnia magna*

*Egle Kelpsiene*¹, *Irene Brandts*², *Katja Bernfur*¹, *Mikael T. Ekvall*¹, *Mariana Teles*² and *Tommy Cedervall*¹, (1)Lund University, Sweden, (2)Universidad Autonoma de Barcelona, Spain

Nanomaterials can adsorb biomolecules to their surface and form a protein corona. In the present study, we investigated the protein profile bound to different sizes of aminated and carboxylated polystyrene (PS) nanoparticles after passing through the digestive tract of the freshwater zooplankton *Daphnia magna*. We found that acutely toxic aminated 53 nm PS nanoparticles binds a different set of proteins compared to other non-toxic PS nanoparticles. A higher amount of proteins appeared to be bound to the aminated PS nanoparticles. The fact that the aminated nanoparticles bound a larger number of proteins, agrees with the aggregate size results. The protein bound to toxic nanoparticles can be divided into two groups. One group of proteins which function is related to the digestive system, whereas the other group of proteins can be related to the epithelium, intracellular structures, and processes. Finally, we observed that not only proteins bind to surfaces of the nanoparticles. Triglycerides effectively bind to 200 nm carboxylated PS nanoparticles but not to the other tested nanoparticles. These results provide information about the composition of the corona formed on surfaces of nanoparticles after short-term (4 h) incubation with *D. magna*.

1.01.T-02 High-Throughput Screening of Phototactic Behaviour in *Daphnia magna*: From Vertical to Horizontal Responses to Light

*Carlos Barata Dr*¹, *Marina Bello*² and *Cristian Gómez-Canela*³, (1)CSIC, Spain, (2)University Ramon Llull IQS, Spain, (3)School of Engineering, Institut Químic de Sarrià-Universitat Ramon Llull, Spain

Animal behavioural trait responses are increasingly being used in environmental risk assessment. Nevertheless, behavioural responses are still hampered by a lack of ecological relevance and standardisation. This is the case for diel vertical migration of zooplanktonic species. Previously we developed a vertical oriented behavioural hardware able to reproduce phototactic fish induced depth selection in *Daphnia magna* and its modulation by fish kairomones and psychotropic drugs. This study aims to test if it is possible to use an horizontal 24 multi-well plate maize set up to assess phototactic fish induced responses in *D. magna*. The study was conducted using two clones with opposed phototaxis upon exposure to fish kairomones and using psychotropic drugs known to modulate phototaxis. Acrylic strips opaque to visible light but not to the infrared one were used to cover half of the arena of each of the wells of the multi-well plate. Clone P_{132,85} showed positive phototaxis in either the vertical and horizontal set up and negative phototaxis when exposed to fish kairomones or to the muscarinic acetylcholine receptor antagonists scopolamine and atropine. The opposite behavior was observed for clone F. Diazepam and pilocarpine ameliorate fish kairomone induced negative phototaxis and picrotoxin increased it only on clone P_{132,85} in the vertical set up. The study of neurotransmitter metabolites showed much greater concentrations of dopamine and of glycine in clone F, which may be relate to its negative phototaxis and its observed lower responsiveness to fish kairomones. The results from this study suggest a simple, fast, high throughput assay for *D. magna*, and gains insight on the impacts of natural and psychotropic compounds on the swimming behaviours of a model crustacean species used in ecotoxicology studies.

1.01.T-03 Differential Sensitivity and Synergy in Adult and Larvae Lepidoptera

Claire Badder, Pollution, UK Centre for Ecology and Hydrology, Wallingford, United Kingdom

Differential sensitivity to pesticides between insects may have many biological explanations. One such explanation may be the potential of a species to metabolise the toxicant. Therefore, an awareness of the presence of metabolic enzymes such as cytochrome P450's (CYPS), glutathione-S-transferases (GSTs) and carboxylesterases in a specific species may hold an insight into the potential sensitivity or tolerances the species is likely to have towards chemical toxicants. Here we aim to determine the toxicity of the insecticide cypermethrin and the fungicides azoxystrobin, chlorothalonil and prochloraz to adult and larval stages of the cabbage moth (*Mamestra brassicae*). Using single chemical toxicity data and TKTD modelling, we aim to identify cases of synergism between cypermethrin and the fungicides in binary mixtures. Finally, we begin to explore any differences in sensitivity using the levels of expression of CYPS, GSTs and carboxylesterases in the transcriptome of the larvae and adult. Single chemical tests were analysed using the GUTS_RED_SD model and revealed fungicides had no effect on mortality on cabbage moth larvae. Therefore, no LC₅₀'s could be calculated for azoxystrobin, chlorothalonil or prochloraz. However, the insecticide cypermethrin had an LC₅₀ of 46.3 and 11.6 at 48 and 96 hours respectively. This differed in adult moths as there was a greater tolerance to cypermethrin with LC₅₀ values of 90.5 at 48 hours and 22.7 and 96 hours, a difference of almost 50%. Larval mixture testing identified slight synergy in larvae between cypermethrin and prochloraz and a more pronounced synergistic interaction between cypermethrin and chlorothalonil. No synergism was seen between azoxystrobin and cypermethrin. Adult mixture tests are on-going but it is hypothesised that synergistic effects will be lessened as is seen in the single chemical cypermethrin test. Further, a catalogue was created of CYPS, GST's and carboxylesterases from the transcriptome of cabbage moth larvae. The adult moth transcriptome is underway and will be compared against the larval transcriptome. We hypothesise that differences in sensitivity may begin to be explained by differences in expression of metabolic enzymes. We hope that this multi-faceted approach of lab exposure, GUTS modelling and transcriptomics provides an insight into the power of omics as a predictive tool of toxicity, particularly when used alongside traditional toxicity testing.

1.01.T-04 Experimenting the Plasticity of Sensitivity From Field-Populations of *Gammarus fossarum* in Response to Chronic Cadmium Contamination: Tolerance Acquisition, Transfer and Reversibility

*Auréline Lalouette*¹, *Davide Degli Esposti*², *Laura Garnero*³ and *arnaud chaumot*⁴, (1)INRAE Centre de Lyon-Grenoble Auvergne-Rhône-Alpes, France, (2)INRAE, France, (3)INRAE Lyon, France, (4)Irstea, France

Chronic exposure to metal contamination can induce changes in the sensitivity of populations. An increase in tolerance, transmissible between generations, can be observed in certain cases without being due to genetic adaptation. This particular case of transgenerational acclimatization using non-genetic mechanisms of heredity has been documented in natural populations of the crustacean *Gammarus* historically exposed to metallic geochemical background. In these populations, the acquisition of cadmium (Cd) tolerance has been shown to be consistent with the manifestation of parental effects of exposure. The objectives of our study were then to confirm the existence of Cd tolerance among several *G. fossarum* populations at a regional scale, to better understand the nature of this tolerance acquisition (transitory acclimatation or permanent acquisition of tolerance by the organisms) and to study the mechanisms of transmission between generations. For that, natural Cd-contaminated and uncontaminated field *G. fossarum* populations was used in three laboratory protocols, 1- the returning in clean water in the lab of Cd-contaminated and uncontaminated field *G. fossarum* populations to question the reversible nature of sensitivity, 2- the re-matching spawners from Cd-tolerant and sensitive field populations to study the transfer of the tolerance to progeny and, 3- the establishment of a Cd chronic exposure in the lab at environmentally relevant concentrations to test the mechanisms seen in naturally tolerant populations. This study confirms the existence of natural populations capable of developing mechanisms of tolerance in Cd contaminated environments. Moreover, our results show that tolerance is not fixed for the life time of individuals, not depending therefore on genetic mechanisms or developmental plasticity, while this tolerance can be transmitted between generations by parental effects with a symmetrical role of the two sexes. Thus, the use of invertebrates is of real interest to increase our understanding of long-term effects of chemical contaminations in ecosystems by allowing to conduct environmentally relevant ecotoxicological studies.

1.01.T-05 Predicting the Survival of Field Gammarids Provides Additional Insights on the Impacts of Fluctuating Pesticide Exposures

*Maricor Jane Arlos*¹, *Andreas Focks*², *Juliane Hollender*³ and *Christian Stamm*³, (1)University of Alberta, Edmonton, AB, Canada, (2)University of Osnabruck, Germany, (3)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland

The analytical detection and modelling approaches to assess pesticide exposure in various environmental compartments have substantially improved over the last several decades. However, the threshold values considered in the current regulatory risk assessment are still based on laboratory studies that do not mirror the conditions captured in chemical monitoring and modelling. In this study, we employed a toxicokinetics-toxicodynamic (TKTD) model from the General Unified Threshold model of Survival (GUTS) framework to predict the impact of fluctuating pesticide concentrations on the survival of gammarids (*Gammarus pulex*) in an agricultural stream located in Switzerland. Individual exposure to azoxystrobin, chlorpyrifos and diazinon were predicted to have an acute and/or chronic impact on the survival of gammarids. In contrast, exposure to imidacloprid and propiconazole were predicted to have a low impact as their environmental concentrations must be multiplied by more than 100 before a survival probability of 50% is observed. Our modelling approach subsequently revealed that the duration of exposure drives the effects more than the maximum concentration as typically considered in traditional risk assessments. We further extended the GUTS model to incorporate mixture effects using concentration addition. We found that a considerable impact is expected when gammarids are exposed to organophosphates (chlorpyrifos, chlorpyrifos-methyl, and diazinon), whereas a mild impact is predicted for neonicotinoids (imidacloprid and thiacloprid). Given that the gammarids are exposed to many other environmental contaminants and stressors, a decline in their survival probabilities because of chemical stress will likely influence their individual fitness and/or overall population viability. Additional laboratory and/or field studies are required to validate the mixture assumptions in our model. However, by incorporating the temporal aspects of environmental exposure and the associated consequences on survival, our study added a layer of realism that improves the current risk assessment of pesticides.

1.01 Advantages of using lab and field collected invertebrates in ecotoxicology: Challenges and opportunities for Environmental Risk Assessment (Part II)

1.01.T-06 Biomarker Development in High-Resolution Pesticide Mixture Exposures Using the Springtail *Folsomia candida*

*Ruben Rob Bakker*¹, *Yuliya Shapovola*², *Tjeerd Dijkstra*³, *Dick Roelofs*⁴, *Tom Heskes*⁵, *Cornelis A.M. van Gestel*⁶ and *Katja Hoedjes*⁷, (1)Animal Ecology, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (2)Radboud University Nijmegen, Nederland, (3)University Clinic Tübingen, Germany, (4)Vrije Universiteit, Netherlands, (5)Radboud University Nijmegen, Netherlands, (6)Vrije Universiteit Amsterdam, Netherlands, (7)Vrije Universiteit, Nederland

Invertebrate populations worldwide are in decline, at least partly due to intensive pesticide application. Traditionally, pesticide risk assessment has been based on the results of standardized tests measuring the effects of a single pesticide on the reproduction or survival of model organisms. It is difficult to extrapolate these findings to field conditions as most agricultural soils are polluted by pesticide mixtures and the effects of their (synergistic) interactions on invertebrates are largely unknown. Gene regulatory patterns could be used as biomarkers to determine the type of soil pollution present and its intensity under varying mixture compositions. Generating high-throughput gene expression data of high-resolution exposure intensities, and the development of methods to analyse this data are crucial for linking gene-expression patterns to adverse effects on reproduction, and for subsequent implementation of biomarkers in risk assessment or biomonitoring. In this study, transcriptomic data was obtained for the soil ecotoxicological model species *Folsomia candida* (springtails) under a high-resolution grid-design-exposure of either two

neonicotinoids, imidacloprid and clothianidin, or imidacloprid and cyproconazole, a fungicide. In total the exposure consisted of 168 samples over 25 unique conditions in two experiments. Obtained gene expression data on all pesticides was analysed simultaneously with a joint Gaussian processes (GP) additive model, as GP-models allow for the analysis of non-linear differential gene expression patterns in a grid design. In total, this method identified 2049 differentially expressed genes (DEGs) under the exposure of neonicotinoids and 1080 DEGs under the exposure of cyproconazole. Gene set enrichment (GSE) analysis reveals shared and distinctive gene functions for DEGs under neonicotinoid and cyproconazole exposure, which can be used to identify points of synergistic interaction or used for biomarker development respectively. The candidate biomarkers are identified from distinctive GSE terms and validated on agricultural soils, providing risk assessors with metrics of adverse effects of pesticide presence that can be used on field-relevant mixture exposures.

1.01.T-07 Functional Transcriptomic Fingerprints of Neurotoxic Modes-Of-Action in *Daphnia magna*

Julia Pfaff¹, Hannes Armin Reinwald², Steve Uwa Ayobahan², Julia Alvincz², Bernd Göckener³, Orr Shomroni⁴, Gabriela Salinas⁴, Rolf-Alexander Düring⁵, Christoph Schaefer² and **Sebastian Eilebrecht²**, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (3)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (4)NGS - Integrative Genomics Core Unit, Germany, (5)Justus Liebig University Giessen, Germany

Active ingredients of pesticides, biocides or pharmaceuticals can cause undesirable side effects in the aquatic ecosystem. Therefore, an environmental hazard and risk assessment is required prior to the registration of new active substances. The freshwater crayfish *Daphnia magna* is a model organism for evaluating acute and chronic toxicity in aquatic invertebrates. However, standardized tests using *Daphnia* are limited to immobility and reproductive endpoints and thus provide limited insight into underlying modes-of-action (MoA). Here, we applied transcriptome profiling to a modified acute immobilization assay of *D. magna* to analyze and compare gene expression profiles induced by the GABA-gated chloride channel blocker fipronil and the nicotinic acetylcholine receptor (nAChR) agonist imidacloprid. To detect compound-induced gene expression changes at low effect concentrations, an acute immobilization test with *D. magna* was performed following the corresponding OECD guideline test. 48 hours after test initiation, total RNA was extracted from the daphnids and purified polyA-RNA was subjected to RNA sequencing for differential gene expression analysis. The observed signatures for fipronil and imidacloprid were readily distinguishable between the two compounds at the gene level without major overlap. While fipronil exposure affected a number of metabolic pathways, including ATP synthesis and cholesterol biosynthesis, metabotropic glutamate receptor signaling, and a pathway associated with Alzheimer's disease - the presenilin pathway in mammals, impaired imidacloprid pathways associated with Parkinson's disease, mammalian vasopressin synthesis, GABA synthesis, and aminobutyrate degradation. Our study suggests that the integration of transcriptomics into a modified version of the acute immobilization assay of *D. magna* can be used to differentiate modes-of-action of test compounds of interest at low effect concentrations. Such a combination of systems biology methods with ecotoxicological test guidelines will help to understand the underlying molecular mechanisms of adverse effects on invertebrate organisms and populations, which will be important for ecotoxicological hazard assessment.

1.01.T-08 Physiological Colour Changes in Ecotoxicology

Thomas Knigge¹, Anaïd Gouveneaux², Apolline Chabenat³, Eleanor Feuerhelm⁴, Sarah Hue⁵, Jeanne Legendre⁵, Tiphaine Monsinjon⁵, Alex Ford⁴ and Cécile Bellanger⁶, (1)Université du Havre, France, (2)Université de Caen Normandie, France, (3)University Le Havre Normandie, France, (4)University of Portsmouth, United Kingdom, (5)Université Le Havre Normandie, France, (6)Université de Caen Normandie, France

Many animals display rapid colour changes for the purpose of camouflage. Physiological colour changes can be controlled either nervously, as in cephalopods, or hormonally, as in crustaceans. Both, neuronal and neurohormonal control mechanisms are regulated by neurotransmitters. In cephalopods, serotonin induces the relaxation of the muscle crown leading to pigment concentration in the chromatophores. In crustaceans, dopamine stimulates pigment concentration *via* red pigment concentrating hormone, whereas serotonin ensures pigment dispersion *via* pigment dispersing hormone. Environmental pollutants can potentially interfere with these mechanisms of physiological colour change and cryptic behaviour. We exposed *Carcinus maenas*, *Crangon crangon* and *Sepia officinalis* to waterborne selective serotonin and/or norepinephrine reuptake inhibitors, which are known to alter the levels of serotonin and other biogenic amines in wildlife. Venlafaxine provoked pigment concentration in chromatophores of *S. officinalis* at the same concentration (10^{-4} M) as did serotonin. Fluoxetine alone (5 ng L^{-1}) or in combination with venlafaxine (2.5 or 5 ng L^{-1}) improved uniform, but not disruptive body patterns in newly hatched cuttlefish. *C. crangon* exposed to 10 - 1000 ng L^{-1} fluoxetine for up to one week showed a significant increase in darkening following 30 min on black substrates. Similarly, pigment dispersion in juvenile *C. maenas* transferred from a white to a dark background tended to increase when exposed to fluoxetine at 5 ng L^{-1} , but when exposed to a combination of fluoxetine and venlafaxine at 5 ng L^{-1} each, darkening was significantly impaired. These studies demonstrate that physiological colour changes are susceptible to environmental chemicals that interfere with the neuronal or neurohormonal control of chromatophore movements. Hence, they may serve as indicators of environmental pollution and could point to detrimental effects on behavioural ecology that are important for the animals' survival. Colour change bioassays, therefore, provide a promising tool for environmental testing with the advantage of being non-invasive, inexpensive and relatively straightforward.

1.01.T-09 Organophosphate Pesticides in Aquatic Ecosystems: Study CASE on *Chironomus riparius* Impact at MOLECULAR Level

Ana-Belen Muniz-Gonzalez¹, Valeria Lencioni² and Jose-Luis Martinez-Guitarte³, (1)National Distance Education University (UNED), Spain, (2)MUSE-Museo delle Scienze Trento, Italy, (3)UNED, Spain

Organophosphate pesticides (OPPs) have gained worldwide concern by their persistent and hazard to the environment, surrounding nearly 40% of the global market and in constant increase reaching easily to aquatic systems acting as main OPPs reservoir. Chlorpyrifos (CPF) insecticide has been the most employed for crops protection in Italy derived in intensify presence in surface waters (0.12-15.38 ng/L) along the country. The harmful CPF impact is widely documented reaching to be banned by EPA in August 2021, although as a semi-persistent pollutant, continue to be present in aquatic systems for years. However, the impact on field organisms has been poorly studied apart from our previous experience on *Diamesa* species. Therefore, this work is focused to evaluate the CPF impact at molecular level on *C. riparius* larvae collected in Rio Gola stream (32T 664117 5100540 UTM, October 2020), to check the influence on benthic macroinvertebrates in close contact with polluted sediments. The larvae were exposed at 0.011 µg/L, 0.11 µg/L and 1.1 µg/L for 24 and 72 h, in controlled laboratory conditions (8 light:16 dark hours; 20 °C). Sub-organismal response was evaluated using an array (48 genes) designed for this specie by Real Time PCR. After 24h, *Dis*, and *NHR38* (endocrine system); *GSTo1* (detoxification response); *Proph* (immune system); *XRCCI* (DNA repair), and *LIP* (lipid metabolism) were altered. At 72h higher response was observed *JHAMT*, *Dis*, *NHR38*, *NHR96*, and *FKBP39* (endocrine system); *Cyp4c1*, *Cyp12a1*, *GSTd6* (detoxification response); and *hsp70* (stress response) modulated. Hormone's synthesis inhibition confirmed the endocrine disruptor CPF capacity. Moreover, phase II modulation reinforces the role of CPF as oxidative compound, being confirmed by the immune system activation strongly related to ROS. Lipid metabolism was modulated could limit insect's functions because are essential source of energy (i.e: reproduction). Besides, the DNA damage seems to be drastic at 72h with apoptosis initiation (*Decay*). Finally, the stress response could indicate defective protein folding. Our findings confirm the risk of CPF, at environmental relevant concentrations, affecting the metabolism and future survival on a key aquatic organism. The differences in expression observed between 24 and 72h reinforce the importance to check the molecular modulation along the time in above all organisms as *C. riparius* with short life cycles.

1.01.T-10 How Nano Pesticides Affect Non-Target Organisms: Toxicity of Three Nanopesticides on *Daphnia magna*

Mahleh Eghbalinejad¹, **Maria del Rocio Lopez-Cabeza²**, **Jan Kotoušek³** and **Jakub Hofman⁴**, (1)Research Centre for Toxic Compounds in the Environment (RECETOX), Faculty of Science, Masaryk University, Brno, Czech republic, Czech Republic, (2)Masaryk University, Faculty of Science, RECETOX, Spain, (3)Department of Pharmacology and toxicology, Veterinary Research Institute, v.v.i., Brno, Czech Republic, Czech Republic, (4)RECETOX, Faculty of Science, Masaryk University, Czech Republic

Nanopesticides as a potential solution to solve the risk and drawbacks of conventional formulations of pesticides have been attracting attention in both research and market areas. However, the risk of these new formulations still needs to be studied on non-target species and regulated specifically. In this regard, we prepared three nanopesticides composed of nanoparticles of polycaprolactone (PCL), polyhydroxybutyrate (PHB) and nanostructured lipid carrier (NLC) loaded with the fungicide tebuconazole (TBZ (a.i.)), as well as three suspensions of the nanocarriers without a.i. Then, we assessed the toxicity of all the nanoformulations to an aquatic model, *Daphnia magna*, through immobilization bioassay. For that, in total 28 neonates < 24h old in four replicates were exposed to 5 dilutions of each nanopesticides obtaining a total TBZ concentration of 36, 18, 9, 4.5 and 2.25 µg mL⁻¹. Likewise, the toxicity of the nanocarriers without a.i. was tested as control. The aim is to understand how *Daphnia magna* behaves in different concentrations of a.i. associated with nanocarriers and in the presence of the nanocarriers without a.i. over 48h. The total concentrations, release rate of a.i. and the stability of NPs at time 0 and 48h were checked. According to the results, *D. magna* reacted differently to exposure with each NPs. The dose-response results showed that the EC50 values of all the nanopesticides were high compared to the value for pure TBZ, which shows that the toxicity of all nanopesticides was lower than that of pure TBZ. The toxicity of the NPs decreased depends on the type of nanocarrier as follows: PCL-TBZ < PHB-TBZ < NLC-TBZ. The toxicity of the nanocarrier without a.i. was diverse. As, PCL showed some toxicity while PHB nanocarrier had almost no effect on the immobilization of *D. magna*. Consequently, since the toxicity of the tested NPs were less than that of pure TBZ, they can be a promising solution to address the concern regarding the risk of TBZ in one hand and in other hand as they showed improvement of a.i. solubility. These results are the effect of a 48h exposure of *D. magna* to nanopesticides. Therefore, longer-term exposure and reproduction bioassays are important for robust results, which they are ongoing. In general, as the different nanopesticides and their nanocarriers in the present study showed different responses, it highlights the importance of relevant guidelines for environment risk assessment of nanopesticides specifically.

1.01 Advantages of using lab and field collected invertebrates in ecotoxicology: Challenges and opportunities for Environmental Risk Assessment (Poster)

1.01.P-Mo001 The Comet Assay With Standard Aquatic Test Organisms As an Alternative Test System for an Environmental Risk Assessment of Pharmaceuticals

Marwin Jafari¹, **Maria Vogt²**, **Elke Eilebrecht³**, **Lena Kosak⁴**, **Jasmin Brueckner⁵**, **Kathi Westphal-Settele⁵**, **Ute Kühnen⁶** and **Karsten Schlich⁴**, (1)Fraunhofer IME, Schmallingenberg, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (3)Ecotoxicology, Fraunhofer IME, Schmallingenberg, Germany, (4)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallingenberg, Germany, (5)Umweltbundesamt / German Environment Agency, Germany, (6)German Environment Agency, Germany

Human pharmaceuticals find their way into aquatic ecosystems e.g. via municipal wastewater, where they pose a potential threat to aquatic organisms. A comprehensive environmental risk assessment (ERA) is necessary to minimize their risks. In accordance to the guidance on human pharmaceuticals for an ERA, effects on aquatic organisms are determined based on standardized guidelines including, among others, the *Daphnia magna* Reproduction Test (OECD 211). The EMA guideline for ERA was published in 2006 based on the efficacy of active substances in previous years. Meanwhile there are more potent active

substances, putting into question whether the test systems still offer sufficient protection for aquatic organisms. In a previous project (German Environmental Agency, FKZ 3718 65 420 1) alternative test systems for an ERA were identified. One of the identified test systems was the Comet Assay, a genotoxicity test that quantifies DNA damage by measuring the fraction of DNA that migrates out of a nucleus during gel electrophoresis (Tail intensity or TI%), with environmentally relevant organisms. Therefore, we established the Comet assay with the invertebrate *D. magna* and tested the effect of several pharmaceuticals either used in oncology (e.g. Cyclophosphamid) or cardiologica (e.g. Edoxaban) to account for genotoxicity as a potential adverse effect of pharmaceuticals. *D. magna* were exposed for 48 hours in accordance to the OECD 202 with test concentrations chosen to result in sublethal effects. After exposure, immobility was recorded and immobile daphnids were discarded. *Daphnia* cells were isolated and purified via filtration. The cells were mixed with agarose and pipetted onto microscopy slides. The slides were then incubated in a lysis solution to remove membranes. A treatment in an alkaline solution was performed causing the DNA to unwind and separate into single strands. Gel electrophoresis was performed and the slides were washed and dried overnight. The gels were stained using the DNA dye Vista Green and examined under a fluorescence microscope. Images were evaluated using the software CaspLab in order to determine tail intensity (TI%) values. The comet assay on *D. magna* was successfully established. In a calibration with hydrogen peroxide an increase in median TI% of over 60% was determined confirming that the method is capable of detecting genotoxicity. Of the pharmaceuticals tested so far, only Edoxaban showed a dose dependent increase in TI%.

1.01.P-Mo002 Impact of Carbon Nanotubes on an Emerging Cellular Organism: Physarum polycephalum

Manon Ternois¹, Audrey Dussutour² and Emmanuel Flahaut³, (1)CRCA and CIRIMAT, France, (2)CRCA-CBI UMR CNRS 5169 UPS, France, (3)CIRIMAT UMR CNRS 5085 UPS INPT, France

Carbon nanotubes (CNTs) are a category of nanomaterials with applications in all fields (energy, transports, composite materials and environment) due to their exceptional mechanical, optical and electronic properties. However, their use should depend on the non-toxicity of these nanomaterials, and little is still known on their impact on living beings^{1,3,4}. This study evaluated the toxicity of double-walled carbon nanotubes (as a model of CNTs in general) on the unicellular organism *Physarum polycephalum*, which, due to its simplicity of organization and behavioural complexity², is a model of choice. The objective was to assess the fate of CNTs within the cell of *Physarum polycephalum*, and to evaluate their impact on the behaviour of the latter. For this purpose, organisms were contaminated along three routes of exposure (topical, food, environment) in order to determine the internalization of CNTs. The food exposure was the more efficient. Accumulation and excretion of CNTs within the cell were then assessed only by food exposure of the organism. No bioaccumulation and a fast excretion from the cell were observed. From a behavioural point of view, impacts on the migration speed, the fusion process and the cognitive performance were also investigated.

1.01.P-Mo003 Polyethylene Impacts in Fatty Acids and Carbohydrate Profiles of the Estuarine Species *Scrobicularia plana*

Paola Talarico¹, Silvia Lomartire², Carolina Rocha³, João Marques³ and Ana Marta Goncalves⁴, (1)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Pianopoli, Italy, (2)MARE - Marine and Environmental Sciences Centre, Faculty of Sciences and Technology, University of Coimbra, Italy, (3)University of Coimbra, MARE - Marine and Environmental Sciences Centre, Portugal, (4)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Coimbra, Portugal

Microplastic (MP) pollution in marine environments is a topic of emerging concern. Due to their ubiquity and small size, these particles are easily internalized by marine organisms, causing adverse biological responses. Bivalves are considered bioindicators of environmental health due to their wide distribution, ability to filter large volumes of water, sessile behaviour and ecological and commercial importance. Biomarkers, such as fatty acids (FAs) and carbohydrates (CHs), have been recently proven to be powerful tools to detect and evaluate an organism response to contaminants' exposure. The present study assesses the biochemical (FAs and CHs content) and ecotoxicological responses of two size classes (big and small) of the estuarine bivalve *Scrobicularia plana* exposed to cospheric polyethylene (PE) microparticles (75-90 µm). Organisms were exposed to environmental relevant and also higher concentrations of virgin PE microparticles (30 particles L⁻¹, 90 particles L⁻¹, 150 particles L⁻¹, 450 particles L⁻¹) for 96h. Results showed that PE ingestion occurred at all concentrations and microparticles accumulated in the visceral mass of *S. plana*, with the small size being the most affected class. PE exposure caused significant decreases in polyunsaturated fatty acids (PUFAs) content, including some essential fatty acids (EFAs), which are important compounds for their growth, reproductive ability and overall fitness. Concerning CHs results, PE exposure significantly decreased xylose, galactose and glucose contents. The decrease in glucose content can be interpreted as an exploitation of glycogen reserves for glucose availability caused by the condition of stress induced by the presence of the pollutant. The decrease in long-chain fatty acids, such as PUFAs, might be a consequence of depletion of glycogen reserves. As available glucose declines, *S. plana* started exploiting other energy sources to compensate such loss of energy, triggering lipids hydrolysis. These alterations may affect the overall fitness of the organisms and may cause changes in their nutritive value and thus along the trophic food chain, with potential implications for human health. As bivalves are consumed without removal of the digestive tract, they represent an important route of MP exposure for humans and ecotoxicological data on the effects of MPs are urgently needed as potential consequences on human health are still unknown.

1.01.P-Mo004 Polyethylene Impacts on the Antioxidant Defence System of the Estuarine Species *Scrobicularia plana*

Jorge Gutierrez Serrano¹, Andreia Filipa Mesquita², Silvia Lomartire³, João Marques⁴ and Ana Marta Goncalves⁵, (1)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Las Rozas de Madrid, Spain, (2)CESAM & University of Aveiro, Portugal, (3)MARE - Marine and Environmental Sciences Centre, Faculty of Sciences and Technology, University of Coimbra, Italy, (4)University of Coimbra, MARE - Marine and Environmental Sciences Centre, Portugal, (5)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Coimbra, Portugal

Plastics have become a substantial part of modern life and ubiquitous in all environments. Microplastics (MPs) are emerging

contaminants in marine environments and pose a serious threat to the marine ecology. MPs arise from land sources, deterioration of larger plastics, or intentionally manufactured as “primary” or “virgin” microbeads. MPs can be found in diverse shapes and sizes, and their long-term effect is yet unknown. Estuarine ecosystems, as transitional systems between marine, fluvial, and terrestrial environments, represent a hotspot for MPs pollution, where sediments are most likely the final sink. MPs ingestion has been reported in a wide variety of marine species, still the ecotoxicological effect on marine ecosystems is poorly understood. The benthic bivalve *Scrobicularia plana* was selected for its capacity to filter pollutants and the role it plays in the functioning of estuarine communities. For this study, organisms of two size classes (big and small) were exposed to relevant environmental virgin polyethylene (PE) microparticles (75-90 μm) and also higher concentrations (C1 = 30 MPs L⁻¹, C2 = 90 MPs L⁻¹, C3 = 150 MPs L⁻¹, and C4 = 450 MPs L⁻¹) to assess the ecotoxicological and biochemical effects of this pollutant. A battery of biomarkers was selected to determine the ecotoxicological effects of PE microparticles and to assess the potential use of enzymatic biomarkers for PE bioassays, including the activity of antioxidant enzymes (glutathione peroxidase (tGPx), glutathione reductase (GRed), glutathione-S-transferase (GST), Catalase (CAT) and Superoxide dismutase (SOD)) and the lipid peroxidation occurrence (TBARS). PE microparticles did not show lethal effects for *S. plana*. However, alterations occurred in the activities of the antioxidant enzymes and lipid peroxidation. Clams of both size classes showed dose-dependent responses at the highest concentrations (450 MPs L⁻¹), significantly increasing the activities of GST and GRed. A trend is observed between the antioxidant enzymes CAT, SOD, and tGPx for both size classes. The results indicate the suitability of *S. plana* as an indicator for the presence of virgin PE microparticles in aquatic environments. Furthermore, this work reports that GST activity increases significantly under the highest concentration of MPs (450 MPs L⁻¹), suggesting to be the best enzymatic biomarker to assess the presence of PE microparticles.

1.01.P-Mo005 Toxicity of Cigarette Butts and Their Associated Chemicals on the Freshwater Invertebrate *Chironomus riparius*

Francesca Molinari¹, Marion Blanchard², Therese Nitschke³, Bethanie Carney Almroth⁴ and Agathe Bour³, (1)Department of Biology and Environmental Sciences, University of Gothenburg, Göteborg, Sweden, (2)Ecole Nationale Supérieure Agronomique de Toulouse (ENSAT), France, (3)University of Gothenburg, Sweden, (4)Goteborg University, Sweden

Cigarette butts are one of the most commonly found litter items in the global environment. Their distribution spans from streets to beaches, rivers and oceans. Once ignited, the smoke produced by the tobacco mixture contains many harmful substances such as nicotine, PAHs, formaldehyde, hydrogen cyanide, lead and arsenic. These substances are partially trapped into the cigarette filter, which, once present in the environment, can release the chemicals into the environment. While the effects of smoking cigarettes are well understood, the effect of cigarette butts on the environment is still to be better researched. The aim of this study was to investigate the effects of cigarette butt leachates on the aquatic environment. For this purpose, we used the model organism *Chironomus riparius* (midge larvae), a widely spread and abundant organism in freshwater ecosystems. The invertebrate larvae are in direct interaction with both sediment and water, making them representative of both compartments, an interesting trait for the experiments we carried out. Cigarette butts were left to leach in containers containing sand and freshwater. The two matrices were then separated. Chironomid larvae were exposed either to contaminated sand or contaminated water, complemented with clean water or sand, respectively. This experimental design allowed us to study where the cigarette leachates are more prone to accumulate and therefore which organisms, benthic or pelagic, would be most at risk. We also followed a multi-endpoint approach, exposing the organisms at different life stages and for different amounts of time (from 7 days to 3 months), assessing endpoints such as growth, development and teratogenicity. Our results show strong evidence that leachates from cigarette butts impact *C. riparius*. More pronounced effects were observed when comparing the sediment phase to the water phase. This indicates that chemicals contained in cigarette butts can leach and enter both the sediment and water phases, but with a stronger affinity to sediment, potentially putting benthic organisms more at risk. Benthic organisms are essential for ecosystem functioning. In cigarette polluted basins, a loss of benthic species might mean the collapse of an entire ecosystem. We suggest that more experiments be conducted on different species of benthic organisms in order to confirm that cigarette butts are particularly toxic to sediment dwelling organisms.

1.01.P-Mo006 Relevance of Mysid Shrimps Toxicity Tests for Risk Assessment in Europe

Guido Gonsior, Aquaculture, Ecotox, Marine Science, GG BioTech Design, Homberg (Ohm), Germany

Mysid shrimp (*Americamysis bahia*) shows high sensitivity to pollutants. This finding increases the impact of marine test systems on risk assessment. But it is not clear if this is also relevant for the European zone and if sensitivity of the mysid shrimps is comparable to common species in Europe. We present data of the sensitivity of the mysid shrimp *Americamysis bahia*, native to the east coast of the United States in comparison to species in the East and North Sea (e.g., *Praunus flexuosus*). These data might be useful to evaluate the relevance of mysid shrimps tests for the risk assessment in Europe.

1.01.P-Mo007 Biochemical, Physiological, and Reproductive Effects of Glyphosate (FAENA®) and 2,4-D (HERBIDEX®) on the Tropical Cladoceran *Ceriodaphnia rigaudi*

Alma Rodríguez-Miguel¹, Armando Vega López² and **Felipe Fernando Martínez-Jerónimo²**, (1)Instituto Politécnico Nacional-Escuela Nacional de Ciencias Biológicas, Mexico, (2)Escuela Nacional de Ciencias Biológicas, IPN, Mexico

Herbicides have contributed to increasing agricultural production, but the intensive usage of these chemicals can produce significant damage in the environment, mainly through the affection of no target species. The herbicides glyphosate and 2,4-D are used worldwide for weed control; the first is a non-selective contact herbicide that inhibits the synthesis of aromatic amino acids needed for protein formation, whereas 2,4-D is an auxin hormone that inhibits the cellular division of meristematic tissue, causing the reduction of apical growth in plants. Aquatic organisms are exposed to herbicides reaching the water by leaching, running-off,

or adsorption to particulate matter. *Daphnia magna* is a Cladoceran frequently used in toxicity studies. However, it is important to consider tropical species such as *Ceriodaphnia rigaudi*, a zooplankter distributed in México. The objective of this study was to determine the toxic effects that the mixture of glyphosate- and 2,4-D-based commercial formulations produce in the reproduction, physiology, and biochemistry of *C. rigaudi*. LC₅₀'s (48h) (25°C, 16:8h light: darkness) were determined to be 1.09 mg L⁻¹ for glyphosate and 233 mg L⁻¹ for 2,4-D. Then, a chronic toxic assay was carried out during a whole life cycle. The tested concentrations were 0.0625, 0.125, 0.25, and 0.5 Toxic Units (TU) of the mixture of FAENA® and HERBIDEX®. During the tests, samples of 30 neonates from each clutch were picked up to analyze effects. The concentration of proteins, carbohydrates, and lipids and the activity of the enzymes CAT, SOD, and GPx were determined for each clutch. The 0.5 UT mixture of herbicides significantly decreased longevity. There was a delay of one day at the age of first reproduction in 0.125 and 0.5 UT concentrations. The accumulated progeny and the number of clutches decreased significantly at 0.5 UT. Abortions increased as the concentration of the mixture did. The content of proteins increased in the highest concentrations (0.125, 0.25, and 0.5 UT). Carbohydrates decreased up to 80% compared with the control, and lipids were significantly different in the treatment of 0.125 UT. The activity of the SOD was stimulated twice, but the activity of CAT and GPx was inhibited. The simultaneous presence of two herbicides in the water may lead to increased toxicity, causing more negative effects on aquatic organisms than that expected in single exposures.

1.01.P-Mo008 Finding the Optimal Conditions for Ecotoxic Experiments With the Larvae of the Terrestrial Land Crab *Cardisoma guanhum*

Concepcion Rodriguez-Fourquet², Concepcion Rodriguez-Fourquet² and Marie Corujo², (1)University of Puerto Rico at Bayamon, United States, (2)University of Puerto Rico at Bayamon, Puerto Rico

The land crab *Cardisoma guanhum*, one of the keystone species on the island of Puerto Rico, has a complex life cycle composed of a terrestrial adult stage and a larval aquatic stage; composed of zoea and megalopa stages. During this aquatic phase, *C. guanhum* zoeas are affected by environmental factors such as food availability, temperature, and salinity, affecting the metamorphosis during the larval stage. Given this, we established the goal of discovering the ideal conditions for the development of *C. guanhum* larval stages and determining the set of conditions necessary for developing phthalates bioassays. Gravid *C. guanhum* females were captured in the wild and transported to the laboratory. Zoeas were removed from the females and immediately transferred to the experimental vials. The zoeas were exposed to three different temperatures, three different salinities, and two different food regimes. The zoeas were also subjected to several treatments such as various water quality, buffers prepared with various water quality, and different glassware cleaning conditions. The survival was recorded in each of the experiments. We found that the zoea exposed to 35 ppt and temperatures between 21°C and 27°C showed the highest survival. The food regimes showed that an excess and constant supply of *Artemia salina* newly hatched nauplii showed a tendency to higher survival of zoeas. The exposure of *C. guanhum* zoeas to different water quality conditions, to buffers prepared with different water quality conditions, and to different glassware cleaning regimes showed no survival difference among the treatments. We concluded that we had identified the optimal conditions for future toxicity experiments with phthalate.

1.01.P-Mo009 Investigation of Different Food Sources for a Chronic Laboratory Test With *Cloeon dipterum*

Julius Alberti, RWTH University Aachen, Aachen, Germany

In routine toxicity testing or regulatory evaluation of chemicals, standard organisms that are easy to maintain are often used. These organisms are not always sensitive enough to ensure a correct evaluation of the chemical. Besides the standard organisms, there are non-standard organisms like mayflies which are very sensitive to certain chemicals. In recent years, there has been a growing interest in keeping a mayfly species in the laboratory for toxicity testing. An important aspect for keeping mayflies is the food source. It has been shown that the development rate of the mayfly larvae is directly related to the quality of the offered feed. To reproduce comparable results, the food source must provide enough energy for the larvae to develop well, and any mortality or developmental delay effect must be due to the substance being tested. In this work, different food sources for the mayfly species *Cloeon dipterum* were investigated regarding their practicability and quality. The tests were carried out with locally collected larvae of *C. dipterum*. For each test set 6 replicates with 5 larvae each were prepared. First two fish foods and periphyton cultivated on tiles were tested. Secondly, incubated poplar leaves as whole and as a powder were tested. Again, in parallel with periphyton. The experiments were stopped as soon as all larvae had emerged or had died. The development of the larvae was examined 3 times a week. In order to investigate an increase of mortality caused by the monitoring procedure, a further non-invasive test with periphyton tiles as food source was performed. Here, only the vitality was checked every 7 days. In the test with the artificial fish food 1 15% of the larvae emerged while, 85% of the larvae died. With the artificial fish food 2 only 55% mortality was observed. The parallel periphyton test showed the lowest mortality (30%). In the second run, the mortality in the periphyton test was higher (80%). Feeding with leaves resulted a slower development of the larvae, resulting in an increased duration of the test. The mortality was 55% - 60% and first dead larvae were observed early in the test. In general, larvae fed with fish feed developed slower compared to the test with periphyton tiles. Also, larvae died earlier and in smaller stages. In the non-invasive test, 40% of the larvae died. The regular examination of the larvae does not seem to have a negative influence on the test. Overall, the periphyton tiles turned out to be a promising feed for larvae of *C. dipterum*.

1.01.P-Mo010 Behavioural and Enzymic Activities Changes Under Chronic Exposure of Neurotoxic and Non-Neurotoxic Pharmaceutical in Benthic Invertebrate

Wing Sze Chan¹, Henriette Selck² and Martina Santobuono², (1)Roskilde University, Roskilde, Sweden, (2)Roskilde University, Roskilde, Denmark

Among the emerging contaminants, pharmaceuticals are considered one of the most pertinent substances that may pose threats to

the aquatic ecosystems. Pharmaceuticals are designed to be directed at specific metabolic and molecular pathways in selected organisms. Thus, they are assumed to still be biologically active when entering the ecosystem and may therefore result in unpremeditated impacts on non-target organisms. Neurotoxic and non-neurotoxic pharmaceuticals have different mode of action and therefore cause different impacts on the organisms. In addition, environmental stressors, such as food availability and temperature, may interact with contaminant exposure to affect uptake and action of pharmaceuticals in organisms. An enhanced understanding of the mode of action of pharmaceuticals in aquatic organisms under different environmental stressors is crucial to assess the possible impacts at organism to population level. This project examines the chronic impacts of low concentrations of sediment-associated pharmaceuticals: Fenofibrate (lipid regulator), naproxen (nonsteroidal anti-inflammatory drug), fluoxetine and sertraline (antidepressants) to the deposit-feeding oligochaete, *Tubifex tubifex*, using non-conventional endpoints (i.e., burrowing, feeding activity) and enzymatic activity (e.g., AChE, GST) following chronic exposure under different environmental settings. The presentation will discuss the approach to construct Adverse Outcome Pathways (AOPs) for the selected pharmaceuticals: 1) a study on the changes of enzyme activities in *T. tubifex* under chronic exposure of neurotoxic and non-neurotoxic pharmaceuticals, 2) the use of non-conventional endpoints to assess the impact of chronic pharmaceuticals exposure on organisms, 3) an understanding of the impacts of environmental stressors on the mode of action of the pharmaceuticals and the response of the organisms, and 4) construction of AOPs to link behavioural and enzymic changes under chronic exposure of pharmaceuticals in benthic invertebrates.

1.01.P-Mo011 Effect of Diesel Particulate Matter on *Caenorhabditis elegans*: Neuro-Behaviour and Neurodegeneration *Nivedita Chatterjee*, INL International Iberian Nanotechnology Laboratory, Vila Nova de Gaia, Portugal

This study aims to elucidate whether the Diesel particulate matter (DPM) cause alterations in neuro-behaviours in *C.elegans*. Potential long-term toxicity (7 days) and acute toxicity (24h) were assessed in the dose range of 0.1 to 100 µg/ml. We found significant alterations in stress response, locomotion behaviour at sub-lethal dose. In connection with neuro-behavioural (dat-1) analysis, we found that marked impairment in dopaminergic function. *C.elegans* is an excellent model for neurodegenerative disease, such as Alzheimer's disease (AD), characterized by amyloid protein aggregation, otherwise soluble proteins. Our preliminary data evidenced that DPM cause amyloid protein aggregation in the model system (ongoing study). In summary, DPM exposure could impair neuro-behaviour and accelerate the ageing-related neurodegenerative disease in the model system.

1.01.P-Mo012 High Throughput Investigation of Amphipod Reproductive Behaviour

*Bidemi Green-Ojo*¹, *Lena Grinsted*², *Matthew Parker*² and *Alex Ford*², (1)University of Portsmouth, Portsmouth, United Kingdom, (2)University of Portsmouth, United Kingdom

Precopulatory pairing is a reproductive strategy in which a mature male holds a mature female until she moults and copulation occurs. The use of precopulatory pairing as a behavioural endpoint in ecotoxicology was first demonstrated in the 1970s where precopulatory pairing was used to determine mating success. This qualitative behavioural response can be measured as time of disruption of pairs, repairing time or post-dosing observation of pairs for reproductive success. Although this mechanism is sensitive, there has been a steady decline in its use in toxicity testing as it can be onerous. This study aims to provide an overview of past and current trends on the use of precopulatory pairing and discuss the optimisation of this technique using video tracking technology to evaluate the effects of plastic additives on the marine amphipod, *Echinogammarus marinus*. Pairs were separated and individuals were exposed to high concentrations (50 and 5000) µg/l of di-ethylhexyl phthalate (DEHP) and dibutyl phthalate (DBP). The repairing activity was recorded using Zantiks MPV unit for 15 mins. The repairing time and the percentage of animals paired in the control and the exposed group were analysed. This approach to toxicity testing is a sensitive, reliable and cost-effective means of detecting the early warning effects of harmful environmental pollutants.

1.01.P-Mo013 Sertraline and Fluoxetine Chronic Exposure - Possible Sublethal Effects on the Key Benthic Invertebrate *Capitella teleta*

*Martina Santobuono*¹, *Wing Sze Chan*² and *Henriette Selck*¹, (1)Roskilde University, Roskilde, Denmark, (2)Roskilde University, Roskilde, Sweden

Sertraline and fluoxetine are two selective serotonin reuptake inhibitors commonly prescribed to treat depression, anxiety, and post traumatic disorders in humans. Because Wastewater Treatment Plants (WWTPs) are not equipped to efficiently remove pharmaceuticals from wastewater, antidepressants are widely detected in the environment in the range of ng L⁻¹ and µg L⁻¹. These low concentrations might pose a risk to the resident species, especially in a long-term exposure. Since hydrophobic compounds easily sorb to organic matter, they tend to concentrate in sediments. Sertraline and fluoxetine are within these lipophilic chemicals, thus their presence in the water column could be less relevant than in sediment. However, not many studies have focused on sediment exposure of pharmaceuticals. Polychaetes are fundamental organisms for the geochemistry of benthic environments, and among them, *Capitella teleta* is a key species in organically enriched habitats, where it can reach densities of more than 100.000 individual/m². We tested the impact of sediment-associated fluoxetine and sertraline on conventional (e.g., mortality) and non-conventional (e.g., burrowing- and feeding behavior) endpoints. Since antidepressants are neurotoxic chemicals, we also assessed acetylcholinesterase (AChE) enzymatic activity changes. The results will be discussed.

1.01.P-Mo014 Integument Colour Change: Tracking the Inhibition of *Oppia Nitens* Growth As a Sub-Lethal Indicator of Soil Toxicity

*Kayode Jegede*¹, *Hamzat Fajana*² and *Steven Siciliano*², (1)Wageningen Environmental Research, Netherlands, (2)University of Saskatchewan, Canada

Growth is an important toxicity end-point in ecotoxicology but is rarely used in soil ecotoxicological studies. Here, we assessed

the growth change of *Oppia nitens* when exposed to reference and heavy metal toxicants. To assess mite growth, we developed an image analytic technique to measure colour spectrum change of the mite integument as a proxy for growth change. We linked the values of the red, green, blue, key-black and light colours of mites to different growth stages. Based on this concept, we assessed the growth change of mites exposed to cadmium, copper, zinc, lead, boric acid or phenanthrene at sublethal concentrations in LUF 2.2 soil for 14 days. Sublethal effects were detected after 7 days of exposure. The growth of *O. nitens* was more sensitive than survival and reproduction when exposed to copper ($EC_{50_{\text{growth}}} = 1360 \text{ mg/kg}$ compared to $EC_{50_{\text{reproduction}}} = 2896 \text{ mg/kg}$). Mite growth sensitivity was within the same order of magnitude as mite reproduction, when exposed to zinc ($EC_{50_{\text{growth}}} = 1785$; $EC_{50_{\text{reproduction}}} = 1562 \text{ mg/kg}$). At least 25% sublethal effects of boric acid and phenanthrene were detected in the mites but growth was not impacted when *O. nitens* were exposed to lead. Consistent with previous studies, cadmium was the most toxic metal to *O. nitens*. The mite growth pattern was comparable to mite survival and reproduction from previous studies. Mite growth is a sensitive toxicity endpoint, ecologically relevant, fast, easy to detect, and can be assessed in a non-invasive fashion, thereby complementing existing *O. nitens* testing protocols.

1.01.P-Mo015 The Effects of Life Stage on the Sensitivity of *Folsomia candida* to Cyproconazole and Teflubenzuron

*Saúl Fernandes*¹, *Kees Buskermolen*², *Diana Ilyaskina*³, *Matty Berg*² and *Cornelis A.M. van Gestel*¹, (1)Vrije Universiteit Amsterdam, Netherlands, (2)Vrije University Amsterdam, Netherlands, (3)Environment & Health, Vrije Universiteit Amsterdam, Amsterdam, Netherlands

To halt the loss of ecosystem services provided by terrestrial ecosystems, it is increasingly important to understand the effects of chemical stressors on the role of service providing units (SPU). Collembola are soil micro-arthropods with relevant roles in organic matter decomposition and nutrient cycling. For this reason, the registration of active ingredients used in plant protection products requires the assessment of their long-term effects on species of Collembola, such as *Folsomia candida*. The guidelines provided by the Organisation for Economic Cooperation and Development for such tests recommend the use of juvenile age-synchronized animals with 10 to 12 days old. In several studies these guidelines are modified by, e.g., using older animals at the beginning of the test, to compare the effects of an active ingredient with species of Collembola with slower life cycles. To determine the influence of the age of *F. candida* on the results of the toxicity test, we assessed the effect of two active ingredients on *F. candida* with an age difference of 10 days old. The fungicide cyproconazole (CYP) and the insecticide Teflubenzuron (TEF) were selected to clarify if the differences in sensitivity caused by the age of animals are observed for chemicals with distinct modes of action. After exposure to the chemicals, the dose-response curves obtained for mortality and reproduction of 10-12 or 20-22 days old springtails were compared. For CYP, the EC_{50} ($122 \text{ mg kg}^{-1} \text{soil}_{\text{dw}}$) for the effects on reproduction was significantly lower for the older compared to the juvenile springtails (EC_{50} of $241 \text{ mg kg}^{-1} \text{soil}_{\text{dw}}$). For TEF, the LC_{50} for the younger springtails was significantly lower ($0.51 \text{ mg kg}^{-1} \text{soil}_{\text{dw}}$) compared to that for the older animals ($0.91 \text{ mg kg}^{-1} \text{soil}_{\text{dw}}$). Even though the reproduction of both life stages was significantly inhibited by TEF, no significant difference was observed between different ages. These results show that the life stage of *F. candida* at the beginning of the toxicity tests can significantly influence the results obtained. Additionally, the influence of animal age on the test outcome was partially dependent on the active substance tested. This life-stage dependent effect should be considered in future studies to understand how pesticides can influence the role of SPU.

1.01.P-Mo016 Untargeted Lipidomics to Assess the Response of the Non-Targeted Species *Folsomia candida* to Sub-Lethal Concentrations of Teflubenzuron

*Diana Ilyaskina*¹, *Marissa Kateva*², *Saúl Fernandes*², *Marja Lamoree*³ and *Pim Leonards*², (1)Environment & Health, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (2)Vrije Universiteit Amsterdam, Netherlands, (3)VU University, Department Environment & Health, Netherlands

Increased rates of pesticide production brought serious concerns regarding their impact on non-targeted organisms in the environment. Soil organisms as Collembola (or springtails) widely contribute to soil fertility and the nutrient cycle in ecosystems. Therefore, springtails are an important model for ecotoxicological risk assessment (ERA). Classical approaches as reproduction, growth, and mortality are the main test systems used in ERA. Molecular “omics” studies have become an important part of ERA to study the mode of action of pesticides for non-target species. Untargeted screening of molecular changes can provide a more detailed picture of the sub-lethal effects of chemicals present in low concentrations in the environment. In this work, untargeted lipidomics was applied to study the potential toxicity effects of Teflubenzuron on the springtails *Folsomia candida*. Springtails were exposed (7 days) to three environmentally relevant concentrations (0.0056, 0.0139, and 0.0348 mg/kg soil) of Teflubenzuron. Teflubenzuron showed a wide range of significant alterations in the lipid profile. Mainly phospholipids (PC and PE), triglycerols (TG), and fatty acids (FA) were affected. These lipids are primarily involved in membrane synthesis, lipid storage and energy metabolism. Teflubenzuron exposure showed an increase of oxidised forms of TG and FA in springtails which can be indicators of oxidative stress. Moreover, the increase of oxidised polyunsaturated FA (PUFA), shown on all levels of exposure, may cause severe problems since PUFA play a vital role in organisms' development. The decrease of TG can probably be linked to stored lipids which were used as an additional energy source to cope with stress. The decrease in TG in combination with the upregulation of monounsaturated FA and sterol esters indicates the balancing of lipid storage in the body. Dysregulation of PC and PE lipids, associated with the endoplasmic reticulum (ER) and mitochondria, can indicate ER stress. ER is closely connected with lipid droplets synthesis and regulation. Alteration of PE can indicate the disruption of the mitochondria membrane and could further lead to oxidative stress and potential malfunction of glucose metabolism. Hence, a combined study of lipidomics and classical ERA approaches can contribute to a better understanding of the toxicity of Teflubenzuron from the molecular to the population level.

1.01.P-Mo017 Older Age Reduces the Sensitivity of *Daphnia magna* Neonates to the Chitin Synthesis Inhibitor Teflubenzuron

Simon Schmid¹, You Song² and Knut Erik Tollefsen³, (1)NIVA - Norwegian Institute for Water Research, Oslo, Norway, (2)Norwegian Institute for Water Research (NIVA), Oslo, Norway, (3)NIVA - Norwegian Institute for Water Research, Norway

Chitin is a major component of the arthropod exoskeleton and its synthesis is an essential process for arthropod development. It contributes to development by facilitating periodical shedding of the exoskeleton and replacing it with a new one (also called molting). Both, chitin synthesis and molting, are ultimately orchestrated by the hormone 20-hydroxyecdysone. As these processes are conserved in arthropods, they can be targeted to develop strategies for arthropod pest management. One of the substances marketed for this purpose is teflubenzuron, an arthropod growth regulator from the compound class of benzoylphenylureas. As teflubenzuron interferes with chitin synthesis, an endocrine controlled process that occurs periodically, we hypothesized that the age at the time of exposure is a determining factor for the sensitivity of neonatal *Daphnia magna* to the compound. We therefore exposed *D. magna* neonates of different age windows (0-4 h, 4-8 h, 8-12h, 0-12h and 0-24h) to different concentrations of teflubenzuron (0.1, 0.5, 1, 2, 4 and 6 µg/L) for 48 h and monitored molting and survival after 24, 36 and 48 h of exposure. Our results show that the endpoint of molting is generally accompanied by high variability within the data, even with narrow synchronization windows (0-4h). Analysis of dose response curves (comparison of 48h EC50s) revealed that younger *D. magna* neonates are more sensitive to teflubenzuron than older ones, where the youngest animals (0-4 h old) are three times more susceptible to teflubenzuron than the oldest (8-12 h old), and about one order of magnitude more susceptible than animals synchronized according to OECD test guideline 202 (0-24h old). Together, we demonstrate the importance of age in acute *D. magna* tests with substances interfering with chitin synthesis. Our results might have implications in the development and refinement of testing strategies for substances interfering with chitin synthesis in arthropods. Acknowledgements: This project has received funding from the European Union's Horizon 2020 research and innovation program under the Marie Skłodowska-Curie grant agreement No 859891 and supported by NIVA's Computational Toxicology Program, NCTP (www.niva.no/nctp).

1.01.P-Mo018 Physiological Colour Change in Cuttlefish Skin Explants As an Innovative Tool for Contaminant Risk Assessment

Anaid Gouveaux¹, Sano Mamoudou¹, Nicolas Elie¹, Apolline Chabenat², Céline Thomasse¹, Christelle Jozet-Alves¹, Anne-Sophie Darmailacq¹, Ludovic Dickel¹, **Thomas Knigge³** and Cécile Bellanger⁴, (1)Université de Caen Normandie, France, (2)University Le Havre Normandie, France, (3)Université du Havre, France, (4)Université de Caen Normandie, France

Colour change is a widespread ability among animals known to fulfil a range of biological functions: thermoregulation, UV-protection, crypsis or even communication. It can be achieved either by the production, degradation or chemical modification of pigmented structures (*i.e.*, morphological colour change) or by changes in their intracellular distribution (*i.e.* physiological colour change). Depending on the taxa, the physiological colour change mechanisms can be controlled by nervous and/or hormonal pathways, with which many environmental contaminants can potentially interfere. Hence, quantitative approaches of physiological colour change may provide new opportunities for toxicological risk assessment. Cephalopods provide well studied models for their colour change abilities. Their skin is a complex organ that includes a variety of chromatophores (yellow-, red-, and dark-pigmented cells) laying on top of light-reflecting leucophores and iridophores. Dynamic colour changes in cephalopods mainly involve the mechanical action of chromatophore-associated neuromuscular structures, resulting in the dispersion or concentration of pigmented organelles. Thus, we have developed an *in vitro* bioassay combining the preparation of skin explants from the common cuttlefish (*Sepia officinalis*) with a standardised, reproducible protocol of image acquisition and a software able to quantify the chromatophore activity in response to the topical application of contaminants. To address the specific problem of detecting and individualising overlapping chromatophores that the existing methods based on segmentation do not solve, we developed an algorithm based on deep learning. Its performances are illustrated here by the analysis of responses to selective serotonin reuptake inhibitors (SSRI-antidepressants) and putative endocrine disrupting chemicals.

1.01.P-Mo019 Application of Molecular Tools to Update Aquatic Ecotoxicology Monitoring

Valeria Manfredi¹, Kevin Gough¹, Helen Rees² and Nadine Taylor³, (1)The University of Nottingham, United Kingdom, (2)ADAS, United Kingdom, (3)Cambridge Environmental Assessments, United Kingdom

The field of aquatic ecotoxicology has developed validated gold standard methods to identify, assess and reduce relevant contamination in aquatic ecosystems (Schmitt-Jansen et al. 2008). Both zooplankton and phytoplankton are used in ecotoxicological studies as they are bioindicators of water quality (Parmar et al. 2016) and anthropogenic stressors can adversely impact community assemblages and ecosystem function. To date, the study of freshwater planktonic organisms has been challenging as taxonomic identification requirements are frequently expensive, time-consuming and often require a specialist in the field (Elias-Gutierrez et al. 2018). Using molecular techniques, plankton identification is becoming easier and more accurate (Djurhuus et al. 2018). The overall objective of this project is to apply metabarcoding techniques to both identify and quantify the relative abundance of indicator-genera within in-field ecotoxicity studies, to replace or complement traditional microscopy techniques. Firstly, a database was created by retrieving all the available sequences in NCBI GenBank and BOLD for selected zooplankton and phytoplankton genera. Here we present a comparative analysis of molecular (sequence numbers) and morphological (abundance counts) data, focusing on nine taxonomic groups, to show baseline variation in the zooplankton community throughout the season. The 18S hypervariable region was sequenced for 35 zooplankton samples collected from five different mesocosms at CEA, Boxworth between May and September 2020. The morphological data of the seasonal mesocosms samples showed a seasonal variation of the nine most abundant genera. When compared to a previous study conducted on 12 mesocosms at the same site (Brooks et al. 2019), a similar seasonal pattern for the majority of genera was found. The molecular

results are expected to support the hypothesis that DNA metabarcoding can augment the morphological identification for estimating the diversity and composition of the zooplankton assemblage.

1.01.P-Mo020 Spatio-Temporal Patterns in the Gene Expression of the Copepod *Temora longicornis* in Response to Chemical Pollution

*Ilias Semmouri*¹, *Karel De Schamphelaere*¹, *Colin Janssen*² and *Prof. Jana Asselman*³, (1)Ghent University (UGent), Belgium, (2)University of Ghent, Belgium, (3)Ghent University, Belgium

Due to their rapid responses to environmental variation, planktonic organisms are used as bio-indicators of ecosystem changes. With the need for better understanding the impact of a changing environment on zooplankton communities, zooplankton monitoring programs have been carried out in the marine environment globally since the early 20th century. Most zooplankton monitoring studies focus mainly on variability in biodiversity and biomass. However, this approach is hindered by challenges in the identification, which is time-consuming, complicated and requires biological expertise. Advances in practical, cost-effective molecular approaches, such as (meta)barcoding, helped overcome the issues with morphology-based biomonitoring. Yet, a more comprehensive molecular data set would be able to identify and assess the impact of the main drivers of changes in the marine ecosystem, rather than only determining species richness. Since responses to environmental stress are initially genome-driven, a genetic understanding on the physiological responses to stress can help predict potential responses to a changing environment in the future. In this project, we focus on the potential effects of various environmental stressors (changes in temperature, salinity and concentration of PCBs and PAHs as a proxy for chemical pollution) on the gene expression of the calanoid copepod species, *Temora longicornis*, the dominant zooplankton species of the southern part of the North Sea. Therefore, this study investigated transcriptome-level profiles of adult *T. longicornis* that were collected at four stations in the Belgian part of the North Sea (BPNS) at different time points in a four year sampling campaign. Zooplankton samples were collected with the research vessel (RV) Simon Stevin on 35 (bi)monthly sampling campaigns in 2018 till 2021 (start: 20th February 2018, end: 22d of December 2021). From the obtained data, we aimed to identify the most active metabolic pathways and we tried to place these results into a broader context of physiological activities. Next, we constructed gene-co-expression networks, identified hub genes and we tried to obtain a mathematical relationship between these networks/hub genes and (1) the measured environmental variables and (2) phenotypic characteristics of interest (i.e. densities and biomass), defined by a generalized additive model. As such, we aim to identify molecular endpoints that can be consistently anchored to phenotypic changes under multi-stress conditions and at the same account for potential biological variability.

1.01.P-Mo021 Standardized and Reproducible Quantitative Approaches to Screen Antibiotics and Organophosphates Pesticides Effects on Freshwater Planarian: Setting the Stage for High-Throughput Screening in (Eco) Toxicology

*Lucia Rejo*¹, *Jean-Michel Malgouyres*², *Elsa Bonnafé*² and *Caroline Vignet*¹, (1)INU Champollion/University of Albi, France, (2)Centre Universitaire Jean-François Champollion Albi France, France

For the two last decades, the number of toxicological studies using freshwater planarian have been steadily increasing, showing the planarian to be a really promising alternative model to assess pollutant that may ends up in aquatic environment. Planarian have been suggested as a bioindicator of the quality of freshwater habitat. Freshwater planarians are invertebrate flatworm worldwide distributed, easy to collect, and to maintain in lab. Their small size allows medium to high-throughput screening of toxicity on a whole-animal system. Planarian can enable the assessment of toxicity of pollutant on many levels: 1) they are secondary consumers feeding on other aquatic invertebrates, planarians are good indicators of chemical risk on the aquatic ecosystem; 2) the planarian nervous system share the same neuronal subpopulations and neurotransmitters as the mammalian brain, they are potential screening tools for predicting pollutant toxicity for mammals. In this study, we design a standardized, reproducible quantitative protocol to evaluate the effect of two chemicals used in agriculture: gentamicin, a broad-spectrum antibiotic, and an organophosphate pesticide, chlorpyrifos through multiple approaches. Planarian were screened for mortality at 7 concentrations of chlorpyrifos over a 24 h period. Effects of sublethal concentrations of chlorpyrifos and 3 concentrations of gentamicin, were screened through quantitative assessment of multiple behaviours. Planarian responses were evaluated with 3 behavioural challenges: exploratory behaviour, response to light stress and negative phototaxis. These tests have shown to be reliable and repeatable for toxicological screening in lab.

1.01.P-Mo022 Variations in the mRNA Expression After Short- and Long-Term Exposure to Metformin on Adult Marine Mussels

Wulan Koagouw, School of Applied Sciences, Indonesian Institute of Sciences, Brighton, United Kingdom

The widely prescribed antidiabetic drug metformin has the potential to accumulate and persist in water bodies, with little-known consequences for aquatic biota. Here, we report the biological responses of a sentinel organism, the blue mussel *Mytilus edulis*, exposed to a range of concentrations of metformin found in the aquatic environment, and also exceeding those levels, representing a worst-case scenario. The effects on several target genes in mussels' gonads are discussed following short- and long-term exposure to metformin. Metformin induced variations in the mRNA expression of all transcripts investigated here, with some transcripts (*VTG*, *V9*, *CASP8*, *FAS*) displaying fluctuating results. Several transcripts followed concentration-dependent trends, mostly in the short-term exposure, as shown by the expression of *ER2* and *HSP70*, whilst *BCL2* expression also showed a dose-dependent result after long-term exposure. The monotonic responses exhibited by some transcripts indicate their potential as biomarkers of metformin exposure. The remarkable variation in expression also observed between short- versus long-term exposures reflects the importance of contact time between metformin and the organism in the natural environment, as shown by all transcripts.

1.01.P-Mo023 Investigating the Background Individual Metabolomic Variability of the Freshwater Invertebrate, *Gammarus pulex*

*Thomas Miller*¹, *Mariana Santos*², *James MacRae*², *Nicolas Bury*³, *Stewart Owen*⁴ and *Leon Barron*⁵, (1)Brunel University London, United Kingdom, (2)The Francis Crick Institute, United Kingdom, (3)University of Suffolk, United Kingdom, (4)AstraZeneca, United Kingdom, (5)Kings College London, United Kingdom

The (pseudo)persistence of emerging contaminants and other organic micropollutants in the environment is a cause for concern among the organisms that are exposed to them. Recently, 'omics technologies are increasing in their application within environmental toxicology to understand the effects of these exposure scenarios in both lab and field collected organisms. However, metabolomics is an emerging field and to interpret the use of metabolite data in the understanding of toxicological responses is challenging. The variability in individual metabolomes for a species, or a "background metabolome" should be established to determine possible confounding factors such as age, biological sex and moulting (among others) that may influence data interpretation. Furthermore, for field-collected invertebrates previous exposure history could be an important consideration when using them in environmental risk assessment. Thus, we have characterised the effect of these factors on the metabolic variability in the freshwater invertebrate, *G. pulex*. Herein, an analytical method is presented for the extraction and non-target analysis¹ of the metabolome in *G. pulex*. Briefly, a dual phase liquid extraction was used followed by HILIC-HRMS to enable detection and annotation of metabolic features extracted from individual animals (~5 mg dw). Animals collected from the field were analysed immediately and compared to animals that were extracted after a set period of acclimatisation to laboratory conditions. The variability of metabolomes was analysed using XCMS and MetaboAnalyst. The results indicated that sex, moulting stage and acclimatisation period affected the metabolic variability and factors that are likely to influence metabolomic analyses should be investigated to aid understanding of pathways involved in effect-based studies, especially where these approaches might be used to develop adverse outcome pathways. Furthermore, it may be prudent to pre-select animals based on these confounding factors to reduce noise in the data. Overall, the characterisation of metabolic variance for invertebrates along with the use of metabolomics shows a very powerful approach for understanding adverse effects that may be associated with environmental contaminants.

1.01.P-Mo024 Neurotransmitter Systems in Marine Invertebrates and Their Potential Perturbation by Environmental Pollutants

*Sarah Hue*¹, *Tiphaine Monsinjon*¹, *Cécile Bellanger*² and *Thomas Knigge*³, (1)Université Le Havre Normandie, France, (2)Université de Caen Normandie, France, (3)Université du Havre, France

Neurotransmitter systems are major elements in the transmission of information between the central nervous system and target organs for the regulation of physiological functions. These systems are highly conserved in the animal kingdom. Therefore, neurotoxic compounds could interact with the same targets in vertebrates as invertebrates. In some invertebrates, monoaminergic neurotransmitters (serotonin, dopamine, norepinephrine, octopamine) can influence neurohormones. Thus, a modulation of these systems by environmental pollutants may induce endocrine disruption. Such endocrine disruptive effects remain sparsely studied in marine invertebrates. To shed light on neuro-endocrine perturbation, it is necessary to better understand the functioning of these monoaminergic systems in marine invertebrates. We here present a comparative approach including two species covering two important phyla of marine animals: the green crab *Carcinus maenas*, a crustacean, and the cuttlefish *Sepia officinalis*, a mollusk. The different monoamines in the nervous systems of both species are mapped using immunohistochemistry and quantified by LC-MS/MS following the exposure to putative endocrine disrupting compounds.

1.01.P-Mo025 Planaria As an Alternative Approach to Animal Testing in the Future

*Lucia Rejo*¹, *Jean-Michel Malgouyres*², *Florence GERET*², *Elsa Bonnafé*² and *Caroline Vignet*¹, (1)INU Champollion/University of Albi, France, (2)Centre Universitaire Jean-François Champollion Albi France, France

The adoption of the 3R rules (reduce, refine and replace) encourages to limit the use of vertebrate animals in scientific research and aims at developing new model organisms. Invertebrates become increasingly more popular in order to replace vertebrates. Their relatively high sensitivity to pollutants makes them promising as screening tools to predict the toxicity of various molecules in vertebrates including mammals. Planaria is an invertebrate flatworm living in freshwater, worldwide. It's well known for its regenerative capacities, and low maintenance requirements. Planaria are endemic invertebrate organisms, easy to collect locally, kept in controlled conditions, and are not subject to regulation in terms of animal experimentation. Planaria is emerging today as an *in-vivo* model for (eco) toxicological study. Planaria has a sensitivity comparable to other well-established freshwater invertebrate models such as daphnia but with some additional advantages. Planaria can regenerate itself and possess a nervous system with all the molecular characteristics of higher vertebrates such as central nervous system and neurotransmitters. The standardization of experimental practices is crucial for the consistency and comparison of data between laboratories. Four planarian species are commonly used for toxicological studies but have different sensitivities to the same chemicals. The aim of this presentation is to highlight advantages of using planaria as an (eco)-toxicological model. Three steps are presented: First by implementing data from literature on using planaria as model, secondly by proposing a standardized protocol in behavioral study and third by validating the use of the planaria as an (eco)-toxicological model.

1.01.P-Mo026 Caenorhabditis elegans Reproduction As a Chronic Endpoint for Fast Screening in Ecotoxicology

*Mafalda Castro*¹, *Cecillie Henriksen*¹, *Ioanna Karadimou*¹ and *Nina Cedergreen*², (1)University of Copenhagen, Denmark, (2)Plant and Environmental Sciences, University of Copenhagen, Frederiksberg, Denmark

In vitro assays are fast and high throughput tests that also reduce the need for vertebrate testing. However, there is still need for whole-animal testing that can i) capture wide-arrays of toxicity mechanisms and ii) show how a chemical behaves in a

compartmentalized model. The nematode *Caenorhabditis elegans* is a widely used model to assess toxicity of sediment, soil, pore water and aqueous samples. Considering its small size (up to two mm in length) and short life-cycle, *C. elegans* could be an especially useful whole-organism with a chronic endpoint (i.e., reproduction) for high-throughput tests. The aim of this work was to explore different measures of *C. elegans*' reproduction output such as offspring number, offspring size and biomass (offspring size × number) and evaluate its sensitivity towards common environmental contaminants and stressors compared to other commonly used model organisms. *C. elegans* reproduction tests are carried out by exposing pre-pregnant adults to the stressor of interest for over 72 hours and recording the number of offspring produced by a single adult. We additionally registered the number and size of offspring and total biomass with the aid of image processing software and compared their responses to the standard toxicant benzalkonium chloride (BAC). To evaluate the sensitivity of *C. elegans* towards different common environmental contaminants, we used the list of 12 organic water pollutants of different modes of action carefully curated by Altenburger and colleagues (2018). Our results indicate that biomass might be a more sensitive and comprehensive endpoint for *C. elegans* reproduction when compared to number of offspring per reproducing adult, capable of capturing different modes of action (i.e., both number and size of offspring). In addition, although *C. elegans* does align with other widely used whole-organism assays such as daphnia and zebrafish, it is, however, on average one order of magnitude less sensitive despite the endpoint being reproduction and therefore hypothesised to be more sensitive than survival.

1.01.P-Mo027 Integrated Biomarker Response in Signal Crayfish *Pacifastacus Leniusculus* Exposed to Diphenhydramine
Mrs. Anna Koubová¹, Van Tuyen Nguyen², Adam Božik², Antonín Kouba², Josef Velišek³ and Vladimír Zlabek², (1)Faculty of Fisheries and Protection of Waters, University of South Bohemia in Ceske Budejovice, Ceske Budejovice, Czech Republic, (2)University of South Bohemia in Ceske Budejovice, Czech Republic, (3)University of South Bohemia v Ceske Budejovice, Czech Republic

Pharmaceuticals have been repeatedly detected as emerging contaminants, particularly in streams receiving a large amount of treated wastewater. Their continuous discharge, relative stability in the environment, and bioaccumulation in living organisms are the main predictors of potential ecotoxicity effects on non-target aquatic biota. Diphenhydramine (DPH) is a pharmaceutical with multiple mode of action, primarily designed as the antiallergy therapeutic drug. Among antihistamines, this drug is a significant contaminant repeatedly detected in surface waters. Signal crayfish (*Pacifastacus leniusculus*) was selected in our study as a model organism due to its' ecosystem importance, rapid growth, large body size, and easy culture. We investigated a subchronic effect of low (2 µg/L), environmental (20 µg/L), and elevated concentration (200 µg/L) of diphenhydramine on crayfish. Antioxidant enzyme activities, lipid peroxidation, and acetylcholinesterase activity were assessed as toxicological biomarkers. Integrated biomarker response indicated the highest drug-induced toxicity effects on crayfish gill and muscles at elevated diphenhydramine concentration. In contrast, the highest effect was observed in the hepatopancreas after exposure to environmental concentration. Diphenhydramine did not significantly affect acetylcholinesterase activity under any tested drug concentration. We conclude that the integrated biomarker approach is an effective tool for evaluating the toxicity effects of pharmaceuticals on aquatic invertebrates. The research was supported by the Ministry of Education, Youth and Sports of the Czech Republic – projects "CENAKVA" [LM2018099], and CZ.02.1.01/0.0/0.0/16_019/0000869 PROFISH.

1.01.P-Mo028 Successful Development of a Test Protocol for the Dung Beetle *Onthophagus Taurus* for Usage in the Environmental Risk Assessment of Veterinary Pharmaceuticals (VMPs)

Eiko Wagenhoff¹, Adam Scheffczyk², Andreas Duffner³, Thomas Moser¹ and Jörg Römbke², (1)Eurofins Agroscience Services Ecotox GmbH, Germany, (2)ECT Oekotoxikologie GmbH, Germany, (3)Eurofins Agroscience Services Ecotox GmbH, Niefern-Öschelbronn, Germany

For more than two decades the environmental risk of veterinary pharmaceuticals (VMPs) is assessed before these products can be marketed in the EU. This is especially true for parasiticides because of their direct entry into the environment and their biocidal mode-of-action. Once in the environment, these VMPs can impact ecosystem functions, in particular the decomposition of dung, and also dung organism biodiversity. A taxon that reaches high abundances in dung pads and that is considered as threatened under the current worldwide insect decline are dung-breeding beetles. The OECD guidance 122 for testing of dung beetles (OECD 2010) provides a protocol using the larvae of *Aphodius constans*. This species is winter-active and endures the summer in a resting stage. It became evident that it is hardly possible to culture this species under lab conditions. Consequently, beetles have to be caught in the field which is only possible from December to April. A further shortcoming of the current test protocol is that only larval mortality is taken into account. Over the past decade, a test protocol with *Onthophagus taurus* was developed and ring-tested. After several improvements, this species can now be cultured in the lab and thus, tests including reproductive endpoints can be conducted all the year round. Currently, the test system is running reliably and results using Ivermectin as reference item are reproducible. Moreover, several studies under GLP have already been conducted in different laboratories and their results have been used in the Environmental Risk Assessment of VMPs. Here, the test set-up is described and results of the final ring-test and control and reference item data from GLP studies are presented. The authors propose that the test protocol for *Onthophagus taurus* should be integrated into the existing OECD guidance document 122.

1.01.P-Mo029 Comparing the Sensitivity of Field Collected Lentic and Lotic Mayfly Species After Chronic Exposure to the Insecticide Fipronil in the Laboratory

Kirsten Germing, Maria Vogt and Christoph Schaefers, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany

Aquatic insects are often exposed to environmental pollutants, e.g. plant protection products. Especially aquatic mayfly larvae are frequently exposed and show high sensitivities against such contaminants. For the risk assessment, often standardized test systems

with *Daphnia* sp. are used but can cause an underestimation of the risk since they are less sensitive. Thus, in Europe we are still lacking standardized test systems with more sensitive species like mayflies, particular for chronic tests. At Fraunhofer IME, two test systems for chronic toxicity tests with mayfly species are performed. In both tests, the insecticide Fipronil is used as test substance with concentrations of 0.037, 0.075, 0.15, 0.3 and 0.6 µg/L. Field collected larvae in early development stages are used in both tests. During the tests, the grazing larvae are fed with diatoms of *Navicula* sp. grown on small tiles. Test solutions and food tiles are replaced twice a week. In the first test, a chronic test system for the lentic mayfly *Cloeon dipterum* is used. As endpoints the development throughout the test, emergence, immobility and mortality of the larvae are examined. The test is performed in glass beakers filled with 500 mL test solution under conditions of standing water until emergence of all introduced larvae. The development stages of each larvae are determined twice per week until all larvae have emerged or died. Emerged individuals are sampled for further transcriptomic analysis. In the second study, a chronic toxicity test with lotic mayfly larvae of the family Heptageniidae is performed under stream conditions. The individuals are placed individually in small cages that circulate through a test unit thereby creating a specific flow of around 0.1 m/s in each cage. The larvae are exposed for at least 21 days. The endpoints immobility and mortality are determined twice a week. The body length of each animal is measured prior test start and again at the end of the study to determine the endpoint of larval growth. Both tests were already started. First results of the test with *C. dipterum* show the trend of a reduction in the development rate of the larvae exposed to the two highest concentrations on day 20. An increase of mortality with larval growth is observed. The entire results of the ecotoxicological tests and the transcriptomics of *C. dipterum* will be presented.

1.01.P-Mo030 The Estuarine Bivalve *Scrobicularia plana* As a Model Species for the Assessment of Chemical Stress Caused by an Ubiquitous Flame Retardant

Irene Bermúdez Gutiérrez¹, João Marques² and Ana Marta Gonçalves³, (1)University of Coimbra, MARE - Marine and Environmental Sciences Centre, Department of Life Sciences, Calçada Martim de Freitas, 3000-456 Coimbra, Portugal, Portugal, (2)University of Coimbra, MARE - Marine and Environmental Sciences Centre, Portugal, (3)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Coimbra, Portugal

Tris(2-butoxyethyl)phosphate (TBOEP) is a flame retardant widely used in most industries. Its occurrence in aquatic environments is vast, having been detected in several matrices worldwide, including Portuguese estuaries. TBOEP produces toxicity to aquatic species through oxidative stress and endocrine disruption. Still, investigation is scarce and toxicity assays are limited to standard freshwater species cultivated under laboratory conditions. There is a lack of information about chemical stress in marine environments, as well as studies using organisms collected in field. *Scrobicularia plana* is a bivalve species from brackish waters. This invertebrate is proposed as a model for ecotoxicological assays due to its sensitiveness and easy handling, besides its great abundance in intertidal soft-substrate waterbodies of NE Atlantic from Norway to the Mediterranean and West African regions. This work evaluates TBOEP's toxicity in *S. plana* collected at the Mondego estuary in Figueira da Foz (Portugal), in terms of behaviour and molecular responses. The biomarkers selected are the activity of glutathione-S-transferase (GST), the thiobarbituric acid reactive substances (TBARS) and the protein content. Endpoints were assessed in organisms after field collection, after acclimation to lab conditions (20 psu filtrated water, constant aeration, 12h^L:12h^P, 20±2°C) and after TBOEP exposure, to avert confounding factors when linking the biomarkers' responses to the contamination. The experimental design consisted in 96h of exposure to TBOEP (0.1, 1 and 10 mg/L). In terms of behaviour, more syphon activity and less reaction to the stimulus were observed at the exposures. GST activities remained unaffected by the exposures and by the settled lab conditions when compared with the field. Regarding TBARS, lower values under lab conditions than in the field were observed, due to its high sensitiveness. The presence of TBOEP increased the levels of TBARS quantified when compared with the control, suggesting the occurrence of lipid peroxidation. Further investigation is needed to confirm a potential defense mechanism involved, thus, biochemical profiles are being analyzed. The species, endpoints and experimental design here proposed contribute to knowledge of toxicity assessment of specific chemical stress by identifying suitable biomarkers. Nonetheless, further studies with new endpoints will provide a better understanding of TBOEP's toxicity in marine environments.

1.01.P-Mo031 Automatic Counting of *Artemia* Nauplii and Cysts - Applications in Marine Ecotoxicology

Sizenando Nogueira Abreu¹, Fatima Jesus², Amadeu Soares³, Rui Martins⁴ and Miguel Oliveira e Silva⁴, (1)Aveiro University, Portugal, (2)CESAM & University of Aveiro, Portugal, (3)Universidade de Aveiro, Portugal, (4)University of Aveiro, Portugal

The ecotoxicological evaluation of the chronic effects of chemicals in the reproduction of marine species commonly includes a counting procedure of the progeny of the exposed individuals in early development stages, e.g. nauplii. Considering marine model species, the counting of nauplii in ecotoxicology bioassays is very difficult to perform, due to the small size and also due to the erratic movements of the nauplii. *Artemia* spp. have been widely used as a biological model in toxicity testing bioassay due to the cost-efficiency and its cysts high adaptabilities to harsh under laboratory conditions, being acute mortality and acute cyst hatchability, two of the three sensitive endpoints commonly used; thus, it would be highly valuable to perform the counting automatically. This study aims to assess the performance of a computer-based technology (Patent US10591401, Patent CA2965273C, Pending patent EP3214426A1: Oliveira e Silva et al. 2020) on counting *Artemia salina* and *A. franciscana* nauplii and cysts, by comparing the automatic counts with the results of manual countings. At least 55 comparing runs (manual vs computer) were performed for each species, having from n=0 up to n=200 nauplii in the vial (50mL solution). The procedure was repeated considering *A. salina* cysts, with 10 runs, having from n=0 up to n=100 cysts in the vial (50mL solution). The comparison of the automatic vs manual counts of *Artemia* spp. nauplii and cysts show that the automatic counts of nauplii and cysts showed a 99% accuracy and a relative standard deviation of 1.7%, being y=1.00x with r²>0.999 linear correlation. These results show that the computer-based counting device accurately counted the organisms, thus showing its applicability as a replacement of manual counting. This tool might also be applicable to assess acute cyst hatchability, starting by quantifying the

number of total cysts to be submitted to the bioassay, and later by quantifying the subsequent hatched organisms (nauplii) under test. This computer-based counting might be extended to other marine organisms of similar size, thus facilitating reproduction, hatchability, and life-cycle bioassays in marine ecotoxicology.

1.01.P-Mo032 Comparative Study of Three Soil Arthropods Extraction Method (MacFadyen; Tullgren Funnel (Burkard); Modified Berlese-Tullgren) in South of France

Aude Cazanave¹, Josep Roig¹ and Stefan Dehelean², (1)Eurofins MITOX Group, France, (2)Eurofins-Mitox, Netherlands
Soil micro-arthropods, such as mites and springtails, are largely represented in most soils. They play an important role on decomposition processes and are important reservoirs of biodiversity in ecosystems. The potential impact of plant protection products on the structure of the soil micro-arthropod communities can be assessed in dedicated studies or as part of larger arthropod studies focused on the different arthropod habitats, including soil, by different methods. The aim of this study is to compare different soil arthropod extraction methods. The soil micro-arthropods were sampled with soil cores and extracted for identification with MacFadyen, Tullgren funnel or the modified Berlese-Tullgren methods. The extraction efficiency of these 3 methods were compared by the number of specimens and the diversity per sampling method and per unit of soil sampled. Soil cores were sampled simultaneously in 12 locations in a meadow under the same conditions such as soil moisture and temperature. 6 intact cores of 5cm diameter and 5cm depth were collected per location for MacFadyen extraction, 2 intact cores of 11 cm diameter and 5cm depth for Burkard extraction and 5 cores of 8cm diameter and 5cm depth, with the soil mixed and standardized to 1kg sample, for the modified Berlese-Tullgren setup. With this experiment, the Burkard method showed a statistically significant higher extraction efficiency in terms of abundance of specimens and diversity of Collembola than the MacFadyen method when 2 cores per location are taken for Burkard extraction and 6 cores per location are taken per MacFadyen extraction based on the recommendations of the manufacturers and guidelines. The modified Berlese-Tullgren with mixed soil showed a statistically significant lower extraction efficiency for Acari and Collembola compared to MacFadyen and Burkard methods. On the other hand, regarding extraction efficiency standardized by 500g of soil, the extraction of the MacFadyen method was more efficient for Poduromorpha collembolans, with statistically significant higher numbers in comparison to Burkard and modified Berlese-Tullgren and more efficient for the total number of Collembola than the modified Berlese-Tullgren. The observed diversity of collembolans/500g soil in the MacFadyen method was not statistically significantly different from the Burkard method, but both showed statistically significantly higher diversity of arthropods extracted than the modified Berlese-Tullgren method.

1.01 Advantages of using lab and field collected invertebrates in ecotoxicology: Challenges and opportunities for Environmental Risk Assessment (Virtual Only)

1.01.V-01 Assessment of the Response of *Artemia franciscana* Exposed to Detergents

Alma Sobrino-Figueroa Dra¹, Alberto Perez-Rojas² and Sergio Alvarez-Hernandez², (1)Universidad Autonoma Metropolitana, Mexico, (2)Autonomous Metropolitan University-Iztapalapa, Mexico

Detergents are widely used in daily personal care and household cleaning products, as well as in a variety of industrial applications. Large quantities of these products are discharged into wastewater that reaches treatment plants or directly into the aquatic environment in areas where there is no wastewater treatment. Because in our country the studies with detergents are scarce in this paper was evaluated the toxicity of these compounds on *Artemia franciscana*. Static tests were carried out with duration of 96 hours. 80 organisms were exposed to sublethal concentration (1 mg/L) of different types of detergent (2 for general use, 1 biological product and 2 dishwashers) plus a control without toxic. Every 24 hours was determined the stress degree in the organism estimating the O:N index, also was determined the level of lipid peroxidation, evaluating the Tbars. Significant differences were observed between the control response and the organisms exposed to detergents ($p < 0.05$). The O:N ratio had a value above 20 which indicates that the organisms were not in a state of stress, after 24 hrs of exposure, except for the test with the dishwasher detergent. A significant decrease of this index was observed at 72 hrs in all tests with values less than 9, a fact which indicates that the organisms were in a high stress state. MDA levels were higher in organisms exposed to dishwasher detergent (145.4 to 213 nM MDA/g), the value obtained in the control was 2.4 nM MDA/g Because the wastewater treatment is limited and detergents are discharged directly into the environment is important to know the potential adverse effects of these compounds to propose mitigation measures.

1.01.V-02 Biomarkers Evaluation on *Crassostrea Palmula* in La Paz Bay BCS , Mexico

Alma Sobrino-Figueroa Dra¹, Alberto Perez-Rojas² and Sergio Alvarez-Hernandez², (1)Universidad Autonoma Metropolitana, Mexico, (2)Autonomous Metropolitan University-Iztapalapa, Mexico

The native oyster *Crassostrea palmula* has permanent populations along La Paz Bay. We used the species to determine their response to xenobiotics with an evaluation of 3 biomarkers: oxidative stress (Tbars), AchE inhibition and genetic damage (micronucleus frequency). The studies were carried out in samples of the gill tissue obtained from oysters in three localities, two related to city activities and the other away from city influence, to detect the presence of toxic and genotoxic substances, and to evaluate the use of this biomarkers as a reliable tool in environmental biomonitoring studies. Thirty adult oysters (5.15 ± 0.58 cm) were collected in winter (February 2018) and summer (August 2018) in each locality. The results indicated that there are significant differences between the sites. The biomarkers presented values similar to the control (oysters kept under controlled conditions in the laboratory), in the oyster samples collected in the area without influence of the city in comparison with those obtained in organisms collected in urban-influenced areas. The results agree with the pollutants levels registered in the place where the oysters were collected. This biomarker seems to be a good tool in environmental biomonitoring studies.

1.01.V-03 Comparative analysis of CMIT/MIT toxicity across *Daphnia pulex* strains using epigenetics and proteomics

Jiwan Kim and Jinhee Choi, University of Seoul, Korea, South

The genome and epigenome of an organism respond to a variety of environmental cues and can alter physiological responses in order to adapt to the surrounding environment. Consequently, the adaptation process, whether genetically and/or epigenetically derived, is an important consideration in evaluating the adverse outcomes of toxicants since it has the potential to change the sensitivity and tolerance of organisms to certain stressors. In this study, we aimed to identify the difference in sensitivity and epigenetic response to chemicals using different field-collected *Daphnia* populations which were adapted to different habitats. To this end, comparative toxicity to the mixture of 5-Chloro-2-methyl-3(2H)-isothiazolone and 2-methyl-3(2H)-isothiazolone (CMIT/MIT), which is an isothiazolinone biocide broadly used in various types of consumer products, was carried out by investigating the alterations in mortality, reproduction, physiological traits, global DNA methylation and proteome. Results showed that intra-species difference in sensitivity (*Daphnia pulex* from Rennes (DPR) vs. *Daphnia pulex* from Alsace (DPA)) is greater than inter-species difference (*Daphnia magna* from Rennes (DMR) vs. *Daphnia pulex* from Rennes (DPR)). DPR has larger body size, higher heart rate and higher sensitivity to CMIT/MIT than DPA. Interestingly, the trend of alteration in global DNA methylation level differed between the two populations. Proteomic analysis also supported that DPR and DPA-specific protein alteration and the associated pathways can cause the observed difference in susceptibility and epigenetic response to CMIT/MIT. Therefore, intra-species variation should be considered in evaluation of ecotoxicity to biocide chemicals since the sensitivity to chemicals varies depending on the environment where organisms are adapted. Additionally, epigenetic programming might be altered by environmental factors and can contribute to the observed differences in sensitivity to chemicals.

1.01.V-04 Comprehensive Assessment of WATER Quality Based on Physiological State Evaluation of Indigenous Freshwater Mussel (*Unio pictorum*) and Heavy Metal Contents in 3 Matrices: CASE Study on the Transborder Narva River Russia-Estonia

Tatiana Kuznetsova, Saint-Petersburg Scientific Research Center for Ecological Safety Russian Academy of Sciences, Russian Federation

The sustainable existence of aquatic ecosystems implies a stable state of water bodies with high water quality, their plant and animal components. Bivalve mollusks are the main and numerous representatives of the biota of fresh waterbodies of the Leningrad Region, which is actively involved in maintaining the equilibrium state of the ecosystem, as well as in self-purification processes. The purpose of the study was to conduct a comprehensive study of the ecological state of the coastal water area of the Narva border river (Russia-Estonia, the river bank 3 km from the city of Ivangorod, Kingisepp district of the Leningrad region). Using an automated bioelectronic system of non-invasive cardiac activity monitoring, the background characteristics of the heart beatings of bivalves (*Unio pictorum*) from the Narva River were studied, the time of cardiorythm recovery after a short-term functional load (change in salinity to 6 ‰ within 1 hour) was calculated, indicating the good adaptive potential of the mollusk cardiosystem. In soft mussel's tissues, the contents of heavy metals (HMs, in particular Cd, Ni, Cu, Zn and Pb) were determined. MPI and BCF were calculated for each metal. Data (2019 and 2020) of the Nevsky-Ladoga Basin Administration of the Russian Federation FSBI "North-West Administration for Hydrometeorology and Environmental Monitoring" on the content of HMs in the surface water of the Narva River in this river target, closest to the sampling site, were also used, indicating good quality of the surface waters. The results showed good physiological state of mollusks, low content of HMs both in mussel's tissues and in sediments, as well as in the surface water of the Narva River in studied site. The results seems to be useful for the developing of methods for integrated assessment of the health of aquatic ecosystems in transborder areas.

1.01.V-05 Effects of Bisphenol a on the Growth and Reproduction of 4 Species of Cladocerans

Alma Sobrino-Figueroa Dra¹ and Wendy Paredes Hernandez², (1)Universidad Autonoma Metropolitana, Mexico, (2)Autonomous Metropolitan University-Iztapalapa, Mexico

Bisphenol A (BPA) is a compound present in plastics type 3 and 7 that are used to make water bottles, baby bottles, disposable tableware, toys, food can liners and PVC products. This compound is harmful because it acts as endocrine disruptor. Its effects are known mainly in fish. The objective of this work was to evaluate the effects of Bisphenol A on the growth and reproduction of 4 species of cladocerans: *Daphnia magna*, *Ceriodaphnia dubia*, *Moina macrocopa* and *Chydorus* sp. Initially, an acute bioassay of 48 hours duration was carried out where 5 concentrations of BPA were tested, to determine the LC₅₀ (Lethal Concentration 50). Subsequently, a sublethal bioassay (21 days) was performed with 2 concentrations (LC₅₀/100, LC₅₀/10) where it was evaluated: time of the first molt, number of molts, time of the first spawning, number of spawning and growth rate. The LC₅₀ values obtained in the toxicity bioassays ranged from 5.4 ± 1.97 to 12.1 ± 3.8 mg/L, the most sensitive species was *Moina macrocopa*. Regarding the time in which the first molt occurred and the time of the first spawning, significant differences were observed between the organisms exposed to BPA and the control group (p > 0.05). An increase in time was observed for cladocerans to molt and have their first spawn. The number of spawning in organisms exposed to Bisphenol A was lower compared to the control group. In addition, a decrease in the growth rate was observed from 1.5% to 44.9%. From the results obtained we can conclude that BPA in sublethal concentrations affected the reproduction and growth of cladocerans, confirming that it has an endocrine disruptor effect on *Daphnia magna*, *Ceriodaphnia dubia*, *Moina macrocopa* and *Chydorus* sp.

1.01.V-06 Genotoxic Effect of Three Metals and Their Mixtures on Japanese Oyster *Crassostrea gigas*

Alma Sobrino-Figueroa Dra¹, Alberto Perez-Rojas² and Sergio Alvarez-Hernandez², (1)Universidad Autonoma Metropolitana, Mexico, (2)Autonomous Metropolitan University-Iztapalapa, Mexico

The Japanese oyster is an introduced species that grows in the Mexican Pacific coastal systems, because of its economic importance we performed an evaluation of the genotoxic effects of the metals: Cd, Cr and Pb and their mixtures on Japanese

oyster juvenile. Bioassays, with a duration of 72 hours, were carried out with 5 concentrations of each metal and their mixtures (1:1). Lethal concentration 50 (LC₅₀) were determined in the assays. Subsequently, a test lasting 10 days was carried out where the juvenile oysters were exposed to a sublethal concentration (LC1). At the end of the exposure period, the evaluation of lipoperoxidation (Tbars) and genetic damage (comet assay) in gill tissue was carried out. The toxicity of metals and their mixtures, based on the LC₅₀ calculated was (high to low effect): Cd > Cr > Pb. The most toxic mixtures were Cd + Cr and Cd + Cr + Pb. The degree of lipoperoxidation of gill tissues was high in oysters exposed to Cd and the mixture of the three metals. The Kruskal-Wallis test indicated that significant differences exist between the level of DNA damage in organisms exposed to different metals and the control group. The metal with major genotoxic effect was Cadmium followed by Chromium. Lead showed the lowest genotoxic effect. The mixtures with the highest genotoxic effect were Cd + Cr + Pb and Cd + Cr. It is important to continue research and monitoring to detect responses that indicate possible damage to oyster populations by the action of different tensors, to prevent irreversible deterioration of the stocks in the medium and long term.

1.01.V-07 Sublethal and Sub-Chronic Ecotoxicity of Five Synthetic Cathinones in Two Aquatic Organisms

Ariana Pereira¹, Ana Rita Carvalho², Bruno Castro³, João Soares Carolla⁴, Carla Fernandes⁵, Maria Tiritan⁶ and Cláudia Ribeiro⁷, (1)Rua Central de Gandra, CESPU/IUCS/TOXRUN, Gandra, Portugal, (2)TOXRUN – IUCS, CESPU, Portugal, (3)CBMA; IB-S, Portugal, (4)CITAB, Portugal, (5)CIIMAR; LQOF - FFUP, Portugal, (6)TOXRUN – IUCS, CESPU; CIIMAR; LQOF - FFUP, Portugal, (7)TOXRUN - IUCS, CESPU; CIIMAR, Portugal

The abuse of psychoactive substances (PAS) has increased dramatically in the last years. PAS enter sewage systems and reach the wastewater treatment plants, which are not designed for their removal, leading to their frequent detection in effluents and aquatic ecosystems. Special attention has been given to synthetic cathinones (SCat), popular among consumers for recreational purposes. PAS are designed to change nervous system function, posing unpredictable adverse effects non-target organisms. Considering the scarce information available on SCat ecotoxicity, it is urgent to assess their toxicity on exposed organisms. This work aimed to study the toxicity of five SCat using two organisms of different trophic levels as model organisms: the microcrustacean *Daphnia magna* and the protozoan *Tetrahymena thermophila*. For that, a sublethal assay using daphniids was carried out at a single concentration of 10 µg/L to evaluate reproductive, biochemical, morphophysiological and behavioral effects. Additionally, a sub-chronic assay using the protozoan was carried out at concentrations ranging from 1.25 to 40 mg/L to evaluate effects on growth. Regarding microcrustacean, a generalized increase in the fecundity of the organisms was observed for all tested SCat although a significant increase was found for 3,4-dimethylmethcathinone (3,4-DMMC). On the other hand, 3-methylmethcathinone interfered with morphophysiological parameters, such as body size and heart rate. Concerning the protozoan, 3,4-DMMC also showed higher toxicity comparatively to the other SCat, causing a significant growth inhibition, while exposure to the remaining SCat did not affect growth. The present study showed low potential toxicity of SCat to the protozoan, except for 3,4-DDMC; in contrast, SCat interfered with reproductive and morphophysiological endpoints in *D. magna*. Further studies are ongoing to extend the current knowledge about SCat toxicity effects on these non-target aquatic organisms. **Acknowledgments:** This work was supported by national funds through FCT by means of the research project EnantioTox (PTDC/CTA-AMB/6686/2020) and the programmes UIDB/04423/2020 and UIDP/04423/2020. A. Pérez-Pereira acknowledges the PhD grant BD/CBAS/CESPU/04/2021.

1.02 Alternative Approaches to Animal Testing for Ecotoxicity Assessments: Exploring Approaches and Avenues for the Future (Part I)

1.02.T-02 Exploring an Underlying Assumption of Baseline Toxicity QSARs for Fish Using a Mechanistic Bioaccumulation Model

James M Armitage¹, Jon Arnot² and Roger van Egmond³, (1)AES Armitage Environmental Sciences, Inc, Canada, (2)ARC Arnot Research & Consulting Inc., Canada, (3)Unilever, United Kingdom

Baseline toxicity QSARs are well-established in the scientific literature and are useful tools for predicting acute toxicity in fish (LC₅₀s) or for including as part of the weight of evidence informing a Mode of Action (MOA) classification where empirical LC₅₀s are available for comparison. Because these QSARs are derived using equilibrium partitioning ratios (e.g., $1/LC_{50} = a \log K_{OW} + b$), they do not explicitly account for biotransformation of the chemical and its potential influence on the relationship between external concentration and internal body burden. The main objective of this study is to explore this key underlying assumption of typical baseline toxicity QSARs using a mechanistic bioaccumulation model (BIONIC v3.0) to relate external concentrations (LC₅₀s) to internal body burdens with and without considering biotransformation. To assess the extent to which the equilibrium assumption is approached, the BIONIC v3.0 model was applied to simulate bioconcentration factors (BCFs) and Critical Membrane Concentrations (CMC₅₀s) for a set of established nonpolar and polar “narcotics”. The simulations were parameterized based on test conditions, partitioning data and biotransformation rate constant estimates (k_B) generated using two available QSARs. The predicted BCFs are then compared to available empirical data ($n = 76$ observations). Predicted and empirical BCFs were highly correlated ($r^2 = 0.91$), there was no large systematic under- or overprediction and the Mean Absolute Error (MAE) corresponds to agreement within a factor of 2.5 on average. Broadly speaking, predicted CMC₅₀s for the case study chemicals based on the corresponding LC₅₀s are in the expected range (20–200 mmol/kg lipid). The predicted internal body burdens are often within a factor of two of the equilibrium (i.e., $k_B = 0$) values despite many chemicals exhibiting rapid biotransformation (i.e., predicted $k_B > 1/d$). The reason that BCFs are similar is that predicted gill elimination rate constants (k_W) are greater than biotransformation rate constants and accordingly the predicted BCF approaches $BCF = k_U / k_W$, which is consistent with equilibrium. This type of toxicokinetic behaviour (i.e., $BCF \sim k_U / k_W$ paradigm) underlies empirically-derived

baseline toxicity QSARs and is an important consideration when assessing other baseline toxicants which may not behave the same way with respect to the relative importance of gill elimination and biotransformation (i.e., $BCF \sim k_U/k_B$ paradigm).

1.02.T-03 Machine Learning As a Tool to Predict the Toxicity of Chemicals Across Taxa

Jimeng Wu¹, Christoph Schuer¹, Simone D'Ambrosi², Lilian Gasser³, Lorenz Ammann⁴, Julita Stadnicka-Michalak¹, Fernando Perez-Cruz³, Kristin Schirmer¹ and Marco Baity-Jesi¹, (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Università di Roma La Sapienza, Italy, (3)Swiss Data Science Center, Switzerland, (4)Swiss Federal Research Institute WSL, Switzerland

One of the pillars of modern civilization is the ability to synthesize and/or use an enormous range of chemicals, which allow for new and improved products and serve as pharmaceuticals, pesticides, food additives and the like. However, in order to know that use of these chemicals does not harm human- and ecosystem health, it is crucial to investigate the impact of these chemicals on those organisms potentially exposed. Usually this is done through in-vivo testing. Yet, beyond its obvious ethical implications, in-vivo testing is not scalable to large amounts of taxa and chemicals, because of its strong requirements in terms of time, money, and highly trained personnel. Machine learning comes in as a viable alternative with the potential of allowing us to explore the impact of large numbers of chemicals on many taxa: harmlessly, quickly and cheaply. We develop machine learning models that can quickly infer the mortality of a chemical on a certain fish species and highlight the importance of including information on both chemical and taxonomy as input features. We then analyze ways of comparing the reproducibility of in-vivo experiments with that of machine learning models trained on similar data, highlighting that these comparisons are generally unreliable, and propose to upper bound the reproducibility of in-vivo experiments, instead of trying to exactly estimate it. Finally, we introduce an operational way of showing whether *in-vivo* mortality can be well-captured by in-vitro assays on fish-cell lines, finding evidence that it indeed can. Thus, machine learning and *in-vitro* assays present themselves as valid alternatives to animal testing, if we will be able to assess their limitations when utilized in out-of-domain settings (e.g. exotic chemicals and species).

1.02.T-04 Reduced Transcriptome Arrays (EcoToxChips) to Derive Transcriptomic Points-Of-Departure (tPODs) for 17 α -Ethinylestradiol in Fathead Minnow Embryos

Markus Hecker¹, Jessica Ewald², Jianguo Xia³, Natacha Hogan⁴, Jessica Head², Doug Crump⁵, Nil Basu² and Alper James Alcaraz¹, (1)University of Saskatchewan, Canada, (2)McGill University, Canada, (3)McGill University Macdonald Campus, Canada, (4)University of Saskatchewan, Saskatoon, Saskatchewan, Canada, (5)Environment and Climate Change Canada, Canada

Traditional toxicity testing is challenged because it relies on time-consuming and expensive exposure studies with live animals. New approach methods (NAMs) that utilize mechanistic information and alternative test systems show significant promise to address these challenges and support chemical hazard assessment. Recent studies suggest that benchmark doses (BMDs) derived from whole transcriptome experiments are reasonably predictive and protective of apical BMD. However, whole transcriptome analyses require sophisticated facilities and highly trained experts for data evaluation and interpretation, limiting accessibility of such approaches to the broader testing community. This study compared transcriptomic points-of-departure (tPODs) derived from whole and reduced (375 gene targets) transcriptomes of fathead minnow embryos exposed to 17 α -ethinylestradiol (EE2). RNA was extracted from pooled whole embryos after short-term exposure of non-protected life stages to graded concentrations of EE2, and then subjected to RNAseq and qPCR (EcoToxChip) analysis. BMD analyses yielded tPOD estimates that closely approximated apical PODs found in the literature. tPOD estimates were comparable between data sets generated with RNAseq and EcoToxChip analyses. However, the reduced gene set did not permit the estimation of the median of the 20 most sensitive gene BMDs (omicBMD20), which has been shown to be the most sensitive endpoint when deriving tPODs from RNAseq experiments. Both analysis types identified the same top dysregulated genes that were predominantly associated with estrogen signalling. While there are some remaining uncertainties regarding the precision with which reduced gene sets derived from EcoToxChips can predict BMDs in a regulatory context, this study suggests that tPODs derived from short-term exposures with non-protected life stages of fish show significant future promise to support chemical hazard assessment. This study is part of the EcoToxChip project (www.ecotoxchip.ca).

1.02.T-05 Transcriptomic Profiles of a Respiratory Inhibitor and Growth Targeting Insecticide Reveal Links to Impaired Bone Mineralization and Lipid Homeostasis in Zebrafish Embryos

Hannes Armin Reinwald¹, Julia Alvincz², Gabriela Salinas³, Henner Hollert⁴, Christoph Schaefer² and Sebastian Eilebrecht², (1)Fraunhofer-Institut für Molekularbiologie und Angewandte Oekologie IME, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (3)NGS - Integrative Genomics Core Unit, Germany, (4)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany

Classical acute chemical hazard assessments focus on determining the concentration level at which a compound demonstrates adverse effects. However, this provides little to no mechanistic insights about the observed effects and is even less informative for sublethal and low concentration effects e.g. on the endocrine or reproductive system. Combining system biology methods (e.g. transcriptomics) with classical assays allows for the identification of molecular compound-specific fingerprints in a model system. To derive accurate adverse effect predictions from molecular fingerprints, mode of action (MoA) specific markers need to be identified. Therefore, we tested two insecticides with distinct MoA in the target organism in a modified version of the Fish Embryo Acute Toxicity test (OECD 236). Fenazaquin (FAZ) is a respiratory chain inhibitor targeting the mitochondrial complex I electron transporter, while pyriproxyfen (PPF) is a juvenile hormone mimic in insects and was recently shown to induce reproductive endocrine effects in zebrafish. Both compounds were tested at two different sublethal exposure conditions (low=LE and high=HE). At 96 hpf, total RNA was extracted, and subjected to full mRNA sequencing. Transcriptomic profiles were

screened for common sets of differentially expressed genes (DEGs) among both treatment conditions and then functionally linked to respective biological processes using overrepresentation analysis (ORA). Based on the selection of 127 potential marker genes, our analysis showed distinct gene clusters enriched between the two different MoA on the transcript level. On the functional level this pattern is conserved as both compounds interfere with distinct biological processes. PPF primarily affects steroid metabolic processes, estrogen response-related stimuli and lipid homeostasis. In contrast, FAZ affects the cell tissue organization and bio mineral tissue development, consequently affecting bone mineralization. We show that the integration of transcriptomics into a modified version of the acute zebrafish embryo toxicity test can be used to differentiate the molecular profiles of respiratory chain inhibitor FAZ from potentially endocrine active PPF, even at low exposure concentrations. We demonstrate that the combination of system biology methods with ecotoxicological test guidelines is an effective method to understand and distinguish underlying molecular mechanisms of adverse effects in non-target organisms.

1.02 Alternative Approaches to Animal Testing for Ecotoxicity Assessments: Exploring Approaches and Avenues for the Future (Part II)

1.02.T-07 A Framework to Demonstrate the Applicability of New Approach Methodologies in Environmental Risk Assessment

Maria Blanco-Rubio¹, Mathura Theiventhran², Danilo Basili³, Predrag Kukic⁴, Iris Muller⁵, Claudia Rivetti⁶, Geoffrey Hodges⁴ and Bruno Campos⁴, (1)Unilever/Safety and Environmental Assurance Centre SEAC, United Kingdom, (2)UnileverSafety Environmental Assurance Centre, United Kingdom, (3)University of Cambridge, United Kingdom, (4)Unilever, United Kingdom, (5)Unilever Safety Environmental Assurance Centre, United Kingdom, (6)Unilever, Sharnbrook, United Kingdom

Current regulatory frameworks for assessing the environmental safety of chemicals are centered around *in vivo* data for standard representative species. This traditional approach is based on apical effects studies performed on whole organisms. However, there is a regulatory and ethical drive towards a paradigm shift incorporating new approach methodologies (NAMs) and a greater mechanistic understanding of toxicological responses across species. Mechanistic-based approaches allow the generation of points of departure (PoDs) (e.g., NOEC and/or LC50 and functional endpoints), to identify mechanisms of action and a variety of biological effects. However, there are still few examples of the application of these data in ERA. Here we propose a framework, exemplified with a case study by using Chlorpyrifos (CPS), for the use of NAMs in ERA to demonstrate the utility and the applicability of mechanistic-based information to complement and strengthen current ERA practices without the need for generating new animal data. The overall strategy involves the collection of effects data to provide a comprehensive set of PoDs including *in vivo*, *in vitro*, and *in silico* endpoints. Analysis of cross-species extrapolation approaches pointed that CPS molecular targets (ACHE/BCHE) and toxicity pathways are conserved throughout the animal kingdom. This information when coupled with bioactivity data from several sources confirmed the mechanism of action of CPS as ACHE Receptor Agonist, as well as invertebrates as the most sensitive taxa, specifically crustaceans. This case study demonstrates that the integration of traditional *in vivo* data and *in vitro* functional assays coupled with computational tools can build confidence in safety decision-making, validating our proposed framework for the use of NAMs in ERA. This framework provides confidence that invertebrates are the most sensitive taxa; sensitivity of most species where the target and pathways are conserved is either similar or less sensitive than crustaceans and highlights the potential use of a wealth of mechanistic data sources to inform safety decisions for data-poor (traditionally *in vivo*) chemicals as a surrogate. The results show this framework can be used as part of a weight of evidence approach to provide increased confidence in decisions making, and the insights will help gain a better mechanistic understanding of the potential expected toxicity effects.

1.02.T-08 Design and Optimization of a Serum-Free Culture Medium for the Rainbow Trout Cell Line RTgill-W1

Barbara Jozef¹, Zhao Rui Zhang², Hans-Michael Kaltenbach², Melanie Fischer¹ and Kristin Schirmer¹, (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)ETH Zurich, Switzerland

Efforts to replace fish for regulatory testing have resulted in the development of strategies and assay procedures based on permanent fish cell lines, especially of rainbow trout (*Oncorhynchus mykiss*). At the core of one such assay, capable to predict fish acute toxicity on chemical exposure, is the rainbow trout gill cell line (RTgill-W1). This assay has recently been approved by international standardization organisations, leading to the ISO standard 21115 and the OECD test guideline 249. However, while the assay as such is performed in a simple exposure medium without addition of animal components, RTgill-W1 cells are grown routinely in Leibovitz' L-15 medium (L-15) supplemented with 5-10% fetal bovine serum (FBS). FBS is a problematic supplement, both scientifically and ethically. We therefore have set out to develop a serum-free formulation, capable of supporting RTgill-W1 cell proliferation, by a systematic, bottom-up medium design. A high-throughput 96-well plate RTgill-W1 cell proliferation assay was developed and optimized to enable systematic screening of serum-free media components, individually and in mixture. Numerous supplements were tested. Some improved metabolic activity compared to cells in L-15, while others led to significant cell proliferation, comparable to cells cultured with 5% FBS. This was confirmed by direct whole-well cell counting after staining of cells DNA. The novel medium formulation enables RTgill-W1 cells to proliferate in the absence of serum. Fine-tuning of supplement concentrations, relying on rational experimental design for response surface methodology, will allow for a fully optimized medium design. Adaptation of RTgill-W1 clones to this new serum-free medium, including attachment, passaging and freeze/thawing are well underway – we may not be far from having the first fully defined culture medium for at least one type of fish cells.

1.02.T-09 Intrinsic Clearance Efficiency of the Three-Dimensional Rainbow Trout (*Oncorhynchus mykiss*) Hepatocyte Model When Assessing Three Different Fragrance Chemicals

Maria T. Hultman¹, Prem Chand Chand², Lu Hostettler³, Karina Petersen⁴, Heike Laue³ and Adam Lillicrap⁵, (1)Norwegian Institute for Water Research, Oslo, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Givaudan Schweiz AG, Switzerland, (4)The Norwegian Environment Agency, Norway, (5)NIVA, Norway

Hydrophobic chemicals which are not biotransformed have the potential to bioaccumulate in tissue and lipid reservoirs of aquatic organisms such as fish, causing both short and long-term biological effects. The assessment of a chemical's potential to bioaccumulate in fish requires determination of its physicochemical properties (e.g. log Kow) as a screening method or conventional animal (*in vivo*) test methods (OECD TG 305). Due to ethical and economical concerns, the development of alternative methods to measure *in vitro* biotransformation rates in primary hepatocytes (RT-HEP) and S9 fractions (RT-S9) from rainbow trout were established (OECD TG 319A/B) to improve existing *in silico* predictions. Due to the limited lifetime of RT-S9 and RT-HEP, these assays are not suitable to measure very slowly biotransformed chemicals. Three dimensional hepatic spheroids from rainbow trout (RT-SPH) with a longer assay duration has recently developed. The aim of this study was to determine the biotransformation rates of three different fragrance chemicals (log Kow 4.5-5.1) using RT-SPH, one slowly (Cashmeran, CASH), one moderately (Ambrofix, AMB) and one rapidly (Cyclohexyl salicylate, CS) biotransformed in the TG 319 A/B assays. The RT-SPH viability was measured during the full period of incubation (0-72 h) and decrease of the parent chemicals in active and heat-inactivated spheroids analysed by GC-MS. The *in vitro* intrinsic clearance rates ($CL_{IN\ VITRO,INT}$) were compared amongst RT-SPH, RT-S9 and RT-HEP. The RT-SPH were viable and a log-linear depletion was obtained during the whole period of incubation (up to 72 h) for all chemicals tested. Around 50% of the initial amount of CS, AMB and CASH was biotransformed between 4 and 48 h. Decrease in the heat-inactivated control was negligible (< 20%) for all three chemicals. The $CL_{IN\ VITRO,RT-SPH}$ rates of AMB and CS were 5- and 25- fold lower, compared to the RT-HEP $CL_{IN\ VITRO,INT}$. CASH, which is slowly biotransformed in both RT-S9 and RT-HEP, displayed a similar CL rate in the RT-SPH. However, extrapolation to the *in vivo* whole body biotransformation rate (K_B) displayed the RT-HEP and RT-S9 (0.05 and 0.06/d, respectively) underestimated the *in vivo* K_B (2.11/d) which was derived from the BCF by a factor of ca. 35-40, whereas RT-SPH did so by a factor of 5 (0.43/d). The RT-SPH are highly metabolically competent for at least 72 h and may better reflect the *in vivo* scenario when measuring compounds with slow CL rates.

1.02.T-10 Cytotoxicity and Modes of Toxic Action (MoA) of Ionic Liquids (ILs)

Eunhye Bae, M.Sc.¹, Stephan Beil², Maria Koenig³, Beate Escher⁴, Stefan Stolte² and Marta Markiewicz⁵, (1)Institute of Water Chemistry, TU Dresden, Germany, (2)Technical University of Dresden, Germany, (3)Helmholtz Centre for Environmental Research – UFZ, Germany, (4)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (5)Institute of Water Chemistry, Technical University of Dresden, Dresden, Germany

ILs have gained a broad interest because of their tunable physicochemical properties, which permits a wide range of industrial applications. In parallel, the rising concerns of ILs entering the environment have prompted efforts to gain knowledge about the adverse effects. Despite of increasing knowledge on their toxic effects, the modes of toxic action have been studied only in a limited number of cases and no consensus has been reached yet. *In vitro* assays using reporter genes enable to identify MoA of chemicals and their implementation in high-throughput screening (HTS) culminates in the Tox21 database where more than 10,000 chemicals are tested in ~50 *in vitro* bioassays. By employing HTS and Tox21 database analysis, this study aims to unravel the MoA of ILs to tease out structure-activity relationships. We tested 45 ILs in two reporter gene cell lines: AREc32 assay for the detection of oxidative stress response and AhR-CALUX assay for the detection of aryl hydrocarbon receptor activation. Additionally, the reported cytotoxicity data from IPC-81 assay was used. Effects and cytotoxicity data were expressed as the concentrations triggering 10% effect (EC_{10}) and viability inhibition (IC_{10}) and used to derive toxic ratio (TR) with a baseline toxicity QSAR using liposome-water partition coefficient ($\log K_{lip/w}$) as a descriptor. Concentration-effect data for the 74 ILs were extracted for 10 assays from Comptox dashboard and processed to calculate the specificity ratio (SR). ILs did not activate any reporter genes but showed pronounced cytotoxicity. The cytotoxicity was mostly higher than the baseline QSAR prediction and large differences were observed between cell lines. Notably, elongation of the side chain results in higher cytotoxicity, implying the side chain length can be responsible for the change of MoA of ILs. Specific effects were found in aromatase inhibition and mitochondrial membrane potential (MMP) assays from Tox21 data analysis. These findings can be supported by the structural similarity between known aromatase inhibitors and ILs. Moreover, many ILs as well as aromatase inhibitors were found to induce mitochondrial toxicity and apoptosis. Taken together, we speculated that aromatase inhibition and/or mitochondrial toxicity can be potential MoA of ILs. This work suggested an approach to use reporter gene assays and Tox21 data enabling to narrow the future research focus for better understanding on the MoA of ILs.

1.02 Alternative Approaches to Animal Testing for Ecotoxicity Assessments: Exploring Approaches and Avenues for the Future (Poster)

1.02.P-Th001 Understanding Biotransformation of the 'Novel' Organophosphate Ester, Bisphenol-A Bis(Diphenyl Phosphate) (BPADP): In Silico, In Vitro and Non-Target Analysis (NTA) Approaches

Sofia Herczegh, B.Sc. Hon., EPT¹, Shaogang Chu² and Robert Letcher³, (1)Carleton University, Canada, (2)Environment and Climate Change Canada, Canada, (3)Environment and Climate Change Canada, Ottawa, ON, Canada

Organophosphate esters (OPEs) have seen increased production and use as both flame retardants and plasticizers, often as replacements of the several banned brominated flame retardants (BFRs) such as polybrominated diphenyl ethers (PBDEs). A growing trend in the industry towards larger and more complex OPE molecular structures adds a new dimension to the biological stability and biotransformation of longer chained, higher molecular weight, 'novel' OPEs. However, little is known about the environmental fate, stability and bioaccumulation of 'novel' OPEs due to a lack of toxicokinetic, biotransformation and

metabolism data in exposed biota. The objective of this study is to characterize the biotransformation of bisphenol-A bis(diphenyl phosphate) (BPADP) for the first time using an *in vitro* Wistar-Han rat liver based microsomal assay. In conjunction with the *in vitro* assay approach, *in silico* modelling and Non-Target Analysis (NTA) are applied to address the hypothesis that metabolites of BPADP include bisphenol-A (BPA) and diphenyl phosphate (DHP). Rat liver S9, microsomal and *in vivo* rat metabolites were predicted *in silico* using the publicly available OECD Toolbox v4.4.1TM. *In vitro* assays were conducted in accordance with published assay methods. The metabolism kinetics of BPADP were investigated to determine the concentration of BPADP that is $\gg 2x K_m$, ensuring maximal rate of reaction (V_{max}) and zero order kinetics. Zero order kinetics has been achieved at a dosing concentration of 2 μM for multiple OPEs, thus BPADP depletion and DHP formation were quantified during a 10 minute incubation at a concentration range between 0.5 μM (356ppb) and 2.5 μM (1780ppb). Time-dependent biotransformation assays were conducted following the same procedure, over a two-hour incubation. *In silico* modelling predicted DHP as both an *in vitro* and *in vivo* rat metabolite, with BPA predicted as the most probable *in vivo* rat metabolite. BPADP is shown to undergo *in vitro* microsomal metabolism with an average (n = 3) 44.6% BPADP depletion. BPA remains unconfirmed as an *in vitro* metabolite of BPADP, however DHP can be confirmed with a low but quantifiable average 1% recovery of DHP. NTA of *in vitro* samples via Liquid Chromatography coupled to a Q-Orbitrap-HRMS/MS are ongoing. Biotransformation was found to occur at a slower rate compared to legacy OPEs such as TPHP, which is likely attributed to the complex structure, high molecular weight and low solubility of BPADP.

1.02.P-Th002 Understanding the Drivers of Quantitative Structure-Activity Relationships' Predictability

Melanie Douziech¹, Peter Fantke², Mikolaj Owsianiak² and Mark Huijbregts³, (1)Agroscope, France, (2)Technical University of Denmark, Denmark, (3)Radboud University, Netherlands

Alternative techniques to animal testing for chemical risk assessment are needed to face the ever-increasing number of new chemicals brought to the market. Quantitative Structure-Activity Relationships (QSARs), are one example of approaches used to infer on chemical toxicity without conducting animal tests. QSARs rely on different modelling techniques using everything from basic molecular properties, quantum mechanics to biological or environmental characteristics to estimate toxicity values for taxa or individual species based on a linear regression or machine learning algorithms. The predictive power of these QSARs is, however, not always tested on a fully independent dataset. Furthermore, it is not clear how the predictive power of QSARs can be improved. Here, we aim to investigate the predictive power of a diverse set of published QSARs for freshwater toxicity with an external dataset and to evaluate which QSAR characteristics mainly determined the differences in predictive power. First, a QSAR database was created gathering QSARs estimating (no-)effect concentrations of freshwater species. So far, 551 different QSARs from 113 studies estimating 17 different endpoints for 41 distinct species were gathered. Second, measured effect data for a large set of chemicals was gathered. Third, standard chemical properties of the chemicals for which measured effect data was available were estimated using the PaDEL and OPERA software. The QSARs gathered were then applied to the chemical dataset, while excluding estimates outside their applicability domain. Finally, the predictive power of each QSAR was estimated over all chemicals and species combinations if effect data was available for at least 10 different chemicals using the Nash Sutcliffe model efficiency coefficient (NSE). Only 49 QSARs could be fitted to the final set of chemicals with measured effect data (N = 2396) and only 34 yielded results for at least 10 chemicals. The NSE for these QSARs ranged from -66 to 0.89, with half of the QSARs having NSE above 0.2. More research is needed to understand this very large variability in QSAR performance and to explain why the predictive power of some QSARs is worse than the grand mean across effect data (NSE < 1). The next steps will address (i) the inclusion of additional QSARs in the database and (ii) the development of linear mixed effect models to understand which QSAR characteristics drive the predictive performance.

1.02.P-Th003 OECD Validation of the Rapid Androgen Disruption Activity Reporter (RADAR) Assay

Andrew Tindall¹, Sarah Bancel², Marthe Chabanon², Ioanna Katsiadaki³, Marion Sebire³, Jessica Rieder⁴, Helmut Segner⁴, Azora König⁵, Elke Eilebrecht⁶, Lena Kosak⁷, Tetsuro Okamura⁸, Maki Sakurai⁸ and Gregory F. Lemkin¹, (1)Watchfrog S.A., France, (2)Laboratoire Watchfrog S.A., France, (3)Cefas, United Kingdom, (4)University of Bern, Switzerland, (5)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (6)Fraunhofer IME, Germany, (7)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (8)IDEA Consultants, Inc., Japan

It is now widely accepted that a large number of environmental pollutants can interfere with the normal functioning of the androgen axis. Testing of androgen axis activity under REACH in whole organism models would require the use of huge numbers of adult or juvenile fish and mammals. We developed a transgenic medaka line capable of revealing the level of activity of the androgen axis by emission of green fluorescence. This stable transgenic line harbours a portion of the *spiggin1* gene promoter upstream of GFP coding sequence. The *spiggin1*-GFP line responds specifically to androgen axis signalling. It is capable of identifying pro-androgenic and anti-androgenic chemicals acting via a variety of modes of action (MoAs) such as androgen receptor agonists and antagonists, aromatase inhibitors, aromatase expression inducers or repressors, 5 α -reductase inhibitors and estrogens. The sensitivity of the line is similar to that of the 21-day androgenised female stickleback screen and uses eleutheroembryonic life stages, which are non-compliant with the EU definition of a laboratory animal. The RADAR assay is performed with twenty newly hatched transgenic eleutheroembryos of the *spiggin1-gfp* medaka line per exposure condition. The assay is performed in six-well plates for 72 h with media renewal every 24 h and can be automated, including the readout. The eleutheroembryos are exposed to test chemicals in the presence and absence of 3 $\mu g/L$ of 17 β -methyl testosterone, allowing quantification of the effects of chemicals acting via MoAs requiring the presence of an aromatisable androgen (e.g., aromatase inhibition, androgen receptor antagonism) as well as those more easily detected in the absence of an aromatisable androgen (e.g., androgen receptor agonists). **1. 2. 3.** During the OECD interlaboratory validation study, it was demonstrated that the RADAR

assay is transferable between laboratories. It can be read using a variety of manual or robotised fluorescence imaging systems and can be performed with either embryos shipped from a supplier or with embryos bred on site. Results of the validation study matched the expected results and a draft test guideline is currently in the final stages of evaluation by the OECD. The RADAR assay provides an ethical solution to reduce the number of adult fish used for endocrine testing.

1.02.P-Th004 Science Policy on 3Rs and NAMs - a Current Overview of Opportunities for Implementation in Upcoming Regulation Revisions

Leonie Mueller¹ and **Francois Busquet²**, (1)RWTH Aachen University, Institute for Environmental Research, Germany, (2)Altoxtox, Belgium

Over the last decades ecotoxicological and toxicological research developed a wide range of alternative approaches to animal testing (or New Approach Methodologies (NAMs)) that are available or will soon be available for regulatory use. In parallel, the European regulatory landscape has created several opportunities for uptake of NAMs. However, uptake of NAMs by regulators is still very limited to this day. With the upcoming revisions of REACH, CLP and the Cosmetics regulation in 2022 as well as the implementation of the EU Chemical Strategy for Sustainability a series of opportunities for inclusion of NAMs is happening. Current initiatives in regulatory policy and science in the EU were reviewed and analysed for importance for the SETAC community. On the political level, the European parliament recently adopted a resolution calling for an action plan to replace animal testing in education, science and regulatory testing. The Resolution created a political momentum that can be used in view of the upcoming regulatory revisions. On the level of EU agencies, EFSA and ECHA both are launching different initiatives with the ambition to accelerate the uptake of NAMs in regulatory science in the EU. In regards to new research initiatives, there are a number of projects, clusters and partnerships that work at the science-policy interface on the topic of NAMs. The European Partnership for the Assessment of Risks from Chemicals (PARC) will develop a Next Generation Risk Assessment road-map. PARC constitutes a unique opportunity to bring together the European communities of regulators, researchers and industry that are involved in risk assessment of chemicals. The Animal-free Safety assessment of chemicals: Project cluster for Implementation of novel Strategies (ASPIS) launched in 2021. The cluster closely cooperates with European institutions such as the EC DG JRC to enable integration of research findings into regulatory legislation such as REACH updates testing requirement. The European Partnership for Alternative Approaches to Animal Testing (EPAA) supports projects that contribute to the acceptance and implementation of NAMs. A recent EPAA workshop presented the successful application of NAMs for a variety of endpoints to particularly tackle worker exposure under REACH. This overview analysis found projects, activities and upcoming regulatory revisions that can be used to develop a blueprint for future activities of SETAC members in the area of NAM research.

1.02.P-Th005 A Semiautomated High Content Workflow for Comparative Assessment of Chemical Effects in *Danio rerio* Embryos

Riccardo Massei¹, **Nico Grasse²**, **Beate Escher³**, **Thorsten Reemtsma⁴** and **Stefan Scholz⁵**, (1)University of Antwerp, Germany, (2)Helmholtz Centre for Environmental Research – UFZ, Germany, (3)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (4)Helmholtz Centre for Environmental Research, Germany, (5)Helmholtz Centre for Environmental Research, Leipzig, Germany

The major goal of chemical risk assessment is to identify the potential adverse health or environmental effect of chemicals. In this context, animal testing played a central role in predicting the effect of hazardous chemicals on human health. Although it has been widely used to predict adverse effect in humans, animal testing using adult animals has started to raise many ethical and economic concerns. The EU project PrecisionTox aims at identifying hazards of chemicals using a suite of non-mammalian alternative model organism and in vitro tests, including the zebrafish embryo test. Embryos of the zebrafish (*Danio rerio*) represent a valid alternative to standard animal testing and align with the 3Rs concept. Therefore, the main goal of the present study is to apply a previously developed semi-automated high content workflow to assess the adverse effect of 250 chemicals using automated imaging and behavior tracking for the assessment of developmental (neuro)toxicity. Zebrafish eggs were exposed in 96-well plates for 96 hours to chemicals covering a wide spectrum of mode of actions. Embryotoxicity was assessed at 24 and 96 hpf by monitoring mortality, motor behavior and morphological changes. Motor behavior was assessed using a video tracking system under different light conditions and morphology was assessed at 96 hpf. Preliminary results showed specific effect patterns in zebrafish embryos. Cadmium chloride caused strong teratogenic effects and 15 different type of malformations. Ethoprophos led to a decrease in all types of analyzed motor behavior without causing mortality or altered phenotypes. Sodium arsenite caused a reduced activity on the STC and PMR at concentrations higher than the mortality benchmark dose. It showed to the highest number of malformations if compared to the other four chemicals. Unexpectedly, pirinixic acid a general decrease in the motor behavior and 7 type of malformations. Finally, dimethyl sulfoxide showed a weak effect on nearly all endpoints. Our preliminary results support that a semi-automated assessment of chemicals *Danio rerio* is possible and that distinct effect patterns can be obtained. Effect levels will be compared with predicted unspecific effect concentration, internal concentrations and used to classify chemicals by their toxicologically relevant mode of action, e.g. for application of read across of chemicals for human toxicity.

1.02.P-Th006 Transcriptomic Points-Of-Departure (tPODs) at Early LIFE Stages of Phylogenetically Distant Fishes Exposed to 17 α -Ethinylestradiol and Fluoxetine

Alper James Alcaraz¹, **Kamran Shekh²**, **Phillip Ankley¹**, **Jonathan Challis¹**, **Taylor Lane³**, **Susari Malala Irugal Bandaralage⁴** and **Markus Hecker¹**, (1)University of Saskatchewan, Canada, (2)University of Alberta, Canada, (3)University of York, United Kingdom, (4)University of Saskatchewan, Saskatoon, Saskatchewan, Canada

The development of new approach methods (NAMs) that aim to reduce the use of live animals in toxicity testing is urgently

needed to meet current regulatory mandates to assess the toxicological risks of the vast and rapidly increasing number of chemicals used by society. However, many NAMs including current *in vitro* and *in silico* systems are limited in accurately estimating apical toxicity thresholds as they do not represent the complex interactions occurring within an organism after a toxic insult. This study aimed to use a short-term embryonic exposure assay with three phylogenetically distant ray-finned fishes to derive transcriptomic points-of-departure (tPODs) and to compare these with apical PODs. Two emerging contaminants of concern, 17 β -ethinylestradiol (EE2) and fluoxetine (FLX) were used as test chemicals. Embryos of white sturgeon (WS), rainbow trout (RBT), and fathead minnow (FHM) were exposed to graded concentrations of EE2 and FLX until four days post-hatch and subjected to mRNA sequencing. Transcriptomic benchmark dose (BMD) analyses yielded tPOD estimates that closely approximated apical PODs found in the literature. tPOD estimates for the median of the 20 most sensitive gene BMDs (omicBMD₂₀) were the most protective estimates across species and across chemicals, while annotation-based tPOD estimates derived from pathway enrichment analyses (pathBMD) appeared to be less sensitive. tPODs from RBT were the most protective of chronic apical effects for both EE2 and FLX, while FHM was the least sensitive species. This study highlighted that, despite some remaining uncertainties, tPODs derived from short-term non-protected embryo-larval/alevin exposures were protective of chronic apical PODs, and therefore, show significant promise as a NAM to support chemical hazard assessment and regulatory decision making.

1.02.P-Th007 Development and Characterization of a Double-Crested Cormorant Hepatic Cell Line for Chemical Screening

*Tasnia Sharin*¹, *Doug Crump*² and *Jason O'Brien*², (1)University of Ottawa, Canada, (2)Environment and Climate Change Canada, Canada

There are currently no available cell lines for the ecologically relevant colonial waterbird species, the double-crested cormorant (DCCO). DCCOs are high trophic level aquatic birds that are used for routine contaminant monitoring programs in the Laurentian Great Lakes and marine coasts of Canada. Developing a DCCO cell line for *in vitro* toxicological screening will ideally provide improved understanding of the effects of environmental chemicals given the large differences in sensitivity between laboratory and wild avian species. In this study, an immortalized DCCO hepatic cell line, DCH22, was established from the liver of a day 22 embryo as a potential alternative to primary double-crested cormorant embryonic hepatocytes (DCEH) for chemical screening. DCH22 cells were cultured for over a year and had hepatocyte-like morphology. Exposure to PCB-126 induced CYP1A activity in DCH22 cells cultured as 2D monolayers and 3D spheroids. Induction of CYP3A activity was observed following exposure to carbamazepine, dexamethasone and metyrapone in 3D spheroids. Preliminary results suggest that DCH22 cells have CYP1A and CYP3A activity supporting their potential use as an alternative to primary DCEH for chemical screening. This cell line will be used to screen benzotriazole UV stabilizers (BZT-UVs), among other priority chemicals, in future studies.

1.02.P-Th008 Cytotoxicity of Sea-Dumped Chemical Munitions in Rainbow Trout Gill (RTgill-W1) and Human Colon Adenocarcinoma (Caco2) Cells

*Joao Barbosa*¹, *Colin Janssen*² and *Prof. Jana Asselman*³, (1)Ghent University Laboratory of Environmental Toxicology and Aquatic Ecology, Belgium, (2)University of Ghent, Belgium, (3)Ghent University, Belgium

Following the First and Second World Wars colossal amounts of munition, including conventional explosives and chemical warfare agents, were sea-dumped in coastal and off-shore sites all over the globe. As a consequence of decades of exposure to seawater, munition shells are expected to be highly corroded thus allowing the release of toxic chemicals to the environment. Despite the growing environmental concern, the toxic potential of dumped munition and their reaction products is largely unknown. In this study, the cytotoxicity of thiodiglycol, 1,4-oxathiane and 1,4-dithiane, three metabolites of the chemical warfare agent sulphur mustard frequently detected in environmental samples from dumpsites, was assessed in rainbow trout gill (RTgill-W1) and human colon adenocarcinoma (Caco2) cells following 24 hours and 24 and 48 hours exposure, respectively. For that, a combination of three viability assays was used following the test guideline 249 from OECD. The obtained results for RTgill-W1 allowed the estimation of the LOECs of 50 mg/L and 100 mg/L for 1,4-dithiane and 1,4-oxathiane, respectively, which correspond to the 96 hours LOEC in fish, while a NOEC of 100 mg/L was estimated for thiodiglycol. Similarly, for Caco2, 1,4-dithiane also proved to be the most toxic of the tested chemicals with the LOECs of 6.25 mg/L and 100 mg/L, following 24 and 48 hours exposure. Furthermore, LOECs of 100 mg/L were estimated for 1,4-oxathiane and thiodiglycol following both exposure periods. This first insight on the cytotoxic potential of three relevant sulphur mustard metabolite products reveals that 1,4-dithiane is the most toxic of the tested chemicals, even though all estimated LOECs are well above the concentrations detected in environmental samples, which normally range $\mu\text{g/L}$.

1.02.P-Th009 EcoToxChip Test System: A Toxicogenomic New Approach Method (NAM) for Chemical Prioritization and Environmental Management

*Nil Basu*¹, *Markus Hecker*², *Doug Crump*³, *Jessica Head*¹, *Natacha Hogan*⁴, *Jianguo Xia*⁵, *Gordon Hickey*¹ and *Steve Maguire*¹, (1)McGill University, Canada, (2)University of Saskatchewan, Canada, (3)Environment and Climate Change Canada, Canada, (4)University of Saskatchewan, Saskatoon, Saskatchewan, Canada, (5)McGill University Macdonald Campus, Canada

In response to regulatory and stakeholder calls for New Approach Methods (NAMs), since 2016 our team has set forth to develop, test, validate, and commercialize toxicogenomic solutions (i.e., EcoToxChips, and a data evaluation tool EcoToxXplorer.ca) for the characterization, prioritization, and management of environmental chemicals and complex mixtures of regulatory concern. EcoToxChips have been developed for common laboratory model species representing the most important vertebrate groups in ecological risk assessment (fish-fathead minnow; bird-Japanese quail; amphibian-*Xenopus laevis*), and EcoToxChips for key native species are expected in early 2022 (rainbow trout, Northern leopard frog, double-crested cormorant). EcoToxChips are now

being tested according to a validation plan that has been reviewed by 5 offices in Environment and Climate Change Canada (notably, the Biological Assessment and Standardization Division) along with key project partners (US EPA, US Army Corps of Engineers, Shell, USGS, Eurofins) and social sciences researchers in the team. To date, more than 1,170 EcoToxChips have been analyzed and in this presentation we will summarize key findings from our case studies. In brief, case studies to date consist of 28 distinct chemicals being tested as well as 4 complex environmental samples. Two of the chemicals are being tested in a dose-response manner in three independent laboratories. In addition, 4 of the chemicals are tested in multiple species (species read-across), and 4 chemicals are being tested both in vivo and in vitro. For the majority of test chemicals, dose-response (i.e., to derive transcriptomics points of departures) and RNA-seq data (i.e., to evaluate cross-platform comparisons) are available. Exposure studies are complete for 22/28 chemicals and all 4 complex environmental samples. Notably, 10 of the 28 chemicals are purposefully included for regulatory interests. The interpretation of EcoToxChip results is facilitated through a user-friendly and intuitive cloud-based tool (EcoToxXplorer.ca) that continues to evolve based on feedback. EcoToxXplorer now integrates with information from the AOPwiki and includes our custom EcoToxModule gene sets designed for high-level interpretation of toxicogenomics data. Taken together, these diverse studies are demonstrating how the EcoToxChip Test System can serve as a toxicogenomic New Approach Method that is accessible, standardized and user-validated. Importantly, many partners have regulatory interests, and so the case studies are helping us to purposefully design the EcoToxChip Test System to be one that can be used quantitatively as a decision support tool in regulatory applications including chemical prioritization and guideline development. This study was conducted as a part of a large-scale Genome Canada-funded project (EcoToxChip project - www.ecotoxchip.ca).

1.02.P-Th010 Phytochemical Profile of the Extracts of *Bidens Pilosa* and Its Correlation With Antioxidant ACTivity, Cell Cytotoxicity, and Larvicidal ACTivity

*Oladayo Amed Idris*¹, *Nasifu Kerebba*², *Suranie Horn*³, *Mark Maboeta*⁴ and *Rialet Pieters*⁵, (1)North West University (Potchefstroom Campus), Potchefstroom, South Africa, (2)Department of Chemistry, Makerere University, Kampala P.O. Box 7062, Uganda, Uganda, (3)North-West University, Cape Town, South Africa, (4)North-West University - Potchefstroom Campus, South Africa, (5)North West University, Potchefstroom, South Africa

Bidens pilosa L. has traditionally been used as a flavorant in foods, in the treatment of diseases, and in agriculture as a biopesticide, with no reports of obvious adverse effects. The aims of this study were: i) to determine the cytotoxic effects of 70% ethanol and water extracts of *B. pilosa* on cell cultures using real-time cell analysis (RTCA); ii) the antioxidant activities; iii) larvicidal activities using the SYBR Green I-based fluorescence assay; and iv) to determine the phytochemical profiles using liquid chromatography coupled to a quadrupole-time-of-flight (LC-ESI-Q-TOF-MS) mass spectrometer (Waters Synapt G2). The quantitative analysis of the phenolic compounds in the crude extracts was determined using chemical analysis. The extracts show dose-dependent kinetics. However, only the ethanol extracts exhibited cytotoxic activity on the human liver, HepG2 (cancerous), and African monkey kidney, Vero (non-cancerous) cell lines. At 20 µg/mL, the water extract inhibited *Plasmodium falciparum* by 79.70% and was more potent than the ethanol extracts (inhibition; 30.43%), contrary to the cytotoxic effects shown in RTCA. The ethanol extracts expressed pronounced antioxidant activity and cytotoxicity, probably due to the presence of a higher concentration of flavonols, flavanones, and other polyphenols such as quercetin and kaempferols, in the ethanol extract as compared to the water extract. This study shows that ethanol extract of *B. pilosa* is more potent and could yield better results when used traditionally or for other purposes.

1.02.P-Th011 Comparison of In Vitro to In Vivo Data Generated in Bioaccumulation Studies

*Emma Danby*¹ and *Lindsay Knight*², (1)Covance, United Kingdom, (2)Labcorp Early Development Laboratories Limited, United Kingdom

Fish bioconcentration or biomagnification studies are carried out to determine whether substances have the potential to bioaccumulate and have potential to bio-magnify throughout different trophic levels. There are increasing requirements to conduct these studies on a broad variety of industrial chemicals, pharmaceuticals and crop protection products across the globe, resulting in the use of significant numbers of fish. The preferred method of testing requires three doses of chemical (including a control) with up to 100 fish per dose. However, following the revision to the OECD Test Guideline (OECD 305: 2012) there is now the option to test on one concentration and the control only, providing there is scientific justification. This has the potential to decrease the numbers of fish used in these tests by one third (100 fish per study). There are opportunities to reduce animals further by following new in vitro alternatives such as the OECD 319 study (Determination of in vitro intrinsic clearance using cryopreserved rainbow trout hepatocytes). The liver intrinsic clearance is used directly as an input to physiologically based toxicokinetic (PBTK) models for fish bioaccumulation. Alternatively, this value may be extrapolated to a whole-body (in vivo) biotransformation rate constant using an appropriate in vitro to in vivo extrapolation (IVIVE) model. The in vivo biotransformation rate can be included into in silico models for prediction of bioconcentration factors (BCF). Although novel validated methods exist to conduct in vitro fish bioaccumulation studies, regulators are not yet confident to accept these studies in isolation without supporting in vivo data. This is because they have not seen enough studies of this type submitted and do not have confidence in the direct in vitro/in vivo extrapolation. Direct comparison of data generated both in vivo and in vitro on the same chemicals is therefore needed to drive regulatory acceptance. Here we present results we have obtained in our laboratories comparing predicted BCF values obtained in vitro to those conducted in vivo in an OECD 305 setting on the same test materials.

1.02.P-Th012 Do We Really Need Acute Fish Toxicity Testing in Pesticide Risk Assessment?

*Elena Adams*¹, *Sarah Hartmann*², *Daniel Faber*², *Yvonne Wolf*², *Markus Ebeling*³ and *Eric Bruns*², (1)Bayer AG, CropScience Division, Germany, (2)Bayer Crop Science, Germany, (3)Environmental Safety, Bayer Crop Science, Germany

The current risk assessment (RA) of plant protection products (PPPs) for the aquatic environment is based on the evaluation of the toxicity to various taxonomic groups including extensive vertebrate studies with fish, both acute and chronic. According to the aquatic guidance document, the specific protection goal (SPG) for aquatic vertebrates “aims at protection at the individual level, so that mortality and suffering due to acute toxicity is avoided”. Hence, one of the tier 1 requirements for the authorization of PPPs is the performance of acute fish studies, which is laid down in the Commission Regulation (EU) No 283/2013 for active substances and the Commission Regulation (EU) No 284/2013 for PPPs. However, the Directive 2010/63/EU on the protection of animals used for scientific purposes and the Regulation (EC) No 1107/2009 clearly require the minimization of vertebrate testing. Considering the 3Rs principle (replacement, reduction, refinement), the current approach of testing fish toxicity in both acute and chronic studies needs to be critically reviewed. Therefore, it was investigated whether acute fish toxicity studies are drivers for the overall aquatic RA of pesticides and thus must be deemed necessary to ensure a safe use of PPPs or whether the acute fish toxicity can be covered by either chronic fish studies or other taxonomic groups. For this purpose, we compared the toxicity of 47 active substances comprising 14 fungicides, 21 herbicides and 12 insecticides to fish, invertebrates, sediment dwellers, algae and macrophytes using EU agreed endpoints. Preliminary results demonstrate that the acute toxicity to fish is usually well covered either by chronic fish studies or by other taxonomic groups. The evaluation shows, that the implementation of acute fish toxicity studies is not necessarily required to address the SPG for the aquatic environment. Indeed, it is indicated that there is huge potential to minimize vertebrate testing and thus implement the 3Rs principle in reducing the number of fish to be tested. The use of alternative methods such as the Fish Embryo Acute Toxicity (FET) Test (OECD Test No. 236) or the newly developed Fish Cell Line Acute Toxicity - The RTgill-W1 cell line assay (OECD Test No. 249) might be two promising methods that could replace acute fish toxicity studies in a comprehensive non-vertebrate testing strategy in future without reducing the protectiveness for the aquatic environment and its species.

1.02.P-Th013 Benzalkonium Chloride-Induced Cytotoxicity in Human Cell Lines

Hyejin Kim, Moonjung Hyun, Seonmin Lee and Jeongdoo Heo, Korea Institute of Toxicology, Korea, South

Benzalkonium chloride (BAC) has been used worldwide safely for decades, is a safe and effective product with sterilization effect. However, when inhale BAC, it is known to show extremely high toxicity. Recently, the use of hand sanitizers and disinfectants is increasing due to the COVID-19 pandemic. Therefore, safety evaluation is necessary because it is highly likely to cause toxicity due to directly exposure to the lung and skin. In this study, we evaluated in vitro toxicity of BAC in human lung fibroblast cells and human keratinocyte cells. We showed that BAC induced apoptosis and increased mitochondria dysfunctions including reactive oxygen species (ROS) production and regulation of the mitochondrial permeability transition pore (mPTP). Mitochondrial STAT3 is known to relate to ROS production and mPTP and it was reduced by BAC and hand sanitizer containing BAC. In addition, we confirmed that knockdown of STAT3 reduced the cell viability and reactive oxygen species increased compared to the control group. In conclusion, our results suggest a method to evaluate toxic effects of BAC via mitochondrial STAT3 protein.

1.02.P-Th014 Application of a Biotechnological Metabolization System to Improve the Forecast Power of the Fish Embryo Acute Toxicity Test

Inska Reichstein¹, Sabrina Schiwy², Henner Hollert³ and Andreas Schiwy³, (1)Goethe Universität Frankfurt, Germany, (2)Goethe University Frankfurt am Main, Frankfurt, Germany, (3)Goethe University Frankfurt am Main, Germany

The Fish Embryo Acute Toxicity (FET) Test, according to OECD 236, is an early-life-stage test to evaluate lethal and sublethal effects of chemicals/chemical mixtures on the organismic level of the zebrafish (*Danio rerio*) during the first days of development post fertilization. It was developed and standardized as a substitute for the acute fish test according to OECD 203, in which effects of the test substance/mixture on adult fish are assessed. The use of larvae is considered as a replacement of the more sentient adult animals according to the 3 R's principle (reducement, refinement and replacement of animal experiments), first invented by Russell and Burch in 1959. However, *Danio rerio* larvae have only limited metabolic capacity during the development until 96 hours post fertilization compared to adult fish. This can result in an under- or overestimation of the toxicity of environmental samples or chemical substances. Therefore, the FET is poorly established/accepted in the regulatory context as an alternative to the acute fish test. Thus, this project is intended to investigate whether the FET could be further improved by a preceding metabolism of the sample and thus strengthen its forecast power for regulatory risk assessment. For pre-metabolization, a biotechnological, animal component-free S9 and a conventional S9-fraction (liver homogenate) are used and compared. Both are used to enable the detection of the metabolite's effects in the FET. The effects observed during the test using pre-metabolized substances will be compared to the effects resulting from the non-metabolized parent compounds. Through biotransformation, stronger or weaker effects could then be monitored in the FET, which may better reflect the results from the acute fish test with adult fish with full metabolic capacity. For this study, five model substances are used for which bioactivation is expected to increase their toxicity. It is assumed that both testing approaches result in different concentration-response curves, where (possibly different) (sub-)lethal effects may occur at lower concentrations with pre-metabolized substances compared to the approach using parent compounds. The study aims to develop an applicable method to make the FET results more comparable to the acute fish toxicity data and therefore even more relevant for risk assessment.

1.02.P-Th015 Hepatic 3D Spheroids: The Next Generation of Testing in Toxicology (SPHERTOX)

Prem Chand Chand¹, Tania Gomes¹, You Song², Anastasia Georgantzopoulou³, Merete Grung⁴, Awadhesh Jha⁵, Christer Hogstrand⁶, Heike Laue⁷, Nicolas Bury⁸, Mikkel Lepperød⁹, Konrad Kording¹⁰ and Maria T. Hultman¹¹, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Norwegian Institute for Water Research (NIVA), Oslo, Norway, (3)Norwegian Institute for Water Research, Norway, (4)NIVA, Oslo, Norway, (5)Plymouth University, United Kingdom, (6)Kings College London,

United Kingdom, (7)Givaudan Schweiz AG, Switzerland, (8)University of Suffolk, United Kingdom, (9)University of Oslo, Norway, (10)University of Pennsylvania, United States, (11)Norwegian Institute for Water Research, Oslo, Norway

Alternatives to animal testing have long been sought by implementing the 3Rs (refinement, reduction and replacement), to more efficiently assess the safety of chemicals, endorse ethical considerations and reduce costs of experimental studies. Regulatory legislations have in recent years required more chemicals to be assessed for hazard, increasing the need for toxicity and bioconcentration (BC) testing. Thus, efforts to implement (non-animal) alternative bioassays, with key focus on fish, has intensified. Recent advances within *in vitro* fish acute toxicity and BC assessment have resulted in standardized tests with short exposure times. There is currently no satisfying *in vitro* model accommodating chronic toxicity testing and/or BC assessment of chemicals with low biotransformation rate. The primary objective of the SPHERTOX project is therefore to assess the performance of hepatic 3D spheroids from rainbow trout as an alternative chronic toxicity- and bioconcentration system, alone or in co-culture with other cell types, as an alternative and advanced *in vitro* model with increased comparability towards *in vivo* test systems. To fulfil this objective, SPHERTOX will generate *in silico* and experimental data to develop and evaluate novel and alternative ecotoxicological test methods for fish, with the following main aims: Characterisation of the spheroid model's morphological and physiological properties; Establishment of 3D spheroids as a chronic low-dose and repeated exposure *in vitro* model; Application of spheroids to measure low biotransformation rates of chemicals in bioconcentration assessment; Generation of a multi-compartment co-culturing system using hepatic spheroids and primary gill cells for acute and chronic toxicity testing; Improvement of *in vitro* to *in vivo* extrapolations by using 3D spheroids alone and/or in co-culture; Development and implementation of a causal inference model to identify mechanistic interactions and confounding factors within *in vitro* and *in vivo* toxicity testing. This project seeks to provide both basic and applied knowledge by generating theoretical and experimental data to develop and evaluate the next-generation ecotoxicological methodologies for fish using cutting-edge analytical technologies. The SPHERTOX project is funded by the Norwegian Research council (Project: 324794).

1.02.P-Th016 Modulation of Transient Reporter Vectors of the Xenobiotic Metabolism Pathway in Zebrafish Hepatocytes

Sebastian Lungu-Mitea¹, Yuxin Han² and Johan Lundqvist³, (1)Masaryk University, Faculty of Science, RECETOX, Czech Republic, (2)Swedish University of Agricultural Sciences (SLU), Sweden, (3)Swedish University of Agricultural Sciences, Sweden

Alternative *in vitro* test systems are in high demand within toxicology since the Tox21 paradigm shift in animal testing. Especially within ecotoxicology, coverage of aquatic species-specific assays is relatively scarce. Under these circumstances, transient reporter gene assays could be a quick, economical, and reliable solution. At least as a bridging technology. Nevertheless, users should be aware of inherent technological pitfalls regarding reporter gene assays, such as artefacts induced by reporter vector geometry. Here, we outline the development of an AhR-responsive transient reporter-gene assay in a permanent zebrafish hepatocytes cell line (ZFL), using both synthetic (multi-species consensus sequence) and endogenous, genomic (zebrafish) gene regulatory elements. Further, we disclose how viral, constitutive promoters (CMV, SV40, TK) located on the reporter-gene assay cassettes induce squelching of the primary signal. We designed a novel normalization vector, which bears an endogenous zebrafish-derived genomic promoter (zfEF1aPro) as a countermeasure. Our report depicts how the latter rescues the squelching-delimited system and gives insights into the modulation of transient reporter systems under xenobiotic stress. Lastly, we uncover a multi-level biological organization inhibitory mechanism that might mask effects ("maisonette squelching"). It appears that the ubiquitously used ligand BNF promiscuously activates multiple toxicity pathways of the xenobiotic metabolism and cellular stress response in an orchestral manner, presumably leading to a concentration-related inhibition of the AhR/ARNT/XRE-toxicity pathway and non-monotonous concentration-response curves. Conclusively, we prove transient, fish-derived reporter gene assays to be a potent tool in assessing molecular initiating events. However, we want to point out that such assays need careful development and increased quality control to avoid common technological shortcomings.

1.02.P-Th017 Combined In Vitro Exposure of Polystyrene Nanoparticles and North Sea Marine Oil: Assessing Sensitive Endpoints of Toxicity

Marianne Brookman-Amisshah¹, Monica Olsson² and EL Joachim Sturve³, (1)Biological and Environmental Sciences, Göteborgs universitet, Institutionen för biologi och miljövetenskap, Göteborg, Sweden, (2)University of Gothenburg, Sweden, (3)University of Gothenburg, Sweden

Over the last decade, there has been increased interest in the impact of plastic pollution on the aquatic ecosystem. Micro and nano plastics generated as a result of plastic degradation and the risks posed to aquatic life is of great concern. However, little attention has been given to interactions of these particles with other environment pollutants found in the aquatic environment. This study aims to gain knowledge on the possible toxic effects associated with single and combined exposure of Polystyrene nanoparticles (PSNPs) and water accommodated fractions (WAF) of North Sea marine oil (containing polyaromatic hydrocarbons (PAHs)) on fish *in vitro* models and explore more sensitive *in vitro* assays for the assessment of nanoparticle toxicity. Rainbow trout (*Oncorhynchus mykiss*) cell lines were exposed to a range of concentrations (0.1-100 µg/mL) of PSNPs (25, 100 and 2000nm) alone or in combination with North Sea oil WAFs. Endpoints measured included cytotoxicity using Alamar Blue and CFDA-AM probes, cytochrome P450 1A (CYP1A) activation (EROD activity) and generation of reactive oxygen species (ROS). Exposure to PSNPs alone demonstrated significant changes in cellular metabolic activity, membrane stability and generation of ROS in rainbow trout gill and liver cells. Changes observed were particle size and concentration dependent, little to no changes were observed with the 2000nm, viable cell counts ranged from 60-80% with 100nm and 30-45% in 25nm, suggesting increased toxicity with reduction in particle size. An increasing trend of ROS generation was observed in 25 and 100nm PSNPs exposure only as well as with WAF alone and trends in EROD activity was observed to be induced by WAF only. Pilot studies investigating the combined exposure of similar oil: water fractions and PSNPs demonstrated reduced cytotoxicity by 25-40% at select concentrations in rainbow trout gill and liver cells. In addition to *in vitro* toxicity studies, more sensitive assays including

gene expression analysis for markers of sublethal toxicity will be explored, effects on generation of intracellular ROS, CYP1A induction potential in rainbow trout cells as well as toxicity and behavioural effects in Zebrafish larvae will be conducted to gain an overall picture of the risk associated with these interactions.

1.02.P-Th018 Omics- Based Identification of MOLECULAR Effects of Fungicidal Active Substances in Zebrafish Embryo
*Fatma Marghany*¹, *Steve Uwa Ayobahan*², *Hannes Armin Reinwald*², *Christoph Schaefer*³, *Henner Hollert*⁴ and *Sebastian Eilebrecht*³, (1)*Eco'n' OMICS Attract group, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallingenberg, Germany*, (2)*Fraunhofer IME, Germany*, (3)*Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany*, (4)*Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany*

Active substances of fungicides introduced to the ecosystem in a targeted manner can exert adverse effects on non-target organisms, in particular populating soil and the aquatic ecosystem. Currently, the regulatory authorities prescribe a number of studies for the assessment of environmental side effects, including the analysis of bioaccumulation, environmental fate and toxicity in different model organisms such as earthworm, algae, water flea or fish. However, these studies do not cover substance-induced effects at the molecular level. The application of recent OMICS-technologies allows for a sensitive and global identification of molecular changes at the level of RNA (transcriptomics) and proteins (proteomics). This work aims at the identification of molecular changes induced by a number of FRAC (Fungicide Resistance Action Committee)-classified fungicidal active substances in zebrafish embryo in order to predict the adverse environmental effects and global gene expression changes induced by these substances. Zebrafish embryos were exposed to sub-lethal concentrations of fungicidal active substances for 96 hrs followed by simultaneous RNA and protein extraction from respective samples in order to analyse further effects induced by those substances in transcriptomic and proteomic profiles by applying RNA-Seq (transcriptome) and HPLC-Mass-Spec (proteome) analyses. The resulting molecular fingerprints will provide the basis for a mode-of-action (MoA)-specific screening of active substance precursors under development and monitoring of environmental samples in order to assess the environmental load of fungicide active substances. Deep knowledge about molecular changes induced by active substances with different (MoA) and the linkage with phenotypic and population effects will significantly facilitate the classification of active substances related to their environmental side effects.

1.02.P-Th019 The Onset of Active Gill Breathing in Zebrafish (*Danio rerio*) Larvae Correlates With an Increase in the Sensitivity to Neurotoxic Pesticides

*Nadine Kämmer*¹, *Tanja Reimann*² and *Thomas Braunbeck*³, (1)*Centre for Organismal Studies, Heidelberg, Germany*, (2)*COS University of Heidelberg, Germany*, (3)*University of Heidelberg, Germany*

A major concern about the applicability of the fish embryo toxicity test (FET) as an alternative for the fish acute toxicity test (AFT) is based on the observation of low sensitivities to neurotoxic substances. Given that oxygen uptake in early developmental stages of fish embryos primarily occurs *via* diffusion across the skin, substances which impede or prevent active ventilation of the gills might lead to premature death in adult fish may not be effective in skin-breathing embryos. To investigate if this respiratory failure syndrome (RFS) plays a role for the higher sensitivity of adults, a new acute toxicity test using postembryonic, early gill-breathing life-stages of zebrafish was conducted with chlorpyrifos (CPS), permethrin (PM), lindane (?-HCH), aldicarb (ALD), ziram (ZDMC) and aniline (AN) as test substances. Additionally, a comparative study into oxygen consumption (MO_2), breathing frequency (f_v) and amplitude (f_{amp}), as well as swim bladder deflation as possible side-effects of the RFS was performed with 4 d old skin-breathing and 12 d old gill-breathing zebrafish. Acute toxicity tests revealed that postembryonic larvae represented the most sensitive life-stage for all test substances except PM, if compared to both FET and AFT. In 12 d old larvae, MO_2 , f_v and partly f_{amp} were significantly increased in all treatments, whereas pesticide exposure 4 d old embryos only caused minor effects. Whereas ZDMC and AN showed no significant effect on swim bladder deflation, CPS-, ?-HCH- and PM-exposed fish showed significantly deflated swim bladders mostly in 12 d old larvae, but, in case of ALD, a significant hyperinflation in 4 d old embryos. Swim bladder deflation in 12 d old larvae indicates a potential disruption of gas secretion homeostasis by systemic effects of the respiratory failure syndrome, whereas in 4 d old embryos choline-mediated hyperinflation of the swim bladder dominates over other effects. The induction of the respiratory failure syndrome during the onset of active gill respiration by neurotoxic pesticides apparently correlates well with differential sensitivities of skin-breathing embryos and gill-breathing later life-stages of fish. However, regarding acute lethality, this study also provides striking evidence that conventional toxicity testing with adult fish may also fail to give ecologically relevant predictions of acute toxicity, since adults do not necessarily represent the most sensitive life-stage.

1.02.P-Th020 SNAPFISH - Searching for Refined In Vitro Approaches to Predict Bioconcentration of Chemicals in Fish

*Felix Stibany, Dr.*¹, *Markus Brinkmann*², *Nathalie Iris Grau*³, *Sophia Krause*⁴, *Kai-Uwe Goss*⁵, *Andreas Schäffer*¹ and *Kilian Smith*¹, (1)*RWTH Aachen University, Germany*, (2)*University of Saskatchewan, Canada*, (3)*Institute for Environmental Research, RWTH Aachen, Aachen, Germany*, (4)*Helmholtz centre for environmental research - UFZ, Germany*, (5)*Analytical Environmental Chemistry, Helmholtz Centre for Environmental Research - UFZ, Leipzig, Germany*

The ecotoxicological assessment of chemicals requires information about their bioaccumulation potential in organisms. This is particularly important for hydrophobic organic chemicals due to their high sorption and potential for bioaccumulation. Steady-state BCFs in fish reflect the net result of the various chemical uptake versus loss processes and can be determined directly (e.g., using OECD 305). However, in the context of the 3R-targets for the use of animals in research, alternative approaches to derive BCFs based on *in vitro* and/or *in silico* approaches are required. The main aim of the present study is to obtain *in vitro* metabolic rates from assays based on rainbow trout liver S9 fractions (RT-S9) for a set of reference chemicals, namely pyrene, deltamethrin,

4-*n*-nonylphenol, and methoxychlor. Secondly, the rates determined from these S9 *in vitro* assays shall be compared with several perfused liver experiments using the same strain of fish as for the S9 assays. This comparison provides an intermediate step for testing the *in vitro* – *in vivo* extrapolation (IVIVE) process that considers sorption processes and the different amounts of metabolically active components *in vitro* and *in vivo*. Furthermore, we will report on the application of partitioning-based dosing methods in the S9 *in vitro* assays for a more robust metabolic rate measurements of selected highly hydrophobic reference compounds at defined dissolved concentrations. These make use of albumin as the passive dosing phase to provide fast and reliable release kinetics in the assays. Abiotic partitioning experiments for the albumin and RT-S9 fractions have also been performed for the reference compounds to provide corresponding distribution coefficients. These measured data provide the free fractions of the reference compounds in the assay medium which is needed as part of the IVIVE. Both, the development of partitioning based dosing methods for S9 *in vitro* assays as well as the comparison of S9 *in vitro* data with perfused liver experiments shall finally lead to a refinement of the IVIVE model, which would in turn provide more reliable BCF estimates and thus better predictability of the environmental risk of hydrophobic chemicals.

1.02.P-Th021 A New Network of In Silico Models - LIFE CONCERT REACH Project

Antje Gerloff-Elias¹, Rodolfo Gonella Diaz², Eva Wedebye³, Alberto Manganaro⁴, Paolo Manes⁵, Igor Tetko⁶ and Emilio Benfenati⁷, (1)Knoell, Germany, (2)knoell Germany GmbH, Germany, (3)Technical University of Denmark (DTU), Denmark, (4)Kode srl, Italy, (5)SC Sviluppo chimica S.p.A., Italy, (6)Helmholtz Zentrum Munchen, German Research Center for Environmental Health, Germany, (7)IRCCS Istituto di Ricerche Farmacologiche Mario Negri, Italy

This poster provides an update on the LIFE CONCERT REACH project, which started in 2018 and aims to establish a new, freely accessible, network of in silico models, including both (Q)SAR and automated read-across tools. The EU-funded project will be finalized in 2022 and involves scientific, regulatory as well as industry partners. The network of in silico models should be achieved by linking existing and well-known platforms (such as VEGA platform, the Danish QSAR Database, OCHEM and AMBIT), as well as developing and integrating new models, potentially covering all properties required within the framework of Regulation EC (No) 1907/2006 (REACH). The new network will comprise statistical and knowledge-based (Q)SARs as well as automated read-across tools. The goal of the project is to offer more than 300 freely available in silico models. An interface with the OECD QSAR Toolbox is also envisaged. Furthermore, compliance with current regulatory requirements with regard to reporting (i.e. QMRF and QPRF generation) is also an intended target. Here we present some of the new models, which have been implemented in the last VEGA platform version and are now publicly available. Furthermore, we will give an overall update on goals achieved within the LIFE CONCERT REACH project.

1.02.P-Th022 Sequential Exposure of Zebrafish Embryos to Two Differently Acting Insecticides - a CASE Study With Chlorpyrifos and Abamectin

Afolarin Ogungbemi¹, Stefan Scholz² and Eberhard Kuester³, (1)Helmholtz centre for environmental research - UFZ, Germany, (2)Helmholtz Centre for Environmental Research, Leipzig, Germany, (3)Helmholtz Centre for Environmental Research, Dept. Bioanalytical Ecotoxicology, Germany

Neuroactive chemicals such as organophosphate and avermectin pesticides are frequently detected in the environment. Singly or in a mixture, they could provoke neurotoxic effects and neurological diseases to organisms. Understanding the effects of pesticide mixtures including substances with different mode of action would help in risk mitigation. In order to assess mixtures of neurotoxic compounds, we have used the zebrafish embryo model. Zebrafish embryos (0-120 hpf) are considered as an alternative to animal testing and are increasingly used for hazard assessment. In addition to standard OECD 236 testing with lethal and sublethal effects, recent efforts to expand effect parameters included the assessment of behavior or movement changes in fish embryos as a potential indicator of neuroactivity, e.g. the spontaneous tail coiling (STC). Here, analysis of changes in the STC was used to study the pesticides chlorpyrifos, chlorpyrifos-oxon and/or abamectin. The effect of co- and sequential exposures was analysed with STC and by measurement of the acetylcholinesterase (AChE) inhibition. Results show that both chlorpyrifos and its oxon metabolite induced hyperactivity in the STC test. Chlorpyrifos is a known inhibitor of acetylcholinesterase, but its activity is mediated via the active metabolite, chlorpyrifos-oxon. Coincidentally, only chlorpyrifos-oxon inhibited AChE while chlorpyrifos did not. Further, abamectin which acts by activating Gamma aminobutyric acid receptors (GABA_R) in invertebrates blocked the chlorpyrifos induced hyperactivity but not that of chlorpyrifos-oxon. These results point to a potential GABA_R-related or rather GABA_R analogue inhibition or cross reaction for the parent compound, chlorpyrifos, rather than the AChE inhibiting mechanism.

1.02.P-Th023 Application of In Vitro Fish Cell Line Assays to Predict the Mixture Toxicity of Plant Protection Products

Oliver Körner¹, Nicole Tobler² and Stephan Fischer³, (1)ADAMA Deutschland GmbH, Germany, (2)Arcadis Schweiz AG, Switzerland, (3)aQuaTox-Solutions GmbH, Switzerland

In the context of plant protection products registration, mixture toxicity is one of the most controversial topics in regulatory ecotoxicology. In order to estimate if mixture effects are either additive, antagonistic or synergistic, a comparison of the predicted mixture toxicity (based on single substance toxicity data) versus the experimental mixture endpoints is performed. The same applies for the mixture assessment of plant protection products in the European Union, where the calculated mixture toxicity is compared with the measured toxicity of the formulated product. Formulated products, however, do not only contain active substances but also comprise co-formulants, which are completely ignored in this comparison. Perhaps, the results are therefore inaccurate and could lead to misinterpretations of the underlying mixture toxicity effects. A much more accurate approach could be the concept of “isobolograms”. Isobolograms determine if a mixture shows additive, synergistic or antagonistic effects by plotting the concentrations of two chemicals against each other and representing the amount of the toxicants in the mixture which produces a given biological response. This approach, however, requires a large number of assays on vertebrate species and is

obviously in contrast to the effort that is made to reduce the amount of regulatory vertebrate testing. To explore the mixture toxicity of plant protection products, the present study utilized a rainbow trout gill cell line assay (RTgill-W1, ISO guideline 21115, which served as the basis for the recently adopted OECD test guideline 249). Recent studies displayed not only a high level of repeatability and reproducibility of the cell assay but also an excellent correlation between the endpoint derived from the cell assay and values from standard acute fish toxicity. The present study investigates the applicability of isobolograms to assess mixture toxicity effects in formulated agrochemical products using a cell line assay as an alternative, animal-friendly approach to determine the benefits of this approach for regulatory ecotoxicology and product development.

1.02.P-Th024 Image Based Toxicity Screening of Chemicals in *Daphnia magna*

Cedric Abele¹, Amira Perez², Paula Pierozan², Erik Nylander², Magnus Breitholtz³ and Oskar Karlsson², (1)Stockholms universitet, Sweden, (2)Stockholm University, Sweden, (3)Inst för tillämpad miljövetenskap, Sweden

Green Chemistry is an essential part of EU's new chemical strategy towards a toxic-free environment. Currently, several tens of thousands of chemicals are found on the global market and a majority of them are not fully tested in terms of ecotoxicity. This requires identification of hazardous chemicals and development of new safe-by-design chemicals for their substitution. The research program Mistra SafeChem is targeting a holistic approach to chemicals and promotes a green chemical industry in Sweden. Chemical developers working together with computational and experimental toxicologist to find green solutions for the future and to predict risks already in the design phase. To assess if a chemical is "safe", appropriate testing approaches that allow efficient generation of toxicological effect data is demanded. High content-screening (HCS) describes automated microscopic image acquisition with subsequent quantitative evaluation of multiparametric data sets. This image-based method is, combined with molecular fluorescence stains and antibodies, a well-established technique to observe cellular processes *in vitro*. To help develop ecotoxicological testing, we are combining the standard test species *Daphnia magna* with HCS. This allows us to identify toxic responses after exposure to chemicals, mixtures or environmental samples and generate molecular mechanistic data while keeping the complexity of a whole organism. Since imaging is a non-invasive method, the physiological structure of the test organisms is maintained which allows acquisition of spatiotemporal information. Application of softwares such as ImageJ facilitates fast image analysis and extraction of light intensity data which are proportional to the toxic response of interest. Intensities can be used as semiquantitative measure of toxicity. The simultaneous application of several stains with fluorescence at different wave lengths enables multiplexed analysis in one test object. Combined with time resolved observation of toxic response this can help to fill knowledge gaps in ecotoxicology and further develop adverse outcome pathways (AOPs).

1.02.P-Th025 From Histology to Behavior: Sublethal Effects of Developmental Neurotoxins in Zebrafish (*Danio rerio*)

Maria Fischer¹ and Thomas Braunbeck², (1)COS, Aquatic Ecology & Toxicology, Heidelberg, Germany, (2)University of Heidelberg, Germany

The developing nervous system is extremely vulnerable to exogenous stressors like chemicals. Early life-stage exposure may lead to persistent morphological and behavior alterations. Developmental neurotoxicity (DNT) studies according to OECD TG 426 provide information on neurologic and behavioral abnormalities of rat offspring after exposure to repeated doses of chemicals *in utero*. Given the use of rodents, such studies are extremely time- and cost-intensive and require a large number of experimental animals. As a consequence, although adopted by OECD, data are still scarce, since OECD TG 426 is applied only in cases of strong suspicion of a neurotoxic potential. In contrast, relatively inexpensive experiments with rapidly developing zebrafish (*Danio rerio*) embryos appear as a promising alternative for routine DNT testing. Starting as early as 21 hours post-fertilization, spontaneous tail coiling within the embryonic chorion can easily be recorded to detect behavioral changes. In conjunction with later observations on modifications of swimming patterns, tail coiling recordings may provide valuable insight into manipulations of the developing motoneuron-muscle-system. In order to link behavioral to morphological observations, histological analyses of muscles and motoneurons were made. Thus, the purpose of the present study was to complement various methods to test the neurotoxic potential of chemicals in developing zebrafish embryos with a focus on motoneuron-muscle interactions. Combining behavioral endpoints with histology was hypothesized to provide a hint as to not only the chemicals' targets, but also to adverse outcomes in a complex vertebrate model. Chemicals tested as model compounds were the well-known DNT reference nicotine (positive control) and desnitro-Imidacloprid, a major metabolite of imidacloprid (neonicotinoid) with a higher neurotoxic potency to vertebrates than its parent compound. This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 681002 (EU-ToxRisk; GA, art. 38.1.2).

1.02.P-Th026 Metabolic Products and Toxicity Pathways As Weight-Of-Evidence in the Use of Transcriptomic Points-Of-Departure (tPODs) in Embryonic Rainbow Trout Exposed to Benzo[A]Pyrene

Alper James Alcaraz¹, Sydney Murray¹, Phillip Ankley¹, Bradley Park¹, Katherine Raes¹, Shakya Kurukulasuriya¹, Anita Masse¹, Doug Crump², Nil Basu³, Markus Brinkmann¹, Natacha Hogan⁴ and Markus Hecker¹, (1)University of Saskatchewan, Canada, (2)Environment and Climate Change Canada, Canada, (3)McGill University, Canada, (4)University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Current ecological risk assessment frameworks rely on approaches that require large numbers of live animals and lengthy time for chronic responses to manifest, rendering them costly, tedious, and of significant ethical concern. New Approach Methods (NAMs) such as rapid mechanistic embryo assays are not only more ethically acceptable but can also be more efficient by characterizing molecular events, leading to the derivation of thresholds that could guide decision-makers on identifying or prioritizing chemical hazards. However, instituting such an approach requires careful calibration through multiple lines of evidence. Thus, this study aimed to establish a NAM where a transcriptomics benchmark dose (transcriptomic points-of-departure; tPOD) was derived from short-term exposure experiments with non-protected embryonic stages of rainbow trout (RBT; *Oncorhynchus mykiss*) using

benzo[a]pyrene (B[a]P) as the model compound. In brief, embryo-alevin RBT were exposed to graded concentrations of B[a]P (measured: water control, 0.01% DMSO solvent control, 0.079, 0.35, 1.5, 7.4, and 28.6 µg/L) for 28 days. Benchmark dose analysis of toxicogenomic data (RNASeq) at 4 days post-hatch yielded tPODs of 0.02, 0.15, 1.8, and 0.07 µg/L B[a]P for the median of the 20 most sensitive active genes, 10th percentile of all active genes, mode of the first peak of gene-level benchmark doses, and pathway-level (glutathione metabolism pathway) tPOD, respectively. After 28 days, morphometric analysis showed significant growth inhibition at >7.4 µg/L B[a]P, with notable decreasing trend in body weight. Molecular pathways, biochemical responses (EROD, oxidative stress), and histological alterations will be used to construct toxicity pathway models and B[a]P metabolites will be measured to demonstrate similarities in toxicological perturbations and processes occurring at early life and more advanced life stages of fish as reported in the literature. This study is part of the EcoToxChip project (www.ecotoxchip.ca).

1.02.P-Th027 Optimization of Fish Embryo Acute Toxicity Test Workflows in the Promising Fish Model *Oryzias melastigma* for Marine Ecotoxicology

Jakob Pfefferle¹, Frederic Strobl², Xavier Cousin³, Henner Hollert¹ and Sarah Johann⁴, (1)Goethe University Frankfurt am Main, Germany, (2)Goethe University Frankfurt am Main, Germany, (3)IFREMER, France, (4)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany

The marine medaka, *Oryzias melastigma*, has been identified as a promising model species for marine ecotoxicology and shares many advantages for early life stage testing with the well-established freshwater model species zebrafish (*Danio rerio*) such as easy large-scale culturing and a transparent chorion. The present work aimed on optimizing workflows with *O. melastigma* and the particular focus on the adaptation of standardized procedures such as the Fish Embryo Acute Toxicity (FET) test (OECD 236, ISO 15088) and associated endpoints like locomotor activity or heart rate analysis. In this context, general adaptations related to the test conditions and species-specific characteristics such as, e.g., pre-treatment of embryos, sensitive time windows of exposure (max. 22 hpf), test duration (up to 192 hpf), miniaturization to 96-well plates for higher throughput testing as well as different dechoriation approaches, were performed. In addition, the positive control 3,4-Dichloroaniline was adapted and DMSO as well as MeOH were evaluated as potential carrier solvents (recommended concentration ~ 0.1 %). The optimized marine medaka FET protocol was successfully validated with neurotoxic model compounds (e.g. paraoxon methyl, carbendazim) and is currently applied to investigate environmental extracts. For a direct sensitivity comparison to zebrafish, species-specific (e.g. embryonic development, onset of biotransformation) as well as external factors (e.g. medium salinity, temperature) were analyzed. In comparison to the chorion of *D. rerio* (1.5 – 2.5 µm), the thicker chorion of the medaka (15 µm) was identified as a critical point and hence, the role of the chorion was further examined. In this context, also the influence of DMSO on chorion permeability and thus, the compound uptake, was investigated using confocal laser scanning microscopy and compared with existing data for zebrafish. Results support the hypothesis that the medaka chorion provides a stronger barrier compared to the zebrafish chorion and hence could be a major factor affecting the bioavailability and resulting toxicity. Since behavioral analysis is an increasingly important endpoint for the ecotoxicological evaluation of neurotoxicity, also a light/dark transition locomotor response test using neuroactive substances was adapted. Typical swimming patterns as reported for zebrafish were observed, indicating a promising potential of this test for the behavioral assessment of *O. melastigma*.

1.02.P-Th028 Effects of a Native and Chemically Dispersed Light Crude Oil on Multi-Level Endpoints in the Marine Medaka *Oryzias melastigma* Embryo Model

Katharina Wolf¹, Jakob Pfefferle², Xavier Cousin³, Henner Hollert² and Sarah Johann⁴, (1)Goethe University Frankfurt, Germany, (2)Goethe University Frankfurt am Main, Germany, (3)IFREMER, France, (4)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany

Adverse effects of crude oil exposure are well-known to manifest even at low concentrations during early development of fish. The present study investigates the applicability of a multi-level endpoint battery in *Oryzias melastigma*, the marine medaka, which is increasingly established as a model organism in marine ecotoxicology. Furthermore, this work addresses the potential changes in resulting toxicity caused by the weathering of crude oil. The fish embryo acute toxicity test (FET) with additional mechanism-specific endpoints on cardio- and neurotoxicity is performed. To evaluate the species sensitivity and applicability as a marine model the present findings will be compared to previous results with the freshwater model *Danio rerio* using identical experimental set ups. Freshly fertilized eggs were exposed to native and chemically dispersed water accommodated fractions (WAF) of a light naphthenic crude oil. WAFs prepared from the dispersant itself and an inert oil were used as controls. WAFs were prepared in embryo medium (25 ‰ salinity) at 10 °C and mixed for 40 h before exposure. Embryos were incubated at 28 °C using a semi-static setup to ensure a steady bioavailability of adverse compounds. The work with *O. melastigma* embryos was performed up to 192 hours post fertilization which corresponds to animal-free testing period. Embryonic development was monitored every 24 h and video sequences were recorded at 120 and 168 hours post fertilization for heartbeat assessment. For further mechanism-specific endpoints on neurotoxicity, oxidative stress and biotransformation activity with enzymatic biomarkers (AChE, CAT, EROD), embryos were exposed to sublethal concentrations (EC5-EC20). In this context, also dechoriation and following swimming behavior alteration tests (light dark transition test) will be performed. First results of the FET showed a concentration-related increase in toxicity and confirmed effects as hemorrhaging, slowed development and decreased heart rate and blood flow. Moreover, cardiotoxicity was shown by evaluation of heartbeat frequency with significantly declined heart rate in WAF exposed embryos. Initial comparison of fresh and weathered oil indicated increasing toxicity after weathering, which will further be examined by chemical analysis of exposure solutions. Overall, the present findings support the applicability of the marine medaka as a relevant and useful model organism for marine ecotoxicology.

1.02.P-Th029 A Review of the Use of the OECD Threshold Approach for Fish Acute Studies

Helen Elizabeth Walton¹ and Michelle Booth², (1)Cefas Lowestoft Laboratory, United Kingdom, (2)Scymaris Ltd, United Kingdom

Fish acute toxicity studies (OECD TG203) are embedded in global regulatory frameworks for chemical risk assessment; however, this study type is ethically controversial as a vertebrate study with a lethality endpoint. Alternative approaches are available (OECD TG236, OECD TG249) but not yet widely accepted by regulatory authorities. Projects are ongoing to support the use of alternative approaches (CEFIC, SWiFT), however, for the meantime, LC₅₀ determinations using OECD TG203 are still required. Fish acute toxicity studies are routinely conducted at Scymaris Ltd. to support global chemical risk assessments for our clients and the OECD threshold approach is used wherever possible. Not only does this approach negate the need for range finding, but it also reduces animal numbers from 42 to 14 fish in most cases. The threshold approach utilises data generated from algae (OECD TG201) and *Daphnia magna* (OECD TG202) acute toxicity studies to set a limit concentration for the fish study. Only if mortality is observed is a full range of 5 test concentrations required. This approach supports the principles of the 3Rs by reducing animal numbers and refinement of the test concentration by utilising data from other test organisms. We conducted a retrospective assessment of the fish acute toxicity studies conducted at Scymaris. The data presented in this poster gives an overview of when the threshold approach has been utilised, the concentrations chosen based on algae and *D. magna* endpoint data and the subsequent numbers of fish used and spared by using this approach. The studies were conducted in compliance with GLP (Good Laboratory Practice) and in accordance with the OECD TG203 or international equivalent.

1.02.P-Th030 Optimization Approach for an Animal-Free High-Throughput Micronucleus Assay

Sarah Hörchner¹, Andreas Schiwy¹, Beat Thalmann² and Henner Hollert¹, (1)Goethe University Frankfurt am Main, Germany, (2)Scinora GmbH, Germany

In vitro bioassays are efficient tools for determining biological effects in environmental samples containing complex mixtures of contaminants. For example, assessment tools are available that predict whether a sample is genotoxic without having to perform a costly and time-consuming animal experiment. Exposure to genotoxic agents can lead to the formation of a phenomenon called micronuclei, which corresponds to the loss of genetic material. Such loss of genetic material can have effects on the cell, the organism, and possibly on the entire population and is, therefore, a major genotoxicity endpoint in standardized *in vitro* assays, such as the OECD Guideline 487 micronucleus test. However, the visual scoring of micronuclei is time-consuming and scorer fatigue can lead to inconsistency. In this regard, more recent technologies like automated scoring, for example, by digital image recording and analysis is a viable, less resource-intensive alternative. According to the OECD Guideline 487 and ISO/DIS 21427-2 2009, the micronucleus assay is originally performed on slides. In this study, the development of an improved high-throughput (HTP) *in vitro* micronucleus assay in multiwell-plates, using an automated imaging microscopy approach to rapidly identify micronuclei is described. Following the 3R principles, we attempted to adapt a transgenic H2B-eGFP V79-4 cell line to a chemically defined medium to reduce the animal-derived components in the assay design. The novel HTP method in 96-well format allows a throughput of 4 samples with 5 concentrations, a negative control, positive control, solvent control, and process control in 4 technical replicates each. In summary, the miniaturized version of the assay, performed in 96-well plates, has several advantages compared to the slide method. Besides increasing sample throughput, reagent reduction and optimized image acquisition were realized. To increase the data throughput of the test and to avoid scorer bias, automatic evaluation is desirable. However, this is limited within the present test design since the nuclei of V79-4 cells do not have a homogeneous appearance and vary greatly in shape and size. Additionally, the reduction of animal components in the test design was challenging and chemical defined media need to be evaluated for the cultivation of cells with round, homogenous nuclei, such as the human A549 cell.

1.02.P-Th031 Effect of Different Sample Preparation Techniques on the Fish Embryo Test (FET): A Comparative Study Using *Danio rerio* and *Oryzias melastigma*

Jakob Pfefferle¹, Henner Hollert², Sarah Johann³ and Riccardo Massei⁴, (1)Goethe University Frankfurt am Main, Germany, (2)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (3)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (4)University of Antwerp, Germany

Fish embryo toxicity tests (FETs) are particularly suitable for the toxicological characterization of environmental samples due to their ecological relevance and high throughput potential. In particular, environmental extracts can be dosed in the FET at different concentration levels to achieve a dose/response relationship for lethal and sub-lethal endpoints. However, an environmental extract needs to go through a series of preparation steps before bio testing. These processes may alter the chemical composition of the sample and lead to an over- or underestimation of the sample toxicity. A comprehensive overview on the effects of different sample preparation procedures on the final outcomes of the FET is still mostly unknown. In this study, we want to compare the effects of different dosing procedures using a freshwater (*Danio rerio*) and marine (*Oryzias melastigma*) fish embryo species. Therefore, an environmental sample collected from an area impacted by greenhouse activities was collected in 2018 using onsite large volume solid phase extraction (LVSPE). The extract was prepared using different enrichment procedures covering two common carrier solvents (DMSO, ME OH) and the direct re-dissolving in exposure medium. Fish embryos were exposed to the extracts following a slightly modified version of the OECD 236. Embryonic development was observed every 24 h and exposure media and organisms were collected for chemical analysis to understand the effect of uptake and substance losses during sample preparation. Preliminary results showed that *D. rerio* has a higher sensitivity than *O. melastigma* (up to 4 fold) to the extract. Furthermore, our results confirmed that different sample preparation procedures are not influencing the FET with *D. rerio*. However, we observed a slightly lower toxicity when the sample was dosed without using carrier solvents ($p < 0.001$). In contrast, different sample preparations influenced adverse outcomes in *O. melastigma* and extracts dosed in methanol induced a higher

toxicity ($p < 0.005$) compared to DMSO, showing the impact of sample preparation on the FET with marine medaka. These results together with a potentially lower sensitivity to environmental extracts in respect to *D. rerio* need to be further interpreted by the chemical analysis of internal and exposure media. Our results underlined the need to achieve a harmonization of sample preparation strategies for testing environmental extracts.

1.02.P-Th032 Comparing Ecosystem and Human Health Damages From Chemicals in Household Products Using Predicted Chronic Hazardous Concentrations

Maryse Suppiger¹, Lei Huang¹, Peter Fantke², Bu Zhao¹, Justin Colacino¹ and Olivier Jolliet¹, (1)University of Michigan, United States, (2)Technical University of Denmark, Denmark

Empirical ecotoxicological data is only available for a limited number of chemicals and species. Thus, predictive models can be utilized when experimental data is lacking. Linear regression and random forest models were developed to predict chronic freshwater hazardous concentrations (HC20) of the species-level chronic NOAEL for chemicals in the US EPA Chemical and Product Database (CPDAT). When acute HC50 data was available, chronic HC20 were predicted using simple linear regression ($N=4,887$; $R^2=0.89$). To generate predictions for chemicals lacking acute HC50 values, chemical toxicity parameters from Open Structure-activity/property Relationship App (OPERA) and Toxicity Estimation Software Tool (TEST) were entered as inputs to a random forest model that was able to predict close to 60% of the HC20 variability ($N=1,828$; $R^2=0.59$), against only $R^2=0.394$ when performing multi-linear regression. When TEST data was missing for a chemical, chemical properties from OPERA were entered into a separate random forest model ($N=4,251$; $R^2=0.371$). After building and training the three models, the models were used to predict HC20 data for 700,000 chemicals, with the highest performing model being used in priority per chemical. Next, HC20 predictions were combined with population-level product usage data from Stochastic Human Exposure and Dose Simulation Model (SHEDS-HT) and extrapolated to the generic USEtox human population. Human toxicity impacts and HC20-based ecotoxicity impacts were modeled in USEtox, accounting for chemical concentration, fate, and transport in environmental media. Damages were expressed respectively in units of disability adjusted life years (DALY/kg emitted) and potentially disappeared fraction of freshwater species (PDF m^3 d/kg emitted). Total PDF and total DALY were analyzed for each chemical and product. Chemicals with the highest human health damage include triethanolamine, dichloromethane, and hydroquinone. Chemicals with the highest ecosystem damage include cyfluthrin, 2-Methyl-3(2H)-isothiazolone, and ?-cyhalothrin. Outdoor spray insecticides were the most damaging products to ecosystems, while leave-on personal care products were the most damaging to population-level human health. Human health and ecosystem damages differ greatly by chemical and product, underscoring the need for individualized analysis for each type of toxic impact.

1.02.P-Th033 Employing Adverse Outcome Pathways for Identifying Hazards Associated With Novel Flame Retardants

Chander Kant Negi¹, Lola Bajard² and Ludek Blaha³, (1)Room No. 311/A29, RECETOX, Faculty of Science, Masaryk University, Masaryk University, Faculty of Science, RECETOX, Brno, Czech Republic, (2)Masaryk University, Czech Republic, (3)RECETOX, Masaryk University, Faculty of Science, Brno, Czech Republic

Organophosphorus flame retardants (OPFRs) have been consistently detected in increasing concentrations in the environmental and human matrices. Growing evidence suggests that numerous health hazards are associated with exposure to OPFRs, including metabolic disease. However, the underlying mechanisms linking exposure with metabolic pathologies remain poorly understood. In the present study, we used human liver cell culture (monolayer and 3D spheroids) to characterize the toxicological effects and potential mechanisms for OPFRs-mediated metabolic disruption. We employed an *in vitro* bioassay toolbox to assess the key events (KEs) in the proposed adverse outcome pathways (AOP) for liver toxicity (hepatic steatosis). We examined nine OPFRs through *in vitro* bioassays for lipid accumulation, mitochondrial dysfunction, expression of several genes related to lipid metabolism and utilized the *in silico* approach to identify the putative molecular initiating events (MIEs). Our findings suggest that the aromatic (aryl-) OPFRs, i.e., tricresyl phosphate (TMPP), triphenyl phosphate (TPHP), 2-ethylhexyl diphenyl phosphate (EHDPP), and the chlorinated OPFR, tris(1,3-dichloropropan-2-yl) phosphate (TDCIPP) induced the lipid accumulation in human liver cell culture by altering the expression of genes encoding for hepatic lipogenesis and mitochondrial dysfunction. Available data from ToxCast and *in silico* molecular docking suggested pregnane X receptor (PXR) and peroxisome proliferator-activated receptor-gamma (PPAR γ) as potential MIEs. Moreover, EHDPP-mediated dysregulation of hepatic lipidome was also observed in human 3D hepatospheroids. Several lipid classes, including sterol lipids, sphingolipids, glycerolipids, glycerophospholipids, and fatty acyls, were disrupted after EHDPP exposure. In summary, our study identifies several OPFRs as a potential risk factor for metabolic pathologies and hazardous for the environment and human health. It also demonstrates the utility of an AOP-based strategy for screening, prioritizing chemicals, and elucidating the molecular mechanisms of toxicity. **Acknowledgments:** Supported by the EU H2020 program under the Marie Skłodowska-Curie grant agreement No. 859891 (PRORISK).

1.02.P-Th034 Effects of 2,4-D Application on Early LIFE Stages of Fish: Bridging Laboratory and Field Work

Gavin Dehnert and William Karasov, University of Wisconsin, Madison, United States

Invasive, non-native aquatic species like Eurasian watermilfoil (*Myriophyllum spicatum*) are rapidly spreading across the United States. One common active ingredient used to control this invasive species is 2,4-Dichlorophenoxyacetic acid (2,4-D). Application of 2,4-D to aquatic environments typically occurs while many freshwater fish are spawning and due to 2,4-D stability in the water column of lakes, many non-target species experience prolonged exposure throughout embryogenesis and larval development. Recent laboratory research has shown that ecologically relevant concentrations of 2,4-D can negatively impact multiple species of freshwater fish species at different points during ontogeny, however, it is poorly understood whether these laboratory results accurately predict impacts in the more complex environment of natural lakes undergoing normal practices of 2,4-D application. Therefore, we investigated the effects of 2,4-D whole-lake treatments on the development and survival of fathead minnows in

lakes undergoing treatment using mobile, in situ, and laboratory exposure systems. We also examined how specific water parameters could alter the toxicity of 2,4-D on the development and survival of fathead minnows. Fathead minnow larvae were exposed to either control lakes or lakes undergoing 2,4-D whole-lake treatment and effects on morphology, survival, and growth were evaluated. Our results demonstrate that exposure of fathead minnow larvae to EPA-permitted 2,4-D whole-lake treatments reduced survival as compared to control lakes which was similar to our previous laboratory results, however, the magnitude of the deleterious effects can be altered specific water parameters (e.g. pH). Altogether, our results shed light on the broader environmental costs of 2,4-D application on non-target organisms, which can help inform and improve risk assessment decisions.

1.02.P-Th035 Toxicogenomic Responses Following Early Life-Stage Lead Exposure Precede and Predict Phenotypic Adverse Outcomes in the Amphibian, *Xenopus laevis*

Markus Hecker¹, Shreyas Jois², Summer Selinger¹, Alper James Alcaraz¹, Shakya Kurukulasuriya¹, Anita Masse¹, Jessica Ewald³, Jianguo Xia⁴, Doug Crump⁵, Nil Basu³ and Natacha Hogan², (1)University of Saskatchewan, Canada, (2)University of Saskatchewan, Saskatoon, Saskatchewan, Canada, (3)McGill University, Canada, (4)McGill University Macdonald Campus, Canada, (5)Environment and Climate Change Canada, Canada

Current standardised protocols employed to generate amphibian-specific data for chemical hazard assessment are reliant on tests that use a large number of animals. However, there is a gradual shift toward new approach methods (NAMs), including using short-term early life-stage (ELS) exposures coupled with transcriptomic responses to identify specific molecular toxicity pathways that precede and contribute to the adverse effects of chemicals. The objective of this research was to determine if such an approach could identify early toxicological mechanisms of lead (as a model compound and environmentally relevant metal) and predict apical outcomes of ecological relevance for amphibians. In brief, embryos were exposed at 48 hours post-fertilization (hpf) to 70, 210, or 630 µg/L lead nitrate (Pb(NO₃)₂) for three weeks. Tadpoles in the high lead group (630 µg/L) had reduced total body length and increased incidence (46.3%) of developmental abnormalities at the end of exposure. Analysis of toxicogenomic data (RNASeq) after 96 h of lead exposure revealed 328 significantly dysregulated genes including those related to DNA repair, cell cycle, apoptosis, immune function and metabolism. While the phenotypic response (developmental abnormalities) was only seen at the highest lead exposure concentration, there were common dysregulated metabolic pathways at both lead concentrations indicating their mechanistic contribution to the altered growth and developmental abnormalities observed in this study. Results from targeted gene expression analysis conducted using a XL EcoToxChip, a species-specific gene expression array, supported the RNASeq data with high concordance between the two platforms in terms of identified dysregulated pathways and technical performance. This study demonstrates how gene expression profiling can help identify molecular mechanisms of chemical toxicity in ELS amphibians and could be used to screen chemicals with the potential to cause adverse outcomes. This study is part of the EcoToxChip project (www.ecotoxchip.ca).

1.02.P-Th036 Identification and Toxicity Assessment of Potentially Toxic Cyanobacterial Metabolites From Two Brazilian *Microcystis* Strains

Mariana de Almeida Torres¹, Ernani Pinto², Martin Jones³, Colette Michèle vom Berg⁴ and Elisabeth Janssen⁵, (1)Universidade de Sao Paulo, Brazil, (2)CENA/USP, Brazil, (3)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (4)Eawag Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (5)Eawag, Switzerland

Anthropogenic contaminants seriously threaten aquatic ecosystems, yet, natural toxins represent a permanent risk to the aquatic biota. Cyanobacterial blooms are a worldwide concern due to their ability to synthesize a wide variety of bioactive secondary metabolites (so-called cyanopeptides), and only a few classes have their toxicological potential elucidated - such as the microcystins. Nevertheless, the risk associated with most of the cyanopeptides classes in aquatic environments and drinking water remains overlooked. To explore the risk of cyanopeptides, we used the zebrafish (*Danio rerio*) in early life stages. Larval fish survival and changes in morphology were assessed for 120h exposure to HPLC-purified extracts of two different cyanobacterial species commonly found in bloom episodes in Brazil (*M. aeruginosa* - NPCD-01 strain – and *M. panniformis* - MIRS-04 strain). The cyanobacterial extracts were first fractionated by HPLC, and the fractions analysed by LC-HRMS to identify the set of peptides present in each fraction of each strain. Acute toxicity towards the zebrafish embryos was studied for the pooled HPLC fractions (aiming to study the toxicity of the whole extract) and one single fraction containing a predominant peptide (>90% of total peptides). The Fish Embryo Toxicity tests were performed with the samples dissolved in dilution water, following the OECD Guideline 236 (2013). LC-HRMS of both cyanobacterial extracts showed that the MIRS-04 strain produces microcystins (hepatotoxins) and cyanopeptolins, which are mainly known for inhibiting serine proteases. As for the NPCD-01, a microcystin non-producer, the most abundant cyanopeptides produced by this strain are microginins (proteases inhibitors), with reports of genotoxicity towards *Allium cepa* and toxicity against crustaceans (LC50 values in the low mg/L range). When exposed to the pooled fractions, fish mortality increased with concentration, pointing to acute toxicity for both strains in the same comparable low micromolar range. Fish mortality observed in the experiment with the isolated from the MIRS-04 strain (containing Micropeptin K139) indicates that the toxicity is not only attributed to the presence of microcystins, and this is also proved by the results with the NPCD-01 strain, which was as toxic as the MIRS-04 extract, even though it does not produce microcystins.

1.02.P-Th308 Adverse Outcome Pathway Guided Hazard Assessment of Mitochondrial Uncouplers: A Tiered Testing Strategy Using Zebrafish In Vitro Assays and Embryo Toxicity Assays

Maria Christou¹, Maria T. Hultman², Camila Esguerra³, Adam Lillcrap⁴ and You Song⁵, (1)NIVA - Norwegian Institute for Water Research, Norway, (2)Norwegian Institute for Water Research, Oslo, Norway, (3)University of Oslo, Norway, (4)NIVA, Norway, (5)Norwegian Institute for Water Research (NIVA), Oslo, Norway

Oxidative phosphorylation (OXPHOS), that takes place in the mitochondria, is the primary metabolic process that produces

energy in the form of ATP. Chemicals that cause mitochondrial dysfunction, by uncoupling OXPHOS can lead to adverse effects of regulatory concern such as growth inhibition. In ecotoxicity assessments the need for transition from traditional animal toxicity tests to alternative testing strategies is encouraged by various chemical regulatory frameworks (e.g. REACH). This study aims to utilize the adverse outcome pathway (AOP) concept and animal alternatives to develop a tiered testing strategy for hazard assessment of mitochondrial uncouplers. For this purpose, a suite of high-throughput zebrafish *in vitro* assays and embryo toxicity assays have been developed, with the guidance from the newly published AOP linking the uncoupling of OXPHOS to growth inhibition, via a reduction of ATP pool and cell proliferation (OECD project #1.92, AOPWiki, AOP #263). The *Danio rerio* embryos, ZF-L and PAC2 cells were used for AOP-guided hazard assessment. Zebrafish cells and embryos were exposed to the known mitochondrial uncoupler carbonyl cyanide 3-chlorophenylhydrazone (CCCP). *In vitro* and *in vivo* assays were conducted to generate temporal and concentration-response data for the key events defined in the AOP. The initial results showed a decrease in coupling of OXPHOS, ATP pool and cell proliferation in zebrafish cells. Anchoring the effects at the cellular level, the growth of zebrafish embryos exhibited a concentration-dependent decrease after 96 h exposure to CCCP. Survival of zebrafish embryos was also affected by CCCP. The bioassays for measuring the earlier key events in the AOP will also be performed and compared with the *in vitro* results. The present study shows that three out of four key events in AOP 263 could be measured using both *in vitro* and embryo assays. The two test systems displayed different sensitivities to the model uncoupler CCCP. The results will be used to develop a tiered *in vitro-in vivo* testing strategy for more efficient assessment of mitochondrial toxicity and the construction of a quantitative AOP (qAOP) based on AOP 263. Chemical analysis will also be performed to support *in vitro* to *in vivo* extrapolation. *Acknowledgement* - This study was funded by the Norwegian Research Council (project 301397, www.niva.no/en/projectweb/riskaop) and supported by the NIVA Computational toxicology Program (www.niva.no/en/projectweb/nctp).

1.02 Alternative Approaches to Animal Testing for Ecotoxicity Assessments: Exploring Approaches and Avenues for the Future (Virtual Only)

1.02.V-01 A Novel Approach Using *Thraa* α - and *Dre-Mir-499* α - Zebrafish for Screening the Thyroid Endocrine Disruptor

*Inhye Lee*¹, *Suhyun Park*² and *Kyunghee Ji*¹, (1)*Yongin University, Korea, Republic of (South)*, (2)*Seoul National University, Korea, South*

A number of bioassays are commonly used to detect estrogenic and androgenic chemicals in the environment. However, *in vivo* screening tools to identify thyroid endocrine disruptors are generally limited, and most assays cannot provide information on toxic mechanism of a given chemical. In the present study, we aimed to establish a sensitive and rapid screening tool capable of characterizing the mechanisms of thyroid endocrine disruption. We developed a novel *in vivo* thyroid endocrine disruptor screening system employing wild-type, thyroid hormone receptor alpha a knockout (*thr α -/-*), and *dre-miR-499* knockout (*dre-miR-499-/-*) zebrafish embryo. In addition, we verified the validity of this assay using T3, propylthiouracil, and thiamazole. Thyroid endocrine disruptors were successfully screened based on a comparison of larval survival between wild-type and knockout zebrafish embryo/larvae within 96 h. The combination of our *in vivo* screening assay and subsequent characterizations will be a valuable source of information for thyroid endocrine disruptor profiles. *Acknowledgement*: This study was supported by National Research Foundation of Korea (NRF; Project no. 2019R1A2C1002712).

1.02.V-03 Are Global Standard Test Species Suitable for Environmental Risk Assessment of Crop Protection Products in Tropical Environments?

*Alexandra Tscheschke*¹, *Eric Bruns*¹, *Lucilene Yuriko Murakami*¹, *Gustavo Souza Santos*², *Michael Hamer*³, *Carolina Wolff*⁴ and *Peter Dohmen*⁵, (1)*Bayer Crop Science, Germany*, (2)*Syngenta Crop Protection, Brazil*, (3)*Syngenta Ltd, United Kingdom*, (4)*BASF SA, Brazil*, (5)*(None)*

World-wide data requirements for ecotoxicological risk assessments require initial laboratory testing of pesticides to assess their toxicity to aquatic species. Clearly not all aquatic species world-wide can be tested. Thus, surrogate species of fish, aquatic invertebrates, and primary producers are tested, using standard protocols, for assessing the risks of pesticides. These surrogate, standard test species, representing the different trophic levels, have been chosen based on several criteria including sensitivity, ecological relevance and availability. However, they were not chosen based on geographical distribution. Therefore, this study evaluates whether these standard test species, already used in many parts of the world, are suitable for use in risk assessments for tropical environments. Data for tropical fish, invertebrate and primary producer species were extracted from the supplemental material by Wang et al. (2019), the USEPA ECOTOX database and peer reviewed literature. For each pesticide, the most sensitive regulatory endpoint for fish, invertebrates and primary producers was selected. The ratios of the endpoint for the tropical species and for the most sensitive regulatory endpoint for the appropriate taxonomic group were determined. Values > 1 indicate that the tropical species are less sensitive than the respective standard regulatory species. In total toxicity endpoints for more than 40 different pesticides on more than 150 different tropical species were collected and assessed. In 96.3% of the evaluated fish data, the tropical fish species were less or similar sensitive (within a factor of 5) than the standard fish species. For the aquatic invertebrates, 93.9% of the evaluated tropical species were less or similar sensitive compared to a standard species. For primary producers, for 96.6% of the evaluated data the toxicity ratio of the tropical and the standard species endpoints resulted in values >1. Overall, in more than 95% of the data comparisons between tropical and standard aquatic species the standard species were more or similar sensitive. In conclusion it can be stated that, for the data set under investigation it was demonstrated that data derived from standard test species were also suitable for use in risk assessments in tropical regions.

1.02.V-04 Avoidance Tests As an Ethical Ecologically Relevant Alternative to Fish and Amphibian Lethality Tests for Chemicals Registration

Matilde Moreira dos Santos¹, Cristiano Araujo², Isabel Lopes³ and Rui Ribeiro⁴, (1)CFE - Centre for Functional Ecology, Portugal, (2)Consejo Superior de Investigaciones Científicas, Spain, (3)University of Aveiro, Aveiro, Portugal, (4)University of Coimbra, Portugal

Despite recent advancements in the search for alternatives to minimize animal testing (e.g. OECD 249), in the tier 1 environmental risk assessment (ERA) for the registration of chemicals fish lethality tests (e.g. OECD 203) are still among the most widely conducted ecotoxicity tests. Ethically, welfare concerns for animal suffering are self-evidently, as the aim is to determine the concentration required to kill 50% of fish, with large numbers of animals being used. Similar welfare concerns arise concerning amphibian toxicity tests, even if they are not yet implemented at the regulatory level, given that from the five available standard guides for amphibian assays only one (ASTM E1439-98) does not involve animal experimentation (*sensu strictu* do not use life stages with any independent feeding). From the traditional toxicological perspective, these forced exposure tests confining organisms to a constant contaminant concentration are designed to derive precise cause-effect relationships needed to best estimate risks of environmental impairment. However, from an ecological perspective, an unreliable level of risk is most likely produced because many fish and amphibian species are known to detect unfavorable conditions and spatially avoid disturbed habitats. Consequently, natural populations can become locally extinct, before any organism dies, because individuals promptly detect and emigrate. Contaminants may act thus as habitat disturbers regulating fish and amphibian dispersion patterns, by provoking emigration from disturbed habitats; but at chemical concentrations well below those that would be estimated as lethal in tier 1 ERA. To halt animal distress, pain and suffering, while gaining ecological relevance in ERA at the ecosystem and landscape level, as urged by many EU legislation (e.g. Directive 63/2010, REACH), the present study intends to review already existing data on avoidance tests with fish and amphibians exposed to a contamination gradient in a design amenable to standardization; being the ultimate goal to discuss the value of implementing avoidance tests as a tool and ultimately ban lethal testing in the ERA for chemicals. Avoidance tests are thus a key alternative ecotoxicity refinement tool to integrate the 3Rs (Replacement, Reduction, Refinement) policy, as well as the new 3Rs (Reproducibility, Relevance, applicability for Regulatory use), in the tier 1 toxicity tests without compromising environmental protection.

1.02.V-05 Daphnia magna As an Alternative Model to Evaluate Toxicity for Eicosanoids Pathway

Sangwoo Lee¹, Kojo Eghan² and Wookeun Kim¹, (1)Korea Institute of Toxicology (KIT), Korea, South, (2)Korea Institute of Toxicology, Korea, South

Eicosanoids play an important role in inflammation, allergy, fever and immune responses. In the eicosanoids pathway, cyclooxygenase (COX) catalyzes the conversion of arachidonic acid to prostaglandins (PG) and is a crucial target of painkiller pharmaceuticals, i.e., COX inhibitors. Thus, toxicological study on eicosanoids pathway is important for new painkiller drug discovery and also for the evaluation of adverse health outcome by environmental contaminants. However, the experimental models are very limited. This study was to develop an alternative model for evaluating toxicity on eicosanoids pathway. To this end, we used *Daphnia magna* model as alternative model. In this present study, COX inhibitors, such as celecoxib, naproxen and mefenamic acid, were chosen. *Daphnia magna* was exposed to those chemicals for 24 h. The analysis of related gene transcriptions (*COX*, *pla2*, *PGDsyn*, *LTB4dh*, and *LOX*) by qPCR were followed. In addition, the concentration of eicosanoid molecules, such as arachidonic acid and prostaglandins, were analyzed by LC-MS/MS. Multiple reaction monitoring was used for the selective quantification of target molecules. After the exposure, transcriptions of the *LTB4dh* and *COX* genes were up-regulated. In addition, the whole-body level of arachidonic acid which is converted by COX was increased by the three COX inhibitors. From the gene transcriptions and eicosanoid molecules analysis, it is shown that *D. magna* has similar eicosanoids pathway with other vertebrate models. This might show the plausibility of *D. magna* as an alternative model to assess the toxicity of the eicosanoids pathway.

1.02.V-06 Development of LOW Invasive Methods for Biomarkers Assays in Amphibians: Tests on the Saliva

Loïc Cattin¹, Laurent Boualil², Brigitte Guillet³ and Nathalie Chevre⁴, (1)University of Lausanne, Lausanne, Switzerland, (2)Institute of Earth Surface Dynamics, University of Lausanne, Lausanne, Switzerland, (3)University of Rennes 1, France, (4)University of Lausanne, Switzerland

Worldwide biodiversity is declining at an unprecedented rate with amphibians being the most threatened vertebrate group. A major cause of their decline is the exposure to human related contaminants released into the environment. However, few ecotoxicology articles are published on amphibians each year. Due to their terrestrial and aquatic lifecycle, they can be exposed to many contaminants. This may be the case with pesticides application in fields, if individuals are present, or in the vicinity. It can also occur later, if the molecules or its degradation products are persistent enough to be transported by runoffs to the water bodies. Amphibians can therefore be impacted at all stages of their lives and their permeable skin makes them vulnerable to the absorption of undesirable molecules. Biomarker measurement makes it possible to look at individuals' exposure to contaminants by looking at molecule's activity variations in the organism. For example, the exposure to contaminants can generate a change of detoxifying¹ or regulatory² enzyme's activity and confirm that the individual's body is under stress. In 2017, searchers (Mingo *et al.*) used common wall lizards' saliva to measure biomarkers. They detected an activity difference before and after they were exposed to pesticides. This minimally invasive method follows the 3RS principles which aims to reduce, refine and replace animal use in science. Moreover, it allows for fast sampling with buccal swabs and does not require organs' recovery from euthanised individuals. In the present study, we used amphibians' saliva and liver samples and measured three enzymatic biomarkers (GST¹, EROD¹, AChE²). The experiment was made on *Xenopus laevis* raised in laboratory conditions. These organisms were euthanized for technical reasons and we tried to get as much data as possible from those, following the 3RS rules. We also collected

Ichthyosaura alpestris saliva samples in the field. All biomarkers were detected in liver samples, whereas only GST and EROD were in saliva samples. From this dataset, the aim was 1) to assess whether saliva can be used to predict changes in enzyme activity in the liver which is a key organ for the body detoxification 2) to see if morphological traits (size, weight) influence biomarkers' activity. First results show that some biomarkers can be detected in saliva. Its use could replace more invasive methods when possible and facilitate the sample collection in laboratory and in the field.

1.02.V-07 Dichlorvos (DDVP) Pesticide Toxicity on 3 Species of Fishes

*Alma Sobrino-Figueroa*¹, *Alberto Perez-Rojas*² and *Sergio Alvarez-Hernandez*², (1)Universidad Autonoma Metropolitana, Mexico, (2)Autonomous Metropolitan University-Iztapalapa, Mexico

The pesticide Dichlorvos (DDVP) is an organophosphate compound, used for the control of ectoparasites in fish, considered by the EPA as highly toxic. Because studies on the effects of this product in fish are scarce, the objective of this work was to evaluate its toxicity and their effects on 3 biomarkers: growth, lipid peroxidation (lipoperoxidation) and the activity of the acetylcholinesterase (AChE) enzyme in *Chirostoma jordani*, *Danio rerio* and *Poecilia* sp. Initially, a test with duration of 96 hours was carried out where the juveniles of the different species were exposed to 5 concentrations of the pesticide to determine the lethal concentration 50. Subsequently, a bioassay with a duration of 10 days was carried out where the fish (juveniles) were exposed at 2 sublethal concentrations (LC₁ and LC₅), at the end of the exposure period the biomarkers were evaluated (n = 10). The LC₅₀ values obtained in the toxicity bioassays ranged from 4.82 ± 1.95 mg L⁻¹ to 0.0013 ± 0.00067 mg L⁻¹, *Chirostoma jordani* was the most sensitive species to DDVP. The growth rates of the exposed organisms were between 19 to 75% lower than those observed in the control group. There was a decrease of between 21 to 80% in the activity of the enzyme AChE and the degree of lipoperoxidation in the tissues increased up to 180%. The pesticide used in this work is not very persistent in the environment but the results of this study indicate that its effects in sublethal concentrations were irreversible, because the organisms do not feed.

1.02.V-08 Evaluation of Tissue Integrity and Lipid Distribution in the Liver Tissue of Fish *Poecilia reticulata* After Exposure to Iron Oxide and Glyphosate Nanoparticles

*Victoria Costa da Silva*¹, *João Marcos Faria*¹, *Lucas Guimarães*¹, *Ryan Rezende*², *Thamires Arantes Sardinha*², *Gustavo Cardoso*³, *Lucas Camilo Moraes Alves*¹ and *Simone Sabóia-Moraes*³, (1)Federal University of Goiás, Brazil, (2)ICB UFG, Brazil, (3)Universidade Federal de Goiás, Brazil

Iron oxide nanoparticles (IONP) have been investigated as potential tools for environmental remediation, as they are magnetic and present, when functionalized, the surface capacity to adsorb glyphosate, as described in the literature. Thus, it is necessary to evaluate the toxicity of the association of IONP and glyphosate in aquatic organisms. For this purpose, 7 female fish of the species *Poecilia reticulata* were tested in triplicate, exposed for 7, 14 and 21 days to the treatments: 1) ferric chloride (FeCl₃) in 0.3 mg L⁻¹ (IFe) - as a dissolute part of IONP; 2) IONP+GBH1: 0.3 mgFe.L-1 IONP + 0.65 mgGLY.L-1 (GBH); 3) IONP+GBH2: 0.3 mgFe.L-1 IONP + 1.30 mgGLY.L-1; and 4) IONP+GLY: 0.3 mgFe.L-1 of IONP + 65 mg. Glyphosate P.A L-1 (GLY) and a control group (GC) was maintained. After that, part of the animals remained for 7, 14 and 21 days in reconstituted water for recovery. All were euthanized and dissected, liver samples were fixed in 2.5% glutaraldehyde, post-fixed in 1% OsO₄ solution, embedded in Epon 812 resin, sectioned 0.5 μm thick and stained with toluidine blue or hematoxylin for lipid labeling and tissue integrity assessment. In GC animals, lipids were distributed in droplets significantly smaller and more dispersed than in treated ones. On the other hand, in animals treated with IFe, IONP+GLY and IONP+GBH there was the formation of circulatory, regressive and progressive changes that indicated high inflammatory activity during exposure, which was confirmed by the presence of sites of melanomacrophages with lipofuscin zones in large quantities, mainly in the IFe group and due to the increase in the size and volume occupied by the lipid droplets in the IONP+GLY and IONP+GBH treatments, already during the post-exposure the lipid droplets decreased in size over time, and there was a reversal of the inflammatory changes. Coming to the conclusion that exposure to IONP associations with GLY and GBH were hepatotoxic to guppies, but these fish were able to recover after 21 days of exposure. The analysis of cell and tissue biomarkers contributed to the understanding of toxicity, as well as in resilience of aquatic organisms exposed to associations in order to support the development of safe environmental remediation practices.

1.02.V-09 High-Throughput Ecotoxicology With a Rainbow Trout Gill Cell Line

*Johanna Nyffeler*¹, *Felix Harris*², *Christopher Schaupp*¹, *Steven Lasee*³, *Clinton Willis*⁴, *John Nichols*¹, *Brett Blackwell*¹, *Kevin Flynn*¹, *Daniel L. Villeneuve*¹ and *Joshua Harrill*⁴, (1)U.S. Environmental Protection Agency, United States, (2)ORAU student contractor at USEPA, United States, (3)ORISE grantee at USEPA, United States, (4)USEPA, United States

The United States Environmental Protection Agency's tiered hazard evaluation strategy is currently human-centric and does not include high-throughput (HT) in vitro assays for ecotoxicologically-relevant species. In 2021, the Organisation for Economic Co-operation and Development adopted test guideline 249 (OECD TG249) for cell viability testing in rainbow trout gill cells (RTgill-W1). Adjusting the assay results for in vitro disposition and conducting in vitro to in vivo extrapolation, excellent correlation to in vivo survival data was found. At present the assay is conducted in 24-well plates, which limits throughput. The goal of the present study was to miniaturize the assay to 384-well format while following OECD TG249 to the extent possible. Moreover, imaging-based HT phenotypic profiling (HTPP, 'Cell Painting') will be conducted in parallel to obtain information about sub-cytotoxic bioactivity of chemicals. RTgill-W1 cells were successfully expanded. One day after plating in 384-well format, media was exchanged, and cells treated with chemicals. After 24 h of exposure, viability stains (alamar blue, CFDA-AM, neutral red) were applied and measured using a plate reader. HTPP plates were labeled to visualize seven different cellular structures, followed by imaging and quantification. In a preliminary experiment, the positive control chemical 3,4-dichloroaniline affected cell viability at

500 uM, but phenotypic changes were already apparent at 5 uM. The established assay will be used to screen a set of 231 environmental chemicals. Of those, 128 have available rainbow trout in vivo toxicity data, 60 have been used in rainbow trout in vitro experiments, 110 have been tested in the HTPP assay in human U-2 OS cells and 29 were detected in the Great Lakes. For all chemicals, nominal in vitro points-of-departure (POD) will be estimated. Adjusting for in vitro disposition and applying HT toxicokinetics, this POD will be extrapolated to chemical concentrations in water used for in vivo exposures. For 12 compounds, chemical concentrations found in the different compartments will be analytically measured. To conclude, a low cost, HT test system suitable for screening large libraries of chemicals for cytotoxicity and phenotypic effects to fish gill cells was established. This expands the current first tier of the hazard evaluation strategy with inclusion of the first ecologically relevant species. *This abstract does not reflect USEPA policy.*

1.02.V-10 Investigations on Fish Acute Toxicity of Fragrance Ingredients, Involving the Chinese Fish Species and the Zebrafish Embryo

Zhimin Zhou¹, Yunfei Bai², Tenghui Su², Dainan Zhang², Zhen Wang³, Frederic Begnaud⁴, Sylvia Gimeno⁵ and **Jing You**⁶, (1)School of environment, Jinan University, China, (2)Jinan University, China, (3)Marine Biology Institute Science Center Shantou University, China, (4)Firmenich, Switzerland, (5)Firmenich SA, Belgium, (6)Jinan University, Guangzhou, China

While toxicity data with zebrafish (*Danio rerio*) have been routinely used and accepted worldwide for evaluating the risk of chemicals to aquatic vertebrates, the recent Order of the Ministry of Ecology and Environment of China now requires to generate fish toxicity data in a local laboratory and with the local species Chinese rare minnow (*Gobiocypris rarus*). This represents an additional regulatory constraint that may result in redundant testing, additional animal uses and costs since the Chinese rare minnow is not part of OECD recommended fish species. A recent review concluded for this dataset that juvenile Chinese rare minnow is more sensitive than the zebrafish juveniles and embryos, especially to metals and that tests with zebrafish embryos could serve as an alternative for the juvenile fish acute toxicity test across fish species. In order to understand the application to fragrance ingredients, we have selected 29 fragrance ingredients belonging to various chemical classes and with a variety of physicochemical properties, for which good quality zebrafish acute toxicity data were available and tested them according to the OECD TG 203 with juvenile *G. rarus* and to the OECD TGD 236 with embryo *D. rerio*. Both chemical toxicity distribution (CTD) and chemical ratio distribution (CRD) models were established to systematically compare the sensitivity among juveniles of *G. rarus* and *D. rerio*, as well between *D. rerio* embryos and juveniles. The results of CTD models showed that for the fragrance ingredients tested, the sensitivity of juvenile *G. rarus* was similar to that of juvenile and embryos of *D. rerio*. In addition, the similar sensitivity of juvenile and embryos of *D. rerio* to fragrance ingredients confirms the suitability of replacing juvenile with zebrafish embryos. The CRD comparisons reveal that juvenile *G. rarus* was less sensitive by a factor of ~2 to juvenile *D. rerio* for ingredients belonging to the Verhaar-Class 3 and ECOSAR-Esters class. The outcome of this comparative experiment supports so far our earlier literature review that concludes the fish toxicity data with *G. rarus* can be used in chemical registrations outside China, and that there is no scientific justification to repeat animal tests.

1.02.V-11 Is a Water Control Needed in Fish Early Life Stage Toxicity Studies Using Solvents?

John Green¹, **Christopher Fassbender**², Gilly Stoddart³ and Lennart Weltje, Prof. Dr.⁴, (1)JohnWGreen-ecostats.com, United States, (2)PETA Science Consortium International e.V., Germany, (3)PETA Science Consortium International e.V., United Kingdom, (4)Ecotoxicology, BASF SE, Germany

A team of scientists in the European Union and the United States led by the PETA Science Consortium International e.V. has been exploring whether both water (negative) and solvent controls are needed in aquatic studies that use solvents. A database of toxicity endpoints for multiple species and solvents has been evaluated for systematic differences between the water and solvent controls and to develop representative dose-response curves. Extensive computer simulations were conducted to determine the potential impact on EC_x estimation and NOEC values of using only the solvent control in fish early life stage (FELS) toxicity studies that use solvents. The design of the simulation study drew on previous research by numerous authors with regard to the effects of solvents at the levels allowed in FELS studies. The collected database comprises a minimum of three species of fish (Fathead Minnow (*Pimephales promelas*), Sheepshead Minnow (*Cyprinodon variegatus*) and Rainbow Trout (*Oncorhynchus mykiss*)) and three solvents (dimethylformamide (DMF), acetone, and triethylene glycol (TEG)). The study explored all response variables required in FELS toxicity studies including hatching success, time to hatch, time to swim-up, larval survival (intermediate and total) and abnormalities, and fish length and weight at study end. Computer simulations covered the observed ranges of variability (including heterogeneity or overdispersion) and concentration-response shapes in each type of response across species. The study explored both model selection and model averaging for EC_x estimation including standard normality-based models and generalized non-linear mixed models. Standard normality-based hypothesis tests (Williams and Dunnett, Cochran-Armitage), non-parametric methods (step-down Jonckheere-Terpstra and Dunn) and generalized linear mixed models provided NOEC values; the analysis adjusted both NOEC and EC_x for overdispersion or variance heterogeneity. Analysis of each simulated dataset included (a) pooled water and solvent control, (b) water control only, and (c) solvent control only, to give side-by-side comparison of results (NOEC or EC_x) using the three choices for control(s). The findings from this work will inform whether two controls are necessary for FELS studies.

1.02.V-12 Morphological and Functional Characterization of Brown Trout Primary Hepatocyte Spheroids As a Tool for Toxicological Studies

Rodrigo Alves¹, Célia Lopes², Prof. Eduardo Rocha² and **Tânia Madureira**³, (1)ICBAS - U.PORTO, 4050-313 Porto, Portugal, (2)ICBAS and CIIMAR, University of Porto, Portugal, Portugal, (3)CIIMAR and ICBAS, University of Porto, Portugal, Portugal

Monolayer cultures obtained from fish primary hepatocytes have been used either to test the mechanistic effects of chemicals or to

assess compound's toxicity in the liver. Three-dimensional (3D) systems have emerged as models that can better mimic *in vivo* conditions, an obvious advantage over traditional two-dimensional (2D) cell cultures. In fish, the establishment of 3D hepatocytic models is not as developed as in mammals. Therefore, there is still a long way to go towards expanding these models to more fish species and to better characterize those 3D cultures. In this study, it was established a long-term culture of primary brown trout hepatocyte spheroids obtained from 1 year-old brown trout (*Salmo trutta fario*) juveniles by using a two-step collagenase perfusion procedure. The aim was to obtain a 3D fish hepatocytic model with a well-defined timeline characterization in terms of morphology and functionality. Brown trout primary hepatocyte spheroids were maintained in culture along 25 days post-isolation at 18 °C, without additional supply of O₂/CO₂ and at constant agitation (± 100 rpm). Hepatocytes were plated at a density of 5×10^5 cells/mL in 6-well microplates using 3 mL of DMEM/F-12 with 15 mM HEPES, 1% of antibiotic/antimycotic solution and 10% charcoal FBS. Sampling was performed at days 8, 12, 16, 20 and 25 post-isolation. At each time point, a defined number of spheroids were photographed under a light microscope and biometric parameters such as diameter, area and sphericity were obtained using the AnaSP software. Hepatocyte viability was checked in all sampling days by using lactate dehydrogenase and resazurin assays. To evaluate the general hepatocyte morphology, spheroids were fixed in formaldehyde, submitted to a routine histological processing and stained with hematoxylin and eosin. Quantitative real time-polymerase chain reaction (RT-PCR) was used to monitor the potential changes in the mRNA levels of a selection of functional target genes, namely in terms of hepatic metabolism and transport. Our study contributes to a better comprehension of morphology and functionality of brown trout primary hepatocyte spheroids allowing a more detailed knowledge of this model with great potential to be used in toxicological studies. **Funding:** Supported by FCT and ERDF (UIDB/04423/2020 and UIDP/04423/2020) and ICBAS.

1.02.V-13 Species and Life Stage Sensitivity of Chinese Rare Minnow (*Gobiocypris rarus*) to Chemical Exposure: A Critical Review

Yunfei Bai¹, Tenghui Su¹, Dainan Zhang¹, Zhen Wang², Sylvia Gimeno³ and Jing You⁴, (1)Jinan University, China, (2)Marine Biology Institute Science Center Shantou University, China, (3)Firmenich SA, Belgium, (4)Jinan University, Guangzhou, China

Chemical production and consumption in Asia are increasing at an unprecedented rate, calling for advancing regulations for chemical management. Under the New Chemical Substance Notification in China, information on ecotoxicological effects of chemicals is mandatory for the simplified registrations of chemicals with the requirement that one ecotoxicological test is conducted locally. It is now mandatory to use the native fish species, Chinese rare minnow (*Gobiocypris rarus*). However, its chemical sensitivity compared to that of standard fish species, such as the fathead minnow (*Pimephales promelas*) or zebrafish (*Danio rerio*) is still unclear. Here, we performed a holistic literature review on fish toxicity data from 1997 to 2020. Species sensitivity among *G. rarus*, *P. promelas* and *D. rerio* and life stage sensitivity of *G. rarus* were systematically investigated for various chemicals using both chemical ratio distribution and probabilistic chemical toxicity distribution approaches. Comparatively, the Chinese native fish species, *G. rarus* was more sensitive than *D. rerio*, particularly to metals. Juvenile and adult *G. rarus* were more sensitive than its larva and embryos. The observed lower sensitivity of *G. rarus* embryo was likely due to the thick embryonic chorion, discrepant methods to collect embryos and paucity of toxicity data, implying the necessity to standardize *G. rarus* embryo tests and validate the sensitivity with various types of chemicals. This unique review allows to conclude that *G. rarus* studies could be used in worldwide registrations and that further investigations are needed to use *G. rarus* embryos as alternatives to the fish test.

1.02.V-14 Sublethal Effects of E-Cigarette Vaping Liquid on Zebrafish Larvae: A Preliminary Study

Ines Lacchetti¹, Mario Carer¹, Kevin Di Domenico¹, Walter Cristiano² and Laura Mancin³, (1)Italian Institute of Health (ISS), Rome, Italy, (2)University of Torino, Italy, (3)Istituto Superiore di Sanità, Italy

The use of electronic cigarettes as an alternative to the conventional tobacco cigarette is becoming increasingly frequent even among teenagers and pregnant women. Vaping devices are, among those available on market, more appreciated by many users for their supposed non-toxicity and the possibility to smoke without tobacco. E-cigarette vaping liquids and aerosols actually contain a mixture of many different substances such as diethylene, glycol, formaldehyde, metals and other volatile organic compounds such as benzene and toluene, which could potentially have adverse effects on human health. Furthermore, the massive use of e-cigarettes can also give effects to aquatic ecosystems. The aim of the study is to investigate the potential effects of the e-cigarette liquid with the use of zebrafish. In particular, zebrafish embryos have been exposed to different concentrations of the liquid and to a flavour separately. Several endpoints were considered to evaluate the different modes of action of the substances, such as morphological parameters (teratogenicity), the measurement of heartbeats (cardiotoxicity), the coiling activity tail (CAT) and the locomotor behavior (neurotoxicity). All parameters have been recorded and evaluated through the use of specific softwares. The results underline how the exposure to vaping liquids is cause of several developmental effects in zebrafish embryos, and neurotoxicity has been detected at different concentrations of the products. The study also confirms zebrafish as a good test organism for its sensitivity and versatility. More studies are needed to better understand the toxicity of this electronic devices and in order to protect human health and ecosystems.

1.02.V-15 Towards High Throughput Determination of Biotransformation Rates of Chemical Mixtures Using Isolated Perfused Trout Livers

Matthew Schultz¹, Sophia Krause² and Markus Brinkmann¹, (1)University of Saskatchewan, Canada, (2)Helmholtz centre for environmental research - UFZ, Germany

Bioconcentration factor (BCF) is an important criterion in chemical risk assessment that describes the bioaccumulation potential of chemicals. While BCF as determined from *in vivo* whole-fish exposures is still considered the gold standard to inform this criterion, there is growing concern in academia, governments, and industries about the suitability and reproducibility of this test,

especially for chemicals that are biotransformed. Alternative approaches using *in vitro* biotransformation assays based on hepatocytes or liver sub-cellular fractions in combination with *in vitro-in vivo* extrapolation (IVIVE) models have been developed as potential replacements. However, extrapolation to BCF is complicated by confounding factors, e.g., extrahepatic biotransformation and quality issues with experimental BCFs. Therefore, there is a need for an *ex situ* model at an intermediate level of biological organization. A recently developed method is that of the rainbow trout isolated perfused liver, seeking to reduce uncertainty of extrapolated clearances of chemicals in IVIVE. The present study seeks to obtain hepatic clearance data of five environmental contaminants of interest within the isolated perfused trout liver and cross-validate with prior standardized *in vitro* methods. Livers of sexually immature rainbow trout were cannulated *via* the hepatic portal vein and perfused for up to six hours with a physiological buffer spiked at varying concentrations of pyrene, phenanthrene, 4-*n*-nonylphenol, deltamethrin, and methoxychlor. Afferent and efferent samples were taken in 15-minute intervals across the perfusion period. Samples were analyzed using high-performance-liquid-chromatography with fluorescence detection (HPLC-FLD) and gas-chromatography (GC) to calculate hepatic extraction fraction and clearance. Results demonstrate that this experimental method can be used to validate IVIVE models, as illustrated by the excellent fit of predicted versus measured hepatic clearance values. This study has the potential to settle an important debate in this field and enables scientists to focus on other factors to allow for confident predictions of bioconcentration in fish.

1.03 Computational new approach methods (NAMs) supporting regulatory decision making for chemical safety (Part I)

1.03.T-03 The Source to Outcome Predictor (STOP) - a Conceptual Tool for Next Generation Risk Assessment (NGRA)

Knut Erik Tollefsen¹ and Viviani Girardin², (1)NIVA - Norwegian Institute for Water Research, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway

Knowledge of how single chemicals and their complex mixtures affect organisms, e.g., their mode of action (MoA) and how these perturbations translate into adverse effects (outcomes), is continuously increasing due to extensive bioassay testing activity worldwide. However, generation of such effect data, typically by bioassays ranging from classical (eco)toxicological tests to New Approach Methodologies (NAMs), is rapidly generating disparate data sets that are not easily integrated. Efforts to link MoAs to adverse outcomes at individual and population levels using Adverse Outcome Pathways (AOP) lends a great promise to facilitate such integration, and developing computational approaches to harvest AOP-informed data and conduct quantitative evaluations for mechanistically informed hazard and risk assessment are thus highly warranted. Integration of AOP knowledge, quantitation of the event relationships across the AOP continuum (quantitative AOPs), developing *In vitro* to *In Vivo* Extrapolations (IVIVE) and interpretation of these in terms of ecological exposure relevance are thus quickly becoming a bottleneck for successful use of an ever increasing amount of data. This applies in particular to the transition from single chemical assessment to cumulative hazard (CHA) and cumulative risk (CRA) assessments of “real world” exposure scenarios, where a high degree of complexity reigns and standardised approaches are still lacking. The present work aims to demonstrate how a Source-To-Outcome Pathway (STOP) framework, taking advantage of the Aggregated Exposure Pathway (AEP) to address complex exposures and AOPs to provide weight-of-evidence-based definition of causal relationships between stressors and adverse outcomes across different levels of biological organization, can be supportive of Next Generation Risk Assessment (NGRA). The chosen approach takes advantage of the AOP knowledgebase to identify relevant AOPs for a given exposure scenario and use this to select relevant bioassays and toxicity data from different levels of biological organisation for subsequent use in hazard and risk assessment. A case study representing typical assemblies of priority pollutants and compounds of emerging concern was used to demonstrate the utility of the approach and how an end-user friendly Graphical User Interface can be used to support NGRA. Acknowledgements: RCN 268294 “MixRisk”, and NCTP: NIVA’s Computational Toxicology Program, NCTP (www.niva.no/nctp).

1.03.T-06 Free In Silico Tools to Predict Multiple Properties and Activities by QSAR

Ester Papa, Linda Bertato and Nicola Chirico, University of Insubria, Italy

In the last 20 years, our research group has developed many validated QSARs for the prediction of different endpoints relevant to support the hazard and risk assessment of heterogeneous organic chemicals. As the number of these QSARs increased over time, it became evident that new tools were needed to ease their dissemination and application not only amongst experts, but also among users that are not necessarily QSAR experts. This work is the result of a process, which combines our experience in software development with the most recent progresses of our research in the field of toxicokinetics and PBT profiling. Since 2018 four software have been developed by our research group: QSARINS-Chem standalone version, QSARINS-Chem ECO.44, IVBP-Suite and QSAR-ME Profiler. They have been developed using the Java™ language thus allowing their execution on different platforms like, for example, Windows™, Mac OS™ and Linux. Both the two QSARINS-Chem versions allow for a detailed analysis of individual models and of the predictions generated for multiple endpoints. The *in vitro* Biotransformation Prediction Suite (IVBP-Suite) is dedicated to the prediction of *in vitro* intrinsic hepatic clearance in mammals using reactivity based QSARs and complements the QSARINS-Chem ECO.44 software. IVBP-Suite calculates predictions of multiple models in batch and provides combined output. Finally, QSAR-ME Profiler further expands the concepts of QSARINS-Chem ECO.44 and IVBP-Suite by pooling their functions as a single package. It additionally includes the automatic detection and analysis of chemical structural similarity, for a better profiling of the chemicals of interest. These software, developed to be complementary in their functionalities, have been designed to be user-friendly considering both their graphical interface and the steps to follow to apply the QSARs. Furthermore, they simplify and streamline the application of our QSARs, which are provided in bundle, and can be applied to generate single or combined predictions. QSARINS-Chem standalone version, QSARINS-Chem ECO.44 and IVBP-Suite are freely downloadable from the internet (<http://dunant.dista.uninsubria.it/qsar/>). QSAR-ME Profiler is currently under development and will be available soon on the same website.

1.03.T-07 MechoA Profiler Recently Integrated in the OECD QSAR Toolbox: What Can It Do for You?

Franklin Bauer, Carole Charmeau-Genevois, Pascal Bichere and Paul Thomas, KREATiS, France

The MechoA (Mechanisms of Toxic Action) scheme is a structural alerts model to predict the molecular initiating events (MIE) and some subsequent key events for a wide domain of species, chemical groups and mechanisms. The first version of MechoA scheme has been published back in 2018 and is regularly updated. The main utility of MechoA scheme is to reliably define category of substances for read-across approach and develop QSAR for (eco)toxicity endpoints, based on a common mechanism of toxicity. To improve its ease of use for such applications and enhance its visibility, the MechoA scheme has been integrated as a new profiler in the OECD QSAR Toolbox (QTB) as a free downloadable add-in, named iSafeRat® Mechanisms of toxic Action profiler. A few case studies will be taken during the presentation, showing how to install and use the MechoA profiler in the QTB, and showing that it can highlight both similarities and differences that cannot be easily captured using conventional profilers. To make a good use of the MechoA profiler, it is important to understand the meaning of each MechoA class, which will be explained in the presentation. MechoA alone gives the information that you could get only by running many other profilers (e.g. Protein binding + oxidative phosphorylation uncoupling + MOA classification by Verhaar / OASIS). It is also much more informative than using the most commonly used classifications, i.e. Verhaar scheme, because it provides: (i) Information on the mechanisms that happen in different species, (ii) Some basic information about the metabolism of substances, (iii) A specific text to explain the MechoA for each single prediction, which can give mechanistic clues to explain the MIE behind (eco)toxicological effects, (iv) references to more recent literature and knowledge than old profilers. There are also some limitations with this first version: It is currently slow to run, but we are working on a more efficient version. Moreover, because of the way the QTB itself is designed, MechoA profiler is not handy to use as a subcategorization, because in this step, you cannot easily remove or add categories to be kept in 1 or 2 clicks. We are discussing with the QTB management group for the improvement of this functionality. We are also working on the integration of the alerts of Sapounidou et al. (2021) in the MechoA scheme to achieve an even more complete scheme, with a better coverage of aquatic toxicity mechanisms.

1.03.T-08 A Comparison of Mode- and Mechanism-Based In Silico Methods to Classify Environmental Toxicants Leading to an Improved Classification Scheme

Mark Cronin¹, David Ebbrell¹, James Firman², Franklin Bauer³, Maria Sapounidou¹, Geoffrey Hodges⁴, Bruno Campos⁴, Jayne Roberts⁴, Steve Gutsell⁴, Paul Thomas⁵ and Mark A. Bonnell⁶, (1)Liverpool John Moores University, United Kingdom, (2)School of Pharmacy and Biomolecular Sciences, Liverpool John Moores University, Liverpool, United Kingdom, (3)KREATiS SAS, L'Isle d'Abeau, France, (4)Unilever, United Kingdom, (5)KREATiS, France, (6)Environment and Climate Change Canada, Canada

Classification schemes are vital to assign chemicals appropriately to optimise the use of quantitative structure-activity relationships (QSARs) and read-across to fill toxicity data gaps. Well-used schemes, such as Verhaar and Russom, perform such classification on the basis of broad modes of action. Recently, novel schemes, notably those from MechoA and Sapounidou, have refined the process through a greater mechanistic interpretation of toxicity. Whilst information on all schemes has been published, there has yet to be a systematic assessment of the merits of the schemes. The aim of this investigation was to compare the schemes for classification in terms of coverage, mechanistic relevance and applicability to risk assessment scenarios, in addition to looking for opportunities to improve and integrate the schemes overall. The schemes were evaluated against over 5,550 chemical structures. The Verhaar and Russom schemes were run in the OECD QSAR Toolbox (v4.4) and ChemProp respectively. MechoA was run as a standalone platform and has been integrated into OECD QSAR Toolbox v4.5. The Sapounidou scheme was coded into 183 SMARTS strings representing specific, reactive and narcotic mechanisms of action and run in a KNIME Workflow. There was reasonably good concordance between the classifications from the different schemes. The Verhaar and Russom schemes showed the lowest levels of coverage (for Russom all compounds were classified as narcotic if not classified to another mechanism, however many compounds were found to be out of domain). The mechanistically-based schemes have greater coverage of reactive and specific alerts as well as providing direct access to knowledge and meta data. For instance, where possible, the Sapounidou scheme classification is based on the Molecular Initiating Events derived from the relevant Adverse Outcome Pathway (AOP). Knowledge of the AOP will enable greater use of weight of evidence through the application of NAMs to support approaches such as read-across. The outcome of the comparison led to the decision that the two mechanistic methods should be merged, which is part of an ongoing project.

1.03 Computational new approach methods (NAMs) supporting regulatory decision making for chemical safety (Part II)

1.03.T-01 From Causal Networks to Adverse Outcome Pathways

Anze Zupanic¹, Vid Modic¹, Roman Li², Colette Michèle vom Berg³ and Ziva Ramsak¹, (1)National Institute of Biology, Slovenia, (2)Philip Morris International, Switzerland, (3)Eawag Swiss Federal Institute of Aquatic Science and Technology, Switzerland

A decade ago, adverse outcome pathways (AOPs) have been put forward as a tool for organizing toxicological knowledge across different levels of biological organization, from the initial interaction of chemicals with the biological system (MIE = molecular initiating event) to the individual and population level effects relevant for environmental risk assessment (AO = adverse outcome). As of August 2021, only around 400 AOPs have been submitted to the AOP-wiki. There is therefore an urgent need to accelerate the development of new AOPs. Here we present a new approach for development of AOPs, based on a thus far AOP-untapped toxicological resource – causal toxicological networks (CTN). Here, we show a semi-automatic pipeline to transform CTNs into a set of candidate AOPs, and develop two new neurotoxicity AOPs (AOP 399 and AOP 410 on the AOP wiki). Weight of evidence analysis shows that AOPs developed in this way feature high biological plausibility for the key event relationships (KER), while usually lack evidence for key event (KE) essentiality and empirical evidence necessary to transform them into quantitative AOPs.

1.03.T-02 EcoToxXplorer: A Web-Based Platform for Comprehensive Toxicogenomics Data Analysis

Jessica Ewald¹, Othman Soufan¹, Guangyan Zhou², Orcun Hacariz¹, Peng Liu¹, Gordon Hickey¹, Steve Maguire¹, Guillaume Pain³, Natacha Hogan⁴, Markus Hecker⁵, Doug Crump⁶, Jessica Head¹, Jianguo Xia⁷ and Nil Basu¹, (1)McGill University, Canada, (2)McGill University, Afghanistan, (3)Universite Laval, Canada, (4)University of Saskatchewan, Saskatoon, Saskatchewan, Canada, (5)University of Saskatchewan, Canada, (6)Environment and Climate Change Canada, Canada, (7)McGill University Macdonald Campus, Canada

Toxicogenomics data are likely to play a key role in the transition from traditional to alternative toxicity testing methods. The costs of acquiring such data continue to drop, and an ever-increasing number of researchers and regulators would like to get involved in the world of toxicogenomics. However, these data are complex, and analyses typically require advanced programming skills and a deep knowledge of statistics and genomics resources, and as such, are usually handled by expert bioinformaticians. The objective of this project was to design EcoToxXplorer (www.ecotoxxplorer.ca) as a next-generation bioinformatics tool that is high performance, intuitive, and universally accessible to handle transcriptomics data for the purpose of chemical risk assessment and environmental management. The primary EcoToxXplorer analysis pipeline was built for analyzing qPCR data measured with custom EcoToxChip arrays from six ecological species (model organisms: Japanese quail, fathead minnow, African clawed frog; native species: double-crested cormorant, rainbow trout, northern leopard frog). The pipeline includes steps for QA/QC, filtering and normalization, differential analysis, interactive functional analysis, and report generation. The functional analysis is tox-focused, including integration with the AOPwiki and our custom EcoToxModule gene sets that were designed for high-level interpretation of toxicogenomics data. EcoToxXplorer can also process FASTQ files through a Galaxy server and microarray/RNA-seq counts tables through a NetworkAnalyst interface for the same six ecological species of regulatory relevance in North America. The current version of EcoToxXplorer is the result of continuous development since 2017 by the EcoToxChip project team. The development was organized around design-thinking principles in that we iteratively presented the tool to various user groups from academia, government, and industry for testing, and then refined it based on their feedback. This study was conducted as a part of a large-scale Genome Canada-funded project (EcoToxChip project - www.ecotoxchip.ca).

1.03.T-04 Using Genome Resources to Understand Invertebrate Pesticides Sensitivity and Mixture Responses

David Spurgeon¹, Stephen Short², Elma Lahive², Alex Robinson³, Claire Badder⁴ and Peter Kille⁵, (1)Centre for Ecology & Hydrology, United Kingdom, (2)UK Centre for Ecology and Hydrology, United Kingdom, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (4)UK Centre for Ecology & Hydrology, United Kingdom, (5)Cardiff University, United Kingdom

Understanding why some species are more sensitive than others to a given chemical is perhaps the most fundamental challenge in ecotoxicology. In this talk, we will highlight how the growing volume of genome and transcriptome data can be mined to identify the nature of the toxicokinetic and toxicodynamic traits that govern sensitivity. Using examples from comparative studies with arthropods and earthworms, we will show how sensitivity can be attributed to the genome complement of species, the presence of key residues in receptor binding domains, and, for the first time, on tissues specific expression patterns. We generated whole genomes and tissue specific transcriptomes for multiple terrestrial annelid and arthropod species. These genomic resources provided a basis for investigating the potential drivers of species sensitivity in three case studies of differential sensitivity between annelids and arthropods for the organophosphate chlorpyrifos, among earthworm species for the neonicotinoid imidacloprid and of differential mixture effects between azole fungicides and pyrethroid insecticide for both taxa. Bioassays identified cases of differential sensitivity between different earthworms and arthropods. Genomic approaches then allowed us to investigate the bases of these differences. 1. Chlorpyrifos. Earthworms (*Lumbricus rubellus*) showed an approximate order of magnitude lower sensitivity to chlorpyrifos than a soil arthropod (*Folsomia candida*). This difference could be linked to tissue specific cholinesterase orthologue expression. 2. Imidacloprid. A large-magnitude (>30-fold) difference in sensitivity for imidacloprid between earthworms. This difference can be explained by difference the expression of different isoforms of sub-unit of the nicotinic acetylcholine receptor that contain amino acid residue associated with strong or weak imidacloprid binding. 3. Mixtures. Difference in the degree of synergy found between different mixtures in arthropod and earthworms. This difference has been linked to the potential for one chemical to affect the toxicokinetic of another by inhibiting phase one and two metabolism to different extents.

1.03.T-09 Integrating Informatics to Broaden the Taxonomic Domain of Applicability for Adverse Outcome Pathways

Carlie LaLone¹, Marissa Jensen² and Sara Vliet¹, (1)U.S. Environmental Protection Agency, United States, (2)University of Minnesota-Duluth, United States

The adverse outcome pathway (AOP) framework provides a means to capture existing knowledge about a biological pathway and understand the evidence for causal linkages from molecular level perturbations to apical outcomes of regulatory concern. Typically, AOPs are developed considering available knowledge from a limited number of model organisms, with generalized comments regarding potential extrapolation to other species within similar taxonomic groups (e.g., all vertebrates). However, to gain confidence in the extrapolation of the AOP to other species the Organisation for Economic Cooperation and Development (OECD) Users Handbook recommends evaluation of structural and functional conservation across the levels of biological organization [1]. Advances in bioinformatics allow for broadening the taxonomic domain of applicability (tDOA) to provide evidence of structural conservation across certain key events (KEs) and key event relationships (KERs) that include protein interactions. Additionally, existing data from available literature can be systematically extracted to provide functional evidence for pathway conservation. In instances where the conservation of the KEs or KERs are determined primarily by traits or characteristics of the organism (e.g., presence/absence of a particular organ/tissue; colony structure or lack thereof) a decision tree can be used to examine tDOA capitalizing on various publicly available databases that capture such species-specific information.

Results from the US Environmental Protection Agency's Sequence Alignment to Predict Across Species Susceptibility tool (SeqAPASS; seqapass.epa.gov/seqapass/) have been used to demonstrate how such computational approaches can inform the tDOA, further expanding the utility of the AOP framework to build evidence of conserved pathways across taxa. Coupled to SeqAPASS, systematic methods have also been applied to gather lines of evidence for functional conservation [2, 3]. Together these approaches strengthen the weight of evidence for tDOA in the AOP framework and provide users of AOPs confidence for broader application across species in the context of research and decision-making. The challenge is integration of these approaches in a streamlined manner for rapid input in the AOP-Wiki (<https://aopwiki.org/>). Through demonstrated application of these approaches for AOP development centered on tDOA, data has been generated to inform such integration.

1.03 Computational new approach methods (NAMs) supporting regulatory decision making for chemical safety (Poster)

1.03.P-We001 Strengthening Skin Sensitisation Predictions Combining Enhanced MechoA and In Silico Skin Penetration Predictions

Carole Charmeau-Genevois, Franklin Bauer, Emel Ay-Albrecht and Paul Thomas, KREATiS, France

The iSafeRat® Mechanism of toxic Action (MechoA) Profiler (included in OECD Toolbox 4.5) is an *in silico* model based on structural alerts which predicts Molecular Initiating Events (MIE). Among these, certain MechoA classes detect electrophilic parent substances and metabolites. These direct- and/or pro- or pre-reactive substances are responsible for hapten-protein complex formation as the MIE, a necessary, but insufficient, predictor of the adverse outcome pathway (AOP) for skin sensitisation (SS). In this study, MechoA, which was previously tested for its performance to identify Skin Sensitisation for the substances listed in Cosmetics Europe skin sensitisation database (CESSD) is combined with other *in silico* tools, notably a skin penetration model, to boost the already good level of accuracy previously observed. In the first study, a raw comparison of predictions for SS based on MechoA classes, a good correlation was observed between chemicals triggering MechoA 3 and/or 4.3 and/or 4.4 and positive results observed for SS in the experimental studies. The probability of this positive prediction being correct was 62% relative to human clinical data and of 57% relative to LLNA data. Positive predictivity relative to *in vitro* methods was between 49 – 78% of which, MechoA 3 only correlated with 49% DPRA positives. A strong correlation was observed between negative results identified in SS studies and chemicals with a MechoA prediction that doesn't include MechoA classes 3, 4.3 and 4.4. The probability of these negative predictions being correct was 83% relative to human clinical data and 78% relative to LLNA data. Negative predictivity relative to *in vitro* methods was between 57 – 95%. Chemicals triggering MechoA classes other than MechoA 3 correlated with 74% of negative results in DPRA. Therefore, MechoA can be used to reliably predict non skin sensitiser (78 – 83%), and to predict with moderate reliability (57 – 62%) potential skin sensitisers based on the protein-binding mechanism. In this study we present results of the statistical gain in specificity and sensitivity of SS predictions for substances and metabolites by including the iSafeRat® dermal absorption model. Other improvements to detect more subtle electrophilic groups associated with mild skin sensitisation are also presented.

1.03.P-We002 Development and Validation of a Tiered Assessment Approach Towards Prediction of Acute Toxicity Within the Fathead Minnow

James Firman¹, Nicoleta Spinu², Samuel Belfield² and Mark Cronin², (1)School of Pharmacy and Biomolecular Sciences, Liverpool John Moores University, Liverpool, United Kingdom, (2)Liverpool John Moores University, United Kingdom

It is widely accepted that the manner through which assessment of chemical safety has traditionally been performed – that is, by means of costly and animal-intensive *in vivo* protocols – is increasingly outmoded. Despite desire to facilitate eventual replacement of such procedures, development of alternatives acceptable for adoption within a regulatory setting has proved challenging. Whilst many New Approach Methodologies (NAMs) are available, both *in vitro* and *in silico*, general confidence in the capacity of any one technique to adequately reflect corresponding *in vivo* hazard remains low. The derivation of verdicts based upon the weight of evidence sourced from a variety of appropriate NAM, as opposed to reliance upon individual outcomes, is proposed as a means through which uncertainty in judgment may be reduced. This concept has been formalised in the “tiered assessment” approach, whereby a sequential testing strategy covering collections of related NAMs is applied. Previously, we reported the construction of a tiered assessment pathway describing acute oral lethality within the rat – employing statistical techniques in order to derive probability estimates that compounds may hold membership within each of a series of GHS categories describing extent of toxic potency (defined by LD50 range). Within the present study, the approach is extended to prediction of acute ecotoxicity: specifically, the regulatorily-relevant endpoint of lethality towards the fathead minnow (*Pimephales promelas*) following 96-hour exposure. Adopting GHS aquatic toxicity directives, categorical representations of acute hazard (incorporating four classes) were assigned to greater than 600 organic substances holding appropriate *in vivo* LD50 data. Compounds were subject to three tiers of NAM screening: the first a structure-based assessment scheme intended to identify potential mode-of-action. A second stage integrated a battery of *in silico* methodologies, drawing both from existing and novel QSAR models – prior to a third and final round which sought to incorporate supporting *in vitro* data. Following consideration of results emerging from each tier, probability that a substance might belong to each of the four GHS categories was computed by means of ordinal logistic regression. Comparison to corresponding *in vivo* assignment allowed contribution of each NAM grouping to be assessed, backed by a quantitative expression of confidence.

1.03.P-We003 Using Species Toxicity Information to Improve the Predictive Ability of QSAR Models

Magdalena M. Mair¹ and Tobias Pamminger, Dr.², (1)Statistical Ecotoxicology, University of Bayreuth, Bayreuth, Germany, (2)Bayer Crop Science, Germany

Ideal hazard assessment would capture the toxicity of chemicals and pollutants for all organisms living in a contaminated

environment. As this is not feasible, the hazard for untested species needs to be estimated from the data generated for a subset of surrogate species. In practice, assessment factors are applied to protect potentially more sensitive species and to account for the uncertainty that arises from extrapolating from standard lab conditions to the environment. Robust protection of the environment is thus achieved by a combination of experimental toxicity information for surrogate species and the application of a safety factor. This approach relies on the assumption that the observed effects for a surrogate species can predict the adverse outcome for non-tested species, at least to some degree. If this is true, the addition of species level hazard information should improve the predictive performance of quantitative structure-activity relationship (QSAR) models. To test this, we developed QSAR models for different target species and chemical stressors and compare the predictive performance of models including only traditional chemical traits (e.g. molecular fingerprints and physico-chemical properties) with models that include additional toxicity information for other tested species. We use hazard data provided by the US environmental protection agency via the ECOTOXicology Knowledgebase and focus on the prediction of acute LD50 and LC50 values. These values were combined with relevant chemical traits and available species toxicity measures, including LD50/LC50 values and EC50 values for other non-lethal effect endpoints. Machine learning models were used for the predictions and the importance of single traits and trait groups (chemical traits vs. toxicity traits) were assessed. Overall, our findings support the trait-based approach, and we argue that hazard information for non-focal species can be interpreted similarly to chemical traits and can add to the predictive ability of QSAR models.

1.03.P-We004 The Online Freely Accessible Tool for Similarity Screening to Identify Chemicals of Potential Concern

Pim Wassenaar¹, Emiel Rorije², Martina Vijver³ and Willie Peijnenburg⁴, (1)National Institute for Public Health and the Environment (RIVM), Bilthoven, Netherlands, (2)National Institute for Public Health and the Environment RIVM, Netherlands, (3)CML Leiden University, Netherlands, (4)VSP, RIVM, Bilthoven, Netherlands

Screening and prioritization of chemicals is essential to ensure that available evaluation capacity is invested in those substances that are of highest concern. To facilitate the identification of substances of potential concern, we recently developed structural similarity models that evaluate the structural similarity of substances with unknown properties to known Substances of Very High Concern (SVHC) [Wassenaar et al. 2019; <https://doi.org/10.1016/j.comtox.2019.100110>]. Substances that are structurally similar to known SVHCs might be selected for further evaluation, as a high resemblance in chemical structure could be an indication of comparable effects ('similar property principle'). Separate similarity models have been developed for three groups of SVHCs, including SVHCs with (1) carcinogenic, mutagenic or reprotoxic properties (i.e. CMR), (2) persistent, bioaccumulative and toxic, or very persistent and very bioaccumulative properties (i.e. PBT/vPvB), and (3) endocrine disrupting properties (i.e. ED). These models showed promising performance statistics and appear to be more robust than expert judgements. Upon obtaining more experience with the application of the similarity models, we identified several methodological aspects that could be further optimized to improve the performance of the models. Particularly, the PBT/vPvB model misclassified many substances due to amongst others insufficient consideration of the type and number of halogenated fragments and aromatic structures, the SVHC-categorization insufficiently reflected the current SVHC status, and the binary nature of the prediction limited the interpretation of the results. Therefore, the current study aims to improve the performance of the models by (1) separating the known SVHCs in more specific subgroups, (2) by (re-)optimizing similarity models for the various SVHC-subgroups and (3) by improving interpretability of the predicted outcomes by providing a confidence score. In addition, the underlying reference dataset of SVHC substances was updated. The improvements as described in this study are directly incorporated in a freely accessible web-based tool, named the ZZS similarity tool: <https://rvszoekstelsysteem.rivm.nl/ZzsSimilarityTool>. Accordingly, this tool can be used by risk assessors, academia and industrial partners to screen and prioritize chemicals for further action and evaluation within varying frameworks, and could support the identification of tomorrow's substances of concern.

1.03.P-We006 Deriving Baseline Toxicity QSARs for Ionizable Organic Chemicals by Using Experimental and Computational Membrane-Water Partition Coefficients

Andrea Gredelj¹, Elin Barrett², Jayne Roberts³, Thomas Potter⁴, Alexandre Teixeira⁵, Nicola Bettles⁶, Geoffrey Hodges³ and Mark Miller⁴, (1)Unilever SEAC, United Kingdom, (2)Unilever/Safety and Environmental Assurance Centre SEAC, UK, (3)Unilever, United Kingdom, (4)Durham university, United Kingdom, (5)Unilever, UK, (6)Unilever/Safety and Environmental Assurance Centre SEAC, United Kingdom

Quantitative structure-activity relationships (QSARs) for predicting (eco)toxicity provide a viable alternative for *in vivo* testing in chemical safety assessment. The majority of published QSARs derived for non-specific toxicity (narcosis) rely on the octanol-water partition coefficient (K_{ow}) as a proxy for the lipophilicity of chemicals. Non-specific toxicity (narcosis) is driven by critical accumulation in the phospholipid membranes, resulting in disturbance in their integrity and function. Biological membranes are ordered and anisotropic 3-dimensional structures. Therefore, the main limitation and criticism of octanol being used as a surrogate for lipophilicity is that being a homogenous isotropic media, it cannot adequately describe membrane interactions of chemicals such as ionisable organic compounds (IOCs). Due to their amphiphilic nature, surfactants pose unique challenges with regards to the determination of K_{ow} due to their tendency to accumulate at the octanol-water interfaces and exhibit electrostatic, in addition to hydrophobic, interactions. The membrane-water partition coefficient (K_{mw}) provides a more biologically relevant and methodologically defensible potential alternative to K_{ow} and has been previously shown to perform as well as K_{ow} for predicting the toxicity of neutral narcotics. It also provides a prospective alternative for IOCs and surfactants both in predictions of environmental partitioning processes and toxicity. In this work, we explore the derivation of QSARs for (eco)toxicity of these "hard to predict" chemicals, particularly concentrating on cationic, anionic and zwitterionic surfactants for which K_{ow} is difficult to determine. We will present initial QSARs developed using the K_{mw} values, based on both experimental and computational approaches, combined with the literature toxicity data. Considering that experimental determination of K_{mw} can be complex, time-

consuming and costly, we also explore the application of two computational methods for deriving K_{mw} , based on coarse-grained simulations and COSMOmic calculation, with experimental data serving as their validation sets.

1.03.P-We007 An In Silico Membrane Model for the Screening of Gastrointestinal Absorption of Chemicals of Environmental or Occupational Concerns

Shenghong Wang¹, Zhizhen Zhang¹, Dingsheng Li¹, Siena Illa² and Li Li¹, (1)University of Nevada, Reno, United States, (2)University of Nevada Reno, United States

Parallel Artificial Membrane Permeability Assay (PAMPA) has been proposed as a new approach method (NAM) to screening the effective permeability (P_e) of chemicals through the gastrointestinal tract to help effective regulatory decision making for chemical safety. While PAMPA has gained advocacy for its application towards pharmaceuticals, its use for chemicals of environmental or occupational concerns is still rare. Since chemicals of environmental or occupational concerns differ from pharmaceuticals in hydrophobicity and volatility, there is a need for a systematic understanding of mass transfer in PAMPA, if we seek to expand the applicability of PAMPA. We develop a computational model to simulate the mass transfer of chemicals in laboratory PAMPA for mechanistic insights into P_e measurements. The model's performance is evaluated by an agreement between predicted and measured permeabilities of 1383 chemicals. The evaluation shows that the model provides reasonable or conservative estimates for 91% of chemicals in the evaluation set, within a short period simulation time of fewer than five seconds, indicating that the model is efficient and protective of human gastrointestinal absorption of chemical substances. The model predicts an inverted U-shaped dependence of P_e on the octanol-water partition property ($\log K_{OW}$ for neutral compounds and $\log D_{OW}$ for ionizable compounds), with the maximum P_e occurring in $\log K_{OW}$ or $\log D_{OW}$ ranging between 0 and 2. The model estimates a high membrane retention rate for hydrophobic chemicals, as well as the loss of volatilization to the headspace of the PAMPA apparatus for highly volatile chemicals. Notably, the measured permeabilities of hydrophobic chemicals are remarkably sensitive to specific experimental conditions, e.g., frequency of stirring, and incubation time, making P_e measurements under different conditions less comparable. More important, for highly hydrophobic chemicals, steady-states mass transfer, which is the fundamental assumption of PAMPA can never be achieved. In conclusion, our in-silico model not only has the power to predict the P_e values of PAMPA accurately and rapidly. The use of our developed model can not only help cost-effective decision-making for tens of thousands of chemicals in commerce but also predict the permeability for chemicals whose P_e cannot be experimentally determined due to constraints of hydrophobicity or volatility.

1.03.P-We008 Developing High-Throughput Methods for the Hazard Assessment of Chemicals and Particles in *Daphnia magna*

Magdalena M. Mair¹, Vivian Gräß² and Matthias Schott³, (1)Statistical Ecotoxicology, University of Bayreuth, Bayreuth, Germany, (2)University of Bayreuth, Germany, (3)Animal Ecology I, University of Bayreuth, Bayreuth, Germany

Standard experiments for the toxicity assessment of single substances towards the keystone species *Daphnia magna* are time-consuming and labour-intensive: acute immobilization tests for the determination of LC50 values take 48 (OECD test no. 202); in life history tests, *Daphnia magna* females are exposed to the test substances for 21 days and daily checks are required (OECD test no. 211). These tests are essential tools for the regulatory risk assessment in aquatic environments, as mortality and reproduction are important toxicity endpoints that likely affect population dynamics. Due to the time-consuming design, the number of chemicals that can be tested with these experimental setups is however limited and can neither account for the large number of substances found in contaminated environments, nor for the large number of candidate substances in product development. In addition, pollutants such as micro- and nanoplastic particles (MNPs) cannot be tested in one-pollutant-one-test approaches, because they are too complex. Each MNP has a unique set of properties, e.g. plastic type, size, shape, age, coating, additives, and therefore assigning MNPs to discrete classes is difficult. To allow for a risk assessment for small scale particles a large number of different MNPs has to be tested to create datasets that are large enough for predictive modelling approaches. We address these experimental constraints of standard test procedures by developing high-throughput methods for the evaluation of *Daphnia magna* swimming behaviour and heart rate measurements. Changes in the swimming behaviour of daphnids are early indicators of stress and later on – immobilization. Heart rates change rapidly in response to stress in general, both resulting in shorter total experimental times. To reduce the manual lab work, we use video recordings and an automated video analysis pipeline combined with automated object detection based on machine learning methods. We show that these methods are less time-consuming and at the same time are good proxies for traditionally derived LC50 values and reproduction effects. We argue that the implementation of high-throughput methods for the evaluation of quick stress responses is beneficial in situations where large amounts of chemicals or pollutants have to be tested within reasonable time periods. We will discuss our approach as a valuable alternative to currently used methods without substantial loss of information.

1.03.P-We009 Development of the Exposure and Safety Estimation (EAS-E) Suite Platform to Integrate New Approach Methods and Data for Chemical Assessments

Alessandro Sangion¹, Li Li², Liisa Toose, M.Sc.³, Trevor Brown⁴, James M Armitage⁵ and Jon Arnot³, (1)ARC Arnot Research and Consulting Inc. and University of Toronto Scarborough, Canada, (2)University of Nevada, Reno, United States, (3)ARC Arnot Research & Consulting Inc., Canada, (4)TNB Research, Canada, (5)AES Armitage Environmental Sciences, Inc, Canada

Environmental and human health risk assessments require quantitative exposure data for thousands of chemicals in various systems. Understanding the processes that determine chemical exposure provides critical insights for risk management decisions for the safe and sustainable use of chemicals by society. Multi-media mass-balance fate, toxicokinetic (bioaccumulation), and exposure models are often necessary for exposure and risk estimation. These mechanistic (process-driven) models require chemical-specific input data such as physical-chemical properties, toxicokinetic data, environmental degradation half-lives,

production volumes and emission rates. However, for many of the chemicals requiring evaluation, these data are limited, not standardized and documented across multiple databases. To reduce animal use and address significant data gaps, New Approach Methods (NAM) like in vitro bioassays and validated Quantitative Structure Activity Relationships (QSARs) can be used; however, their application often requires expert judgement and a careful evaluation of the results (e.g. Applicability Domain). Most importantly databases and models are not integrated; chemical evaluators need to gather information from many diverse sources to perform assessments. Here we introduce the Exposure And Safety Estimation (EAS-E) Suite platform to bridge the gap between evolving scientific research and regulatory assessment challenges. EAS-E Suite is a free on-line platform developed to facilitate knowledge translation to various stakeholders on issues in exposure assessment and environmental health. EAS-E Suite is comprised of chemical information databases, QSARs for predicting chemical information if measured data are unavailable, and models and tools to aid chemical assessment decision-making. EAS-E Suite provides opportunities to address regulatory challenges for new and existing chemical assessments for ecological and human health objectives to support a One Health approach to chemicals management and to guide the safe and sustainable production and use of chemicals in society. A case study illustrates how the platform integrates various data sources and knowledge across multiple disciplines to reduce uncertainty, improve chemical management and support decision-making.

1.03.P-We010 Risk Assessment of Honey Bee Stressors Based on In Silico Analysis of MOLECULAR Interactions

Monica del Aguila Conde¹ and Ferdinando Febbraio², (1)CNR-IBBC, Naples, Italy, (2)Institute of Biochemistry and Cell Biology (CNR-IBBC), National Research Council (CNR), Italy

The honey bee *Apis mellifera* is an important pollinator and has a fundamental socio-economic role in Europe's food production. Throughout the last decade, a decline of this species has been observed globally. The decline of honey bee colonies is thought to be linked to several stressors, including pesticides and other chemicals used in agriculture. The current risk assessment of pesticides in Europe is focused on lethal effects and lacks reflection on sublethal effects. A better understanding of the effects that exposure to pesticides produce on honey bees is still needed. In this context in silico methodologies such as docking analysis of toxic chemical ligands and proteins could be used as a first step to identify affinity and possible interactions at the molecular level. Currently, dozens of 3D structures of proteins from *Apis mellifera* are present in online databases including odorant-binding proteins, pheromone binding proteins, beta-synthase and protein from the immune system. This study aims to investigate in silico interactions of bee proteins and pesticides to produce a risk assessment analysis that can enhance the protection of honey bees in Europe. For this purpose, a protein structures dataset for *Apis mellifera* was obtained from protein data banks and extended with proteins of homologous organisms. Similarly, the 3D structures of the EU authorised pesticides were obtained from online databases. The molecular docking analysis was performed with AutoDock vina. For each protein from honey bees, a ranking based on the affinity of chemicals for specific and non-specific binding sites on the macromolecule was developed. The possible effects of the identified interaction (protein-toxic compound) were investigated through a literature search. This was linked to potential effects on reproduction, communication, fly and spatial orientation among others. Also, documents (reports) from international organizations, such as EFSA or FAO, and monitoring data were collected to obtain a picture of the sites affected by increased bee mortality. These results were related to the results obtained from the ranking-based affinity. Finally, a risk assessment analysis of the identified molecular stressors of honey bees was performed. The results of this study are considered a starting point to identify new sources of possible stress for honey bees and thereby contribute to the overall understanding of the honey bee decline.

1.03.P-We011 Characterizing Uncertainty in Computational New Approach Methodologies (NAMs) for Chemicals Risk Evaluation: A Typology Framework

Jerry Achar¹, Gunilla Oberg¹, Jeroen van der Sluijs² and Milind Kandlikar³, (1)University of British Columbia, Canada, (2)University of Bergen, Norway, (3)The University of British Columbia, Canada

New approach methodologies (NAMs) that employ computational prediction of risks of chemicals aim to support chemical safety evaluation to protect human and environmental health. A major challenge in using computationally driven NAMs is uncertainties, such as in the quality of input data and model accuracy. Decisions based on the prediction outcomes of NAMs can be misleading if associated uncertainties are not well characterized and communicated. This work aims to identify and qualitatively characterize uncertainties related to the development, use, and outcome of recent computational NAMs studies. We identify and characterize uncertainties in the input parameters and variables, data gaps, model prediction, and output and outcome interpretation. Guided by the characterized uncertainties, we propose an uncertainty typology framework and demonstrate contexts where the framework can be applied. Our study indicates that explicit uncertainty characterization and the use of a typology framework are critical steps to ensuring transparent and reliable predictions of the potential risks of chemicals using NAMs.

1.03.P-We324 Improving Ecotoxicity Assessment Results by Splitting Species Sensitivity Distributions (SSD)

Susan Oginah¹, Leo Posthuma², Michael Z. Hauschild³ and Peter Fantke³, (1)DTU (Technical University of Denmark), Denmark, (2)RIVM, Netherlands, (3)Technical University of Denmark, Denmark

Characterizing ecotoxicity effects, whether as integral part of chemical safety assessment, life cycle impact assessment, or environmental quality contexts, requires to address differences across chemicals in their potential to cause harm on ecosystems. Improving ecotoxicity effect assessment needs digitalization methods and big data analysis to characterize chemical impacts on ecosystem health accurately. There are ~10,000 chemicals with available measured in vivo data, but we still lack a systematic understanding of the different effects of chemicals on specific species groups and the relevance of such understanding on ecotoxicity effect quantification. To address this gap, we introduce a systematic approach for linking chemicals to effects on specific species groups via (a) mapping chemicals to chemical classes, toxic modes of action (MoA), and target species groups,

and (b) combining mapping results with quantified species sensitivity distributions (SSD) for specific species groups. Based on our results, we aim to determine chemicals for which we need to split SSDs as suggested earlier to address more vulnerable species groups and improve the accuracy of ecotoxicity effect factors. As a starting point, we considered and curated experimental data for freshwater species in our analysis from the original database, following a semi-automated approach. SSDs were then built and uncertainty quantified based on intra-species variability from reported test data extrapolated to chronic EC10 equivalents across all species and species groups per chemical. For comparing species groups per chemical and targeted MoA, we used the 20th percentile (P20) point on each SSD. When comparing single and split SSDs per chemical, we could identify two main groups of chemicals. The first group shows non-overlapping uncertainty 95% confidence interval (CI) ranges around their split SSDs, indicating that particular species groups are significantly more sensitive to exposure for the concerned chemical than other species groups. The second group of chemicals shows either overlapping 95% CI ranges around their split SSDs, or split SSDs that cross each other due to differences in slopes, indicating that chemicals are not affecting particular species groups more than others. These results suggest that splitting SSDs can increase the reliability of chemicals that inhibit a specific MoA in certain species groups.

1.03 Computational new approach methods (NAMs) supporting regulatory decision making for chemical safety (Virtual Only)

1.03.V-01 A Novel Molecular Modeling Framework to Predict Protein-Ligand Interactions to Detect Endocrine Disrupting Potential of Chemicals

Zlatomir Todorov and Paul Thomas, KREATiS, France

There is a need for new approach methodologies (NAMs) to identify substances with an endocrine disrupting (ED) modality. Our goal is to provide an accurate, high-throughput, expandable and customizable tool for molecular modeling that can be used to detect potential ED modality. The interaction of chemicals with proteins is a key to investigate the disruption of endocrine pathways. Among the computational methods that could investigate such interactions, molecular docking (Mol. Dock.) is a technique that has a reasonable tradeoff between computational investment and accuracy of predictions. In the scientific process allowing for such a prediction to deal with the level of statistical complexity presented by the problem, at midterm Mol. Dock. is used as a kernel around which a sophisticated framework must be built. Arguably, there is currently no publicly available “gold standard” computational framework entirely fit for purpose to handle this model, hence, our team is building our own computational framework. Fundamental parts of the framework consist of third-party software, while the linking of software and certain analysis strategies were developed entirely by our team. Our framework under active development, it has open architecture allowing for new datasets, new features, and new methodologies to easily be incorporated, leading to a vast potential for customization and for collaboration. To date our tool can investigate 6 ED EATS targets with a total of 96 protein conformations, this application domain and the span of the conformational space will be extended in the future. This poster presents the latest version (2.0) of the framework, introduced as a novel tool for molecular modeling and analysis of protein-ligand complexes. Furthermore, the application of the framework is illustrated with a case study investigating the binding propensity of a set of chemicals (including some with suspected ED potential) towards biological targets from the EATS modalities.

1.03.V-02 A Quantitative Index to Incorporate Transcriptomic Data Into Weight-Of-Evidence Approaches for Ecological Risk Assessment

Martina Cecchetto¹, Luca Peruzza², Elisa Giubilato³, Ilaria Bernardini², Giulia Dalla Rovere², Antonio Marcomini⁴, Francesco Regoli⁵, Luca Bargelloni², Tomaso Patarnello², Massimo Milan² and Elena Semenzin¹, (1)Ca' Foscari University of Venice, Italy, (2)University of Padua, Italy, (3)University Ca Foscari of Venice, Italy, (4)University of Venice, Italy, (5)Università Politecnica delle Marche, Italy

The rapid computational improvement in ecotoxicogenomics analyses, alongside their technological affordability, has brought new insights into the adverse effects of chemicals on aquatic organisms. In the field of ‘omics’ technologies, there is a growing interest towards transcriptomics which investigates genomic-scale changes in RNA expression, indicating both temporary and persistent genome alteration. In this work, a methodology is presented to quantitatively elaborate transcriptional data obtained from aquatic organisms exposed to chemicals with the aim of integrating this information into a Weight of Evidence approach to support ecological risk assessment. The methodology makes use of results from the application of Gene Set Enrichment Analysis (GSEA, Subramanian et al., 2005) to recent studies investigating the response of *Mytilus galloprovincialis* and *Ruditapes philippinarum* exposed, under controlled laboratory conditions, to environmentally realistic concentrations of contaminants, i.e. pharmaceuticals, herbicides, per- fluoroalkyl substances, and fragrances. A set of mathematical algorithms was designed to translate the severity of transcriptional alterations in exposed organisms into a quantitative hazard index. The degree of de-regulation of gene sets organised into higher biological themes together with the relevance of each biological theme in terms of physiological reactions contribute to the calculation of the hazard index. The outcome, expressed on the scale 0-100%, is classified according to five hazard classes (from absent to severe), providing an evaluation of the early individual effects of chemical exposure. The application to the experimental datasets proved that the model can effectively discriminate different levels of adverse transcriptomic response when compared with expert judgement. This methodology can serve as a proof of concept for the integration of “genomic tools” in ecological risk assessment based on multidisciplinary investigations. To this end, the proposed quantitative “transcriptomic” hazard index can in future be incorporated in a quantitative Weight of Evidence approach, where the integration with results from other types of analysis (lines of evidence, LoEs), such as chemistry, bioavailability, ecotoxicological bioassays, benthic communities and cellular biomarkers, can contribute to elucidate the role of chemicals in adverse ecological effects.

1.03.V-03 Development and Analysis of Toxicity Screening Models Based on ToxCast Data Using Various Machine Learning Algorithms and MOLECULAR Fingerprints

Su-yong Bea and Jinhee Choi, University of Seoul, Korea, South

Machine learning and deep learning approaches have been increasingly used in various fields including toxicology. High-throughput screening (HTS) is used to produce large amounts of biological data. The ToxCast program uses HTS to screen biological activity to suggest potential toxic effects. The ToxCast program conducted 1474 in vitro ToxCast assays using over 9227 chemicals. In this study, we used 799 ToxCast assays to train activity predictive models and the data was curated through the following conditions: For each assay dataset, 30 models were trained by combining 6 algorithms (Gradient Boosting Tree, Random Forest, Multi-layered Perceptron Network, k-Nearest Neighborhood, Logistic Regression, Naive Bayes) and 5 molecular fingerprint representations of the chemical (MACCS, Morgan, Layered, RDKit and Pattern fingerprint). The process was carried out using the KNIME platform. The synthetic minority oversampling technique (SMOTE) was used to balance the data, and accuracy and F1 score were used as evaluation criteria of model performance. As a result, 799 models were selected, and 35 models with good performance were selected based on F1 score and accuracy. Finally, models predicting similar results for chemicals with similar structures were classified. Since biological activity data is relatively small in quantity and difficult to mass-produce, it is important to utilize and study existing HTS data to help address these problems. We present 35 models and expect that our result can be used as a cornerstone for a wider range of in silico toxicity prediction research.

1.03.V-04 Identification of Human Diseases Associated With Household Chemicals Using Comparative Toxicogenomics Database

Jinseon Son, Jaeseong Jeong and Jinhee Choi, University of Seoul, Korea, South

Household chemical products provide substantial benefits to human life, so their use is steadily growing in modern societies. However, the misguided use of household chemicals can potentially cause significant harm to human health, as demonstrated in the terrible incident in Korea (2011), where biocidal chemicals were used as disinfectants for household humidifiers. This tragedy substantially showed that more rigorous toxicity assessments covering various uses of chemicals is essential to household chemical product safety management. In this study, to gain insight into the human health implications of chemicals found in household products, human diseases associated with household chemicals were identified using the Comparative Toxicogenomics Database (CTD, <http://ctdbase.org/>). For CTD analysis, permitted chemicals listed in the Korean ‘Act on the Safety Management of Household Chemicals and Biocides’ were analysed, and we selected five use categories (Coating, Detergent, Disinfection, Air freshener and Insect repellent) according to the number of chemicals. Representative chemicals (Sulfuric acid, Phosphoric acid, Propane, Kerosene and Ethanol) for each use category were selected based on volume used, and were used to collect chemical-induced disease, associated gene and phenotype information from CTD. For each use category and their representative chemicals, we suggested a priority list of chemical-induced diseases and associated genes and phenotypes. This study emphasizes that analysis using a database with comprehensive toxicity information can support and facilitate further studies on priority settings for management of potentially exposed household chemicals. Acknowledgement: This work was supported by a grant from the Korean Ministry of Environment through ‘Environmental Health R&D Program’ (2021003310005).

1.03.V-05 Integrating -Omics Data With Benchmark Dose Analysis to Develop an Adverse Outcome Pathway for Hepatocellular Carcinoma

Fatima Baldo, Jaeseong Jeong and Jinhee Choi, University of Seoul, Korea, South

Allyl alcohol is an allylic alcohol used as a precursor in the manufacture of plasticisers, pharmaceuticals, resins, acrolein, military poison and herbicides. Inhalation exposure to ally alcohol can occur via degradation of chemicals found in e-cigarette vapor. Allyl alcohol undergoes alcohol dehydrogenase (ADH) oxidation to form acrolein leading to hepatotoxicity and eventually hepatocellular carcinoma (HCC). In this study we present an adverse outcome pathway (AOP) for HCC. An AOP is a theoretical framework that integrates existing knowledge to describe the effect of a substance from its initial interaction with a biological system (molecular initiating event) cascading through the different levels of cellular, linked together by key event relationships required to produce a toxic effect (adverse outcome), in this case, HCC. We use benchmark dose (BMD) analysis to identify the pivotal point at which key events in the AOP occur. The BMD is the dose that causes a predetermined change in the response rate of an adverse effect. In this study we extracted human gene expression data of allyl alcohol exposure from Open TG GATES (<http://toxico.nibiohn.go.jp/english/>), calculated the BMD and mapped the values onto genes and biological processes to identify the important processes initiated at these values. Disease and biological process data were collected from the Comparative Toxicogenomic Database (<http://ctdbase.org/>) to build the AOP. We found that the pathways leading to HCC were time and dose sensitive. The most sensitive process leading to HCC at 2hr exposure is “intrinsic apoptotic signaling pathway in response to nitrosative stress” via DDIT3 modulation eventually activating “cell cycle arrest” and “inflammatory response”. “Endothelial cell activation involved in immune response” was activated via TCIM modulation, leading to “cell migration”. At 24hr exposure, we found “negative regulation of non-canonical Wnt signaling pathway” via modulation of RNF213 leading to “epithelial to mesenchymal transition”. “Negative regulation of protein kinase C signaling” via modulation of MYADM lead to “apoptosis”. We suggest an AOP for HCC based on the modulation of DDIT3, TCIM, RNF213 and MYADM.

1.03.V-06 Artificial Intelligence-Based Toxicity Prediction of Environmental Chemicals: Future Directions for Chemical Management Applications

Jaeseong Jeong and Jinhee Choi, University of Seoul, Korea, South

Recently, research on the development of artificial intelligence (AI)-based computational toxicology models that predict toxicity without the use of animal testing has emerged, because of the rapid development of computer technology. Various computational

toxicology techniques that predict toxicity based on the structure of chemical substances are gaining attention, including the quantitative structure-activity relationship. To understand the recent development of these models, we analyzed the databases, molecular descriptors and fingerprints, and algorithms considered in recent studies. Based on a selection of 84 papers published since 2014, we found that AI models have been developed to predict approximately 30 different toxicity endpoints using more than 20 toxicity databases. For model development, molecular access system and extended-connectivity fingerprints are the most commonly used molecular descriptors. The most used algorithm among the used machine learning techniques is the random forest, while the most used algorithm among deep learning techniques is a deep neural network. The use of AI technology in the development of toxicity prediction models is a new concept that will aid in achieving a scientific accord and meet regulatory applications. The comprehensive overview provided in this study will provide a useful guide for the further development and application of toxicity prediction models. Acknowledgment: This work was supported by a grant from the Korean Ministry of Environment through 'Environmental Health R&D Program' (2021003310005).

1.04 Environmental Epigenetics: Short-term and long-term effects and challenges for both ecotoxicology and human toxicology (Poster Corner)

1.04.PC-Mo01 Integration of Epigenetics Into Multi-Omics Analysis Reveals Alterations in Neurotransmitter Signalling in Zebrafish Embryos Exposed to Tributyltin

Albert Menéndez-Pedriza¹, Jorke Kamstra², Melissa Diogo Faria³, Demetrio Raldua⁴, Joaquim Jaumot⁵, Juliette Legler², Benjamin Pina¹ and Laia Navarro-Martin⁶, (1)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (2)Utrecht University, Netherlands, (3)Institute for Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (4)IDAEA-CSIC, Spain, (5)Institute of Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain, (6)Institute of Environmental Assessment and Water Research, Barcelona, Catalunya, Spain

Environmental exposures to endocrine disruptor chemicals (EDCs) have been proven to significantly affect the epigenetic status of ecotoxicologically relevant species of fish, plants, and invertebrates. However, the mechanism of action remains unclear. For that reason, further studies are needed to better elucidate how EDCs act on epigenetic endpoints capable to regulate gene expression. In zebrafish, a recognized toxicological model species, environmental epigenetics in addition to other omic layers including transcriptomics and metabolomics have been applied to explore holistic molecular perturbations by a great variety of pollutants. Nevertheless, each type of omic data is specific to a single "layer" of biological information, impeding a comprehensive understanding of toxicity mechanisms and key events for adverse outcome pathway development. Therefore, the integration of multi-omics analysis seems to be a powerful tool to efficiently capture, not only the toxic mechanisms but also multifaceted networks from gene to phenotype. In the present study, we have exposed zebrafish eleutheroembryos from 2 to 5 days post-fertilization from 3 to 100 nM of TBT. Whole genome bisulfite sequencing revealed that DNA methylation was affected in a dose-response manner, affecting genes related to neurotoxicity. Results from RNA sequencing showed a general, rather unspecific toxicity pattern at higher doses of TBT. This was in concordance with morphometric results previously published. Steroid biosynthesis pathways that lead the synthesis of cholesterol and vitamin D₃ appeared as the modules that become affected at the lowest TBT concentrations. Last, untargeted LC-HRMS metabolomic analysis demonstrated lipid disruption and alterations in taurine and energy metabolism. Results achieved in the multi-omic pathway enrichment were in concordance with the main single omics results. Interestingly, the multi-omic analysis also disclosed that pathways related to neurotransmitter signalling were also significantly affected by TBT exposures. Behavioural testing revealed alterations in behaviour, not only at the end of exposure but also three days after embryos were transferred to clean water. Our results suggest that DNA methylation alterations in neurotransmitter signalling could provoke long term behavioural effects. Altogether, demonstrates the usefulness of multi-omic data analysis to better understand the modes of action of EDCs.

1.04.PC-Mo02 Transgenerational EpiGenetic Effects After Early LIFE Stage Exposure to Perfluoroalkyl Substances

Manon Fallet¹, Michela Di Criscio², Philipp Antczak³, Joelle Rüegg⁴, Nikolai Scherbak⁵ and Steffen Keiter⁵, (1)MTM Research centre Örebro University, Örebro, Sweden, (2)Department of Organismal Biology, Uppsala University, Sweden, (3)Centre for Molecular Medicine, Germany, (4)Uppsala University, Sweden, (5)Örebro University, Sweden

Research shows that the individual lifestyle of an organism can influence its phenotype and maybe also the phenotype of its offspring. The different genetic and non-genetic components of the inheritance system and their mutual interactions are key mechanisms to generate inherited phenotypic changes. Once released into the environment, pollutants represent a serious threat to human and environmental health and their exposure may also affect subsequent generations through transgenerational epigenetic modifications. Thus, there has been growing concern that epigenetic modifications by pollutants mediate adverse health outcomes over several generations. But only a limited number of environmental studies have been published about the effects of pollutants on epigenetic marks and related adverse outcomes and even less investigate changes of epigenetic marks over generations. Poly- and perfluoroalkyl substances (PFAS) are particularly investigated due to long and extensive use in firefighting foams, textiles, and paper products. Among PFAS, perfluorooctane sulfonic acid (PFOS) is the most studied as it is known to be persistent, bioaccumulative, toxic, and undergoes wide transportation across all environmental media. Perfluorobutane sulfonic acid (PFBS) is considered less toxic and is now used in replacement for PFOS. However, preliminary results indicate that PFBS alters epigenetic marks; thus, further investigations are needed to study the impact of PFBS on organisms over several generations. Therefore, we will study the transgenerational epigenetic inheritance of PFAS to increase our understanding of how these compounds impact epigenetic mechanisms and related adverse effects. For that purpose, we will induce a precocious (0-2hpf post-fertilization) and chronic (28 days) exposure of two PFAS: PFOS and PFBS, on zebrafish embryos. Then we will study the impact of this exposure on zebrafish transcriptome, metabolic activity, phenotype, and behavior on the exposed generations (F1) but also

on the subsequent unexposed ones (F2-F3), to investigate the transgenerational effect of PFAS. Finally, we will look at the epigenetic and genetic components to decipher the molecular mechanisms involved beyond the transgenerational effects of PFAS.

1.04 Environmental Epigenetics: Short-term and long-term effects and challenges for both ecotoxicology and human toxicology (Virtual Only)

1.04.V-01 DNA Methylation and Epigenetic Biomarkers for Xenobiotic Exposure in Mediterranean Fin Whales

Cristina Panti¹, Annalaura Manciac², Giacomo Limonta³, Matteo Baini³, Luigi Abelli² and Maria Cristina Fossi³, (1)Department of Physical Sciences, Earth and Environment, Cristina Panti, Siena, Italy, (2)University of Ferrara, Italy, (3)University of Siena, Italy

Mediterranean cetaceans are increasingly exposed to a plethora of anthropogenic impacts, including the pressure exerted by chemicals pollutants. Among the different effects, as a result of the exposure to environmental pollutants, epigenetic modifications, such as DNA methylation (DNAm), can occur and subsequently to affect and regulate gene expression. Hyper- and hypo-methylated genes on fin whale (*Balaenoptera physalus*) skin biopsies sampled in the Pelagos Sanctuary (North – Western Mediterranean Sea) have been identified by DNAm profiling through reduced representation bisulfite sequencing (RRBS) in organisms with different contaminant loads. The expression of a panel of genes (hypo-methylated genes: CCDC93, SETD1A, SMARCA2, PKP3; hyper-methylated genes: OTX1, PCBP3, CLSTN1, SHANK1, GRAMD4) were quantified by droplet digital PCR (ddPCR). The variations in the expression of the selected genes, which are mainly involved in cell differentiation and functioning of vascular and nervous systems, were evaluated according to the sex of organisms and the contaminant (plastic additives) load measured in the blubber of the same individuals to evaluate the effects of environmental stress on DNAm and, thus, on gene silencing or transcriptional activation. The up- and down regulation of panel of hyper- and hypo- methylated genes revealed a correlation between the levels of contaminants and the expression of the selected genes. These results provide a first insight on the potential use of a panel of biomarker genes related to epigenetic modifications, which can be used as prognostic markers for genetic adaptation of a vulnerable species to a changing environment in such a contaminated environment as the Mediterranean Sea.

1.05 Investigating endocrine-disrupting properties of chemicals: developments and challenges towards new approach methodologies (NAMs) (Part I)

1.05.T-01 Endocrine-Disrupting Potential of Sediment in South African Harbours

Monique Labuschagne¹ and Riale Pieters², (1)North-West University - Potchefstroom Campus, South Africa, (2)North West University, Potchefstroom, South Africa

South Africa is surrounded by a coastline of about 3000 km. There are eight main ports in South Africa which include the ports of Mossel Bay, Cape Town, and Richards Bay. Richards Bay and Cape Town can be classified as industrial ports, Cape Town being the second busiest port in the country. Mossel Bay is a recreational harbour. Tributyltin commonly used in harbours have been known to cause endocrine disruption. In this study sediment sampled from these three harbours were analysed to determine if there is any (anti-)androgenic activity. The MDA-kb2 human breast cancer cell line is genetically modified with the mouse mammary tumour virus (MMTV) luciferase neo reporter gene construct. The MDA-kb2 cells have endogenous androgen and glucocorticoid receptors (AR and GR respectively). The MMTV reporter gene is activated when ligands bind to the AR or GR—resulting in the expression of luciferase. The sediment samples were extracted with 2:1 hexane:acetone and evaporated to make up 1 mL of concentrated extract in methanol. The cells were exposed to the samples (0.02–5 g/mL) in triplicate. Reference compounds testosterone (T) (1.6–85 ng/mL) and flutamide (F) (2.1–500 µg/mL) were dosed in the activation and the inhibition assay respectively. The light emitted by the samples were compared to the standard curves of the reference compounds and expressed in terms of T or F-equivalents. Agonistic effects were found at four of the total samples (n=12) indicating the presence of likely AR agonists. Richards Bay 1 represented the highest activation with 135%, with a BEQ₅₀ of 1.9x10⁻⁹ ng T-eq/g sediment. Half of the 12 samples caused an antagonistic response with no evidence of cytotoxicity. Most of the sites in the Richards Bay area inhibited the AR. The BEQ₅₀ of the quantifiable samples ranged from 6.93x10⁻⁶ µg F-eq/g–7.85x10⁻⁵ µg F-eq/g. Evidence of agonistic effects was observed during the inhibition assay: 6 of the 12 samples, with Cape Town 5 having an activation of 168%. This is likely due to a synergistic effect between the extracted compounds and testosterone. No cytotoxicity was observed for the samples with quantifiable luminescence response: cell viability was higher than 60% in the MTT viability assay. The compounds extracted from the samples indicated AR activation and inhibition. The Richards Bay area had the most evidence of endocrine disruption. This could be due to the aluminium smelters located at the Richards Bay harbour.

1.05.T-02 How Endocrine Disruptors May Affect Thymus Plasticity in Seasonally Spawning Fish

Matthieu Paiola¹, Frauke Seemann², Aurélie Duflor³, Julie Hétru³, Catarina Moreira⁴, Patricia Pinto⁵, Thomas Knigge⁴ and Tiphaine Monsinjon³, (1)University of Rochester Medical Center, United States, (2)Texas A&M University, Corpus Christi, United States, (3)Université Le Havre Normandie, France, (4)Université du Havre, France, (5)CCMAR Centre of Marine Sciences, Portugal

Thymus and associated T cell-maturation are evolutionary conserved elements of adaptive immunity. The thymus is a highly plastic organ, the size and function of which changes in relation to reproductive functions. In mammals, puberty accelerates thymic involution with the rise of plasmatic gonadal hormones. In fish, thymic plasticity is also governed by environmental parameters such as temperature, photoperiod and food availability. During winter-season, the European sea bass, *Dicentrarchus labrax*, experiences lowered temperatures and reduced food intake. At the same time reproductive investment increases as the

fishes accomplish gametogenesis. We, therefore, analysed thymuses of juvenile fish by monthly samplings from 95 to 460 days post-hatching (dph), covering the first seasonal investment into gonad development. Animals were kept either in constant conditions, or in conditions mimicking natural variation of photoperiod and temperature. Temperature turned out as a key parameter that regulates the number of thymocytes. Gonadal development impacted both, the size of the thymus and thymic T cell-maturation, as increasing gonadosomatic indices reduced thymocyte number, their viability and the proportion of T cells. In constant conditions, however the number of thymocytes exponentially increased with the body weight up to 310 dph. We could further show that oestrogen modulates thymus development and thymus plasticity. Our results suggest that seasonal spawners regulate thymic plasticity and T cell-maturation *via* sex steroid hormones thereby attenuating adaptive immunity in order to adapt to winter-season and gametogenesis. As a matter of consequence, oestrogenic endocrine disrupting chemicals can interfere with this seasonal alternation of immune and reproductive function.

1.05.T-03 Species-Specific Activation of Human and Zebrafish Nuclear Receptors

*Anna Toso*¹, *Clementine Garoche*², *Abdelhay Boulahtouf*², *Marina Grimaldi*², *Aurelie Escande*³ and *Patrick Balaguer*²,
(1)INSERM, Montpellier, France, (2)INSERM IRCM, France, (3)Université de Montpellier, France

The spread of endocrine disrupting chemicals (EDCs) in the environment has recently raised concern about human and wildlife health. The molecular initiating event (MIE) of an adverse outcome pathway (AOP) induced by an EDC can be detected using *in vitro* cell lines expressing nuclear receptors (NRs), known to be targets of EDCs. While cell lines expressing human NRs have been widely used for the screening of suspected EDCs, cell lines expressing NRs of other species are less recurrent, leading the ecotoxicological evaluation of EDCs to extrapolate mammalian data to other species and raising doubts about their reliability. In this regard, we have established different cell lines expressing human (h) or zebrafish (zf) estrogen (ER), androgen (AR), progesterone (PR), glucocorticoid (GR) and mineralocorticoid (MR) receptors to investigate interspecies differences. Our results on ER expressing cell lines showed that endogenous, environmental, and synthetic ER ligands can induce transcriptional activity of ER subtypes with differences in selectivity and sensitivity. We also reported that many steroids had agonistic activity on hPR while being antagonist of zfPR. As regard the effects of chemicals on GR, few tested steroids showed differences in activation as were agonist on hGR and antagonist on zfGR. Moreover, on the hMR and zfMR, h and zfAR we are performing a screening of a bank of environmental chemicals, including pesticides, industrial compounds and pharmaceuticals in order to reveal if these known targets of man-made compounds present any relevant interspecies differences. Overall, we will identify the h and zfNRs for which interspecies differences in their activation by steroids and environmental chemicals exists. Due to the huge number of chemicals that need to be monitored and regulated, an integrated risk assessment which includes an in-depth analysis of the existing literature, *in silico* and *in vitro* data is needed to minimize animal testing as far as possible and assess at the same time the harmful effects of EDCs on human and wildlife health. To improve the EDC risk assessment, we therefore propose the integration of gene reporter assays expressing zfNRs in the evaluation of EDCs in aquatic toxicology.

1.05.T-04 Transcriptomic Responses to Sexual Endocrine Active Substances in Zebrafish Embryo

*Steve Uwa Ayobahan*¹, *Hannes Armin Reinwald*¹, *Julia Alvincz*², *Orr Shomroni*³, *Gabriela Salinas*³, *Christoph Schaefer*², *Elke Eilebrecht*¹ and *Sebastian Eilebrecht*², (1)Fraunhofer IME, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (3)NGS - Integrative Genomics Core Unit, Germany

Active substances of biocides or pesticides as well industrial chemicals can trigger adverse effects in environmental organisms with a far-reaching impact on ecosystems. To avoid such harmful effects, chemical manufacturers are required to provide data for environmental hazard and risk assessment of these chemical substances prior to their registration. Endocrine disruption - interference with the hormone system of the organism - is of particular concern because it can have long-lasting effects on populations even at relatively low substance concentrations. However, standardized assays for evaluating the impact of endocrine active substances on reproduction are expensive, in terms of both resources and animal use. Therefore, there is a need for alternative, cost-effective approaches, using animal replacement methods, with better predictive power to support hazard assessment. Omics-methodologies are attractive for collecting consistent high content data to discern chemicals modes of action (MoA) for hazard and risk assessment prioritization. To this end, we applied transcriptome profiling to a modified fish embryo toxicity test to analyze and compare estrogen and androgen-mediated endocrine disruption fingerprints induced by ethinylestradiol, tamoxifen, methyltestosterone and flutamide. Upon the 96 hours exposure, we did not observed any statistically significant mortality, neither in the control nor in the treatment groups. Although no significant phenotypic changes were observed following zFET endpoints, results from transcriptomic analysis revealed a concentration-dependent increase in the number of differentially regulated genes. Functional classification and overrepresentation analysis of the observed DEGs identified response to hormone, steroid metabolic process and cellular response to estrogen stimulus to be significantly perturbed. Our study demonstrates that omics-methodologies can significantly improve the identification of endocrine substances targeting reproductive physiological processes. The identified transcriptome fingerprints and in particular the identified signatures can be utilized for assessing sexual-related impairment of endocrine active agents in zebrafish embryos. Future screening approaches developed on the basis of such data will enable for an *ab initio* development of greener substances with less adverse effects on the aquatic environment.

1.05.T-05 Bisphenol a Alters Eye Morphology and Visually Mediated Behavior in Zebrafish (Danio rerio) Larvae and Juveniles Via Thyroid Hormone System Disruption

*Sina Volz*¹, *Karin Lund Kinnberg*², *Annette Duus*³, *Rikke Poulsen*⁴, *Lisa Annie Baumann*⁵, *Martin Metabolomics Hansen*⁶ and *Henrik Holbech*³, (1)Syddansk Universitet, Denmark, (2)SDU, Denmark, (3)University of Southern Denmark, Denmark, (4)Environmental Science, Aarhus Universitet, Denmark, (5)University of Heidelberg, Heidelberg, Germany, (6)Aarhus

University, Denmark

The endocrine disruptor bisphenol A (BPA) is well known for its anti-estrogenic effect in vertebrates. In addition, it has been shown to disrupt amphibian metamorphosis, which is regulated by the thyroid hormone system (THS). Yet, the THS is not only initiating the metamorphic transformation from tadpoles to adult frogs but plays an essential role in the development of all vertebrates. In zebrafish larvae, THS disrupting chemicals have been shown to impair swim bladder inflation and interfere with eye development. The present study assessed the effects of BPA on the THS and eye development in zebrafish larvae and juveniles. Its aim was to further the understanding of how BPA affects the THS in developing zebrafish and to identify apical effects caused by this interference. To this end, zebrafish eggs were exposed to BPA for either seven (larvae study) or 63 days and histological assessments of the eyes and thyroid follicles, as well as behavioral studies, were performed. Larval whole-body thyroid hormone levels are currently being analyzed and will be presented. The results of the histopathology showed that eye morphology, specifically the thickness of distinct retinal layers, was significantly altered in larvae and juveniles. Furthermore, increased thickness of the thyroid follicular epithelium was observed in juveniles, indicating a compensatory response of the thyroid hormone system to a disruption caused by BPA. In behavioral studies with zebrafish larvae, a decreased swimming activity was observed in BPA-exposed individuals in response to changing light conditions (green, red, and white light, darkness). Taken together these findings suggest that BPA disrupts the THS in zebrafish thereby altering eye morphology and visually mediated behavior. This work provides further evidence that eye morphology is a suitable endpoint for assessing THS disrupting effects in both zebrafish larvae and juveniles.

1.05 Investigating endocrine-disrupting properties of chemicals: developments and challenges towards new approach methodologies (NAMs) (Part II)

1.05.T-06 Molecular Fingerprint of Thyroid Hormone System Disruption in Zebrafish (*Danio rerio*) and Its Reversibility *Rikke Poulsen*¹, *Pauline Pannetier*², *Lisa Gölz*², *Thomas Braunbeck*², *Lisa Annie Baumann*³ and *Martin Metabolomics Hansen*⁴, (1)Environmental Science, Aarhus Universitet, Denmark, (2)University of Heidelberg, Germany, (3)University of Heidelberg, Heidelberg, Germany, (4)Aarhus University, Denmark

Early vertebrate development is partly regulated by thyroid hormones (THs) and can therefore easily be disrupted by environmental pollutants that interact with the TH system (thyroid hormone system disrupting chemicals, THSDCs). It remains a question what the molecular fingerprint of this disruption is and whether effects are reversible. In a previous study, we show that continuous THSDC exposure of zebrafish embryos (*Danio rerio*) to two model THSDCs: propylthiouracil (PTU), a TH synthesis inhibitor, and tetrabromobisphenol A (TBBPA), which interacts with TH receptors, impacts the transcriptome as well as eye development and that the effects are partly reversible after a short recovery period of 3 days. In the current study we applied untargeted metabolomics and targeted analysis of 13 THs to look at the molecular signature accompanying the physiological events. Zebrafish embryos were exposed until 5 days post fertilization (dpf) to either PTU or TBBPA. Subsequently, half of the embryos were moved to clean water, to check for reversibility of effects, while the other half remained exposed until 8 dpf. Whole-body samples (n=20 animals per replica, N = 3 replicates), and dissected eyes and tails (n=40, N=3) to detect tissue-specific effects, were collected at 5 dpf and 8 dpf and homogenized for extraction of THs and metabolites. Preliminary analyses of the metabolome showed that >21 000 metabolite features are detectable in the samples, which can be grouped into 6923 compounds. Multivariate analysis of the data currently obtained confirmed the trend observed in the physiological endpoints: The treatment with the THSDCs caused changes in the metabolome compared to controls, however after the 3-day recovery period the metabolite pattern has been largely readjusted to control levels. In the targeted analysis of THs, it was possible to quantify 8 of the THs and several of these were affected by the treatments. In the recovery treatments compensatory responses and adaptation were observed, hence the morphologic, physiologic and transcriptomic effects were mirrored in the metabolome and further identification and annotation of metabolites will soon reveal the exact molecular fingerprint of the two model THSDCs in zebrafish embryos

1.05.T-07 The Impact of Thyroid Hormone System-Disrupting Chemicals on Zebrafish (*Danio rerio*) Eye Development *Lisa Golz*¹, *Lucia Vergauwen*², *Pauline Pannetier*³, *Dries Knapen*², *Henrik Holbeck*⁴, *Thomas Braunbeck*³ and *Lisa Annie Baumann*⁵, (1)COS University of Heidelberg, Germany, (2)University of Antwerp, Belgium, (3)University of Heidelberg, Germany, (4)University of Southern Denmark, Denmark, (5)University of Heidelberg, Heidelberg, Germany

Thyroid hormones (THs) serve multiple functions; among others, THs regulate neurosensory, specifically eye, development in vertebrates. Also in fish, eye development is known to be directly regulated by THs and can therefore be used as thyroid-related endpoint in endocrine disruptor testing with fish. To investigate this, a set of THSDCs with different modes of action was selected to examine their impact on eye development after exposure during different life-stages of zebrafish (*Danio rerio*). Propylthiouracil, perchlorate, iopanoic acid and triiodothyronine were first tested for their toxicity in order to avoid interference with lethal concentrations in further testing of endocrine effects. Changes in thyroid follicle morphology of transgenic zebrafish embryos with fluorescent thyroid follicles were assessed to confirm specific impact on the TH system. Subsequently, exposure experiments were performed (1) until 5 days post fertilization (dpf) according to OECD test guideline (TG) 236, (2) until 28 days post hatch (dph) according to TG 210 or (3) until 60 dph according to TG 234. Effects on eye development were assessed by means of classic histology as well as immunohistology of different photoreceptors. For the development of an adverse outcome pathway (AOP) for disrupted eye development by THSDCs in fish, a detailed literature review was performed covering approximately 80 studies into the effects of TH level modification on eye development of fish. Based on the literature analyses and our experimental test battery with different model THSDCs, there is strong evidence that eye development and swim bladder inflation combined with TH level measurements and analyses of thyroid follicle morphology (histology or transgenic lines) could

be validated for implementation as thyroid-sensitive endpoints into existing TGs for endocrine disruptor testing with fish. Fundingby: This project has received funding from the European Union’s Horizon 2020 research and innovation program, under grant agreement no. 825753 (ERGO) and European Commission contract no. 07.0203/2018/794670/ETU/ENV.B.2 (“Development of a study protocol for regulatory testing to identify endocrine disrupting substances in biotic systems”).

1.05.T-08 Thyroid Hormone System Disruption Is LIFE Stage Specific in Fish: The CASE of Swim Bladder Inflation in Zebrafish

Imke Van Dingenen¹, Lucia Vergauwen¹, Brett Blackwell², Daniel L. Villeneuve² and Dries Knapen¹, (1)University of Antwerp, Belgium, (2)U.S. Environmental Protection Agency, United States

Thyroid hormone system disruption (THSD) negatively affects multiple developmental processes and organs. Recently, an adverse outcome pathway (AOP) network was described, linking THSD to impaired swim bladder inflation and reduced swimming performance in fish. The swim bladder consists of two different chambers, an anterior and posterior, which inflate at different timepoints during development. During early embryonic development, inhibition of thyroid hormone (TH) activation (the conversion of thyroxine to triiodothyronine by deiodinase (DIO) enzymes) leads to impaired inflation of the posterior chamber. Inflation of the anterior chamber in juveniles is affected not only by inhibition of TH activation, but by inhibition of TH synthesis as well. In the present study, we examined the underlying mechanism through which THSD affects the posterior swim bladder by characterizing the timeframe during which the bladder is sensitive to DIO inhibition. Zebrafish embryos were exposed to iopanoic acid, a DIO inhibitor, during specific time windows. These time windows were chosen based on the three phases of posterior chamber development in zebrafish: the budding, pre-inflation and inflation phase. The budding and pre-inflation phase mark the formation of the swim bladder and the three structural tissue layers. During the inflation phase, the embryos gulp air to inflate the swim bladder. Impaired swim bladder inflation was observed in embryos exposed during the budding and pre-inflation phase, but not in embryos exposed during the inflation phase. These results indicate that the development of the bladder is sensitive to THSD, whereas the inflation process itself is not. To further elucidate the mechanism through which THSD affects the posterior swim bladder, additional analyses will be performed. These include gene transcription analysis, where both genes important in swim bladder development and inflation will be assessed, and analysis of TH levels. Knowledge gained in this research is not only relevant for the swim bladder but for other adverse effects of THSD as well. It is difficult to identify endpoints that are specific to THSD. Building a more comprehensive understanding of how THSD affects the different endpoints might allow us to identify more specific (combinations of) THSD biomarkers. These may then aid in further development of THSD screening methods. The contents of this abstract neither constitute, nor necessarily reflect, US EPA policy.

1.05.T-09 Consolidating the Interpretation of the Xenopus Eleuthero-Embryonic Thyroid Assay (XETA)

David Du Pasquier¹, Gregory F. Lemkine¹, Lennart Weltje, Prof. Dr.², Jessica LaRocca³, Vincent Kramer³, Daniel Pickford⁴, Oliver Körner⁵, Benoît Salinier⁶ and Laurent Lagadic⁷, (1)Watchfrog S.A., France, (2)Ecotoxicology, BASF SE, Germany, (3)Corteva Agriscience, United States, (4)Syngenta Limited Bracknell Berkshire RG EY, United Kingdom, (5)ADAMA Deutschland GmbH, Germany, (6)Laboratoire Watchfrog S.A., France, (7)Bayer Crop Science, Germany

The Organization for Economic Cooperation and Development (OECD) has set up a conceptual framework for the testing and assessment of endocrine disruptors. Different *in vitro* and *in vivo* standardized methods (test guidelines, TG) are categorized into five levels of increasing biological complexity. Detection of thyroid active molecules is addressed by mammalian and amphibian testing. Amphibian testing takes advantage of the THs’ exclusive control of anuran metamorphosis. The Amphibian Metamorphosis Assay (AMA) detects the actions of thyroid active molecules via physiological endpoints relevant for metamorphosis. In addition, in June 2019, the OECD validated the *Xenopus* Eleutheroembryonic Thyroid Assay (XETA) in the test guideline program. The XETA utilizes eleutheroembryos to detect modulation of thyroid signalling by thyroid active chemicals. The assay is transcription-based and uses a transgenic line expressing the Green Fluorescent Protein (GFP) under the control of a promoter directly regulated by TH. The response measured is fluorescence of embryos. When transcription of the genomic construct is activated or inhibited following chemical exposure, the embryos express more or less GFP and therefore emit more or less fluorescence compared to unexposed embryos. The XETA TG has been validated through an international effort via the OECD. The test of a set of 14 reference thyroid active chemicals with various known MoA (Mode of Action) demonstrated the transferability, reliability and reproducibility of the XETA but also highlighted the need for more data to consolidate the interpretation of the XETA with regards to the MoA that can be detected by this assay. In the present study, we selected 17 additional chemicals for which AMAs were available. In total, 31 reference chemicals have now been tested in the XETA. Information on the MoA is available for each test chemical. Overall, studies in line with the AMA are now available for a subset of 23 chemicals, allowing a comparison between the outcome of XETA and AMA. The results show that the XETA and AMA provide highly consistent results for different thyroid-related MoA, except NIS inhibition. This situation opens the possibility to use the AMA or the XETA or the two assays sequentially for regulatory assessment of chemicals or to screen for thyroid activity during the development of new chemicals.

1.05.T-10 Evaluation of an Adverse Outcome Pathway Network for Thyroid Hormone System Disruption Across Taxonomic Groups

Lucia Vergauwen¹, Jason O'Brien², Carlie LaLone³, Daniel L. Villeneuve³ and Dries Knapen¹, (1)University of Antwerp, Belgium, (2)Environment and Climate Change Canada, Canada, (3)U.S. Environmental Protection Agency, United States

Thyroid hormone system disrupting chemicals (THSDCs) are widely regarded as potential threats to human and environmental health. Thus, efforts are underway within both the human health and ecotoxicology communities to develop screening assays capable of identifying THSDCs and to describe adverse outcome pathways (AOPs) that link thyroid hormone system disruption

(THSD) to adverse outcomes. When combining all AOPs for THSD in fish, mammals and amphibians, a cross-species AOP network for THSD emerges. While historically, human toxicological assessments of chemical safety have relied on rodent assays and ecotoxicological assessments have relied on non-mammalian assays including fish and amphibians, this cross-species AOP network provides an opportunity to break down this wall and explore avenues for integration of data from assays using different vertebrate taxa. AOPs describing THSD were retrieved from the AOP-Wiki (aopwiki.org). By filtering the resulting AOP network based on the currently described taxonomic domain of applicability of the AOPs (i.e., fish, amphibians or mammals), it was found that AOPs have been developed with a focus on one specific taxonomic group. While mammalian AOPs largely focus on developmental toxicity (DNT) as the adverse outcome, fish and amphibian AOPs thus far mostly lead to impaired swim bladder inflation and altered amphibian metamorphosis, respectively, both taxon-specific adverse outcomes. Other adverse outcomes include thyroid carcinoma, kidney toxicity, altered visual function, hearing loss and reduced fertility. Based on this evaluation, we identified data gaps and prioritized AOP development efforts. AOPs leading to altered visual function have high potential for cross-species AOP development. Since developmental neurotoxicity (DNT) is often considered the most important outcome of THSD in humans, and no AOPs for DNT in fish and amphibians exist, DNT was highlighted as an additional priority for cross-species AOP development and a potential route to expedite the use of fish and amphibian assays for predicting effects in humans. Next to DNT, there are other adverse health effects with potential for cross-species extrapolation including reduced fertility, hearing loss or neurosensory development in general, and kidney toxicity. Finally, another important gap is the lack of AOPs describing THSD in birds and reptiles. *The contents of this abstract neither constitute, nor necessarily reflect, US EPA policy.*

1.05 Investigating endocrine-disrupting properties of chemicals: developments and challenges towards new approach methodologies (NAMs) (Part III)

1.05.T-11 The Rapid Estrogen ACTivity In Vivo (REACTIV) Assay - Results From the OECD Validation Exercise

Andrew Tindall¹, Ioanna Katsiadaki², Marion Sebire², Hiroshi Yamamoto³, Gitte Petersen⁴ and Gregory F. Lemkine¹, (1)Watchfrog S.A., France, (2)Cefas, United Kingdom, (3)National Institute for Environmental Studies, Japan, (4)DHI Water and Environment, Denmark

Estrogen axis activity is currently being evaluated for a large number of chemicals, including obligatory testing for plant protection products under the Biocidal Products Regulation in Europe. Similar projects are also ongoing in Asia and North America. This has led to ethical and logistical problems which could be greatly reduced if whole animal, physiologically relevant, embryonic fish models, not compliant with the European definition of a laboratory animal, were available for medium throughput screening and prioritisation of chemicals. We developed an assay based on the use of transgenic medaka fish eleutheroembryos harbouring the *choriogenin h* promoter driving expression of *gfp* (*chgh-gfp*), the Rapid Estrogen ACTivity In Vivo (REACTIV) assay. The structural role of choriogenin proteins in egg formation suggests that this biomarker may, like the highly related vitellogenin biomarker, not only reveal estrogen axis activity, but may also accurately predict impaired reproduction. In addition to the lead laboratory in France, partner laboratories in the UK, Japan, Denmark, the USA and Germany have been recruited for the interlaboratory validation exercise. The test chemicals chosen for this exercise cover a wide range of mechanisms of action. The REACTIV assay is performed by exposing newly hatched fry of the *chgh-gfp* line to the test chemical in the presence and absence of testosterone (30 µg/L). This allows quantification of the effects of chemicals acting via mechanisms of action revealed in the presence of an aromatisable androgen (e.g. aromatase inhibition, estrogen receptor antagonism) as well as those more easily detected in the absence of estrogen axis signalling such as estrogen receptor agonists. Exposure studies are carried out in six-well plates for 24 h with one test group of eleuthero-embryos per well. The ongoing OECD validation exercise has so far produced some encouraging results. The transferability of the assay as well as its ability to identify chemicals acting on estrogen axis signalling, either at the receptor level or on downstream steroidogenesis and its selectivity have been demonstrated. The eleutheroembryonic life stages on which the assay is based, fall outside of the EU definition of a laboratory animal, in line with the 3R's principle of animal replacement. This assay is currently being evaluated by the OECD as a level 3 screening assay.

1.05.T-12 Optimising Concentration Setting for In Vivo Endocrine Disrupting Chemical Identification Studies

Natalie Burden¹, Michelle Embry², Raechel Puglisi² and Fiona Sewell³, (1)NC3Rs, London, United Kingdom, (2)Health and Environmental Sciences Institute (HESI), United States, (3)NC3Rs, United Kingdom

There is growing regulatory demand for fish and amphibian *in vivo* data to support identification of chemical-induced endocrine activity and disruption. To ensure that only endocrine-specific effects are detected and aid data interpretation, improvements to concentration-setting guidance are needed. This will help avoid triggering unnecessary further vertebrate tests and the use of concentrations that cause unnecessary suffering in test animals. Determining the most appropriate highest concentration – or maximum tolerated concentration (MTC) - for these studies is problematic, e.g. there is inconsistency in how this is defined and recommended within different Organisation for Economic Co-operation and Development (OECD) test guidelines. This work aims to provide a consensus definition of the MTC for fish and amphibian endocrine tests and develop an optimised strategy for concentration setting. Preliminary analysis of regulatory fish (rainbow trout) acute toxicity data on 22 substances assessed the appropriateness of setting the MTC using 1/3rd of the acute LC₅₀ value or 1/10th of the acute LC₅₀ value. These values were compared to the no observed effect concentration (NOEC) and lowest observed effect concentration (LOEC) to evaluate if (sub)lethal symptoms of toxicity were observed in proximity to the selected MTCs. Comparing acute outcomes with the MTC derived from 1/3rd LC₅₀, in 5/22 (23%) of cases the MTC would not be appropriate as it exceeded the LOEC for (sub)lethal effects. In 7/22 cases (32%) the MTC may not be appropriate as it fell between the NOEC and LOEC values for sublethal effects. Comparing acute outcomes with the MTC derived from 1/10th LC₅₀, in 1/22 (5%) of cases the MTC would not be appropriate as it exceeded the LOEC for sublethal effects. In 4/22 (18%) of cases the MTC may not be appropriate as it fell between the NOEC

and LOEC values for sublethal effects. These results highlight the potential for confounded outcomes in fish endocrine tests depending on how the MTC is selected. Next steps include: 1) conducting the same comparisons for fathead minnow data; 2) conducting the same analysis for amphibians; and 3) comparing different approaches for MTC setting with endocrine-relevant endpoints in fish short term reproduction and amphibian metamorphosis assays to determine a) whether overt toxicity was observed in the test concentration range, and b) if this range was sufficient to allow for detection of endocrine activity.

1.05.T-13 The Population Relevance of Endocrine-Mediated Adversity for Non-Target Organisms: Challenges and Future Needs

Laura Villamar-Bouza¹, Maria Arena², Aude Kienzler³ and Domenica Auteri⁴, (1)European Food Safety Authority (EFSA), Parma, Italy, (2)EFSA - European Food Safety Authority, Italy, (3)European Commission - Joint Research Centre, Italy, (4)Auteri, Italy

In June 2018, a guidance document for the implementation of the ED criteria has been published. Similar to the ED criteria, the guidance is based on the definition of WHO/ICPS of an endocrine disruptor: a substance should be considered an ED if it causes 'A change in the morphology, physiology, growth, development, reproduction or life span of an organism, system or population, in the case of non-target organisms, that results in an impairment of functional capacity, an impairment of the capacity to compensate for additional stress or an increase in susceptibility to other influences'. The criteria also stipulate that, in applying the WoE approach, the assessment of the scientific evidence shall consider the adverse effects on reproduction, growth/development, and other relevant adverse effects which are likely to impact populations of non-target organisms. Thus, when defining adversity for non-target organisms the relevance of the observed effects in laboratory studies for the maintenance of the population needs to be addressed. This means that different levels of extrapolation are needed: from laboratory to field conditions and from individual to population. It is known that populations of non-target organisms in the natural environment are able to compensate the effects observed in laboratory to a certain extent and some ED related effects are only transitory. However, from a regulatory perspective, the population relevance of the effects observed in laboratory studies is assumed by default, with few exceptions, unless further proven. The aim of the present work is to present: I. the overview of the challenges identified following the implementation of the ED criteria and the application of the ECHA/EFSA guidance with regard to the population relevance of ED-mediated adversity on non-target organisms (e.g. vertebrates); II. the gaps identified for the determination of the population relevance of the adversity and the future research needs. Based on the experience gained with the evaluations done so far for pesticides, further research is needed on: (i) the extrapolation from lab to realistic field conditions; (ii) the pattern of effects for each taxon which may lead to population impairment; (iii) the use of population models for addressing the population relevance including consideration on e.g. the species to model.

1.05.T-14 New Approach Methodologies (NAMs) for the Endocrine Activity Toolbox: Environmental Assessment for Fish and Amphibians

Constance Mitchell¹, Michelle Embry² and Natalie Burden³, (1)HESI, United States, (2)Health and Environmental Sciences Institute (HESI), United States, (3)NC3Rs, London, United Kingdom

Evaluation of endocrine activity in human and wildlife involves specific *in vivo* and *in vitro* assays used to evaluate relevant pathways. Multiple *in vivo* OECD test guidelines have been validated for mammals, amphibians, or fish, focusing on the estrogen, androgen, thyroid, and steroidogenesis (EATS) pathways. However, these toxicity tests often require the use of a large number of laboratory animals, which are cost inefficient and contradict the 3R principles for animal welfare considerations and increasing mandates to move towards an "animal free" testing paradigm worldwide. New approach methodologies (NAMs) hold great promise to identify molecular changes that can be used to predict individual or population effects and to reduce the numbers of animals used in ecotoxicology testing. In a collaborative effort led by HESI and the UK's NC3Rs, experts from government, academia, and industry met in 2020 to discuss the current challenges of endocrine toxicity testing for fish and amphibians. In continuing the cross-sector initiative, follow-up work is focusing on the current state of the science to evaluate chemical endocrine disruption potential in amphibians and fish using NAMs to predict effects for chemicals acting via EATS pathways. This work highlights the challenges of using NAMs for risk or hazard assessment and what is needed to reduce the uncertainties with the use of these tests. Movement towards development and utilization of NAMs not only allow for replacement, reduction, and refinement of animal testing but also provide robust and fit for purpose methods to identify chemicals acting via endocrine mechanisms. We have summarized current NAM methods available for endocrine activity assessment including *in silico*, cell-free & cell-based methods, and embryo models. This effort focuses on endocrine activity evaluation for fish and amphibians, but conservation of many key endocrine pathways across species allows approaches used in other contexts (e.g., human health assessment) to be leveraged. In addition, the use of pathway-based approaches to inform testing applies to non-endocrine mechanisms. These NAMs can be integrated into Adverse Outcome Pathway (AOP) frameworks within a weight of evidence (WoE) approach for hazard or risk assessment. The application and use of the NAMs within an IATA or WoE approach will be described within specific problem formulation contexts – protection goal, data needs, and testing requirements.

1.05 Investigating endocrine-disrupting properties of chemicals: developments and challenges towards new approach methodologies (NAMs) (Poster)

1.05.P-Mo033 In Vitro Evaluation of Potential Estrogenic Compounds on Estrogen Receptors of European Sea Bass (*Dicentrarchus labrax* L.)

Sylvain Slaby¹, Thomas Knigge², Aurélie Duflot¹, Cinta Zapater³, Ana Gómez³, Patricia Pinto⁴ and Tiphaine Monsinjon¹, (1)Université Le Havre Normandie, France, (2)Universite du Havre, France, (3)Instituto Acuicultura de Torre de la Sal, CSIC,

Spain, (4)CCMAR Centre of Marine Sciences, Portugal

Estrogens are important regulators of many physiological processes such as reproduction and immunity and estrogenic action is mainly mediated by hormone binding to estrogen receptors. Specific transcription factors designated nuclear estrogen receptors (Esrs) have been associated with the activation of gene expression by estrogens or structurally similar compounds. Three subtypes of Esrs have been identified in teleosts. Recently, membrane G protein-coupled estrogen receptors (Gpers) have been related to rapid non-genomic responses. Both signaling pathways are found in fish which may express additional gene duplicates for both receptor types. Estrogen-like endocrine disrupting chemicals (EEDCs) are known to have an impact on the environment at large. Aquatic species are particularly concerned as their environment is the final receptacle of several contaminants. Various changes in physiological functions, such as reproduction, development or immunity are well described in the scientific literature. In this context, the identification of EEDCs at the source appears to be of a major interest. OECD *in vitro* assays to screen EEDCs already exist, but they only consider two human Esrs which are not necessarily representative of Esrs found in teleosts. Recently, the importance in teleost of Esr2b as a significant signaling pathway, yet ignored by existing screening tests, was emphasized. Therefore, we propose a more holistic *in vitro* test using gene reporter assay that includes sea bass Esr1, Esr2a, Esr2b, Gpera and Gperb. Transient transfections using transactivation of an ERE or CRE-luciferase reporter assay for the nuclear and membrane receptors, respectively, were performed on HEK293 cell line and validated using 17 β -estradiol (E2). Using this test, we aim at evaluating the estrogenic potency of putative EEDCs included in the European Agency for Chemical Compounds or the French Agency for Food, Environmental and Occupational Health & Safety list: dexmedetomidine, galaxolide, homosalate, thiram, triphenyl phosphate and triclocarban. They are tested singly and in mixture with E2. By considering Esrs and Gpers, risk assessment of EEDCs could be more accurate allowing to understand their mode of action via various signaling pathways. Its routine use should facilitate the identification of problematic compounds, their elimination at source and the protection of environmental health. This work was funded by the Interreg France (Channel) England program (RedPol project).

1.05.P-Mo034 Interaction of the Thyroid Hormone System With Eye Development in Fish: An Adverse Outcome Pathway Approach

Lisa Golz¹, Lisa Annie Baumann², Pauline Pannetier³, Thomas Braunbeck³, Henrik Holbech⁴, Dries Knapen⁵ and Lucia Vergauwen⁵, (1)COS University of Heidelberg, Germany, (2)University of Heidelberg, Heidelberg, Germany, (3)University of Heidelberg, Germany, (4)University of Southern Denmark, Denmark, (5)University of Antwerp, Belgium

To a significant extent, early vertebrate development is regulated by thyroid hormones (THs) and can, therefore, readily be disrupted by environmental pollutants which interact with the TH system (thyroid hormone system-disrupting chemicals, THSDCs). THs serve multiple functions, among others, neuromorphological, specifically eye development in vertebrates: Also in fish, eye development is known to be directly regulated by THs and can, thus, be used as a thyroid-related endpoint in endocrine disruptor testing with fish. However, the interaction between THSDCs and eye development in fish has not yet been sufficiently explored. Especially with regard to ecological consequences of impaired eye development, it is essential to understand the full sequence of events from molecular interaction with the TH system over morphological and physiological changes up to adverse outcomes at individual and population levels. For development of an Adverse Outcome Pathway (AOP) for disrupted eye development by TDCs in fish, a detailed literature review was performed covering approximately 120 studies into the effects of modification of TH levels on eye development in fish. The studies reviewed include a variety of different approaches for detection of TH disruption, including THSDCs, transgenic or mutant fish, microinjection, morpholino oligonucleotides, thyroid ablation, etc.. Endpoints range not only from gene and hormone level modification to cellular changes in the eyes (e.g. size of cells, cell layer structure, organization and amount of photoreceptors, pigmentation, etc.), morphological changes (e.g., eye size or shape), but also include physiological and behavioral changes (e.g. optokinetic response, light response, swimming activity). The literature analysis provides clear evidence that different modes of THSDCs result in impaired eye development in fish. Results confirm the growing evidence that fish eye development is sensitive to THSDC treatment and might represent a promising endpoint for the assessment of thyroid-related effects in fish, maybe being indicative for eye-related effects in vertebrates in general. The AOP will build the basis for further research on the consequences of TH system disruption in fish (vertebrates), yet, a research field still with multiple knowledge gaps. Funding by the European Union's Horizon 2020 research and innovation program, under grant agreement no. 825753 (ERGO).

1.05.P-Mo035 Morphological Changes in the Retina and Thyroid Follicles of Zebrafish (*Danio rerio*) Embryos: CASE Study With Resorcinol

Imen Chabchoubi¹, **Lisa Golz²**, Luisa Reger³, Thomas Braunbeck³, Olfa Hentati⁴ and Lisa Annie Baumann⁵, (1)University of Monastir, Higher Institute of Biotechnology of Monastir, Tunisia, (2)COS University of Heidelberg, Germany, (3)University of Heidelberg, Germany, (4)Higher Institute of Biotechnology of Sfax, Route de Soukra km 4, PO. Box 1175, 3038 Sfax, Tunisia, (5)University of Heidelberg, Heidelberg, Germany

Resorcinol is commonly used as a medicinal ingredient in human dermatology, in rubber industries (about 50% of total use) and the production of high-quality wood glues (about 25% of adhesive markets). Moreover, it has been reported to act as a thyroid hormone system disruptor. Alterations of thyroid hormonal pathways can lead to a variety of adverse effects, because of the crucial role of the thyroid in various metabolic, behavioral and developmental processes. Effectively, inhibition of deiodinase enzymes, which catalyze thyroxine (T4) deiodination to triiodothyronine (T3), can lead to profound disturbances in the regulation of thyroid hormones. To detect endocrine disrupting compounds with adverse effect on thyroid-related processes, alternative tests using zebrafish (*Danio rerio*) embryos have been developed. Thyroid-sensitive endpoints within these tests were swimbladder inflation, eye development, thyroid follicle morphology/histopathology and thyroid hormone levels. The present study examined resorcinol effects on eye development and thyroid follicle morphology following 5 days exposure to up to 100 mg/L resorcinol on early life-

stages of the zebrafish embryos. Compared to the water control, resorcinol reduced the thickness of the retinal pigment epithelium (RPE) as well as the inner and outer segments of the outer nuclear layer (ONL). Ocular malformations and reduced thickness in the internal plexiform layer (IPL) were also noticed. Moreover, the thyroid follicle size showed a significant increase, which confirmed the specific impact on the thyroid hormone system of zebrafish.

1.05.P-Mo036 Targeted vs. Non-Target Identification of Endocrine Disruptors by Gene Expression Analyses As an Additional Ecotoxicological Endpoint in Fish Studies: Challenges and Opportunities

Elke Eilebrecht¹, Cecilia Andrea Diaz Navarrete¹, Sebastian Eilebrecht², Matthias Teigeler¹, Jasmin Brueckner³ and Kathi Westphal-Settele³, (1)Fraunhofer IME, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (3)Umweltbundesamt / German Environment Agency, Germany

When investigating potentially endocrine-disrupting substances using existing test guidelines, it is important to evaluate rapid-response indicative parameters in addition to population-relevant endpoints. They can provide important information on the underlying mechanisms of action. A promising approach is the investigation of molecular endpoints, as they react very quickly to pollutants. This approach was tested in the course of two Zebrafish Extended One Generation Reproduction Tests, which were supplemented at different life stages by qPCR expression analyses of genes identified to be sensitive for the substance-specific modes-of-action. The study detected gene expression changes at different life stages, which fit comparably well to the expected changes for a substance acting as aromatase inhibitor, while the results for an estrogen receptor modulator were less predictable. It was observed that the expression of selected genes highly depends on the life stage and the chosen tissue; for example, expression changes in head tissue might be of less relevance for sex-specific genes; this observation is supported by the literature. However, the approach revealed some limitations, as a targeted analysis of pre-selected genes may hinder the identification of endocrine active substances with unknown MoA. More comprehensive approaches, such as transcriptomics (e.g. by RNAseq), would allow the identification of MoA-specific expression patterns as molecular fingerprints, serving as data base for substances with unknown endocrine activity. Those non-target analyses of gene expression further allow the identification of MoA-specific gene expression biomarkers, which could be more easily combined with existing test guidelines. For application, a tiered approach should be considered. Tier 1 will be represented by the identification of gene expression biomarkers by global gene expression analyses (e.g. transcriptomics) during a screening approach with embryonic fish. Within a second tier, i.e. chronic fish studies like the FELS test will be conducted coupled with an integrated qPCR analyses of biomarkers identified in the first tier. This approach would not only allow the establishment of a causal link between the substance's MoA and the adverse effects, which is prerequisite for the identification of endocrine disruptors, but would also meet the 3R requirements for animal welfare, as no additional animal studies would be required for a substantial gain of knowledge.

1.05.P-Mo037 Effects of Thyroid Hormone Axis Disrupting Chemicals on *Rana temporaria* Metamorphosis

Amandine Aviles¹, Katrine Hulgard², John Green³, Annette Duius², Bente Holbech² and Jane Ebsen Morthorst², (1)Syddansk Universitet, Denmark, (2)University of Southern Denmark, Denmark, (3)JohnWGreen-ecostats.com, United States

Thyroid Hormone Axis Disrupting Chemicals (THADCs) interfere with the functioning of the thyroid hormone axis, resulting in detrimental effects on critical biological functions like brain development in vertebrates. Amphibians are particularly sensitive to THADCs, as thyroid hormones play a critical role in metamorphosis. OECD test guidelines used to investigate the effects of THADCs have been conducted on *Xenopus laevis* and *Xenopus tropicalis*, tropical frog species with a 100% aquatic life cycle, which may not be representative of European semi-aquatic amphibian species. We collected *Rana temporaria* eggs in Spring for three consecutive years, to investigate the effects of three THADCs on the common frog metamorphosis and thyroid histology, using a shortened Larval Amphibian Growth and Development Assay (LAGDA). *Rana* eggs were exposed to 11.9 - 426.5 µg/L sodium perchlorate (SP, 2018), 1.23 - 47.7 mg/L 6-Propylthiouracil (PTU, 2019), and 18.59 to 349.62 µg/L tetrabromobisphenol A (TBBPA, 2020) for around 6 weeks. At the end of the exposure, developmental stage, morphological data (i.e., total length, body weight, and hindlimb length) and thyroid histopathology (i.e., thyroid gland size, number and size of the follicles, follicle cell height) were assessed. We observed that PTU strongly delayed development without affecting growth, thus resulting in younger, bigger tadpoles. PTU also affected thyroid histopathology, inducing a strong increase in thyroid gland size from the lowest concentration, and follicles with more irregular shapes and proportionately less lumen and colloid. TBBPA only slightly decreased total length and increase the size of follicles' lumens, and no effect was observed for SP. All in all, our results showed that thyroid histopathology endpoints are more sensitive than developmental stages and morphological data, and *R. temporaria* may be more sensitive to PTU but less sensitive to SP than described in the literature for *Xenopus*.

1.05.P-Mo038 Reversibility of Thyroid Hormone System-Disrupting Effects on Eye Development of Zebrafish (*Danio rerio*)

Pauline Pannetier¹, Lisa Gölz¹, Rikke Poulsen², Martin Metabolomics Hansen³, Thomas Braunbeck¹ and Lisa Annie Baumann⁴, (1)University of Heidelberg, Germany, (2)Environmental Science, Aarhus Universitet, Denmark, (3)Aarhus University, Denmark, (4)University of Heidelberg, Heidelberg, Germany

Early vertebrate development is partly regulated by thyroid hormones (THs) and can, therefore, easily be disrupted by environmental pollutants which interact with the TH system (thyroid hormone system-disrupting chemicals, THSDCs). It is known that the eye development of fish is directly regulated by THs and can, therefore, be used as thyroid-related endpoint in endocrine disruptor testing with fish. We were interested to see whether THSDC-induced malformations of eyes during early development would be reversible after depuration in clean water. To this end, zebrafish (*Danio rerio*) embryos were exposed until 5 days post-fertilization (dpf) to either propylthiouracil (PTU), a TH synthesis inhibitor, or tetrabromobisphenol A (TBBPA), which interacts with TH receptors. Subsequently, 50 % of the embryos were exposed further to the THSDCs until 8 dpf, and 50 %

were kept in clean water to check for reversibility of effects. Continuous THSDC exposure altered eye size and pigmentation together with changes in the cellular structure of the retina. Interestingly, the effects were partly reversible after the short recovery period of 3 days. The results are in line with changes in TH levels measured in different tissues of the embryos, for example locally in the eyes. Results show that eye development in zebrafish embryos is highly sensitive to THSDC treatment, but eyes are apparently able to recover rapidly from early exposure *via* effective repair mechanisms. **Funding:** This project has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement no. 825753 (ERGO).

1.05.P-Mo039 Implementation of Thyroid-Sensitive Endpoints Into the Fish Early Life Stage Test (FELS, OECD TG 210) With Zebrafish (*Danio rerio*) - Part 1: Thyroid Follicle and Gonad Histopathology

Tomke Ehrlich¹, Johannes Koegst¹, Maximilian Rinderknecht¹, Lisa Gölz¹, Bozidar Raskovic², Thomas Braunbeck¹ and Lisa Annie Baumann³, (1)University of Heidelberg, Germany, (2)University of Belgrade, Serbia, (3)University of Heidelberg, Heidelberg, Germany

Currently, endocrine disruptor (ED) testing is conducted with multiple protocols using various species both for human health and environmental safety evaluation. ERGO, as part of the EU H2020 EURION cluster project, is focused on the optimisation of such existing test guidelines (TGs) for screening for ED effects of chemicals. Modified or new TGs are expected to both comply with the reduction, replacement, and refinement (3R) principle in animal testing and to reduce the time and costs needed for the evaluation and authorisation of new and existing compounds. The Hypothalamus-Pituitary-Thyroid (HPT) axis as a crucial component of homeostasis and developmental processes is preserved across vertebrate classes. Except for thyroid hormone system disruption (THSD), zebrafish (*Danio rerio*) has become a well-established model in ED testing. In order to optimise current testing procedures, the addition of new thyroid-related endpoints to existing TGs with for zebrafish is (over)due. From mammalian and amphibian studies, it is known that the morphology of the thyroid follicular epithelium is directly affected by thyroid hormone system-disrupting chemicals (THSDCs) as a response to interference with TH homeostasis. Consequently, histopathological analyses of thyroid follicles appear mandatory also in tests with fish. To check for the sensitivity of thyroid histopathology in fish, two model compounds with known THSD properties, iopanoic acid (IOP) and potassium perchlorate (PCL), were used to identify effects on thyroid follicle morphology in a fish early-life stage toxicity test (FELS, OECD TG 210). In order to further increase the ecological relevance, an additional recovery phase of 30 d was added after the initial 34 d exposure period. Furthermore, a histopathological analysis of the gonads is currently being carried out to assess crosstalk with the HPG axis. With regard to the target organ, the thyroid, PCL and IOP exposure had no statistically significant effects on thyroid follicle morphology, when measured at 34 dpf. After 64 d however, statistically significant differences in thyroid epithelium thickness were observed in exposure and recovery groups for both substances. The results show that implementation of thyroid epithelium thickness into TG 210 is technically feasible. However, refinement is needed to, e.g., replace amphibian testing. Moreover, life-stage sensitivity and general developmental effects must be considered when analysing THSD in TG 210.

1.05.P-Mo040 Implementation of Thyroid-Sensitive Endpoints Into the Fish Early Life-Stage Test (FELS, OECD TG 210) With Zebrafish (*Danio rerio*) - Part 2: Eye Development and Thyroid Hormones

Maximilian Rinderknecht¹, Johannes Koegst¹, Tomke Ehrlich¹, Lisa Golz², Bozidar Raskovic³, Thomas Braunbeck¹ and Lisa Annie Baumann⁴, (1)University of Heidelberg, Germany, (2)COS University of Heidelberg, Germany, (3)University of Belgrade, Serbia, (4)University of Heidelberg, Heidelberg, Germany

Currently, both for human health and environmental safety evaluation, endocrine disruptor (ED) testing requires multiple studies across different species. The EU H2020 project "ERGO" is focused on the optimisation of existing test guidelines (TGs) relevant to endocrine activity and adversity for human and environmental health. New TGs would be beneficial to the 3R (replace, reduce, refine) principles and would also reduce time and costs for ED testing. The Hypothalamus-Pituitary-Thyroid axis (HPT) is highly conserved and plays important roles in both early development and homeostasis across vertebrate classes. Except for thyroid hormone system disruption (THSD), zebrafish (*Danio rerio*) is already commonly used as a model species in ED assessment. In order to expand existing TGs to allow for a comprehensive assessment using a single species only, new thyroid-related endpoints have to be evaluated in different developmental stages. Given that eye development is directly regulated by thyroid hormones (THs), possible endpoints include eye malformations. For this purpose, a fish early life-stage toxicity test (FELS, OECD TG 210) with iopanoic acid (IOP) and potassium perchlorate (PCL) was conducted. These substances were selected for their known effects on the HPT axis with different modes of action. In addition to the 34-d exposure phase, a recovery phase of 30 d was added to determine the potential to recover from adverse effects on eye development. We assessed the eye-to-body-ratio, the thickness of the inner plexiform layer (IPL), the retinal pigment epithelium (RPE) and the photoreceptor layer (PL) as well as the ratio of the outer segment (OS) of the PRL to the total PRL thickness. These endpoints have previously been shown to be sensitive to disruption of the HPT in zebrafish embryos. Results show that eye malformations also manifest in later life-stages but tend to be reversible after recovery in clean water. Significant differences were observed for the RPE and the IPL at both time points with the OS/PRL ratio showing significant effects at 64 d. These results support the inclusion of the eye development, especially the thickness of the RPE, as a thyroid-sensitive endpoint into TG 210, thus allowing for a comprehensive assessment of ED effects in a single species. This would help reduce the number of amphibian studies required. TH level measurements are ongoing and will provide mechanistic data for our understanding of effects observed at apical level.

1.05.P-Mo041 A New Standard for Endocrine Disruptor Testing in Fish - the Integrated Fish Endocrine Disruptor Test (iFEDT)

Lisa Annie Baumann¹, Pauline Pannetier², Maria Teresa Fagundes², Lisa Gölz², Susanne Knörr², Lucia Vergauwen³, Dries Knapen³, Jane Ebsen Morthorst⁴, Henrik Holbech⁴ and Thomas Braunbeck², (1)University of Heidelberg, Heidelberg, Germany,

(2)University of Heidelberg, Germany, (3)University of Antwerp, Belgium, (4)University of Southern Denmark, Denmark
Various recent EU research projects deal with the optimization of aquatic vertebrate-based test systems for the identification of endocrine disruptors (EDs). Attempts are made to cover all relevant life-stages, to identify EDs with different modes of action, to partly replace existing amphibian tests and to include thyroid-related endpoints in existing fish test guidelines (TGs). For this end, the EU tender project “Integrated Fish Endocrine Disruptor Test (iFEDT)” was designed to establish a new test system that combines and extends two existing fish test guidelines: the Fish Short-Term Reproduction Assay (OECD TG 229) and the Fish Sexual Development Test (OECD TG 234). Propylthiouracil (PTU; 0 - 78 mg/L; n = 4) and ethinylestradiol (EE2; 0 - 10 ng/L; n = 4) were tested as model substances for disruption of the thyroid hormone and the sexual hormone systems, respectively. In addition to endpoints established in the existing OECD TGs (fecundity, growth, gonad histopathology, vitellogenin, etc.), various thyroid-related endpoints such as hormone levels, thyroid histopathology and (eye) development were assessed during the 85-days exposure period. Results from the first experiment indicate that PTU not only impairs the reproductive performance of adult fish and reduces the growth of juvenile fish, but also induces strong thyroid follicle proliferation in all life stages. Moreover, histopathology of the eyes demonstrates that this endpoint is very sensitive to thyroid disruption in younger life-stages. The experiment with EE2 confirms a strong impact on reproduction of parental fish, on gonad development in the offspring and on vitellogenin levels in either life-stage. Based on these observations, the merged test design iFEDT appears to be a promising tool to integrate various important ED modalities in fish into one assay covering all sensitive life-stages. Funding: This study receives funding from the European Commission under contract no. 07.0203/2018/794670/ETU/ENV.B.2 (“Development of a study protocol for regulatory testing to identify endocrine disrupting substances in biotic systems”).

1.05.P-Mo042 New Transgenic Medaka Model to Detect Disruption of Thyroid Signalling

Elise Pesce¹, Andrew Tindall², Gregory F. Lemkine², Laurent Sachs³ and David Du Pasquier², (1)Laboratoire Watchfrog, France, (2)Watchfrog S.A., France, (3)UMR 7221 CNRS/MNHN Muséum National d'Histoire Naturelle, Paris, France

Endocrine disruption caused by chemicals has been considered as a major issue over the last few decades for both human and wildlife health. Identifying endocrine disrupting chemicals in order to limit their usage is therefore a priority. EU authorities has defined a testing strategy to determine the potential endocrine activity on EATS (Estrogen, Androgen, Thyroid, Steroidogenesis) axis. Regarding thyroid disruption, three OECD guidelines using *in vivo* non-mammalian models are validated, all of them are based on amphibian metamorphosis. In the most recent assay, the XETA (Xenopus Eleutheroembryo Thyroid Assay, OECD N°248), an amphibian (*Xenopus laevis*) transgenic line expresses a fluorescent protein which is quantifiable and proportional to thyroid axis activity. To date no OECD test guideline based on fish are available for the detection of thyroid active chemicals. We aim to fill this gap by developing a new test for the detection of thyroid active chemicals using medaka eleutheroembryos (*Oryzias latipes*). This test involves a transgenic line, expressing Green Fluorescent Protein (GFP) under the control of the *thyroglobulin* promoter (a precursor of thyroid hormones). We first identify the medaka sequences presumably involved in the regulation of the expression of *thyroglobulin*. A transgene was then built by cloning this putative promoter upstream of the *gfp* coding sequence. Series of micro-injections were performed in one-cell embryos in order to develop transgenic lines. Screening the offspring reveals that five transgenic lines were obtained with different transmission rates but all having fluorescent thyroid follicles. We are now studying the five transgenic lines to characterize the spatio-temporal expression of the fluorescence and the modulation of fluorescence intensity by pro and anti-thyroid reference chemicals. Variation of fluorescence intensity is expected to reflect the negative feedback loop of HPT-axis. Using this fish test along with amphibian assays will allow a comparative physiology strategy offering a way to understand specific thyroid regulating mechanisms that are not fully elucidated in fish. Developing a test using transgenic medaka offers the possibility to combine this assay with the RADAR and/or REACTIV assays that are currently in OECD validation. This strategy could lead to reduce the time, number of eleutheroembryos and cost associated with EATS assessment in fish.

1.05.P-Mo043 Toward an AOP Network-Based Testing Strategy for the Assessment of Thyroid Hormone System Disruption in Fish

Dries Knepen¹, Lucia Vergauwen¹, Thomas Braunbeck², Daniel L. Villeneuve³, Lisa Annie Baumann⁴ and Henrik Holbech⁵, (1)University of Antwerp, Belgium, (2)University of Heidelberg, Germany, (3)U.S. Environmental Protection Agency, United States, (4)University of Heidelberg, Heidelberg, Germany, (5)University of Southern Denmark, Denmark

Thyroid hormone system disruption (THSD) has been recognized as an import focus area in the context of hazard and risk assessment of chemicals worldwide where further development of assays and endpoints is needed. In particular for fish-based test guidelines (TGs), no endpoints for THSD have been validated yet. Various research projects are currently ongoing or being planned to address this challenge, including the H2020 ERGO project, the EU DG Environment funded iFEDT project, the US EPA Chemical Safety for Sustainability Program and the Horizon Europe PARC partnership. These activities are focused on increasing our fundamental understanding of TSHD, reviewing existing knowledge, and developing a fish TSDH AOP network to support the selection of assays for inclusion in TGs. From the perspective of fish test method development it is especially important to systematically document the high degree of life stage specificity of the different THSD mechanisms and effects in fish. This level of resolution in the domain of applicability description is required to determine which endpoints are relevant in the context of non-protected life stage tests such as the Fish Embryo Acute Toxicity test (OECD TG 236), and which endpoints need to be assessed in juvenile or adult tests. A number of endpoints are currently well documented, including swim bladder inflation, eye development, thyroid follicle histology and thyroid hormone levels. Other endpoints under consideration include fin development, skin pigmentation and gene transcription in target organs. It is likely that the level to which these individual endpoints are specific to THSD may differ and it is therefore anticipated that a combination of endpoints may be required. The envisioned overall implementation strategy is to add endpoints that are supported by OECD-endorsed AOPs to existing fish TGs

by establishing a direct connection between relevant projects of the OECD's AOP development work plan and the work plan for the TGs programme. Specifically, an AOP network for THSD in fish is being developed in project 1.35 of the AOP development programme and a first set of 5 AOPs is currently being considered for EAGMST approval and endorsement by WNT/WPHA. This work will be integrated with project 2.64 of the work plan for the TGs programme, which aims to include thyroid endpoints in existing OECD fish TGs. In this context, a pre-validation effort of a selection of relevant endpoints is expected to start in 2022.

1.05.P-Mo044 Are Hormone Measurements the Best Way to Look for Endocrine Disruption?

Rikke Poulsen¹, Yanis Zekri², Romain Guyot², Frederic Flamant² and Martin Metabolomics Hansen³, (1)Environmental Science, Aarhus Universitet, Denmark, (2)École Normale Supérieure de Lyon, France, (3)Aarhus University, Denmark

Endocrine disrupting chemicals pose a threat to both humans and wildlife. The hypothalamic-pituitary-thyroid axis has been identified as an area with large knowledge gaps and insufficient test guidelines, not at least when it comes to early life stages. In this study we used targeted quantification of 13 thyroid hormones as well as untargeted metabolomics to investigate the molecular fingerprint in mouse plasma following *in utero* and lactational exposure to thyroid hormone system disrupting compounds (THSDC). We tested two chemicals, propylthiouracil (PTU) and tetrabromobisphenol-A (TBBPA), that are known to disrupt the thyroid hormone system but have different molecular initiating events for their toxicity. Pregnant C57Bl/6 mice were exposed to either PTU (1 mg/L in drinking water) or TBBPA (by gavage, 2 mg/kg/day dissolved in oil) from gestational day 7 to postnatal day 14. Pups were then sacrificed and their blood sampled for analysis on a nano-liquid chromatography (LC)-Orbitrap system. Statistical analysis showed no significant effects of the THSDCs on the thyroid hormones. However, metabolomics analysis revealed 85 up- and 152 down-concentrated metabolites due to PTU exposure and 134 up- and 69 down-concentrated metabolites due to TBBPA exposure ($p < 0.05$, fold change > 1.5). Annotation revealed that many of the affected metabolites were involved in fatty acid metabolism incl. linoleic- and alpha linoleic acid metabolism. Hence the study allowed identification of metabolites that might be used as more sensitive key events to assess the thyroid hormone system disrupting potential of putative THSDCs and identify other affected biochemical pathways

1.05.P-Mo045 Comparison of NF Developmental Stage-Matched Control Data in Amphibian Metamorphosis Assay Continuous Quantitative Endpoints (HLL, SVL, WET WEIGHT)

Maria Estebanaranz-Yubero¹, Oliver Körner², Sonja Haaf², Joe Marini³ and Lee Sayers⁴, (1)Environmental Resources Management (ERM), United Kingdom, (2)ADAMA Deutschland GmbH, Germany, (3)Smithers Viscient, United States, (4)Smithers Viscient, LLC, United States

The analysis of continuous quantitative *Xenopus laevis* endpoints such as snout-to-vent length (SVL), hind limb length (HLL), nHLL (normalized by SVL) and wet weight is performed to assess statistically significant differences between the negative control and active substance treatments in the Amphibian Metamorphosis Assay (AMA) for the detection of potential thyroid modes of action according to Guidelines OECD 231 and OPPTS 890.1100. However, the current statistical analysis of these parameters at Day 7 and 21 is routinely performed by using the replicate means or medians of the recorded HLL, nHLL, SVL and wet weight individual values without taking into consideration the different stages of development within each control or treatment replicate. Furthermore, these endpoints are well known to be directly impacted by developmental stage in tadpoles and so using stage-matched data may have an impact in the interpretation of the biological results. This is also the case for tadpole thyroid gland histopathological findings, where it is already recognised in both Guidelines that the most appropriate approach is to use NF developmental stage-matched tadpoles for evaluation. Consequently, individual control HLL, nHLL, SVL and wet weight values on Day 7 and 21 from the available data set have been extracted and evaluated according to NF developmental stage. The analysis presented here aims to develop a NF developmental stage-matched Historical Control Database (HCD) that allows the assessment of potential impact in the outcome of statistically significant results of these thyroid screening parameters, as well as the variability of NF developmental stage-matched control data across different GLP AMA-performing laboratories.

1.05.P-Mo046 Challenges With the New XETA Test System

Bettina Wenzel¹, Stefan Hoger², Jörn Schreitmüller¹ and Magdaléna Cornement³, (1)Innovative Environmental Services (IES) Ltd, Switzerland, (2)Innovative Environmental Services (IES) Ltd, Witterswil, Switzerland, (3)Innovative Environmental Services IES Ltd, Switzerland

The OECD Test Guideline No. 248 (Xenopus Eleutheroembryo Thyroid Assay, XETA) was published in June 2019. Since then, several laboratories have started establishing the test at their facilities. In this poster presentation, the major challenges of the establishment of the test at a new facility are shown. According to the guideline, the establishment phase includes testing four proficiency chemicals at each new facility in order to demonstrate that the desired results can be reached. These reference tests show the high variability within this test and indicate the limitations of this test. One additional challenge discussed will be that not all laws, even within Europe, are equal. The test was developed as an alternative to animal trials and the EFSA recognizes it as such. This means the embryos are not recognized as vertebrates up to the stage where the test ends according to the EU regulations. This is, however, different in Switzerland, where the animals are seen as vertebrates at this stage. Thus, the test is not considered as an alternative to animal tests, which defeats the purpose of replacing the fish tests by the XETA. Further challenges are substance related. Various examples will be shown of substances that cannot be tested with the standard XETA set-up and how these challenges can be overcome. This includes substances that have a very short half-life under test conditions, substances that adhere to plastic, and substances that are degraded by the biological material within the test. The possibility of running this test in a flow-through system is also explored.

1.05.P-Mo047 Retrofitting In Vitro Test Systems for High Throughput Screening of Thyroid Disrupting Chemicals With Metabolic Capacities - a Tiered In Vitro/In Silico Testing Strategy

Sebastian Lungu-Mitea¹, Runze Liu¹, Puja Kumari², Jiri Novak² and Klara Hilscherova¹, (1)Masaryk University, Faculty of Science, RECETOX, Czech Republic, (2)Masaryk University, Czech Republic

Many compounds unfold their toxic potential only after bioactivation, as also encountered for endocrine disruptors. Nevertheless, commonly used HTS approaches for endocrine disruptors do not include xenobiotic metabolism, even though most in vitro test systems do not preserve the metabolic activity of their parent tissue of origin. Retrofitting in vitro test systems with metabolic capacities is a promising strategy to solve the stated issue. However, current approaches hamper HTS applications due to costs and technological practicality. On the contrary, cellular tests systems augmented with external metabolism capacities (liver S9 fractions) seem adjustable to an HTS scenario, as proven for ER and AR (ant-)agonistic effects, if parameters are appropriately adjusted. Here, we report the conceptualization and application of an HTS in vitro/in silico testing battery to assess thyroid disrupting potential. Two HepG2-based reporter cell systems (TH metabolism; TH signalling), an enzymatic turnover assay (TH synthesis), and a TH transporter assay were assessed regarding their compatibility with S9 external metabolization incubations parallel to chemical exposure. The parameters for potential cytotoxicity and cofactor concentrations were optimized. Additionally, in silico biotransformation models (Biotransformer, QSAR toolbox, CTS) are employed to derive consensus metabolites, which are assessed for a potential de- or increase in toxicity via TR a/b and TTR-inhibition QSARs. The obtained in silico data will qualitatively be compared to in vitro results within a tiered testing approach. The depicted HTS testing scenario complies with devised OECD short and midterm strategies on endocrine disruptors. Indeed, S9 liver fractions are animal-derived components that need to be phased out shortly. However, liver S9 fractions currently serve as a consistent regulatory-accepted biotransformation tool within in vitro toxicology until biotechnological alternatives have matured. The project has received funding from the EU H2020 project ERGO (No.825753).

1.05.P-Mo048 Multiple Mechanisms of Action of Pollutants and Their Mixtures in Aquatic Environment Associated With Thyroid Hormone Disruption

Puja Kumari¹, Runze Liu², Marie Smutna³, Jiri Novak³ and Klara Hilscherova², (1)RECETOX, Faculty of Science, Masaryk University, Brno, Czech Republic, (2)Masaryk University, Faculty of Science, RECETOX, Czech Republic, (3)Masaryk University, Czech Republic

While endocrine disruption associated with steroid hormones is a well-described phenomenon nowadays, there is less info related to interference of chemicals with the thyroid hormone (TH) system. Nevertheless, TH plays a crucial role in many vital processes such as metabolic activity, neurodevelopment, swim bladder inflation in fish or amphibian metamorphosis. Xenobiotics that can interfere with the thyroid hormone (TH) system (Thyroid hormone Disrupting Chemicals; TDCs) have been linked with numerous disorders across different species. This poses an urgent need for the development and implementation of suitable methods for the screening of chemicals as well as environmental pollutant mixtures for their TH-disrupting properties. Unlike in steroid hormone systems, receptor-mediated effects are probably not the most important mode of action of TDCs. TH synthesis, transport, and metabolization steps in TH metabolism are likely more important targets for TDCs. We have developed a set of bioassays focusing on prioritized endpoints in thyroid hormone disruption. The assays for the assessment of effect of TDCs on iodide uptake by thyroid cells mediated by Na⁺/I⁻ symporter (NIS) are based on stably transfected human cell line overexpressing NIS and on rat thyroid cell model, and on the detection of uptaken iodide levels by the cells using a non-radioactive, colorimetric Sandell-Kolthoff reaction. Transport of TH is addressed by fluorometric assessment of displacement of TH from its plasma transporter transthyretin (TTR) by TDCs. The TH metabolization step is addressed by a cell model with a reporter gene under transcription control by aryl hydrocarbon receptor (AhR) that plays a significant role in triggering the metabolization systems. Interaction with thyroid receptor signaling is assessed using reporter-gene assay. These assays have been established and optimized for screening of a set of prioritized chemicals and environmental samples from the aquatic environment for their potential to disrupt the thyroid hormone system. The results demonstrate the utility of the newly developed bioassays for high-throughput screening of chemicals as well as environmentally relevant complex pollutant mixtures for the characterization of their thyroid hormone-disrupting potential.

1.05.P-Mo049 Findings on Sexual Development of Zebrafish Exposed to Parabens - Does Metabolization Play a Crucial Role in the Context of Endocrine Disruption?

Dennis Becker¹, Uwe Ensenbach², Elias Luetzen², Martina Mahler² and Reinhard Kreiling², (1)Clariant Produkte (Deutschland) GmbH, Sulzbach, Germany, (2)Clariant Produkte (Deutschland) GmbH, Germany

Parabens, the alkyl esters of p-hydroxybenzoic acid, are widely used as preservatives in consumer products, primarily in cosmetics and pharmaceuticals. Their toxicological profile is well characterized, and they are suspected of having endocrine disrupting (ED) properties. This suspicion is based primarily on studies of estrogen agonistic activity in vitro conducted according to Level 2 of the OECD ED Conceptual Framework. To assess the biological relevance of estrogen receptor bioactivity of parabens, parameters correlating with ED-relevant endpoints from fish studies on propyl- and methylparaben are discussed. Based on REACH requirements Fish Sexual Development Tests (OECD TG 234) on methylparaben and propylparaben had to be conducted. The performed in vivo studies were required by ECHA during the REACH registration process. The evaluation of the ED related endpoints revealed no adverse effects on parameters such as male to female ratio, increase of vitellogenin in male fish, or other population relevant endpoints for methylparaben and propylparaben. Based on the results of both studies, there is no evidence that methyl- or propylparaben has ED properties leading to an adverse effect. One explanation for this observation could be that both parabens are rapidly metabolized in zebrafish and the metabolites have less or no endocrine activity. Consequently, in a second study, the metabolic capabilities in different life stages of the zebrafish towards parabens were investigated. For this

purpose, two different concentrations of methyl- and propylparaben were tested in each case upon 96 h exposed eggs, 14 days exposed juvenile fish and 63 days exposed adult fish. One key aspect was whether early developmental stages exhibit different metabolization rates than older developmental stages. The identification of the metabolites of methylparaben and propylparaben were performed using liquid chromatography high resolution mass spectrometry (LC-HR-MS) and fragmentation experiments (MS/MS). Seven metabolites of methylparaben and eight metabolites of propylparaben were identified. First findings show high capability to metabolize parabens at all 3 life stages of zebrafish. This could be an explanation for the fact that no evidence of an ED related adverse effect was observed.

1.05.P-Mo050 Using the ProtoCol 3 Colony Counter to Quantify Egg Numbers From the Fish, Short Term Reproduction Test

Emma Danby¹ and **Dominic Sacker²**, (1)*Covance, United Kingdom*, (2)*Labcorp Early Development Laboratories Limited, United Kingdom*

The OECD 229 Test Guideline requires daily assessment of reproduction as one of the measurements of test item effect for potential endocrine disruption with a daily desirable egg production at least 10 eggs per female per day in the control. For a valid test this equates to a minimum of 3360 eggs from the control group alone; however, experience has shown that with fathead minnows, egg production can be considerably higher than this with 40-60 eggs per female per day a routine occurrence. To compound this, a typical test requires a minimum of 80 females per test therefore often double this number of fish are usually used for monitoring egg numbers during the pre-acclimatisation stages. Given these higher number of eggs it was decided that a manual counting procedure would extremely time consuming and potentially inaccurate and therefore an automated approach was adopted. A ProtoCol 3 Colony Counter was selected which was able to considerably speed up the counting process with quantification taking less than 2 minutes for each test vessel once the eggs had been collected and stained. On a daily basis, the breeding tiles containing fathead minnow eggs were removed from the test vessels. Once the eggs have released from the tiles, they were stained, sieved and rinsed and placed in a petri dish to be quantified using the Protocol 3 Colony Counter. Some validation studies were conducted to ensure the suitability of the counter: Three different sized (small, medium and large) broods of eggs were collected and prepared for counting using the Rose Bengal stain. Each batch of eggs was counted five times using the ProtoCol 3 Colony and Counter and once each by five different technicians. The length of time taken to manually count the eggs was also recorded. Here we present the results of our validations. The major benefit is the significant reduction in time taken to count the eggs.

1.05.P-Mo051 A Critical Review on Assessing Anti-Androgenic Activity of Chemicals in Fish

Grace Panter¹, **Rebecca Brown¹**, **Laurent Lagadic²**, **Oliver Körner³**, **Alan J. Jones⁴** and **Lennart Weltje, Prof. Dr.⁵**, (1)*wca consulting, United Kingdom*, (2)*Bayer Crop Science, Germany*, (3)*ADAMA Deutschland GmbH, Germany*, (4)*ADAMA, United States*, (5)*Ecotoxicology, BASF SE, Germany*

According to the European Chemicals Agency (ECHA) and the European Food Safety Authority (EFSA) endocrine disrupter (ED) guidance (ECHA/EFSA 2018), to sufficiently investigate the oestrogenic, androgenic and steroidogenesis modalities, a Fish Short-Term Reproduction Assay (FSTRA, OECD TG 229), or 21-day fish assay (OECD TG 230) are preferred. However, concerns have been raised by EFSA and in the OECD GD 150 that such assays may not be sufficiently sensitive to detect anti-androgenic effects of chemicals. This view has led to requests for additional testing, such as the Fish Sexual Development Test (FSDT; OECD TG 234), despite the lack of evidence that such a test would be more sensitive. Therefore, we have conducted a review of *in vivo* studies to assess the sensitivity of fish and the ED relevant endpoints to anti-androgenic substances. Work to date has included: · Use of the United States Environmental Protection Agency's (US EPA's) Sequence Alignment to Predict Across Species Susceptibility (SeqAPASS) database to investigate the conservation of the Androgen Receptor (AR) between vertebrates and fish species. Findings show that the AR is well conserved at all model levels and in all OECD fish model species (e.g. *Pimephales promelas*, *Danio rerio*, *Oryzias latipes*, *Gasterosteus aculeatus*). · ToxCast™ anti-androgenicity scores were used to 15 model anti-androgenic substances for inclusion in the review. · A literature search of the prioritised model substances was conducted which identified over 50 fish *in vivo* studies with endpoints which would be included in an ED assessment. These results have shown that the sensitivity of endpoints to the anti-androgen modality was inconsistent within, and across, the various fish studies when exposed to the most potent anti-androgenic substances. Neither the FSTRA nor the FDST were more sensitive in detecting this endocrine modality. The poster will present the outcomes of the work to date, and evidence on the suitability of fish study designs and endpoints, to detect the anti-androgenic modality.

1.05.P-Mo052 The Interplay of Paraoxonase 1 and Bisphenol a in Metabolic Disruption

Rik van den Boom, **Lucia Vergauwen**, **Katyeny Manuela da Silva**, **Alexander Van Nuijs**, **Adrian Covaci** and **Dries Knapen**, *University of Antwerp, Belgium*

Endocrine disrupting chemicals (EDCs) have long been studied for their effects on steroid hormone pathways. Recent studies have shown that some EDCs also have a metabolic disrupting effect, which could result in fat accumulation in the liver when lipid metabolism is disturbed. However, the details of these interactions are still not fully understood. One such interaction is between EDCs and paraoxonase 1 (PON1), an enzyme with antioxidant functions, known to be associated with fatty liver and to metabolize xenobiotic substances. In order to better understand the mechanism by which PON1 is affected by metabolic disruption via dietary changes or metabolic disrupting chemicals, experiments with zebrafish were performed under different metabolic conditions. First, diet quantity was changed in order to simulate metabolic disruption. Secondly, metabolic disruption was induced by feeding with a custom obesogenic diet in combination with exposure to different doses (5 µg/kg, 50 µg/kg and 500 µg/kg) of a metabolic disruptor, bisphenol A (BPA). During each trial, the weight and length of each fish were followed up.

After 6 weeks, PON1 activities, oxidative stress, BPA concentration, lipid profiles, energy reserves and mRNA expression of genes involved in energy metabolism or downstream effects of bisphenol A are measured in liver tissue to characterize the relations between these parameters. Changes in diet quantity resulted in a difference in condition factors. These changes were correlated negatively with pon1 lactonase activity, which in turn correlates positively with oxidative stress. This resulted in a few hypotheses: 1) This is an attempt to use the antioxidant function of PON1 to reduce oxidative stress, 2) PON1 activity is increased by metabolic signaling pathways, or 3) it is a combination of both. However, the change in the condition factor induced by an obesogenic diet did not result in a different pon1 lactonase activity. Instead, exposure to BPA resulted in an increase in lactonase activity for the highest concentrations. Oxidative stress will be measured in the same samples to test its relation to the changes in lactonase activity. These changes will be compared to internal BPA concentration, changes in lipid profiles, and mRNA expression of relevant genes to obtain more mechanistic insights.

1.05.P-Mo053 Bridging the Gap Between Drug Exposure and Sex-Related Gene Expression in Environmental Toxicology Studies

Alex King¹ and Armin Zenker², (1)University of Applied Sciences and Arts Northwestern Switzerland FHNW, Switzerland, (2)School of Life Sciences, University of Appl. Sc. Northwestern Switzerland, Muttenz, Switzerland

Gender has previously been shown to affect the way individuals respond to toxicological exposure. Genes which allow identification of sex in juvenile zebrafish show potential to aid confounding variables in environmental toxicology trials but the link between these is so far missing. Early expressed gender specific genes where expression is not altered by drug exposure must be carefully and specifically selected for this purpose. Transcriptome data from Next-Generation-Sequencing (NGS) of adult male, adult female and juvenile *Danio rerio* were used to discover sex-specific juvenile-expressed genes. Previous studies were used to classify juvenile-expressed genes to highlight the interference of these juvenile biomarkers with toxicological application to uncover gender-related variations in gene expression during environmental toxicology trials. Four male and eight female genes (*Gapdhs*, *Apobb1*, *Spata6* and *Dmrt1* and *Bmp15*, *Chr4*, *Zpb3*, *Gyg1a*, *Kpna2*, *Ftz-f1*, *gdf9* and *Ipo4*, respectively) show great potential for use in revealing sex related differences during environmental toxicology studies. Discovery of these early sex-determining genes will allow identification of gender-related responses to toxicity testing to improve sex-specific healthcare and the medical treatment of patients.

1.05.P-Mo054 Comparison of Internal Historical Data From Endocrine Disruptor (ED) Screening Assays With Data From the EPA ED Screening Programme

Stefan Hoger¹, Peter Hvorslev, M.Sc.², Armin Peither², Johannes Völker³ and Jörn Schreitmüller², (1)Innovative Environmental Services (IES) Ltd, Witterswil, Switzerland, (2)Innovative Environmental Services (IES) Ltd, Switzerland, (3)NTNU University, Switzerland

Testing for endocrine disruption is an essential part of the regulation of chemical substances in the EU and USA. Key screening assays are the Fish Short Term Reproduction Assay (FSTRA), OECD 229 (OCSPP 890.1350), the 21-day Fish Assay (FA), OECD 230, and the Amphibian Metamorphosis Assay (AMA), OECD 231 (OCSPP 890.1100). In particular for the registration of plant protection products (PPPs) in Europe these assays are critical, since the indication of an effect triggers higher tier tests resulting in additional costs and additional use of animals and, in case of a confirmed endocrine disrupting effect, a ban of the substance on the European market. Since 2019 IES Ltd has been conducting FSTRA, FA and AMA on a regular basis using fathead minnow (*Pimephales promelas*) and the African clawed frog (*Xenopus laevis*). During implementation and performance of these assays we identified gaps in the description of the applied test performance in both the OECD and the OPPTS (OCSPP) guidelines, which may affect the reproducibility and comparability of the outcomes. Given the high importance of these tests for the registration and re-registration of PPPs, existing gaps should be discussed and closed soon. To identify weaknesses of the current procedures, we compared our results for all relevant endpoints (fecundity, nuptial tubercle score, and vitellogenin for the fish tests and determination of the Nieuwkoop-Faber stage, measurement of the hind-limb and snout-vent length for the *Xenopus* test) with data from the Endocrine Disruptor Screening Program, published by the EPA. The results of this comparison will be presented and critically discussed. Moreover, we will provide recommendations to improve the testing procedure, such as the choice of suitable test concentrations.

1.05.P-Mo055 Locomotor Activity of Zebrafish Larvae After Exposure to Plastic Additives

Bidemi Green-Ojo¹, Lena Grinsted², Matthew Parker² and Alex Ford², (1)University of Portsmouth, Portsmouth, United Kingdom, (2)University of Portsmouth, United Kingdom

Plastic additives are added to plastic to improve the functional properties necessary for its end use or application. They are not chemically bound to the plastic and when not properly disposed of, eventually leach out in the environment. These compounds are suspected endocrine disruptors capable of altering the behaviour of affected animals. This study aimed to evaluate the behavioural toxicity of environmentally-relevant concentrations of di-2-ethylhexyl phthalate (DEHP) and dibutyl phthalate (DBP) on zebrafish larvae. Day 0 Zebrafish embryos were exposed to (0,0.5, 5, 50, 500) µg/l and (0, 0.5, 5, 50) µg/l concentration of DEHP and DBP respectively for 96 hours. The survival rate and developmental abnormalities were observed while the locomotive activity was automatically tracked using Zantiks MWP_vb unit. Startle protocol was used to induce movement for 22 mins and the percentage of animals moved during the startle stimulus (light on/off or vibration) was recorded. In animals exposed to DEHP, no mortality was observed, while DBP had 100% mortality in 50 and 500 µg/l after 96 hours. This study found a significant effect of DEHP on startling response in both baseline and vibration conditions. Larvae in 5 µg/l moved slower than those in control and the rest of the exposed group, showing a U-shaped response. The percentage of larvae moved in the baseline, and vibration stimulus had a significant concentration-response effect after exposure to DBP. In conclusion, the tested plastic additives reduced the overall

activity of zebrafish larvae, although the effects were more evident in animals exposed to DEBP than DBP. This suggests that the introduction of vibration as an additional stimulus influenced their startle response. The mode of action of these compounds may cause differences in how they affect the survival and locomotor activity of zebrafish.

1.05.P-Mo056 Comprehensive Analysis of the Literature to Construct AOP Network Related to Metabolism Disorders Induced by Endocrine Disruptors Using the Aop-Helpfinder Tool

Kevin Bernal¹, Florence Jornod², Elias Zgheib³, Etienne Blanc¹, Min Ji Kim³ and Karine Audouze⁴, (1)Université de Paris/Inserm U1124, France, (2)Université de Paris/U1124, France, (3)Université de Paris/ U1124, France, (4)Université de Paris/ Inserm U1124, Paris, France

Adverse outcome pathways (AOPs) are a conceptual framework that support the use of alternative toxicological approaches in chemical risk assessment. AOPs provide structures organizations of known biological perturbations, starting from an initial molecular event (MIE) to an adverse outcome (AO) across several intermediate key events (KEs). To help the development of AOPs and AONs (AOP networks), which are a combination of several AOPs sharing at least one biological event, we have developed a tool named AOP-helpFinder. AOP-helpFinder is based on artificial intelligence, more precisely using natural language processing (NLP) and graph theory to systematically and rapidly explore all available abstracts stored in the PubMed database. It will identify and extract known associations between stressors of interest and KEs, therefore supporting the development of AOPs. Recently a web-server has been created to facilitate the use of this advanced bioinformatics tool. The web server operates with an updated version of the tool, that allows to refine (using machine learning, i.e. lemmatization for text normalization) and reduce (capability to search only in the results/conclusion part of an abstract) the searches. In the context of the H2020 OBERON project, we investigated the applicability of using the AOP-helpFinder tool with an integrated systems toxicology approach to develop an AON related to metabolic disorders, that are among the main adverse health outcome associated with endocrine disrupting chemicals (EDCs). Co-occurring terms (i.e. EDCs and biological events (MIE, KE, AO) from the AOP-wiki database and from in house experts) were identified by the AOP-helpFinder tool. This step allowed to decipher known links between EDCs and biological events, and was followed by a manual curation to select the most relevant publications. Then, AON was proposed, which was enriched by integration of complementary data extracted from other databases (e.g. CompTox). Computational approaches that allow identification, extraction and integration of existing knowledge, appear to be essential to have a better understanding of the mode of action of suspected EDCs, and the biological pathways that may perturb in order to identify their real impact in the human population.

1.05.P-Mo057 Perinatal Exposure to Permethrin and Bisphenol F Alters Lipid Metabolism in Rat Liver

Sara Evangelista¹, Chayenn Dalger², Walter Lichtensteiger³, Margret Schlumpf³, Jesus Tresguerres⁴, Lisa Rancan⁴, Sergio Damian Paredes⁵, Marja Lamoree⁶ and Pim Leonards⁷, (1)Environment & Health, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (2)Vrije Universiteit Amsterdam, Netherlands, (3)GREEN Tox, Switzerland, (4)Complutense University of Madrid, Spain, (5)Complutense University of Madrid Location, Spain, (6)VU University, Department Environment & Health, Netherlands, (7)Vrije Universiteit Amsterdam, Netherlands

Human exposure to EDCs during pregnancy and early stages of life can disrupt normal patterns of brain development and reproductive function, leading to severe pathologies later in life. Environmental studies have linked bisphenols (BPA mostly) and phthalates exposure to neurodevelopmental diseases. However, a wide number of suspected EDCs such as pyrethroids, are hardly studied in relation to neurodevelopmental diseases. Lipidomics showed to be a powerful tool in environmental toxicology in recent years: the key function of lipids in brain homeostasis and liver metabolism makes them exceptional candidates in the discovery of sensitive biomarkers for neuroendocrine toxicity in animals and humans. The liver is the key organ for the maintenance of whole-body lipid homeostasis with the potential to influence brain function. The study investigated, therefore, the effects of two chemicals used worldwide, bisphenol F (BPF), a substitute of the EU-banned BPA, and the pyrethroid permethrin (PMT), on lipid metabolism. Female and male rats were exposed to BPF (0.036 mg/kg; 3.6mg/kg BW/day) or PMT (0.36 mg/kg BW/day; 3.6mg/kg BW/day): the dams were exposed during pre-mating, mating, pregnancy, and lactation; the pups were exposed until postnatal day 6 (PND 6) *via* maternal milk. Lipid profiles were determined in both exposed and control groups, focusing solely on PND 6 rat livers. Liquid chromatography combined with high-resolution mass spectrometry (LC-ESI QTOF) was used for lipidomics analysis. MS features extraction (m/z), signal intensity, RT, peak picking, and lipid MS/MS spectral matching were performed through MS-DIAL. Data normalization and statistical analysis as ANOVA (p-values < 0.05, FDR), PLS-DA and fold change analysis were performed with MetaboAnalyst. The Lipid Ontology (LION) pathway enrichment analysis was also investigated to link lipid disruption to specific cellular compartments in the liver. The results showed that many lipids were affected due to BPF or PMT exposure, and these effects were gender and dose-specific: BPF downregulated triacylglycerols, glycerolipids, and glycerophosphoethanolamines, and upregulated glycerophospholipids, glycerophosphocholines, and fatty acids. PMT upregulated diacylglycerols, diacylphosphocholines, and fatty acids, and downregulated glycerolipids, glycerophosphoglycerols, and triacylglycerols. The results showed that BPF and PMT have significant effects on the liver lipid homeostasis of rat offspring.

1.05.P-Mo058 An Adverse Outcome Pathway Linking Retinoid Signaling Disruption to Craniofacial Malformation and Feeding Behavior Impairment

Audrey Phan¹, Marie Smutna² and Klara Hilscherova³, (1)Masaryk University, Faculty of Science, RECETOX, Brno, Czech Republic, (2)Masaryk University, Czech Republic, (3)Masaryk University, Faculty of Science, RECETOX, Czech Republic
Retinoid acid (RA) is an essential morphogen during fish early development. Its anteroposterior gradient concentration is a key actor during embryonic patterning and morphogenesis. Although retinoid signaling disruption is understudied, recent studies

demonstrated the presence of environmental pollutants with retinoid-like activities. We have identified some gaps in the development of retinoid-associated adverse outcome pathway (AOP), whereas there is already extensive evidence linking the disruption of RA gradient and teratogenicity. In this study, we aim to develop an AOP linking retinoid signaling disruption to functional impairment in fish. Specifically, we propose an AOP linking the agonism of the heterodimer Retinoic Acid Receptor (RAR) / Retinoid X Receptor (RXR) with craniofacial malformation and feeding disruption in zebrafish early development. To trigger the molecular initiating event, we selected compounds activating RAR / RXR through different mechanisms in retinoid signaling. To unravel the temporal concordance and essentiality, we exposed zebrafish embryos during several time windows (0-24hpf; 0-48hpf; 0-72hpf; 0-96hpf) and compare craniofacial malformation at 120hpf with a) dose-response Meckel-Palatoquadrate (M-PQ) angle score and b) morphological chondrocyte assessment. After determining EC20, EC50, and EC80, we perform an ingestion test to explore functional adverse effects at the individual level. According to Dynamic Energy Budget (DEB) theory, the energy uptake is allocated to different physiological functions such as growth, maturation, maintenance, reproduction. A feeding behavior impairment would affect the energy uptake. Consequently, the normal physiological functions could be disrupted and lead to population decline. The project is a part of the PRORISK network, which aims to incorporate mechanistic, ecological, and socio-economic aspects into environmental risk assessment. PRORISK has received funding from European Union's Horizon 2020 research and innovation program under the Marie Skłodowska-Curie grant agreement No. 859891 (MSCA-ETN).

1.05.P-Mo059 Linking Chemical Information and Receptor-Mediated Effects - a CASE Study on 56 European Wastewater Treatment Plant (WWTP) Effluents

Saskia Finckh¹, Warich Leekitratapanisan², Sebastian Buchinger³, Beate Escher⁴, Henner Hollert⁵, Maria Koenig⁶, Martin Krauss⁶, Aliaksandra Shuliakevich⁷ and Werner Brack⁶, (1)WANA, Helmholtz Center for Environmental Research - UFZ GmbH, Leipzig, Germany, (2)GhEnToxLab (Ghent University), Thailand, (3)Federal Institute of Hydrology, Germany, (4)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (5)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (6)Helmholtz Centre for Environmental Research – UFZ, Germany, (7)Department for Evolutionary Ecology and Environmental Toxicology, Goethe University, Germany

Aquatic ecosystems are impacted by mixtures of endocrine disrupting chemicals (EDCs), including different steroids and phenols. These chemicals are released into the environment via wastewater treatment plant (WWTP) effluents, among other sources. Due to their high potencies at low environmental concentrations, they require adequately sensitive detection methods and assessment approaches. Scientists from the field of ecotoxicology have been reporting on the potential of linking information on the occurrence of chemicals (exposure) and adverse biological effects (toxicity) [1, 2]. In the present case study we used chemical and effect-based tools to screen 56 European WWTP effluents for various EDCs. The main objectives were (a) to investigate a combined approach of chemical target screening and receptor-based testing for estrogenicity, glucocorticogenic activity, androgenicity and progestogenic activity (ER⁺-, GR-, AR- and PR-GeneBLazer assay) in treated wastewater, (b) to compare three different receptor-based assays for estrogenicity testing (ER⁺-GeneBLazer, pYES, ER⁺-CALUX®), and (c) to evaluate the potential impact of advanced wastewater treatment technologies on both exposure and toxicity. As a result, steroids and phenols were detected at concentrations ranging from ng/L to µg/L. In the GeneBLazer assays, ER⁺- and GR-activity was detected in 82% and 73% of the samples, respectively, while AR- and PR-activity were only measured in 9% and 20% of the samples, respectively. 17-β estradiol and triamcinolone acetonide were the predominant drivers of estrogenicity and glucocorticogenic activity, respectively. The comparison of BEQchem and BEQbio for ER, GR, AR and PR demonstrated a good correlation of chemical target screening and receptor-based testing results ranging within an order of magnitude above or below ideal correlation. WWTP effluents which have passed an advanced treatment via ozonation and AC were found to be less contaminated, in terms of lower or no detection of steroids and phenols, as well as receptor-mediated activities. Results on estrogenicity from the ER⁺-GeneBLazer assay and the p-YES test showed stronger correlations between BEQchem and BEQbio than the results of the ER⁺-CALUX® assay. This study shows that future water quality monitoring and assessment of certain steroids and phenols can be improved by linking chemical and effect-based screening tools.

1.05.P-Mo060 Interrogation of the GPCRome by Food Contact Chemicals

Molly McPartland¹, Johannes Völker² and Martin Wagner³, (1)Biology, NTNU/Biologi, Trondheim, Norway, (2)NTNU University, Switzerland, (3)Norwegian University of Science and Technology, Norway

The adverse health effects from endocrine-disrupting chemicals (EDCs) in plastic products have been well documented over the past decades. It has become clear that exposure to food contact chemicals (FCCs), that is compounds migrating for food packaging, can interfere with the endocrine system to cause developmental or reproductive toxicity, increased risk to cancers, and disturbances in the immune system. Traditionally, EDC research has focused on nuclear receptors while largely ignoring their potential to interact with cell surface receptors. G-protein coupled receptors (GPCRs) are the largest family of cell surface receptors and are a primary point of research in drug discovery. Emerging research has shown that GPCRs are activated by PCBs, PAHs, pesticides, and other environmental contaminants. In this work, we have utilized the PRESTO-Tango (Parallel Receptorome Expression and Screening via Transcriptional Output, with transcriptional activation following arrestin translocation) to identify the potential of FCCs to act as agonists on a set of 135 previously validated human GPCRs. We show that well-known plastic chemicals, as well as the mixture of compounds present in food packaging, can activate a variety of GPCRs, including melatonin (MT1 and MT2), melanocortin (MC3R), and prostaglandin (PTGER1) cell surface receptors. This agonism has been further validated through secondary beta-arrestin dose-response curves. This work demonstrates that plastic chemicals can activate GPCRs, and, most importantly, highlights that cell-surface receptors are relevant, yet understudied mechanisms of action for

EDCs and other compounds which may be important to the increased incidence and severity of certain non-communicable diseases.

1.05 Investigating endocrine-disrupting properties of chemicals: developments and challenges towards new approach methodologies (NAMs) (Virtual Only)

1.05.V-01 Adult Zebrafish Exposures to a Progestin Mixture and Ethinylestradiol Lead to Gonadal Structural Changes

Miguel Silva, Maria Rocha, José Fernando Gonçalves and Prof. Eduardo Rocha, ICBAS and CIIMAR, University of Porto, Portugal, Portugal

Endocrine disruptors (EDCs) and, in particular, ubiquitous chemicals capable of mimicking natural oestrogens, known as xenoestrogens, have been a hot study area. However, there is a lack of research on the effects of oestrogen and progestin combinations. Over the years, experimental data have pointed to important concerns for species of many taxa, as well as considerable ecological effects. The purpose of this study was to determine the impact on the gonadal volume and gametogenesis kinetics of adult zebrafish exposed to a progestin mix and ethinylestradiol (EE2). Thirty-two zebrafish females and 32 males (in 4 groups) were exposed for 28 days to solvent (ethanol at 0.1%), progestins mix (100 ng/L of levonorgestrel and of megestrol acetate), progestins mix + EE2 (100 ng/L + 10 ng/L) and EE2 alone (10 ng/L). We studied the maturity grade (1 to 5), gonadal volume, and GSI values as a first step. The gonadal volume and GSI did not vary significantly among groups, but there was a marked trend towards lower mean and median values in females exposed to the mixtures and EE2 alone (especially in the latter group). In general, these results agree with comparable studies. In terms of ovarian maturity grading, the control group had a median score of 3, whereas the EE2 and progestin mix groups had less developed maturity scores (1.5). However, there were no significant differences. The progestin + EE2 mix group showed a smaller degree of ovary maturation, significantly differing from the control. Stereology was used to estimate the relative volumes (RV) of the ovarian compartments to refine the semi-quantitative approach. Relative to control (12%), the primary oocytes' RV was greater in all exposed groups (19%). Furthermore, females exposed to EE2 had decreased RV of advanced oocytes stages and increased atresia and stroma. Despite a decreasing trend, and in contrast with the grading, the RV of the mature oocyte compartment did not differ between the control (54%) and progestin + EE2 mix group (33%). The outcome indicates that the EDCs used had a direct influence on gametogenesis, as hypothesised, altering oocyte maturation. Overall, differential effects were found in females after exposure to EE2 and EE2 + progestins. This fact supports that co-exposure to progestins modified the impacts of EE2 alone. The study will be refined by analysing the total volumes of the ovary structures. Acknowledgements: Funded by FCT and ERDF (UIDB/04423/2020, UIDP/04423/2020) and ICBAS.

1.05.V-02 Identification of Thyroid Disruption Molecular Markers Based on Transcriptomic Analysis: Optimization of Protocol Exposure for RNA Sequencing Using Whole Zebrafish Embryos

Celia Martí¹, Noemie De Croze², Marc Georges Leonard¹, Nicolas Buisine³ and Laurent Sachs³, (1)LOréal Research & Innovation, France, (2)LOREAL, France, (3)UMR 7221 CNRS/MNHN Muséum National d'Histoire Naturelle, Paris, France

Nowadays, environmental pollution is rising concern for both human and environmental health. Among others, the evaluation of endocrine disruptor chemicals is a challenge for both regulators and industry. More specifically only a few methods exist to identify Thyroid disruptor compounds (TDC). Those methods are low throughput, and expensive. Moreover, [LM1] some such as the AMA (Amphibian Metamorphosis Assay) do not comply with the animal testing ban of cosmetic regulation. Therefore, it is becoming urgent to develop novel strategies and screening methods to identify TDCs. As thyroid signaling is highly conserved between teleost and mammals, zebrafish embryo is an ethical alternative model for studying both physiological regulations and disruption. Our main objective is to identify and validate robust biomarkers for Thyroid Disruption in the zebrafish, To do so, we design a transcriptomic analysis where embryos are exposed to reference compounds alone or in combination with thyroid hormones. We selected four reference compounds (Iopanoic acid (IOP), Sodium Perchlorate (PCL), Tetrabromobisphenol-A (TBBPA) and 6-propylthiouracil (PTU)) based on their different modes of action on the thyroid signaling pathway. Then we performed FET (Fish Embryo Test - OECD guideline, n°236) as a range-finding test of reference compounds to choose what concentrations fits better to RNA sequencing. Experimentally, a total of three biological replicates containing 40 whole zebrafish embryos each will be exposed, RNAs extracted and deep sequenced. Data will be processed and analyzed with in-house pipelines. Lists of differentially regulated genes (DEG) will be classified in several clusters, each corresponding to a type of biological response. This is an essential step as it makes the transition between raw data and biological results. In addition, biological responses will be modeled with the system biology framework, where DEG will be placed in their functional context by building a network of signaling and metabolic pathways. This set of data, integrated in the context of the H2020 European project ERGO will provide the molecular basis for the development of an adverse outcome pathway network as well as new endpoints and molecular biomarkers.

1.05.V-03 Identifying Potential Endocrine Active Substances on the Canadian Domestic Substances List Using Version 2.0 of the Ecological Risk Classification of Organic Substances Approach: A Case Study

Mark A. Bonnell, Michael Beking and Bryon Shore, Environment and Climate Change Canada, Canada

Environment and Climate Change Canada has recently finished development of version 2.0 of the ERC approach (ERC2) for approximately 12 200 organic substances from the Domestic Substances List (DSL) that did not meet criteria for further risk assessment following Canada's 2006 PBT-oriented categorization exercise. ERC2 is a high-throughput IATA method using many sources of 'alternative data' (new approach methodologies, or NAM) such as *in silico*, *in chemico*, and *in vitro* data to complement traditional *in vivo* sources to provide evidence for risk classification and other regulatory activities. A case study is

presented demonstrating the approach used in ERC2 to identify potentially endocrine active substances. Data were collected for estrogen (E) receptor, androgen (A) receptor, and thyroid (T) receptor interactions, as well as affinity for the aryl hydrocarbon receptor (AhR). Potency-based hazard classification rules were developed to classify ERC2 substances for the above receptor-mediated interactions for *in silico*, *in vitro* data and mammalian and aquatic *in vivo* data nodes. An Adverse Outcome Pathway structure associates the mechanistic data with the *in vivo* data to determine plausible interactions. Confidence scoring rules measure the degree of data availability and consensus among the data nodes using a weighted data preference hierarchy. Relatively few *in vivo* sub-lethal effects data were available for profiling receptor-mediated effects for the ~12 200 chemicals in ERC2, but a high percentage of *in vitro* data and *in silico* predictions were available or generated for ERC2 chemicals. Just under 18% of all ERC2 substances trigger rules for potential endocrine activity identified by the ERC2 receptor-mediated descriptor, regardless of confidence score. Approximately two-thirds of these have low or very low confidence scores, suggesting significant *in vivo* data gaps and lack of potency consensus between data types. Follow-up regulatory actions (e.g., no further action, data gathering, risk/hazard assessment) can be proposed for ECCC future regulatory activities based on the combination of hazard potency (i.e., hazard classification) and confidence score.

1.05.V-04 Investigation of Thyroid Endocrine Disruption of Two Isothiazolinones Using *Thraa*^{-/-} Zebrafish Embryo *Sujin Lee¹ and Kyunghye Ji², (1)researcher, Yongin, Korea, Republic of (South), (2)Yongin University, Korea, Republic of (South)*

Isothiazolinones are widely used as preservatives or biocides in various household chemical products. Toxicity studies have been conducted to investigate the adverse effects to skin sensitization and irritation; however, limited information is available on thyroid endocrine disruption. In the present study, we developed a novel *in vivo* thyroid endocrine disruptor screening system employing wild-type and thyroid hormone receptor alpha a knockout (*thr^a^{-/-}*) zebrafish embryo, and applied them to two isothiazolinones, i.e., benzisothiazolinone (BIT) and methylisothiazolinone (MIT). To test the validity of our *in vivo* thyroid endocrine disruptor screening system, we evaluated the sensitivity profile of *thr^a^{-/-}* to T3 and propylthiouracil. *Thr^a^{-/-}* zebrafish seemed to detect thyroid endocrine disruption with a significantly higher sensitivity than did the wild-type. Two types of zebrafish embryo were exposed to BIT and MIT (0, 0.03, 0.3, 3, 30, 300 µg/L) for 96 h, and compared the larvae mortality. *Thr^a^{-/-}* zebrafish exhibited a hypersensitivity than wild-type to BIT and MIT, suggesting the possibility of thyroid endocrine disruption based on inhibition to bind thyroid hormone receptor alpha. Acknowledgement: This study was supported by National Research Foundation of Korea (NRF; Project no. 2019R1A2C1002712).

1.05.V-05 Studying the Effects of a Xenoestrogen and Warmer Temperature on the Guppy Fish Liver Size and Cellularity *Margarida Vilaça¹, Maria Rocha¹, Sukanlaya Tantawisawaruj² and Prof. Eduardo Rocha¹, (1)ICBAS and CIIMAR, University of Porto, Portugal, Portugal, (2)Learning Institute, King Mongkut's University of Technology Thonburi, Bangkok, Thailand, Thailand*

Pollutants, notably endocrine disruptors, have a negative impact on aquatic habitats and the organisms that inhabit them. When processed by the liver, these chemicals can exert an influence on the organ and produce morphological and functional alterations. Aside from that, the rise in water temperature caused by global warming has unavoidable effects on ectothermic creatures such as fish, including disruptions in metabolic processes, reproduction, growth, and survival rates. However, our understanding of the final combined impacts of endocrine-disrupting chemicals and temperature remains restricted. As a result, the purpose of this study is to see if a higher temperature and exposure to 17-ethinylestradiol (EE2) affect (independently or interactively) fish liver mass and cellularity. To put our hypothesis to the test, we performed a stereological investigation using light microscopy. We utilized 25-µm-thick paraffin sections of livers obtained from an experiment with mature male guppies (*Poecilia reticulata*). The animals were divided into four groups: two solvent control groups kept at 26°C or 29°C for 45 days (simulating warming), and two groups kept at the same temperatures but exposed to EE2 (at a nominal concentration of 50 ng/L). The findings revealed that EE2 and temperature influenced body biometry, with EE2 having a detrimental effect on body mass and length. According to preliminary stereological data, fish from the control groups exhibited larger livers. This fact was consistent with greater body biometry. Furthermore, control fish appear to have bigger or more hepatocytes (this is under analysis). The findings suggest that the higher temperature affected the core structure of the liver. At this stage, we can not tell if the temperature influenced the effects of EE2 on liver variables. Whatever the study's final conclusion, the new data will help to shed light on the still-unknown processes of fish liver reactions to both stimuli. Funding: Supported by FCT and ERDF (UIDB/04423/2020 and UIDP/04423/2020) and ICBAS.

1.06 Metagenomics tools to unravel environmental adverse effects on communities (Poster)

1.06.P-Tu001 RNA Metabarcoding to Reveal Responses of Zooplankton Community to Environmental Stressors *Phillip Ankle¹, Yuwei Xie², Sonya Havens³, Lisa Peters⁴, Jose Luis Rodriguez Gil⁵, Lauren Timlick⁴, John Giesy¹ and Vince Palace⁵, (1)University of Saskatchewan, Canada, (2)Toxicology Center, University of Saskatchewan, Saskatoon, SK, Canada, (3)IISD Experimental Lakes Area (IISD-ELA), Winnipeg, MB, Canada, (4)University of Manitoba, Canada, (5)IISD Experimental Lakes Area (IISD-ELA), Canada*

DNA metabarcoding can provide a rapid, high-throughput method for characterizing responses of communities to environmental stressors. However, within bulk samples, DNA metabarcoding has issues distinguishing live from dead organisms. Here, both DNA and RNA metabarcoding were applied and compared in experimental freshwater mesocosms conducted for assessment of ecotoxicological responses of zooplankton communities to a simulated oil-spill and subsequent remediation practice. Shoreline enclosures were used to simulate an ecological setting exposed to an oil-spill in a boreal lake, with traditional oil collection

methods being applied followed by enhanced monitored natural recovery remediation practice. Additionally, a novel indicator of normalized vitality (NV), sequence counts of RNA metabarcoding normalized by that of DNA metabarcoding, was developed for assessment of ecological responses. DNA and RNA metabarcoding detected similar taxa richness and rank of relative abundances. NV presented relatively greater magnitudes of differential responses of community compositions to treatment compared to DNA or RNA metabarcoding. NV also differed between Rotifer and Arthropoda, possibly due to differential life histories and sizes of organisms. NV could be a useful indicator for characterizing ecological responses to anthropogenic influence; however, the biology of target organisms and subsequent RNA production should be considered when using this approach for ecological assessment.

1.06.P-Tu002 Wastewater Microorganisms Impact the Microbial Diversity of Stream Periphyton and Its Tolerance to Micropollutants

Louis Carles¹, Simon Wullschleger¹, Adriano Joss¹, Rik Eggen¹, Kristin Schirmer¹, Nele Schuwirth¹, Christian Stamm¹ and Ahmed Tlili¹, (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland

Effluents from wastewater treatment plants contain complex mixtures of micropollutants and are of major concern regarding their impacts on the quality of receiving streams. Stream periphyton, a complex community composed of bacteria, algae, fungi and protozoa, plays a crucial role in ecosystem functioning. It has been shown that periphyton tolerance towards micropollutants was increased upon *in-situ* exposure to wastewater. The aim of this study was to determine the role of microorganisms from wastewater effluents in the observed increased tolerance. To achieve this goal, we grew periphyton during 4 weeks in flow-through channels that were continuously alimeted with stream water that was mixed with various fractions of filtered or unfiltered treated urban wastewater. Filtration was meant to remove microorganisms while dissolved nutrients and micropollutants remain unaffected. Tolerance of periphyton to a micropollutant mixture extracted from passive samplers that were immersed in the effluent was determined via short-term bioassays. Impact of wastewater on microbial communities of periphyton was also assessed via sequencing of 16S and 18S rRNA genes in periphyton and compared to stream and wastewater communities. Moreover, 51 micropollutants were analysed in water and periphyton samples. Our results show an increased tolerance for periphyton exposed to unfiltered wastewater, but not to the filtered one. Hence, the removal of ~99% microorganisms from the effluent led to the loss of increased tolerance. Effluent filtration also led to differences in the diversity and composition of periphyton communities compared to the control (without wastewater) and to the communities exposed to unfiltered wastewater. Moreover, the relative contribution of wastewater bacterial communities in periphyton was higher than that of stream communities, especially for periphyton exposed to unfiltered wastewater. These results suggest that microbes originating from the wastewater may have contributed to the increased tolerance, either directly via the colonisation of periphyton by micropollutant-tolerant taxa, or indirectly by modifying species interactions within the community. Overall, our study highlights the need to consider the role of wastewater microorganisms, in addition to in-stream exposure of periphyton to micropollutants, in order to better understand potential impacts on the receiving water bodies.

1.06.P-Tu003 Structural Dynamics of Biofilms Exposed to Contaminants and Effects on River Functions

Sarah Gourgues¹, Maria Soledad Goni², Patrick Baldoni-andrey³, Amiel Boullemant⁴, Clementine Gelber⁵ and Severine Le Faucheur⁶, (1)University of Pau and Pays de l'Adour, France, (2)Université de Pau et des Pays de l'Adour, France, (3)TOTALENERGIES, France, (4)Rio Tinto Aluminium Pechiney, France, (5)TOTAL ONE TECH S.E., France, (6)Université de Pau et des Pays de l'Adour, France

During the last decades, intensified human activities and emerging contaminants have been disturbing the quality of freshwaters. Such hazardous compounds threat and alter the physical and chemical properties of aquatic ecosystems and consequently the global biodiversity, biological processes and functional services provided by rivers. Assessing quality of freshwaters is thus became of high importance. In that context, bioindication evolves into an indispensable tool for water quality assessment. However, current biological monitoring relies mainly on techniques which need highly-qualified personnel and are time-consuming as well as costly. It includes for example capture-based surveys and observations for vertebrates and invertebrates, or microscopic observation and plate-counting for microorganisms. The use of environmental genomic approaches would be a good solution to develop a rapid, efficient and cost-effective method due to the development of high-throughput sequencing and bioinformatics tools. The aim of our study is to define biofilm-based indicator(s) to assess metal impacts on rivers using environmental genomic tools. River biofilms represent a highly diversified biota (bacteria, algae, fungi and meiofauna) and have the interesting feature of responding quickly and in a sensitive manner to changes in water quality. Contaminants could have repercussions on biological organization of these biofilms. Because they are at the bottom of the trophic food chain, impacting these microecosystems would affect biogeochemical cycles of major elements in the river and river functions. To that end, glass slides were exposed to increasing concentrations of cobalt (3 µg/L, 30 µg/L and 60 µg/L) in outdoor mesocosms for 28 days. Growing biofilms were collected by scraping the slides after 7 d, 14 d, 21 d and 28 d of exposure. Cobalt bioaccumulation in biofilms will be determined and its potential impacts on their biological organization will be assessed through molecular approaches. Biofilms are currently analyzed at the level of functional genes related to C, N and S cycles. Bacteria and algae abundance is also assessed using qPCR. Future analyses will examine microorganism diversity as well as their interactions. The overall results will bring insights on the evaluation of metal bioavailability and toxicity towards aquatic communities, and are expected to go deeper into the genomic-based tools improvement in environmental risk assessment.

1.06.P-Tu004 Use of Metagenomics to Assess the Impact of Organic Fertilizers in the Agricultural Soils Microbiomes

Claudia Sanz¹, Marta Casado², Laia Navarro-Martin³, Víctor Matamoros⁴, Josep Bayona² and Benjamin Pina⁵, (1)Environmental Toxicology, CSIC/IDAEA, Barcelona, Spain, (2)Institute of Environmental Assessment and Water Research

(IDAEA), Spanish Research Council (CSIC), Spain, (3)Institute of Environmental Assessment and Water Research, Barcelona, Catalunya, Spain, (4)Institute for Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain, (5)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain

The use of organic fertilizers has been proposed as alternative source of nitrogen and phosphorus for agriculture, with the added benefit of compensating the deficit in organic matter of most European agricultural land. This practice constitutes a paradigmatic example for circular economy, as the ultimate residues of food waste or food production facilities is utilized o increment food production. However, there is a growing concern that it also may recirculate different biological hazards into the food circuit, with the consequent risks for environmental and human health. We present here an study about the persistence of the microbiomes from different organic fertilizers (sewage sludge, pig slurry, and composted organic fraction of municipal solid waste), and of the antibiotic resistance genes (ARG) associated to them into agricultural soils and products. We observed that only minor fractions of the organic fertilizers' microbiome persisted into the soil only few weeks after the fertilization, but that this fraction is likely responsible for the increase in ARG loads observed in the fertilized soils. We also observed that both effects (microbiome colonization and increase in ARG loads) were transient, being almost obliterated six months after fertilization. Finally, our data show that ARG and some bacterial forms from organic fertilizers may reach the agricultural produce (lettuce and radish, in this particular study) and, therefore, that adequate waste management and good pharmacological and veterinarian practices are needed to significantly reduce the presence of these ARGs and of potentially pathogenic bacteria in agricultural soils and plant products.

1.06.P-Tu005 Transfer of Antibiotic Resistance Genes From a Waste WATER Treated Plant Effluent to the Filter Feeding Zooplankton *Daphnia magna*

Marina Sevilla¹, Marta Casado¹, Benjamin Pina² and Carlos Barata Dr³, (1)Institute of Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain, (2)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (3)CSIC, Spain

Antibiotic resistant bacteria from waste water treated plant WWTP effluents are pervasive in aquatic environments. A facilitating role for the emergence of waterborne, multi-drug resistant bacterial pathogens has been attributed to biofiltration but had not yet been substantiated. This study investigated the ability of *Daphnia magna* to reduce antibiotic resistant genes (ARGs) in water and incorporate them. *D. magna* individual juveniles of 4 days old were exposed for 10 days to a WWTP effluent with and without 1 mg/L of the antibiotic doxycycline and then transferred to clean water for an additional 4 days. Experiments were conducted with food: *Chlorella vulgaris* at 5 10⁵ cells/ml, which was cultured in semi-axenic conditions. Results showed negligible effects of the antibiotic on *D. magna* reproduction and successful transfer of several ARGs from WWTP effluents to *D. magna* quantify by qPCR. These included quinolone and sulphonamide resistant genes, blaTEM and blaCTXM.

1.06.P-Tu006 Efficient Reduction of Biohazards From Wastewater by Soil Aquifer Treatment Systems

Claudia Sanz¹, Lurdes Martínez-Landa², Cristina Valhondo³, Marta Casado⁴, Laia Navarro-Martin⁵, Jesus Carrera⁶, Silvia Diaz-Cruz⁷, Juan Hidalgo⁶ and Benjamin Pina⁸, (1)Environmental Toxicology, CSIC/IDAEA, Barcelona, Spain, (2)Tecnical University of Catalonia UPC, Spain, (3)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), France, (4)Institute of Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain, (5)Institute of Environmental Assessment and Water Research, Barcelona, Catalunya, Spain, (6)Institute fo Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain, (7)QA, IDAEA-CSIC, Barcelona, Spain, (8)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain

Under the actual climate change scenario, circular economy represents a suitable option to reevaluate resources such as water with a minimal waste generation. Among all the different initiatives to water regeneration we find wastewater reuse. However, this is severely limited by its potential chemical and biological risks for users, as well as for the environment. Wastewaters contain variable concentrations of many biologically active compounds, including antibiotics (ABs) and represent a substantial biological hazard, as they may contain pathogens, parasites, viruses, antibiotic resistant bacteria (ARB) and antibiotic-resistance genes (ARGs). It is precisely the simultaneous presence of ABs, ARB and ARGs what makes Sewage Treatment Plant (STP) effluents potentially dangerous hotspots for antibiotic-resistance dissemination. Taking this into account, Soil Aquifer Treatment systems (SAT) represent a cost-efficient option to revalue water due to their potential to reduce biohazards from STP effluents. In this study we analysed the reduction of ARGs and pathogenic bacteria in treated effluent from an operational STP (Palamós, N.E. Spain) using two SAT systems upgraded with reactive barriers, one based on vegetable compost/clay and another one based on woodchips/clay, plus a reference SAT system which operated without reactive barrier, composed only by sand. Using a combination of 16s rDNA sequencing and quantitative PCR techniques, we observed a reduction of measured biohazards similar to or better than the ones reported by other tertiary wastewater methods. Taxonomic analysis of the microbiomes sampled before, inside, and exiting the systems showed an ecological succession of bacterial groups, which correlated to the decrease on both pathogen bacteria and ARG loads. Taken together, the data shows the suitability of using SAT systems as tertiary treatments to reduce biohazards from wastewaters in an effective and economically efficient manner.

1.06.P-Tu007 The Gastrointestinal Microbiota of *Gadus morhua* Callarias Originating From a Chemical Munition Dump Site

Wojciech Wilczynski¹, Monika Radlińska², Klaus Wysujack³, Michal Czub⁴, Tomasz Brzezinski⁵, Grzegorz Kowalczyk⁶, Jacek Bezdowski⁴ and Piotr Maszycki⁵, (1)University of Warsaw, Faculty of Biology, Institute of Microbiology, Poland, (2)Institute of Microbiology, Faculty of Biology, University of Warsaw, Poland, (3)Thiinen Institute of Fisheries Ecology, Germany, (4)Instytut Oceanologii PAN, Poland, (5)University of Warsaw Faculty of Biology, Poland, (6)University of Warsaw, Faculty of Biology, Poland

After the First and Second World Wars, several hundreds of thousands tons of munitions containing chemical warfare agents (CWAs) were dumped in the seas. Recent studies have confirmed that CWAs have started leaking from the corroded munitions and their concentrations in the bottom waters are expected to peak in the next decades, which could have serious physiological and ecological consequences for aquatic organisms. In recent years, several studies have documented the toxic effects of CWAs on aquatic species. According to these studies, the condition of fish and macrobenthos inhabiting dumping sites is worse compared to those from non-polluted areas. Moreover, the free-living bacterial communities in the dumping sites are significantly less abundant and diverse. One may expect, that the presence of CWAs would also affect the gut-associated bacterial communities in fish, which is of vital importance for their condition. The aim of this study was to test the hypothesis postulating that Baltic cod collected from the CWAs dump site in the Bornholm Deep have dysregulated gastrointestinal microbiota. In order to verify this hypothesis, metagenomic studies, based on the sequence analysis of the 16S rRNA encoding gene of bacteria present in the gastrointestinal tracts of cod collected from the Bornholm Deep (14 ind.) and a control site (maximally distant from all official chemical warfare dump sites, 10 ind.), were conducted. The results of this study suggest that dwelling in the Bornholm Deep area significantly reduces the taxonomic diversity and affects the composition in the microbiota of Baltic cod, which is likely the result of the vulnerability of most bacterial taxa to the CWAs present in the surrounding water.

1.06 Metagenomics tools to unravel environmental adverse effects on communities (Virtual Only)

1.06.V-01 Keystone Fungal Species Associated with Petroleum Hydrocarbons Bioattenuation in Polluted Niger Delta Soils *Chidinma Peace Okafor¹, Chioma Blaise Chikere¹, Onyewuchi Akaranta¹ and Khayaletu Ntushelo², (1) University of Port Harcourt, Nigeria, (2)UNISA, South Africa*

The microbial diversity index could be used as a reflection of the detrimental effect of a pollutant in the environment. Petroleum hydrocarbons are environmental stressors posing threat to impacted soils of the Niger Delta region of Nigeria. Petroleum hydrocarbon pollution usually alters the physicochemical properties of the soil and in most cases makes the soil very acidic affecting soil microbial diversity. Fungi are known to tolerate harsher environmental conditions than bacteria, hence this study sought to detect fungal species actively involved in petroleum hydrocarbon degradation in the region under very acidic conditions. Enrichment method was used in culture-based isolation of the fungal isolates while shotgun metagenomics with >15M read depth was carried out on duplicate soil samples from 2 different locations; 4.816480°: 6.111690° Oporoma and 5°257.8912: 6°355.5608, Igbuduya community with soil pH of 3.2 and 2.3 respectively. The result shows that compared with unpolluted controls very few fungal genera *Scatylidium*, *Stachybotrys*, *Scedosporium*, *Cladophialophora*, *Cladosporium*, *Aspergillus*, *Talaromyces*, and *Penicillium* were identified from the polluted sites with active genes and metabolic pathways for hydrocarbon degradation. *Stachybotrys* was the only fungus seen across all soil samples investigated hence maybe the keystone fungal genus for hydrocarbon impacted sites of the Niger Delta. This organism could also be used for ecotoxicity testing as well as for bioremediation of the petroleum hydrocarbon impacted soils.

1.07 Novel methods and approaches for assessing effluents and ambient water toxicity

1.07.T-01 The Use of Novel Tests With Non-Standard Species and Methods to Resolve Toxicity As Part of TIEs *William L. Goodfellow¹, Konrad Kulacki¹, and Alexandra Steele¹, (1)Exponent, Inc., United States*

Effluent discharges from municipal and industrial wastewater treatment systems have traditionally been monitored for concentrations of individual chemicals. A substantial limitation to only using chemical specific monitoring is that one needs to know the chemicals in the effluent in order to evaluate their concentrations or have a standard list of chemicals that ensures the net for regulatory compliance is sufficiently broad to protect the quality of receiving waters. To overcome this limitation, as well as to account for the many effluents that contain mixtures of chemicals, whole effluent toxicity testing (WET) or whole effluent assessment (WEA) can more effectively determine whether the effluent is toxic to aquatic organisms in its entirety, rather than by virtue of individual components. Traditional WET or WEA methods use standard test species such as fish, invertebrates, and algae as the analytical detectors to assess whether the effluents are unacceptably toxic even when the specific chemical composition is not immediately known. Should effluent samples be either acute or chronically toxic as determined by WET or WEA tests, an additional strategy termed toxicity identification evaluation (TIEs) is often utilized. TIEs use physical and chemical fractionation procedures to further characterize effluent and to isolate and identify the specific toxicant(s). When non-standard species or novel tests are necessary for the assessment of effluents to account for site-specific considerations of the discharge or receiving stream, one is faced with the challenge of how to further identify the toxicant without the aid of the large chemical toxicity database, like those available for standard species or traditional test methodologies. Therefore, in many instances, when WET or WEA investigations characterize the effluent as toxic, it is difficult to move further, i.e., to identify or remove the toxicant. This presentation will explore strategies to further evaluate effluents while employing novel tests with non-standard species and methods, and still allowing the ability to resolve the specific chemical causing or contributing to the toxic effluent.

1.07.T-02 Critical Review of Effect-Based Methods for WATER Quality Assessment in the Context of Refinery Effluents *Carolin Riegraf¹, Cornelia Kienle² and Etienne Vermeirssen³, (1)Swiss Centre for Applied Ecotoxicology, Switzerland, (2)Swiss Centre for Applied Ecotoxicology, Switzerland, (3)Oekotoxzentrum Eawag-EPFL, Switzerland*

Permitted effluent discharges from refineries may, after required treatment, still release traces of organic and inorganic contaminants, which might pose a risk to the receiving marine or freshwater environments. Often, the contaminants comprise a complex mixture, which is challenging to capture by monitoring only a limited number of chemical parameters and selected pollutants, as currently required by discharge regulations and permits in Europe. Effect-based methods (EBMs) for water quality

monitoring might be considered as complementary elements to chemical analysis in the Refinery BAT (best available technique) reference document as well as in the context of the EU Water Framework Directive. Based on previous research published by Concawe and additional relevant literature, we evaluated several EBMs suitable for monitoring and assessment of refinery effluents. Therefore, the suitability of established EBMs with respect to several criteria *inter alia* commercial availability, general validation maturity, previous application to environmental samples, interpretation of assay results and sensitivity were reviewed. We propose that, for EBM-array testing, samples should be collected directly in refinery effluent discharges using either native composite sampling or (large volume) solid-phase extraction depending on requirements of the selected EBMs. Initially, samples may be collected on a quarterly basis. However, the frequency may be adapted on a later stage depending on the established data basis. Taking into account the above established criteria as well as advantages and disadvantages of the available EBMs, we foresee a mutually supporting and complementary EBM array covering a broad range of refinery effluent specific pollutants as well as various endpoints and trophic levels could be suggested. Such an array might be composed of (i) an acute/chronic growth inhibition assay with green algae, (ii) a chronic water flea assay, both performed in glass vessels, (iii) a luminescent bacteria assay, (iv) the umuC genotoxicity assay and (v) an aryl hydrocarbon receptor activation assay performed in 96-well plates. This five-component EBM array would require validation against different refinery effluents in order to confirm its suitability for a holistic monitoring and assessment of a broad range of refinery effluents. Further, the bioassay selection might be improved according to newly generated data and information aiming to optimize a future EBM-array proposal.

1.07.T-03 Assessment of the Ecotoxicity of Pharmaceutical Residues and Their Removal Options

Diana M Miguez¹ and Hector Garcia², (1)Agua y Ambiente, LATU, Montevideo, Uruguay, (2)IHE Delft, Institute for Water Education, Netherlands

Pharmaceutical wastewater is composed of a cocktail of substances including active ingredients, adjuvants and their respective metabolites which can cause toxicity to aquatic organisms. Unfortunately, the degree of degradation of pharmaceutical wastewaters is highly variable, as in general they include some recalcitrant chemicals. We conducted a case study in a company that produces several drugs. The influent had a high COD (20,000 mg/L) and high toxicity ($LC_{50} > 1\%$). The aim was to investigate what technologies can be applied to reduce the ecotoxicity to *Daphnia magna* by operating a pilot membrane bioreactor (MBR) composed of an aerobic/anoxic system, finding that it contributed to the reduction of concentrations of micro-pollutants with removal rates of 88-94%, but ecotoxicity of pharmaceutical wastewater still persisted. After coupling it to nanofiltration, organic matter decreased in the effluent, but the toxicity did not disappear. The combination of MBR with reverse osmosis was able to eliminate both organic matter and ecotoxicity, demonstrating that the effluent treated in this configuration was non-toxic to *D. magna* ($LC_{50} > 100\%$). Pharmaceuticals were identified and measured by liquid chromatography/mass spectrometry with QTOF detection to demonstrate which were the potential causative agents. Another case study applied advanced oxidation processes (AOPs) to wastewater from a pharmaceutical industry producing antibiotics. We found that among the different AOPs (Fenton, peroxon, ozone) the most efficient was supersaturated ozone. Even when antibiotics can produce harmful effects, such as resistance, the most toxic compounds were quaternary ammonium disinfectants used as plant sanitizers. Although the toxicity appeared to decrease, its ozonation residues produced long-term toxic effects. Furthermore, even when the post-treatment with bacterial activated carbon could deem the effluent non-toxic, the metagenomic analysis showed that *Pseudomonas sp.* were the selected bacteria, possibly causing resistant genes. These studies provide a better understanding of the risk of ecotoxicity of pharmaceutical waste for the aquatic environment, highlighting the need to optimize treatment technologies.

1.07.T-04 The Impact of Species Sensitivity on the Bioanalytical Assessment of WATER Quality

Sebastian Lungu-Mitea¹, Oksana Golovko², Geeta Mandava³, Jiri Novak⁴, Klara Hilscherova¹, Lutz Ahrens³ and Johan Lundqvist³, (1)Masaryk University, Faculty of Science, RECETOX, Czech Republic, (2)University of South Bohemia in CB, Sweden, (3)Swedish University of Agricultural Sciences, Sweden, (4)Masaryk University, Czech Republic

Bioanalytical tools, such as *in vitro* reporter gene assays, are commonly applied in water quality assessment and will likely be augmented to European water regulation soon. Problematically, most suggested bioassays are of mammalian origin and may not be representative of aquatic species. We report the parallel utilization of mammalian and fish reporter gene assays of the xenobiotic metabolism and oxidative stress response to perform a bioanalytical evaluation of the presence and removal efficiency of compounds of emerging concern in wastewater. For the fish, we utilized previously developed zebrafish reporter gene assays of the xenobiotic metabolism in ZFL cells and the oxidative stress response in ZF4 cells. In parallel, HepG2 and MCF7 cells-based reporter gene assays were employed as the mammalian counterparts. Influent and effluent water samples from three Swedish WWTPs were bioanalytically evaluated to derive point estimates ($EC_{IR1.5}$; EC_{10}) and bioequivalents (BEQ). In terms of the oxidative stress response, we found no systematic differences between fish and mammalian bioassays. The derived $EC_{IR1.5}$ values were identical for influent samples and within the same range for effluents. The removal efficiency was somewhat lower for MCF7 than ZF4. However, we observed statistically significant differences in activity induced by the oxidative stress reference compound tBHQ, introducing an up to 5-fold difference in bioequivalent recalculations. Induction of the xenobiotic metabolism response was identical between species for the reference compound TCDD. However, we recorded statistically significant differences in activity between species for the environmental samples, with differences being site-specific. Removal efficiencies were relatively low for the AhR endpoint in both species, with 45-88% per site. The variation in induction patterns between species hints towards the involvement of different toxicokinetic and -dynamic mechanisms. An analysis of the chemical data via iceberg modelling and effect-directed approaches will be conducted to potentially identify the chemical compounds and classes causing alternating responses between species. Conclusively, we depict how different species-based *in vitro* assays might provide different results in water quality assessment, which can impact the calculation of point estimates, points of departure, and bioequivalent values.

1.07.T-05 Androgenic ACTivity of WATER and Sediment Up- and Downstream of a Wetland

Annika Kruger¹, Naledi Mmekwa², Suranie Horn³ and Rialet Pieters⁴, (1)Unit of Environmental Sciences and Management, North-West University - Potchefstroom Campus, Potchefstroom, South Africa, (2)University of Pretoria, South Africa, (3)North West University Potchefstroom, South Africa, (4)North West University, Potchefstroom, South Africa

Environmental water contains chemicals including herbicides, personal care products, household products, and pharmaceuticals which disrupt the endocrine system through interacting with the hypothalamic-pituitary-gonadal axis. Many of the synthetic chemicals show androgenic or antiandrogenic activity resulting in disruption of reproductive development in males. Traditionally water quality is determined with targeted chemical analyses. However, these analyses overlook the biological effect of the compounds occurring in mixtures and the possible toxicity of untargeted compounds. *In vitro* bioassays can be used as an alternative to animals to test for changes in a particular cell type that can predict adverse outcomes such as endocrine disruption which is the biological effect and focus of this study. The aim of the study was to investigate whether water and sediment from a small rural town in South Africa contained ligands that will activate/inhibit the androgen receptor (AR) using an *in vitro* reporter gene assay. The MDA-kb2 reporter gene cell line was used. An MTT [(3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) viability assay was performed to prevent false interpretation of the reporter gene assay. Effluent sampled from the water treatment plant (WWTP) activated the AR (relative effects potency (REP₅₀) = 0.17 ng testosterone-equivalents/μL) while water sampled in the wetland caused AR inhibition (REP₈₀ = 114.5 ng flutamide equivalents/μL). No (ant)agonistic responses were observed for the sediment samples at the concentrations tested. The identity of the compounds in the WWTP effluent should be investigated. The concentration ranges of sediment samples should be expanded to ensure that no AR ant(agonists) are present in the environment.

1.07 Novel methods and approaches for assessing effluents and ambient water toxicity (Poster)

1.07.P-We012 Artificial Infiltration As an Effective Pre-Treatment in Drinking Water Production: An Effects-Based Assessment

Maria Yu¹, Elin Lavonen², Agneta Oskarsson³ and Johan Lundqvist³, (1)SLU Uppsala, Sweden, (2)BioCell Analytica, Sweden, (3)Swedish University of Agricultural Sciences, Sweden

With growing concerns over the deteriorating quality of surface water supplies around the world, groundwater is becoming a more important drinking water source. When groundwater supplies become low, aquifers can be artificially recharged with surface waters. However, surface waters containing contaminants can negatively affect the groundwater quality and should therefore be monitored accordingly. Effects-based bioassays have been applied in the assessment of drinking water; yet very few studies have investigated the artificial infiltration treatment of water using such a bioanalytical approach. The aim of the current study was, thus, to monitor the detection of bioactivities across the entire treatment process of a drinking water system fed artificially infiltrated groundwater. In this system, artificial infiltration of the surface river water takes approximately 6 months. A single sampling event was conducted in the fall season and the samples were enriched by solid phase extraction to a final relative enrichment factor of 50 for the bioanalysis. A panel of cell-based reporter gene assays representing several toxicity pathways was selected: oxidative stress response (Nrf2 activity), aryl hydrocarbon receptor (AhR) activation, and hormone receptor-mediated effects (e.g., estrogen receptor [ER], androgen receptor [AR]). AhR and ER bioactivities were detected in samples collected from the river intake and in the open-air storage basins prior to artificial infiltration. However, the AhR activity decreased and ER activity was effectively removed following artificial infiltration. While the specific chemicals inducing the AhR activity in this study are not known, the AhR is considered an important receptor in multiple physiological functions. In the Nrf2 and AR assays, no bioactivities above cut-off levels were detected in any samples collected along the entire treatment process of the drinking water production from source to tap. Using a suite of bioassays, the current study highlighted the effectiveness of artificial infiltration in reducing bioactive compounds in this raw river water. Further, we demonstrated that *in vitro* bioassays are useful for screening a broad range of effects in drinking water.

1.07.P-We013 Assessment of Online-Biomonitoring Systems to Monitor Varying Wastewater Effluent Compositions

Ali Kizgin¹, Danina Schmidt², Adriano Joss², Juliane Hollender², Eberhard Morgenroth³, Cornelia Kienle⁴ and Miriam Langer⁵, (1)Oekotoxzentrum Eawag-EPFL, Zurich, Switzerland, (2)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (3)ETH Zurich, Switzerland, (4)Swiss Centre for Applied Ecotoxicology, Switzerland, (5)Oekotoxzentrum Eawag-EPFL, Switzerland

Wastewater treatment plants (WWTPs) are a major source of micropollutants to surface waters. To generate knowledge about the presence, potential effects and removal of micropollutants it is a valuable approach to monitor treated wastewater effluent of WWTPs. Currently, monitoring is based on grab or composite samples of the effluent. These samples cannot capture the transient nature of micropollutants in the wastewater. Especially in WWTPs with industrial input, the wastewater composition can be highly variable and a continuous testing would be advantageous, but very labour and cost intensive. A promising concept is to monitor the wastewater effluent by automated online-biomonitoring systems to detect harmful substance peaks. By applying living organisms to constantly monitor water quality, the systems are designed to raise an alarm if the organism's responses exceed a harmful threshold, which can trigger further chemical monitoring or mitigation measures. Currently online-biomonitoring systems are established for drinking water and surface water but only few experiences exist for wastewater. This study demonstrates that an online-biomonitoring battery using algae (*Chlorella vulgaris* in the Algae Toximeter, BBE Moldaenke), water flea (*Daphnia magna* in the DaphTox II, BBE Moldaenke) and amphipods (*Gammarus pulex* in the Sensaguard, WALTER Tecyard) can be adapted for wastewater surveillance. We showed that a back-washable membrane filtration system proved to be indispensable for adequate preparation of treated wastewater for continuous low-maintenance

operation of the online-biomonitoring systems. Only minor deviations in the reaction of the organisms towards treated and filtered municipal wastewater compared to culture medium could be detected. When treated wastewater was spiked with peak concentrations of selected model compounds, such as diuron, chlorpyrifos and sertraline, the organisms exposed in the online-biomonitoring systems showed distinct responses. The observed variety of responses between the systems showed the value of using a battery of online-biomonitoring systems to detect substances of different mode of actions. Strong behavioural changes after spikes did trigger an alarm, whereas only minor ones did not. However, even in those cases, the observed single reaction patterns of the test organisms provided relevant information about the influence of the test substances within the wastewater. To further support the understanding of the reactions of the test organisms exposed to changing wastewater composition, the effects on feeding activity of *G. pulex* were evaluated in parallel and results indicated significant differences between the treatments. Overall, these findings provide an important basis showing that online-biomonitoring systems have the potential to act as alarm systems in the wastewater sector.

1.07.P-We014 Evaluation and Standardization of a Short Term Chronic Method Using *Daphnia magna*

James M. Lazorchak¹, Alex Kascak², William Thoeny², Abigail Johnson³, Leah Glimsdal⁴, David Mount¹, Russ Hockett¹, Camille Flinders⁵ and Michael B. Griffith⁶, (1)U.S. Environmental Protection Agency, United States, (2)Pegasus co US EPA Cincinnati, United States, (3)U.S.EPA ORD Duluth, United States, (4)USEPA, Afghanistan, (5)NCASI, Inc., United States, (6)U.S. Environmental Protection Agency

In 2009, US EPA's Office of Research and Development (ORD) published a paper wherein a 4-d static-renewal survival and growth test was developed for use with *Daphnia magna*. The test results were compared to performance criteria and results from 7-d survival and reproduction tests with *Ceriodaphnia dubia*, to compare the level of sensitivity between the two methods. Results from tests using the 4-d *D. magna* survival and growth method indicated that this method produced consistent results with CVs < 20% with various reference toxicant materials and provided data that were both reproducible and useful for detecting potential toxicity in aquatic environments. Since that publication, there has been an increased interest in using the *D. magna* method in Whole Effluent Toxicity (WET) tests associated with NPDES permits where source water chemistry, i.e. conductivity, may be more appropriate for *D. magna*. In 2020, ORD began re-evaluating the method in a bi-laboratory approach at US EPA laboratories in Cincinnati, OH and Duluth, MN as well as a collaboration with National Council for Air and Stream Improvement (NCASI). During the early testing phase, it was decided to look at influence of different foods and amounts on growth, in addition to revising the test performance criteria from the final control weight being 10 times higher than the initial weight, to one that is based on a minimum final weight criterion. Various food combinations: alfalfa and algae; yeast, cerophyl, trout chow (YCT) plus algae; and flaked food, alfalfa, yeast (FFAY) plus algae were tested in different concentrations to see which gave a consistent final weight. Once the final food and amount was chosen, tests were conducted with three reference toxicants, NH₄Cl, ZnSO₄ and diazinon, using newly released young < 8 hr old with six replicates per treatment. This presentation will highlight the latest progress of the different food and rationing as well as reference toxicant testing.

1.07.P-We015 Microbial Fuel Cells and Constructed Wetlands As a Sustainable Alternative for the Treatment of Hospital Laundry Wastewaters: Assessment of Load Parameters and Genotoxicity

Carlos Lutterbeck, Ênio Machado and Gustavo Stolzenberg Colares, University of Santa Cruz do Sul, Brazil

The present research investigated the sequential use of microbial fuel cells (MBFC) and constructed wetlands (CW) for the treatment of wastewaters generated at a hospital located in a city of the Rio Pardo Valley, Brazil. The MBFC was vegetated with *Chrysopogon zizanioides* whereas *Hymenachne grumosa* was planted in the CW unit. The hydraulic retention time in each unit was of 7 days, totaling 14 days of treatment. The evaluation of the efficiency of the integrated system considered the analysis of load parameters and the genotoxicity potential by the comet assay with *Daphnia magna* before and after the treatments. Regarding the raw wastewaters, the obtained results revealed that the mean values of some of the analyzed parameters were above the maximum emission limits established by Brazilian and international guidelines. Furthermore, the untreated effluents presented a strong genotoxic effect ($p < 0.001$) against *D. magna*. On the other hand, the results of the treated wastewaters showed reductions of 79.8%, 78.6%, 81.6%, 53.1%, 81.5% and 99.9% for COD, BOD₅, Total N, TDC, DOC and Turbidity. Also, the treated wastewaters presented significant reductions ($p < 0.05$) of the genotoxicity. Therefore, the use of the integrated system showed that both units had complimentary effect and presented satisfactory results regarding the removal of the organic load, complying with national and international standards and significantly reduced the genotoxicity. Furthermore, besides being effective, the integrated system can be sustainable from both environmental and economic aspects, especially for developing countries, where there is limited or insufficient wastewater treatment infrastructure.

1.07.P-We016 Novel Application of Machine Learning and Image Analysis to Automate the Sea Urchin Embryo Test

Iker Alvarez¹, Nestor Etxebarria¹, Jose Amigo², Mathilde Monperrus³, Leire Mijangos¹, Naroa Lopez⁴ and Harkaitz Eguirau¹, (1)University of the Basque Country, Spain, (2)University of Basque Country UPV/EHU, Spain, (3)IPREM CNRS UMR 5254 LCABIE, France, (4)Faculty of Science and Technology (UPV/EHU), Spain

Since more and more xenobiotic compounds are being found in the environment, ecotoxicology faces an overwhelming challenge in the identification of toxicants. The combination of high-throughput *in vivo/in vitro* bioassays with high resolution chemical analysis is an effective way to elucidate cause-effect relationships. However, these combined strategies imply an enormous workload that can hinder their implementation in a routine analysis. The purpose of this study was to develop a new high-throughput screening methodology based on image analysis and machine learning to ease the application of the sea urchin embryo bioassay in complex toxicant identification pipelines such as effect-directed analysis. A training set of 242 images was used to calibrate the larvae size-increase and malformation level classification. Two classification models based on partial least squares

discriminant analysis (PLS-DA) were built and compared. Moreover, Hierarchical PLS-DA shows a high proficiency in classifying the larvae, achieving a prediction accuracy of 84% in validation. The scripts built along the work were compiled in a user-friendly standalone app (SETApp) freely accessible at <https://github.com/UPV-EHU-IBeA/SETApp>. The SETApp was tested in a real case scenario to fulfil the tedious requirements of a WWTP effect-direct analysis.

1.07.P-We017 Miniaturized Acute *Daphnia magna* Assay for the Testing of Low-Volume Samples in the Scope of Monitoring Environmental Contamination

Eberhard Kuester¹, George Addo², Pedro Nunes³, Silke Aulhorn² and Dana Kühnel², (1)Helmholtz Centre for Environmental Research, Dept. Bioanalytical Ecotoxicology, Germany, (2)Helmholtz-Centre for Environmental Research- UFZ, Germany, (3)Universidade de Aveiro, Portugal

The regular monitoring of surface- or groundwater quality is most often done on the basis of chemical analysis and ecological assessments. But chemical analysis or chemical monitoring is not a 100 % save assessment method for the overall toxicity of environmental samples as usually not all substances are analyzed and each and every non-analysed substance may exert toxic effects. Ecotoxicological analysis may hence be a supplemental method because the overall toxicity of all bioavailable substances are included. But as most ecotoxicological tests with organisms were originally developed for the assessment of waste water or single chemicals (e.g. EU-REACH regulation) the volumes and replicates used and needed are normally quite large as restriction of volume or numbers of replicate tests was and is not an obstacle. In case of a regular monitoring of water samples the sample volumes for single tests are often restricted because a battery of several tests is used, and at times water samples are concentrated (enriched) which further reduces the available sample volume. In contrast to chemical analysis biological or ecotoxicological tests often need volumes above 200 mL per sample. This may be one reason why ecotoxicological tests such as the acute *Daphnia* assay is not as often used as it might be beneficial. To overcome this obstacle here a miniaturised daphnid assay protocol usable for day-to day monitoring is proposed. As a basis, we used the publication by Grintzalis et al., (2017) for a follow-up literature review. From this literature review three approaches to achieve a reduction in sample volume seemed feasible: reduce the ratio volume-per-neonate, reduce the number of concentrations tested or reduce amount of neonates per replicate or concentration. Subsequently, we adapted the standard acute daphnia test based on the OECD standard to our specific low volume monitoring requirements using water extracts. Multi-well plates were used which had the additional advantage of easier evaluation of daphnia mobility via microscopic inspection. Finally, we confirmed the applicability and sensitivity of our new system by comparing the toxicity values from the standard assay and the miniaturized assay for different compounds either retrieved from literature data or from lab tests. Our approach is likewise applicable for other samples with restricted availability, such as microplastics, and contributes to a reduction in chemical waste for laboratory tests.

1.07.P-We018 A Method for Testing Impact of Pesticides on Amphibians Behavior Larvae

Laurent Boualil¹, Hugo Cayuela², Aurélien Ballu³ and Nathalie Chevre³, (1)Institute of Earth Surface Dynamics, University of Lausanne, Lausanne, Switzerland, (2)Université de Lyon 1, France, (3)University of Lausanne, Switzerland

According to the International Union for Conservation of Nature (IUCN), amphibians are suffering a massive decline. With more than 40% of endangered species, they represent the most threatened group among vertebrates. Amphibians decline is multicausal and pollution is usually considered as one of major factors involved in population decrease and local extinction. Among parameters tested in amphibians' ecotoxicology, molecular biomarkers and morphological traits are commonly measured and compared between tested concentrations. A less investigated branch of amphibians ecotoxicology is the impact of toxic molecules on amphibians behavior. Indeed, although toxicants impacting the nervous and/or the endocrine systems are likely to indirectly impact behaviors such as activity, hardiness or exploration capacity which are known to influence survival and reproduction in amphibians, only few research focused this adverse effect and no standardized protocol were developed for demonstrating and quantifying this assumptions. In this work, we developed an 8 days protocol aiming at evaluating impacts of pesticides on *X. laevis* larvae swimming behavior. Briefly, we exposed freshly fertilized eggs to different concentrations of Chlorpyrifos, an organophosphate pesticide. Embryos were individually exposed from NF stage 8 to 192 hours post-fertilization. From day 6 to day 8, animals swimming behavior was recorded once a day for 10 minutes and the trajectory was extracted using the open-source R package, Bemovi. From this trajectory were extracted the number of recorded moves, the step speed and the total distance traveled during the test. Our results showed the efficiency of our method to demonstrate impacts on larvae swimming behavior components. In addition, this work highlighted a time-dependent impact of exposure on activity parameters suggesting the need of longer protocols and represents an opening toward studies on impact of pollutants to amphibians personality.

1.07.P-We019 The Amphibian Short Term Assay (ASTA)

Laurent Boualil¹, Hugo Cayuela², Loïc Cattin³ and Nathalie Chevre⁴, (1)Institute of Earth Surface Dynamics, University of Lausanne, Lausanne, Switzerland, (2)Université de Lyon 1, France, (3)University of Lausanne, Lausanne, Switzerland, (4)University of Lausanne, Switzerland

According to the International Union for Conservation of Nature (IUCN), amphibians are suffering a massive decline. With more than 40% of endangered species, they represent the most threatened group among vertebrates. Amphibians decline is multicausal and pollution is usually considered as one of major factors involved in population decrease and local extinction. Especially, the use of pesticides in the context of farming activities is suspected to degrade the quality of breeding sites (e.g. lac, swamp, and ponds). Indeed, these molecules are carried by surface and sub-surface runoff as well as drainage into aquatic systems and can be found in high concentrations in surface waters. Freshwater ecosystems are of crucial importance for amphibians' life cycle. In pond-breeding amphibians, embryonic and larval development takes place in aquatic habitats. Environmental conditions experienced over aquatic development are critical since they affect growth (rate and timing) and survival until metamorphosis.

They also have far-reaching consequences for postmetamorphic performances as they influence size and body condition at metamorphosis, two factors directly related to fitness components (survival, growth, and reproduction) at terrestrial stage. Therefore, exposure to chemicals during aquatic development may have a strong detrimental impact on amphibians' population dynamics. In this work, we developed a protocol covering not only the embryonic phase but also 4 days of the larval phase. This method aimed to evaluate impacts of pesticides on molecular traits in addition to morphological and life history traits. Briefly, we exposed *X. laevis* freshly fertilized eggs to different concentrations of Chlorpyrifos, an organophosphate pesticide. Animals were individually exposed from NF stage 8 to 192 hours post-fertilization (hpf) during which three common molecular biomarkers and morphological traits were individually measured at different times. Our results demonstrated the efficiency of our method to evaluate physiological, morphological and life-history traits changes with significant statistical decrease in Acetylcholinesterase activity and body length at 192hpf in addition to growth rate. Besides, in accordance with literature, our results demonstrate a higher response of 192hpf larvae compared to 96hpf embryos, thus re-evaluating the relevance of tests based on embryonic phase only.

1.07.P-We020 Evaluation of the Ecotoxicological Impact of Cigarette Butt Littering in Marine and Freshwater Environments

*Matteo Oliva*¹, *Lucia De Marchi*², *Alessia Cuccaro*³ and *Carlo Pretti*⁴, (1)CIBM, Italy, (2)University of Pisa, Portugal, (3)University of Aveiro, Portugal, (4)University of Pisa, San Piero a Grado, Italy

Cigarette butts (CBs) represent the most littered item in the world and one of the most diffused personal waste on beaches and coastal areas in general. CBs can entrap a wide range of dangerous chemical compounds, such as PAHs, hydrocarbons, trace elements and nicotine, produced both by tobacco combustion and treatment during cultivation and manufacture. The aim of the present work was to evaluate the effect of CB leachates on target species with two batteries of marine and freshwater ecotoxicological bioassays. Marine tests showed an inhibition of growth with the two different marine algal species (*Phaeodactylum tricoratum* and *Dunaliella tertiolecta*), an inhibition of bioluminescence in the bacterium *Aliivibrio fischeri*, an alteration on the correct early development of the serpulid *Ficopomatus enigmaticus* larvae and immobilization of *Acartia tonsa* individuals at both 24 and 48 hours of exposure. Freshwater tests showed again an inhibition of the bioluminescence with *Aliivibrio fischeri* together with a significant stimulation of radical apparatus elongation in two different superior plants (*Cucumis sativus* and *Lepidium sativum*), while *Sorghum saccharatum* showed no statistically significant differences with controls, even if a biostimulation was again registered. Similar results were obtained with the freshwater microalga *Raphidocelis subcapitata*, which showed biostimulation of algal growth. Two other assays were performed with freshwater crustaceans, *Thamnocephalus platyurus* and *Daphnia magna*, underlining no significant differences with controls with both species. With *D. magna*, also the heartbeat rate on adults exposed to different concentrations of freshwater samples was calculated. A significant increase of the bpm in adults exposed to high concentrations of smoked CB leachate was observed after 48 h of exposure. In conclusion it was possible to define a preliminary scenario of the different effects that CB litter can cause to different key organisms in aquatic environments, underlining the importance of monitoring of this "emerging pollutant" in both internal and coastal areas.

1.07 Novel methods and approaches for assessing effluents and ambient water toxicity (Virtual Only)

1.07.V-01 A Novel Floatation-Based Sample Processing Method for Raw Wastewater Testing

*Casey Wegner*¹, *Douglas Sieglaff*², *Jon Roussey*¹, *Tarun Anumol*² and *Stephan Baumann*², (1)Akadeum Life Sciences, United States, (2)Agilent Technologies, Inc., United States

Wastewater testing presents an opportunity to track infectious agent spread in human populations if an appropriate assay can be developed to assess large fluidic volume samples including sludge component. Currently, challenges associated with filtration-based workflows include throughput and requirement of pre-processing steps. The COVID-19 pandemic has highlighted the need for simple but sensitive technologies and workflows to enable environmental monitoring for communicable disease agents. Human biofluids such as urine, stool, or blood are found in sewage and present an efficient pooled-sample source to monitor infectious agents in at the community level. Here we present a workflow enabling assessment of large volumes of wastewater without the need for pre-processing such as the removal of solids from sludge. The approach uses buoyant, functionalized microbubbles for nucleic acid binding. This extraction step is followed by sample clean-up using RNA-binding columns and qRT-PCR. This workflow achieves greater sensitivity analyzing >75% smaller wastewater aliquots, relative to commonly practiced centrifugal ultrafiltration-based methods (i.e., 3-10 mL vs. 45 mL wastewater). Microbubbles are buoyant, hollow glass microspheres (< 20 µm in size) which can be functionalized to capture analytes. Microbubble enabled workflows are not limited by sample volume or container shape and have minimal equipment requirements. Using microbubbles for nucleic acid extraction employs a positive selection protocol in which the microbubbles bind to the desired target – in this case, total RNA including SARS-CoV-2 if present – isolating and enriching the analyte for downstream analysis (e.g., qRT-PCR, next-generation sequencing). This work shows that microbubble nucleic acid extraction can directly interrogate large fluidic volumes of unfiltered raw sewage samples to increase RNA capture for downstream processing.

1.07.V-02 AMPHITOX: A Customized Early LIFE Stage Toxicity Test for a Holistic Assessment

Jorge Herkovits, *Instituto de Ciencias Ambientales y Salud, Fundacion PROSAMA, Argentina*

The aquatic environment is recipient, transporting medium and sink for the majority of xenobiotic chemicals. In order to compare results from different matrices we develop in the early 90s, AMPHITOX as a customized early life stage, sensitive, cost-effective, biological test methods. By reporting acute, short term chronic and chronic results in Toxicity Units it was possible to quantify with the same parameter the toxicity of water, sediments, industrial effluents, soils and leaches establishing thresholds of toxicity

as they can affect biodiversity richness, e.g. the presence in the water column and sediment of normal, sensitive, tolerant and very tolerant species directly related to the amount of toxicity. By reporting teratogenesis both for environmental samples and physico-chemical agents, it was possible to provide information of toxic effects on cell differentiation and morphogenesis as well as disruptions like hydropsy and reduction on oxygen consumption. COVID-19 pandemic provided the possibility to explore potential synergistic effects of SARS-CoV-2 and some high production volume chemicals like Ni, Cd, atrazine, 2,4-D and Bisphenol A. For instance, Bisphenol A, 2,4-D and atrazine could produce osmoregulatory disruption resulting in hydropsy that could be associated to ACE2 receptor expressed in early embryonic stages. ACE2 was associated to intra-alveolar edema and is the main multiorgan entrance point of SARS-CoV-2. Hydropsy was reported in COVID-19 fetus. The same chemicals plus Ni and Cd could be related to COVID-19 severity by means of their effect on oxygen consumption. It is well documented that hypoxia triggers the hypoxia inducible factor (HIF) and hypoxia associated with COVID-19 could imply an over-activation of the HIF system influencing the functionality of 200 genes, including those that regulate apoptosis. Morphological shapes of apoptotic like cells can be observed as toxic effects of different chemicals. Customized early life stage toxicity test provide a huge amount of information from lethality to dysfunctions that contribute to understand the complex effects of physical and chemical agents on living organisms, which seems to include a potential synergistic effect with infectious agents. Considering the increasing complexity of environmental pollution they can contribute as sentinel organisms to a holistic risk assessment towards environmental and human health protection.

1.07.V-03 Developmental Effects of MDMA in Zebrafish - Preliminary Data

Ondina Ribeiro¹, Nadine Peixoto¹, Ana Cruz¹, Cláudia Ribeiro², Luís Félix³, Maria Tiritan⁴ and João Soares Carolla⁵, (1)UTAD, Portugal, (2)TOXRUN - IUCS, CESPU; CIIMAR, Portugal, (3)3s, Portugal, (4)TOXRUN – IUCS, CESPU; CIIMAR; LQOF - FFUP, Portugal, (5)CITAB, Portugal

Illicit drugs are a global problem with significant direct and indirect adverse impacts on human health and on wildlife. Among them, MDMA (3,4-methylenedioxymethamphetamine), commonly known as ecstasy, is a synthetic drug with psychotropic effects and in some countries, it is used in psychotherapy for post-traumatic stress disorder. Human urinary excretion of MDMA and its metabolites contribute to their presence in waste water treatment plants (WWTP) and in water bodies. Because WWTP are insufficient to remove these compounds thus low and high concentrations have been reported in water bodies and ID are suspected to be harmful to exposed aquatic organisms, including fish. Early development stages are prone to adverse effects caused by contaminants or drug consumption in humans, presenting seasonal characteristics related with social behaviour and tourism. Zebrafish (*Danio rerio*) have semi-transparent embryo and consequently this species has been used as a key model to study developmental biology [2] and namely to assess toxic effects during early stages of *embryonic development* [3]. The aim of this work was to evaluate the MDMA effects on embryonic development of *D. rerio*. For that, embryos with 2-3 hours post-fertilization (hpf) were randomly exposed for 96 h to different concentrations of MDMA (0.02, 0.2, 2, 20 and 200 µg/L) to evaluate mortality, larvae size, eye area, yolk area, oedema area, head area, tail curvature and number of malformations. Preliminary data showed that MDMA exposure have no significant effects during embryonic development, for all the endpoints assessed and for all the 5 concentrations tested. The MDMA embryo exposure, in this study, showed no teratogenic effects. Nonetheless, our result agrees in part with Barenys et al. (2021) study, which observed no general developmental delay or general toxicity [1] but their observed the increased in spontaneous tail coiling in zebrafish embryos at 24 hpf and a faster hatching rate [1]. Our data indicated that MDMA is not teratogenic and do not affect mortality, larvae size, eye area, yolk area, oedema area, head area, tail curvature and number of malformations but more studies are important to assess MDMA effects in zebrafish embryo. Funding: This work was supported by National Funds by FCT - Portuguese Foundation for Science and Technology, under the project UIDB/04033/2020 and PTDC/CTA-AMB/6686/2020.

1.07.V-04 Evaluation of the Ecotoxicity of Two Solvents to *Pelophylax perezi* and *Xenopus laevis* Tadpoles

Maria Mendes¹, Sara Costa², Manuel Ortiz Santaliesra³ and Isabel Lopes⁴, (1)Department of Biology, University of Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)Spanish Institute for Game and Wildlife Research (IREC) UCLM-CSIC-JCCM, Spain, (4)University of Aveiro, Aveiro, Portugal

Organic solvents are commonly used in ecotoxicity assays as carriers to promote the dissolution of hydrophobic compounds (e.g., some pesticides, pharmaceuticals, polycyclic aromatic hydrocarbons). In this context, the selection of the solvent and the concentration to be used in bioassays is of most importance because itself may induce toxicity to the biota. Existing guidelines, namely those published by the Organisation for Economic Co-operation and Development (e.g. OECD Guidance document 23, 2019), recommend that the maximum concentration of solvent to be used should not go over 100 µL/L (0.01%), so that the effects observed during the assay are solely a consequence of the exposure to the chemical under study. Acetone and acetonitrile are two solvents widely used in ecotoxicity assays as they can dissolve several chemicals, though only a few studies assessed their lethal and sublethal effects to freshwater biota, namely to aquatic life stages of amphibians. Therefore, this work aimed at evaluating the lethal and sublethal toxicity of these two solvents to tadpoles of two anuran species: the standard species *Xenopus laevis* (autochthonous from sub-tropical/tropical regions) and *Pelophylax perezi*, a species autochthonous from temperate regions (Iberian Peninsula and South France). For this, tadpoles at developmental stages NF46 (for *X. laevis*) and G25 (for *P. perezi*) were exposed, for a period of 96 hours, to 9 and 7 concentrations, for acetone (0.125 to 5%) and acetonitrile (0.0625 to 5%), respectively. Mortality of tadpoles was monitored at each 24 h exposure period and at the end of the assay the following endpoints were also assessed: total length; snout-to-vent length; inter-orbital distance and weight difference. The obtained results revealed that acetone caused mortality above 20% at concentrations equal or above 2 and 5% while acetonitrile at concentrations equal or above 0.25 and 1%, respectively for *X. laevis* and *P. perezi*. As for sublethal effects, acetone induced significant alterations at 1 and 1.5% and acetonitrile at concentrations above 0.25 and 0.0625%, for *X. laevis* and *P. perezi*. These results suggest that

higher concentrations of the two studied solvents may be used in short-term toxicity assays when studying compounds with very low solubility in water.

1.07.V-05 Risk Assessment of Selected Veterinary Pharmaceuticals in Aqueous Solutions and Livestock Farms' Whole Effluents

Beatrice Opeolu¹, Bettina Genthe², Olalekan Fatoki³ and Olatunde Olatunji⁴, (1)Cape Peninsula University of Technology, South Africa, (2)CSIR South Africa, South Africa, (3)KolaDaisi University, South Africa, (4)School of Chemistry and Physics, South Africa

Pharmaceuticals are extensively used in livestock agricultural production for enhanced productivity and profitability. A consequence of this is the release of residues of original parent compounds and their metabolites into the environment. Literature suggests that residues of some pharmaceuticals induce toxic effect on non-target organisms. Ecological and human health risk assessments of selected pharmaceutical compounds in livestock farms effluent and surface water samples were conducted using different bioassays including algal growth inhibition, acute/chronic toxicity, Ames mutagenicity and oestrogenic activities tests. Results showed that pharmaceutical cocktails exerted significant observable effects on the growth (inhibition) and yield of *Pseudokirchneriella subcapitata* relative to controls. Algal response to exposure to cattle and poultry effluents indicated compromised water quality characteristics. Neonates of *Daphna magna* exposed to environmental concentrations of pharmaceutical compounds had 100% mortality in undiluted and 1:2 dilutions after 48 h. All samples tested were "highly acutely toxic"- the toxicity units (TU) values for at least one of the tests fell between 10 and 100 TU. Mutagenicity was 6 to 8-times the natural background rate; low carcinogenic risk was observed for 17 β -estradiol (2.4 μ g/L) especially, via possible accidental ingestion during recreational activities. Cattle and poultry farms effluents were mutagenic, piggery, sheep farm effluents were oestrogenic, and the piggery effluent had the highest toxicity.

1.07.V-06 Temporal Variation of EcoToxicological Risks in Agricultural Ditches

Harry Boonstra¹, Milo Leon de Baat², Michiel Kraak³, Ivo Roessink⁴ and Froukje van der Meer¹, (1)Wetterskip Fryslân, Netherlands, (2)KWR Water Research Institute, Netherlands, (3)University of Amsterdam, Netherlands, (4)Wageningen Environmental Research, Netherlands

Traditional chemical monitoring of water bodies fails to accurately assess and explain ecotoxicological risks, because it does not incorporate the combined action of the complex chemical mixtures present in the aquatic environment. Therefore, there has been an increasing interest in the combination of passive sampling and effect-based methods (bioassays) to identify ecotoxicological risks. Yet, only few studies have used effect-based methods to address temporal variations in toxic pressure. The aim of the present study was, therefore, to assess the temporal variation of ecotoxicological risks in agricultural ditches, and to identify the drivers of these risks by combining passive sampling, bioassays, and chemical analysis. Four locations in the province of Friesland, The Netherlands, were sampled during four consecutive continuous sampling periods. Silicone rubbers sheets and polar organic chemical integrative samplers (POCIS) were exposed in the water bodies for the passive sampling of hydrophobic and hydrophilic organic compounds, respectively. Subsequently, six *in vivo* and sixteen *in vitro* CALUX[®] and antibiotic-activity bioassays were exposed to extracts of the passive samplers. For ecotoxicological risk interpretation, the bioanalytical responses were compared to effect-based trigger values (EBTs). Temporal variation in the identity and concentrations of chemicals was observed at all locations. Six bioassays showed responses above their EBTs and EBT exceedances were observed at all locations and during all sampling periods. Evaluating the joint responses of the entire bioassay battery, distinct differences in bioanalytical response profiles between locations and sampling periods became clear. Temporal variation in ecotoxicological risks was well captured by combining passive sampling and bioanalytical tools, but was poorly explained by target chemical analysis, confirming that ecotoxicological risks were largely caused by the combined action of unmeasured chemicals. To become adequate and future-proof, regular chemical water quality assessment strategies should thus incorporate passive sampling and effect-based methods. Dedicated suspect- and/or non-target analysis may subsequently identify the chemical drivers of the ecotoxicological risks. It is concluded that timing of effect-based monitoring in future monitoring programs should be carefully considered, since this has considerable influence on the chemical water quality assessment.

1.07.V-07 The Impact of COVID-19 Lockdown on the WATER Quality of River Matanza-Riachuelo, Buenos Aires, Argentina

Jorge Herkovits¹ and Jose D'Eramo², (1)Instituto de Ciencias Ambientales y Salud, Fundacion PROSAMA, Argentina, (2)Fundacion PROSAMA, Argentina

Matanza Riachuelo River, originates some sixty kilometers west of Buenos and from the city's earliest days, the river has been a dumping ground for waste and sewage becoming one of the most polluted waterways in the world. Close to five million people live in the Riachuelo's basin. The toxicity of environmental samples from potentially polluted and reference stations were evaluated from the 90's by means of the AMPHITOX test including surface and ground water, leaches, industrial effluents and soils. The data, expressed in acute, short-term chronic and chronic Toxicity Units (TUa, TUsc and TUC) resulted in a maximal value of 1000 TUC, found in a leach, while the lower toxicity value was 1.4 TUa corresponding to two surface water samples. In reference places no toxicity was found. On 3 March 2020, SARS-CoV-2 was confirmed to have spread to Argentina and a nationwide lockdown was established in all the country from 10 May until 17 July, where the lockdown was due to be gradually loosened to lead to the return to normality. In 17 May 2020 surface water samples were obtained from 4 locations along the Matanza-Riachuelo River. The first in the intersection of Route 4 with River Matanza (conductivity 956 μ S/cm²; oxygen 6,4mg/L; pH 5,90), the second in the intersection with General Paz (conductivity 1230 μ S/cm²; oxygen 5,4mg/L; pH 6,24), the third in Victorino de la Plaza Bridge (conductivity 1730 μ S/cm²; oxygen 5,7mg/L; pH 6,20) and the last one in la Boca close to Nicolas

Avellaneda Bridge (conductivity 830 μ S/cm²; oxygen 5.9mg/L; pH 6.43) close to the Riachuelo discharge in Rio de la Plata. Those data imply some level of activities in spite of the lockdown. The water samples were evaluated for toxicity with *Danio rerio* (zebrafish) embryos. 10 embryos by duplicate in 10 mL were maintained in zebratox solution with a constant temperature of 28 C and a maximal exposure time of 240hr. No significative lethality was registered compared with control groups. The results point out that within a few days after the lockdown the water quality improved significantly to the point that no lethal effects were registered even for chronic exposure. It also implies that the highly polluted sediments did not polluted the water column to a toxicity level. Thus, by preventing the discharge of toxic materials in toxic amounts, the river could recover basic condition to sustain a wide range of biodiversity contributing to the further recovery of the watershed towards sustainability

1.08 Understanding and linking effects of contaminants in wildlife across multiple biological levels

1.08.T-02 Revealing the Modes of Action of Hg(II)-Induced Modulatory Effects on the Immune Responses in Waterfowl Upon Viral-Like Immune Challenge With In Vivo Experiments

Biyao Han¹ and Nico van den Brink², (1)Wageningen University & Research, Netherlands, (2)Toxicology, Wageningen University, Wageningen, Netherlands

Trace metals such as mercury (Hg) have been reported to be immunotoxic. Our previous field study showed that even low environmentally relevant levels of Hg exposure affected the immune responses in Arctic Barnacle goslings (*Branta leucopsis*) upon a viral-like immune challenge, mainly via inducing inflammation and impairing B-cell functioning. To verify the results from the field study and give more insights on the causality of Hg-induced immunomodulatory effects, we conducted a controlled *in vivo* experiment with Pekin ducklings (*Anas platyrhynchos domesticus*) as a model waterfowl. Day-old ducklings were exposed to five different levels of Hg(II) premixed in the feed up to 1.00 mg Hg(II)/kg feed for 23/24 days. There were 12 ducklings in each exposure group. 24h before termination, 50% of the ducklings in each exposure group were challenged with 50 μ g/kg body weight (b.w.) poly I:C via intraperitoneal (i.p.) injection, while the other 50% of ducklings received saline solution (0.9% NaCl). On day 23/24, ducklings were euthanized and samples including liver, spleen and plasma were collected. Our results showed that the internal total Hg (tHg) concentrations in the liver of ducklings were strongly correlated with the concentrations in the feed, and nicely covered the range of Hg concentrations found in gosling livers from the field study. The major effects of Hg(II) exposure in ducklings were modulated gene expressions in the spleen, i.e. a downregulation of miR-155 suggesting impaired B-cell functions, and an upregulated expression of iNOS, which could be an indicator for inflammatory effects. Therefore, the findings from the *in vivo* duckling experiment were in line with the field study, and these adverse effects may lead to an affected immune competence at the individual level and a higher risk of infections.

1.08.T-03 Evaluating the Impact of Pesticide Dermal Exposure on Terrestrial Amphibians

Samuel González López¹, Teófila Triana Velásquez², Christina Mordziol³, Silvia Pieper⁴, Gesa Amelung³, Isabel Lopes⁵ and Manuel Ortiz Santaliciestra⁶, (1)Institute for Game and Wildlife Research, IREC (CSIC-UCLM-JCCM), Ciudad Real, Spain, Ciudad Real, Spain, (2)Universidad del Tolima, Colombia, (3)German Environment Agency (UBA), Germany, (4)German Federal Environment Agency (UBA), Germany, (5)University of Aveiro, Aveiro, Portugal, (6)Spanish Institute for Game and Wildlife Research (IREC) UCLM-CSIC-JCCM, Spain

Amphibians are globally considered the most threatened group of vertebrates, with anthropogenic pollution being regarded as one of the main factors contributing to their decline. In their terrestrial stages, they possess a very distinctive skin that is highly permeable to chemical substances and that is involved in a plethora of physiological processes. Therefore, and because these animals frequently occur in agricultural areas, the impact of pesticide application on non-target amphibians is highly relevant. In this study, we investigated the toxicity of dermal exposure to two current-use pesticides, the pyrethroid insecticide alpha-cypermethrin, both as an active ingredient and as a formulation (Fasthrin 10 EC), and the herbicide metsulfuron-methyl, on amphibian terrestrial stages, using Perez's frog (*Pelophylax perezi*) as a model species. To do so, embryos of *P. perezi* were collected and grown in the laboratory until their terrestrial phases. Juvenile frogs were exposed by overspray using a pump calibrated to simulate realistic pesticide application regimes. During the experimental period (7 or 21 days) we recorded survivorship and changes in body condition, as well as analysed histopathological changes on dorsal skin. Besides, we collected samples from their skin secretions to investigate skin peptide bioactivity, and frog tissue samples to examine pesticide residue toxicity accumulation by LC-MS. Results reveal that overspray with alpha-cypermethrin-based insecticides at realistic doses compromises survival of juvenile frogs, and that acute toxicity of the formulation is increased relative to that of the active ingredient. Mortality among individuals exposed to metsulfuron-methyl was observed in the second half of the monitoring period, although no significant differences with the control group were detected. Regarding effects on the skin, we observed changes in the skin epithelium of juvenile frogs exposed to either alpha-cypermethrin or metsulfuron-methyl. The most prominent alteration consisted of an increased stratification and swelling of keratinocytes in the *stratum corneum* (the outermost layer of the amphibian skin). A thicker epidermis could impact the permeability of the skin and affect skin functionality, possibly compromising animals' fitness. Considering the importance of terrestrial amphibian stages in maintaining population dynamics, further attention should be paid to assessing pesticide risks for these stages.

1.08.T-04 Negative Relationship Between Glyphosate Exposure and Female Reproductive Parameters in Iberian Hares (*Lepus granatensis*)

José Manuel Chinchilla Cañaveras¹, María Angeles Riscalde², Vanesa Alzaga³, Pablo R. Camarero¹, Francisca Talavera⁴, Jose Alberto Viñuelas⁵, Pelayo Acevedo⁶, Rafael Mateo Soria⁷ and Monica Martínez-Haro⁸, (1)Instituto de Investigación en Recursos Cinegéticos, IREC (CSIC, UCLM, JCCM), Spain, (2)Universidad de Córdoba, España, Spain, (3)Gestión Ambiental de Navarra,

S.A., Spain, (4) Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (5) Instituto Regional de Investigación y Desarrollo Agroalimentario y Forestal de Castilla La Mancha (IRIAF), Spain, (6) Institute for Game and Wildlife Research, IREC (CSIC-UCLM-JCCM), Spain, (7) IREC (CSIC-UCLM), Spain, (8) IREC-Instituto de Investigación en Recursos Cinegéticos, Spain

Important changes occurred during the 20th century in farmland ecosystems due to an important homogenization of the landscape caused by the reduction of field margins and to the use of a large amount of pesticides and fertilizers. This change in agricultural management has been linked to the loss of plant and wildlife biodiversity. In the specific case of pesticides, there are significant gaps in the knowledge of their secondary or sub-lethal effects on wildlife. Under this context, the aim of this study was to evaluate the relationships between pesticide exposure and reproductive parameters in females of Iberian hare (*Lepus granatensis*), as a sentinel species of the potential effects that the use of pesticides can have on the wildlife of agrarian ecosystems. To carry out this study, residues of 8 pesticides in the gastric content of hunted female hares along with different reproductive parameters were measured in two hunting areas free of pesticides (control 1 and 2, n=18) and from two areas where pesticides are used (treated 1 and treated 2, n=32). Hares from the two pesticide-treated areas showed high prevalence of glyphosate (22.2 and 31.6%; treated 1 and 2, respectively) and in one of these areas (treated 2) also of 2,4-D (12.5%). Fungicides were detected in some individuals (6.6%), and insecticides were not detected. No residues were detected in hares from pesticide-free areas. Hunted females from pesticides-treated areas showed a significantly lower ovarian size and weight than hares from pesticides-free areas. Significant differences were also detected among study areas in the number of atretic follicles, being higher in individuals from one of the pesticide-treated areas (treated 2). Overall, results showed a higher prevalence of pesticide and lower reproductive condition in females from pesticide-treated areas, which in the long-term could have effects at the population level.

1.08.T-05 mRNA Expression-Augmented Contaminant Biomonitoring in a Seabird Using a qPCR Array

Mason D. King¹, John E. Elliott², Doug Crump³, Vicki Marlatt⁴ and Tony Williams⁴, (1) Biological Sciences, Simon Fraser University, Burnaby, BC, Canada, (2) Research Scientist, Environment and Climate Change Canada, Canada, (3) Environment and Climate Change Canada, Canada, (4) Simon Fraser University, Canada

Birds can bioaccumulate persistent contaminants, and maternal transfer to eggs may expose sensitive embryos to high concentrations, but using tissue residue concentrations alone to infer whether adverse effects are occurring suffers from uncertainty and is a major limitation in many biomonitoring programs. Furthermore, efficient and sensitive biomarkers to assess effects caused by contaminants remain limited or unvalidated in many avian wildlife sentinel species, although mRNA expression-based methods are promising. Therefore, we are evaluating spatial and correlational relationships between embryonic contaminant concentrations (total mercury, 20 organochlorine pesticides, 17 perfluoroalkyl substances, 35 polychlorinated biphenyls, and 22 halogenated flame retardants) and the mRNA expression of 24 genes associated with hepatotoxicity in embryonic liver tissue from a wild-collected Pacific Ocean Alcidae seabird, the rhinoceros auklet (*Cerorhinca monocerata*). Fresh, unincubated eggs were collected and artificially incubated in the lab. Pre-hatch embryos were sampled for hepatic tissue, from which total mRNA was extracted, reverse transcribed to cDNA, and assayed by qPCR ($2^{??Cq}$). The remaining embryo carcass was analyzed for total mercury and organic contaminants by mercury analyzer and GC-MS, respectively. Contaminant concentration data and qPCR relative normalized gene expression data is being analyzed with linear models to conduct spatial comparisons of contaminant concentrations and relative normalized gene expression, as well as evaluating correlative relationships between contaminants of concern and relative normalized gene expression. This study provides valuable baseline data on contaminant concentrations in wild seabirds in northwestern North America, and examines the utility of gene expression approaches for use in contaminant biomonitoring and assessing the effects of potential environmental disasters (e.g., oil spills).

1.08 Understanding and linking effects of contaminants in wildlife across multiple biological levels (Poster)

1.08.P-Tu008 VKORC1L1 Gene Expression in Barn Owl (*Tyto alba*) and Common Kestrel (*Falco tinnunculus*) From Different Environmental Settings

Livia Spadetto¹, Antonio Juan Garcia-Fernandez², Pilar Gomez-Ramirez², Mario León-Ortega³, Antonio Zamora-López³, José Manuel Zamora-Marín³, Sarah Díaz-García³, Pedro María-Mojica², Silvia Espin², Pablo Sanchez Virosta², José M. Navas⁴ and Azucena Bermejo-Nogales⁵, (1) Health Sciences, University of Murcia, Murcia, Spain, (2) University of Murcia, Spain, (3) Ulula Research Group. 30100. Murcia. Spain., Spain, (4) INIA - National Institute for Agricultural and Food Research and Technology, Spain, (5) INIA-Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria, Madrid, Spain

Anticoagulant rodenticides (ARs) have been widely used to control rodent populations. The intensive use of ARs causes frequent secondary exposure of non-target wildlife species. The exposure of birds of prey to ARs is of particular interest as they are top predators and may be used as sentinel species. Previous studies have shown that these species may be highly sensitive to ARs. These compounds inhibit the enzyme vitamin K epoxide reductase complex (VKORC) leading to the animal death due to internal haemorrhages. In birds, sensitivity to ARs and also the main component of this VKORC activity vary among species. For example, the main contributor for VKORC activity in chicken is the VKORC1L1 while in turkey it is the VKORC1 but little is known about its regulation in birds of prey. In the present study, we hypothesize that the VKORC1L1 gene expression is differentially expressed in individuals breeding in different environmental settings related with the use of ARs. To test this hypothesis we sampled individuals of a nocturnal species, the barn owl (*Tyto alba*), and a diurnal species, the common kestrel (*Falco tinnunculus*), which potentially feed on rodents in different areas -varying in relation to land uses- in the Region of Murcia (Spain). For gene expression analysis we used blood samples of adults and nestlings. The results showed a differential tendency in the expression of the VKORC1L1 gene respect to land use in both age classes. Interestingly, a 3-fold increase was found in owlets of barn owl breeding in an intensive farming landscape. This tendency was similar in common kestrel chicks. Though preliminary,

the results of this study will therefore allow to better understand the mechanisms of sensitivity to ARs and the intra- and inter-specific differences in the response to these toxic compounds. *Acknowledgement* - This research was funded by a charge of the Ministry for Ecological Transition to INIA (EG17-017), the project PID2019-108053RJ I00/AEI/10.13039/501100011033 funded by AEI, and Seneca Foundation (20945/PI/18). 1.08.P-Tu009 PFAS Toxicity in Birds: Transcriptomic Response and Association With Fatty Acid Composition in Experimentally Exposed Canaries

*Ana Lopez Antia*¹, *Benjamin Pina*², *Lieven Bervoets*³, *Rafael Mateo Soria*⁴, *Silvia Lacorte*⁵ and *Marcel Eens*³, (1)Universiteit Antwerpen, Italy, (2)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (3)University of Antwerp, Belgium, (4)Instituto de Investigación en Recursos Cinegéticos, IREC (CSIC, UCLM, JCCM), Spain, (5)IDAEA-CSIC, Spain

The widespread use of Per- and poly fluoroalkyl substances (PFAS), together with their persistence and bioaccumulation potential, resulted in global contamination of the environment, wildlife and humans. Despite the ubiquity of PFAS, the toxicological and biological effects of these compounds are not well characterized yet. Several studies have been conducted near the 3M fluorochemical plant in Antwerp using songbirds. These studies revealed the highest PFOS levels ever found in wildlife. Furthermore, levels of other PFAS (PFDS, PFHxS and PFOA) were also the highest ever reported in bird eggs. We assessed the effects caused by PFAS in a model species (canaries (*Serinus canaria*)), at environmentally realistic concentrations, across different levels of biological organization. For this purpose, canaries were exposed during a month to water treated with PFOS and PFOA (the two PFAS most frequently detected). Two exposed groups and a control group were included in the experiment. Each experimental group consisted of 30 birds (15 males and 15 females) We studied the transcriptional response of canaries using high throughput sequencing of adipose tissue. This enabled us to assess the molecular key events that initiate the toxicity pathway of these compounds. In addition, using small amounts of blood, we characterized exposure and effect biomarkers (i.e. immune system assays and fatty acid composition), enabling us to establish linkages between key events in the biological cascade. Transcriptomic analyses revealed dysregulation of 1249 transcripts (711 overrepresented and 538 underrepresented relative to controls), showing a clear dose-response to PFAS exposure. Using the annotation from chicken genome, we identified several metabolic pathways significantly affected by PFAS treatment, including lipid, glycerolipid, and sphingolipid metabolism, the Krebs cycle, and the apoptosis pathways. These results can be interpreted as a reduction in lipid catabolism and the activation of programmed cell death, suggesting degeneration of the fatty tissue due to a lipid metabolism disruption by PFAS. In relation to this, we found that exposed females, but not males, presented a lower percentage of unsaturated fatty acids in their red blood cells. All tests were performed using non-destructive samples, which is crucial to reproduce the study in wild birds. This is the first use of whole-genome transcriptomics to analyze the toxic effects of PFAS in songbirds.

1.08.P-Tu010 Exploring the Pollutant Exposure and Its Potential Health Implications in Common Eiders Through Nontarget and Target Analyses

*Amalie Ask*¹, *Martin Metabolomics Hansen*², *Veerle Jaspers*³, *Sunniva Frøyland*⁴, *Juho Jolkkonen*⁵ and *Céline Arzel*⁶, (1)Biology, University of Turku, CGI, Finland, (2)Aarhus University, Denmark, (3)Norwegian University of Science & Technology, Norway, (4)Norwegian University of Science and Technology, Norway, (5)University of Jyväskylä, Finland, (6)University of Turku, Finland

The common eider (*Somateria mollissima*) is a large sea duck found in arctic and temperate regions of the northern hemisphere. Only the females incubate the eggs and they fast for the 26-day long incubation. The resultant loss of body mass has the potential of remobilizing pollutants stored in body tissues. The population of common eider is declining dramatically in Finland with a concurrent shift in the adult sex ratio towards a heavy male bias. While predation of breeding females factors into this, the role of pollutant exposure deserves further investigation as the Baltic Sea is among the most heavily polluted seas in the world. To this end, we collected paired blood samples from females ($n = 28$) in early and late incubation as well as complete clutches from ten nests in spring 2021 at a colony in southwestern Finland. We have already analyzed the blood samples using untargeted metabolomics and nontarget screening of pollutants at Aarhus University. The same blood samples as well as egg samples will be used for targeted analyses in January-February 2022 at the Norwegian University of Science and Technology of organophosphate flame retardants, UV filters, bisphenols, and per- and polyfluoroalkyl substances (PFASs). These results will be presented at the conference.

1.08.P-Tu011 MicroRNAs: A Link Between Pollution and Disease in Migratory Shorebirds?

*Anne-Fleur Brand*¹, *Junjie Zhang*², *Marcel Klaassen*³, *Courtney Waugh*⁴ and *Veerle Jaspers*⁵, (1)Norwegian University of Science & Technology (NTNU), Norway, (2)Norwegian University of Science and Technology, Norway, (3)Deakin University, Australia, (4)Nord University, Norway, (5)Norwegian University of Science & Technology, Norway

Immunomodulation has been linked to chemical pollutant exposure in various species. Yet, the molecular mechanisms underlying the effects of chemicals on the immune system are not well understood. Recently, microRNAs have been identified as post-transcriptional regulators of gene expression and key modulators of the immune system. MicroRNAs are short noncoding RNAs that bind semi-complementary to messenger RNA to prevent their translation into proteins. Changes in microRNA expression have been found after exposure to various chemicals and pathogens (e.g., influenza virus). The presence and stability of microRNAs in biological fluids, including serum, makes them promising, minimally-invasive biomarkers of immunomodulation. In this study, we performed microRNA sequencing of serum samples from shorebirds that migrate along the East-Asian Australasian Flyway (EAAF). Many EAAF shorebird populations are declining, but the role of pollutant exposure in these declines is unclear. The aim of this study is to elucidate the role of microRNAs in pollutant-induced immunomodulation by

comparing serum microRNA profiles with (i) avian influenza (AIV) infection status and (ii) blood pollutant levels. Serum samples from avian influenza-infected (n=8) and non-infected (n=6) ruddy turnstones (*Arenaria interpres*), captured in Australia in 2019, were analysed for microRNAs using next-generation sequencing. Reads were aligned against the ruddy turnstone genome and known microRNA sequences from MiRBase were quantified using miRDeep2. Differential expression analysis was carried out using EdgeR and potential microRNA targets were identified using RNAhybrid. We identified 117 known microRNAs of which four were differentially expressed (DE) in AIV-infected ruddy turnstones. All four DE microRNAs are regulators of immune pathways. Furthermore, eight of the identified microRNAs, including the DE miR-204/211, target AIV genome sequences. These findings might reflect an antiviral response, supporting the notion that serum microRNAs have potential as biomarkers for immunomodulation in avian wildlife. Blood pollutant levels (per- and polyfluoroalkyl substances and heavy metals) and oxidative stress biomarkers are currently being quantified and their influence on microRNA expression will be assessed, to further elucidate the role of microRNAs in pollutant-induced immunomodulation. All results will be presented at the conference.

1.08.P-Tu012 Pollution in the Coastal Wetlands of East Asia and the Decline in Migrating Shorebirds - First Results of the Coast Impact Project

Veerle Jaspers¹, Hebo Peng², Junjie Zhang³, Tobias Ross⁴, Anne-Fleur Brand⁵, Alexandros Asimakopoulos⁶, Tomasz Ciesielski³, Bjorn Munro Jenssen³, Courtney Waugh⁷, Dorte Herzke⁸, Giulia Poma⁹, Govindan Malarvannan⁹, Adrian Covaci¹⁰, Lei Wang¹¹, Michelle Wille¹² and Marcel Klaassen⁴, (1)Norwegian University of Science & Technology, Norway, (2)University of Groningen, Netherlands, (3)Norwegian University of Science and Technology, Norway, (4)Deakin University, Australia, (5)Norwegian University of Science & Technology (NTNU), Norway, (6)Health Research, Inc., Norway, (7)Nord University, Norway, (8)Environmental Chemistry, NILU - Norwegian Institute for Air Research, Tromsø, Norway, (9)University of Antwerp Toxicological Center, Belgium, (10)University of Antwerp, Belgium, (11)Nankai University, China, (12)University of Sydney, Australia

The main purpose of the project is to investigate the influence of pollution and infectious diseases on shorebirds that migrate along the East Asian–Australasian Flyway (EAAF). Many shorebird populations are in severe decline along the EAAF, the reasons for which are largely unknown. Climate change and habitat destruction are considered important contributors to these declines, the role of pollution thus far remaining understudied. Pollutants might nevertheless have an important role to play in shorebirds being in dire straits, potentially affecting the food on which they rely, and having direct and indirect (e.g. through immunomodulatory properties) effects on their survival. COAST IMPACT investigates the impact of pollution on the availability and biodiversity of benthic macroinvertebrates (food resources to shorebird) in coastal wetlands in East Asia, and the resulting combined impact of food availability, pollution, and disease on migrating shorebirds using these wetlands as stop-over sites. In 2018-2021, about ten locations along the Chinese coast were visited to study the abundance and biodiversity of benthic macroinvertebrates and to obtain sediment samples and macroinvertebrates for contaminant analysis. Contaminant analysis for per- and polyfluoroalkyl substances (PFASs), persistent organic pollutants and other emerging contaminants were conducted. In addition, PFASs analysis, and Total Oxidisable Precursor Assay to determine PFASs not amenable to standard analysis were also performed on a limited number of samples. PFASs were analysed in blood samples from several shorebird species with differently reported population statuses (some in severe decline while others are more stable) in Taiwan and Australia. For Australian birds also their avian influenza infection status was assessed. POPs were generally low in all sediment and macrobenthos samples with the vast majority of samples below the quantification limit. The Bohai Sea was shown to potentially be a hotspot for contamination with PFASs and other emerging contaminants (e.g bisphenols and parabens). In addition, the macrobenthos is declining in most of the studied sites. Regarding shorebirds, birds from Taiwan showed significantly higher concentrations than birds from Australia. The reported population status seems to be correlated to total PFASs concentrations in birds sampled in Taiwan. Also, birds with high concentrations of PFASs had a higher chance of being infected with avian influenza.

1.08.P-Tu013 Pesticide Toxicity and Farmland Bird Populations in England

Priyasha Vijendra¹ and Dave Goulson², (1)School of Life Sciences, University of Sussex, UK, (2)School of Life Sciences, University of Sussex, United Kingdom

Agricultural intensification has increased efficiencies and altered farming practises and, the use of pesticides and fertilisers have contributed to this *green revolution*. However, there have been widespread effects of this transformation. In face of these changes, several non-target farmland species have declined. Extensive research has presented the dangers these agrochemicals pose to invertebrates such as pollinators, but less is known about organisms at higher trophic levels. Previous modelling studies have linked the decline of farmland birds with the use of pesticides. Although, many of these are limited as only a single pesticide class or species is considered in the study. This study considers the wider range of pesticides utilised on arable farmland with the aim to better understand the driver behind the immense decline in farmland bird abundance in England. Generalised linear mixed models were used to test for spatio-temporal associations between agricultural usage of 16 pesticides and changes in populations of 30 species (farmland and generalist) between 2007 and 2016. The abundance of half of the farmland species included in the study were negatively associated with one or more pesticide and this was also similar amongst the generalist species. Farmland species have been at risk since the drastic agricultural changes have been introduced but generalist species in farmland areas are also under threat. Although it isn't possible to infer that pesticide application is the causal factor of these declines observed in the findings, the study has highlighted three pesticides that potentially pose the greatest risk and may warrant further research (cyprodinil, glyphosate and prothioconazole). We can conclude that pesticide application has a varying effect across the different species included in this study, but it is also likely that there are multiple factors contributing to the effects we have observed that were not considered here and should be the focus of future research.

1.08.P-Tu014 Does Domestic Pesticide Use Influence Bird Abundance in Private Gardens?

Cannelle Tassin de Montaigu and Dave Goulson, School of Life Sciences, University of Sussex, United Kingdom

Urban greenspaces bring a range of advantages for residents, being associated with improved mental health and well-being, which was even more essential during the lockdowns of 2020 and 2021. Domestic gardens are also a crucial component of cities. In the UK, approximately 87% of households have gardens; this represents about 23 million gardens covering 400,000 ha. Domestic gardens are highly heterogeneous but collectively support considerable biodiversity and ecosystem services such as pollination. Nonetheless, garden pesticide utilisation is often let aside when assessing the risk to wildlife from chemicals. We investigated if the use of domestic pesticides and/or veterinary medicine on pets (cats and dogs) has an impact on the abundance of bird species in private gardens. However, collecting data in private gardens can be arduous in normal times and doubly during a global pandemic. This is why we cooperated with the Garden Bird Watch (GBW) scheme of the British Trust for Ornithology (BTO) by emailing a questionnaire to volunteers on their pesticides usage, cat and dog use of flea and tick treatment. We also obtained the garden information and data on abundance of bird species for the years 2020 and 2021. We obtained data for 733 participants, of which 32% used garden pesticides, and 78.6% and 76.8% treated their dogs and cats, respectively, for fleas and ticks over the last year (at the time of survey). The herbicide glyphosate was the most used garden pesticide (20% of households surveyed). Preliminary analysis found negative relationships between the use of pesticides in gardens with the abundance of certain common garden bird species, such as blackbird (*Turdus merula*), house sparrow (*Passer domesticus*), starling (*Sturnus vulgaris*), or greenfinch (*Carduelis chloris*). Additionally, we explored the impact of urbanisation on bird abundance in private gardens and found that a significantly higher number of birds were recorded in rural areas than in urban areas, but this was probably explained by the general size of gardens, with rural gardens being bigger than urban gardens.

1.08.P-Tu015 Assessing the Utility of Nuptial Pad Morphology for Predicting Reproductive Success in Wild Anuran Populations (*Rana temporaria*)

Frances Orton¹, Catherine Helen Whatley² and Charles Tyler³, (1)Health and Life Sciences, UWS, Glasgow, United Kingdom, (2)School of Science and Sport, University of the West of Scotland, Glasgow, United Kingdom, (3)University of Exeter, United Kingdom

Amphibians are undergoing declines on a global scale. Pollutant induced reproductive toxicity ('reprotoxicity') is thought to be a major contributor to amphibian declines, however, evidence linking reprotoxic effects to population declines is lacking for amphibians. One obstacle for assessing reprotoxicity in wild amphibian populations is the lack of informative biomarkers for pollution exposure with relevance to reproductive health. One candidate biomarker for males is a secondary sexual characteristic, the nuptial pad. Here, we investigated the utility of nuptial pad morphology for predicting mating success in wild male common frogs (*Rana temporaria*) in the UK. Sampling sites were located in Devon (2015, 2020) and in Scotland (2021). On arrival at each pond site, once active breeding had been confirmed by observing pairs of frogs in amplexus, 1-6 replicate tubs (66 cm diameter circular, black plastic) were set-up. Pond water (25L) was added to the tubs, along with 8 males and 2 females. This generated a 4:1 male:female sex ratio, which mimics natural conditions in common frog populations. Breeding behaviour was observed every 45 minutes for each replicate tub and at each successive observation, the identity of the male frog(s) in amplexus was recorded. Breeding data collected from a total of 8 different pond sites in Devon (27 tubs in 2015, 3 tubs in 2020) and 4 pond sites in Scotland (8 tubs in 2021). We found that in all years, male frogs that won the competition for the female more commonly had a longer nuptial pad, with an overall level of 61 % across all years ($n = 76, p < 0.001$). Most winning male frogs had a darker nuptial pad for two of the three study years, with an overall level of 63 % across all years ($n = 76, p < 0.001$). These data suggest that features of nuptial pad morphology are a predictive indicator of mating success in male common frogs. Given that nuptial pads have been identified in all anuran amphibian species analysed so far, nuptial pad morphology has potential for use more widely as a biomarker of male reproductive capability across a broad range of amphibian species.

1.08.P-Tu016 Investigating the Resilience of Native and Invasive Amphibian Species to Salinisation by Mapping Their Coastal Distributions Across the UK

John Howieson¹, Stuart Piertney², Fiona Henriquez³ and Frances Orton⁴, (1)School of Life Sciences, University of the West of Scotland, Glasgow, United Kingdom, (2)University of Aberdeen, UK, (3)University of the West of Scotland, United Kingdom, (4)Health and Life Sciences, UWS, Glasgow, United Kingdom

The salinisation of freshwater ecosystems is a widespread threat to global biodiversity and ecosystem health. Salinisation occurs when excessive salt, most commonly sodium chloride (NaCl), enters a freshwater ecosystem. The two main causes of salinisation of freshwater are road de-icers and seawater inundation, itself caused by climate change induced sea level rise and/or increased frequency of extreme weather events such as storms. Freshwater vertebrates, including amphibians, typically experience negative impacts of salt pollution, with effects ranging from mortality to developmental delays and abnormalities. Apart from a couple of known salt tolerant species, such as the crab eating frog (*Fejervarya cancrivora*), laboratory exposures have demonstrated that many amphibian species are negatively impacted by salt pollution. However, there are now an increasing number of reports of amphibians inhabiting brackish water suggesting that salt resilience in amphibians may be more common than initially thought. Using citizen science sampling followed by environmental DNA (eDNA) species identification, here we have identified the occurrence of the six native amphibian species (common toad, *Bufo bufo*; natterjack toad, *Epidalea calamita*; common frog, *Rana temporaria*; great crested newt, *Triturus cristatus*; smooth newt, *Lissotriton vulgaris*; palmate newt, *Lissotriton helvetica*) and the invasive alpine newt (*Ichthyosaura alpestris*) in freshwater or brackish ponds in coastal areas across the UK. Volunteers provided three water samples, spaced three weeks apart, starting when they first observed spawn/adult amphibians in their respective water bodies. In addition to the eDNA analyses, the salinity of the water samples was also recorded, in order to align species

distributions with actual salinity levels. The species distribution data will allow us to investigate the extent of amphibian occupancy of coastal water bodies in the UK as well as the tolerance of individual species to salinity in the wild.

1.08.P-Tu017 Investigating the Relationship Between Bioaccumulated POPs and Biomarker Response in Spinner Dolphins, *Stenella longirostris*

Bárbara Righetti¹, Daína Lima², Jacó Mattos³, Clei Piazza³, Rafael Lourenço⁴, Karim Luchmann⁵ and Afonso Celso Dias Bainy³, (1)Universidade Federal de Santa Catarina, Florianópolis, Brazil, (2)UFSC, Brazil, (3)Universidade Federal de Santa Catarina, Brazil, (4)Instituto Oceanográfico da Universidade de São Paulo, Brazil, (5)UDESC Laguna, Brazil

In the Brazilian coast, the spinner dolphin, *S. longirostris*, occurs predominantly at oceanic waters, concentrating at the upper continental slope, with occasional sightings at higher depths or along the continental shelf. Due to the overlap of its distribution with oil and gas extraction and production (E&P), *S. longirostris* was included as a priority sentinel species to be used in the ongoing Cetacean Monitoring Project (PMC-BS) carried out by Petrobras at the Santos Basin pre-salt province (25005'S 42035'W, 25055'S 43034'W). This study investigated the relationship between blubber burdens of polycyclic aromatic hydrocarbons (PAHs) and persistent organic pollutants (POPs) and biomarker response measured in the tegument of *S. longirostris*, sampled within the Santos Basin pre-salt province. Skin and blubber samples (n=16) were obtained opportunistically through remote biopsy, during telemetry or visual survey efforts. Blubber samples were analyzed for PAHs and POPs (PCBs, PBDEs and organochlorines). Skin samples were used to quantify glutathione S-transferase (GST) activity, cytochrome P450 1A (CYP1A) protein content and transcript levels of aryl hydrocarbon receptor (AhR), cytochrome P450 1B (CYP1B), estrogen receptor beta (ESR2), heat shock protein (HSP70) and UDP-glucuronosyltransferase (UGT1). To investigate the relationship between bioaccumulated PAHs and POPs and biomarker response, generalized linear models (GLMs) were constructed. Best fitted models indicated that PAHs levels contributed significantly to the observed variance of biomarker data. In particular, PAHs levels were negatively associated to CYP1B, ESR2, HSP70 and UGT1 transcript levels. Apart from PAHs, only mirex was negatively associated with AhR transcript levels and PBDEs were positively associated with UGT1 transcript levels. Regarding to PAHs, the predominance of negative associations may be due to the prevalence of two and three ring compounds, which have been shown to inhibit biomarker response, such as EROD and GST activity in other species. The negative relationship between PAHs and ESR2 also suggests a potential inhibitory effect over reproductive signaling. Taken together, our results suggest that the levels of bioaccumulated contaminants found in these samples, especially PAHs, may be of concern to *S. longirostris* local population and reinforce the need to continually monitor this species in the Brazilian coast.

1.08.P-Tu018 Polycyclic Aromatic Hydrocarbons (PAHs) in Cetacean From Western Mediterranean Coast

Gabriel López-Berenguer¹, Andrea Acosta-Dacal², Ana Macias-Montes², Octavio Luzardo³, José Peñalver⁴ and Emma Martínez-Lopez¹, (1)University of Murcia, Spain, (2)University of Las Palmas de Gran Canaria, Spain, (3)Fundación Parque Científico Tecnológico de la Universidad de Las Palmas de Gran Canaria, Spain, (4)Region of Murcia, Spain

Polycyclic aromatic hydrocarbons (PAHs) are persistent organic pollutants derived from the combustion of organic matter, highly lipophilic and present in all the world's seas and oceans, as well as in the atmosphere and soils. However, the analysis and impact of these compounds on cetaceans are scarce. Cetaceans, which are considered as oceanic sentinels of human and wildlife health, have been suggested to be especially susceptible to the toxic effects of PAHs. The aim of this work was to detect and quantify 16 PAHs in blubber samples from 58 individuals of various endemic cetacean species stranded on the Murcia coastline (Western Mediterranean) between 2011 and 2018. Only six of the 16 studied compounds were detected with detection frequencies ranging from 17.24% (anthracene) to 98.28% (phenanthrene). The concentrations detected are in line with those obtained by other authors in marine mammals from areas with high anthropogenic pressure. Phenanthrene was the PAH showing the highest concentrations (maximum 205.14 µg/kg lw.), followed by naphthalene, acenaphthene, fluoranthene, fluorine and anthracene. Our results in striped dolphin (the species with the largest number of samples, n=40) followed the same distribution pattern than others striped dolphins elsewhere, dominated by naphthalene (46.86 ± 27.48 µg/kg). This compound is used as a precursor in many industrial processes, as well as a component of pesticides and fuels, so high levels in the study area, characterized by its intensive agriculture (up to 10.9% of the total pesticides used in all of Spain), were expected. On the other hand, the profile of PAHs detected in the study area is mainly composed of low molecular weight compounds, which have the lowest carcinogenic and mutagenic potential. However, some studies have demonstrated the greater genetic susceptibility of Mediterranean cetaceans to the adverse effects of PAHs. Therefore, toxic effects affecting the status of studied populations should be addressed. This is the first work assessing PAHs concentrations in cetaceans from the Region of Murcia, so the data presented in this work could serve as a reference for future research.

1.08.P-Tu019 Organochlorine Pesticides, Polychlorinated Byphenils (PCBs) and Polybrominated Dyphenil Ethers (PBDEs) in Seven Mediterranean Endemic Cetacean Species

Gabriel López-Berenguer¹, Andrea Acosta-Dacal², Ana Macias-Montes², Octavio Luzardo³, José Peñalver⁴ and Emma Martínez-Lopez¹, (1)University of Murcia, Spain, (2)University of Las Palmas de Gran Canaria, Spain, (3)Fundación Parque Científico Tecnológico de la Universidad de Las Palmas de Gran Canaria, Spain, (4)Region of Murcia, Spain

Mediterranean Sea is considered as a hotspot for several persistent organic pollutants (POPs), whose potential health end-points include the reproductive, immune and endocrine systems, and are able to cause cancer. Status of most populations of Mediterranean cetacean species is not generally considered to be favorable and chemical pollution is commonly suggested as a probable cause. Long-term biomonitoring of these cetacean populations provide useful information on the POPs-pollution status of western Mediterranean Sea, which might have direct impact in wildlife and human health. We used blubber from 7 different species of cetaceans (n=57) stranded along the Murcia coastline (SE Spain) between 2011 and 2018 to study 16 different

organochlorine pesticides (OCPs), 18 polychlorinated biphenyl (PCB) congeners and 8 polybrominated biphenyl ethers (PBDE) congeners. DDE and methoxychlor accounted for more than 80% of the OCPs in all species. Mean DDE/tDDT ratio was over 0.9 for all the studied species, which indicates the absence of recent exposures to DDT in these individuals. PCB pattern was dominated by PCBs 180, 153 and 138 and was homogeneous between species. On the other hand, PBDE pattern was dominated by BDE 47, although the rest of the composition was highly variable among species. Striped dolphin was the species showing the highest concentrations of most OCPs (tDDT 4752 ± 7415 mg·kg⁻¹ lw.; methoxychlor 2263 ± 2920 mg·kg⁻¹ lw.), PCBs (6490 ± 9550 mg·kg⁻¹ lw) and PBDEs (73 ± 103 mg·kg⁻¹ lw), generally followed by bottlenose dolphins and common dolphin, which could be explained by their feeding behavior in shallower waters closer to the coast. No significant differences were found among sexes and length was generally not significantly correlated with any compound, although higher concentrations were obvious for older individuals. We lacked enough samples to assess temporal trends. The magnitude of the pollutant concentrations reported in this work was generally lower than those reported for cetacean species in the western Mediterranean. This fact could be explained either by a temporal decrease of these pollutants or different analytical procedures. Although all of these compounds have been banned from decades ago, they are still found at detectable concentrations in cetacean tissues. However, the concentrations found in this study are below those toxicity thresholds reported for marine mammals by different works.

1.08.P-Tu020 Release of Nickel Particles From Mining ACTivity in New Caledonia: Organs Disruption on Eels, *Anguilla marmorata*

*Ophelie Germande Student*¹, *Isabelle Baudrimont*², *Peggy Gunkel-Grillon*³, *Yannick Dominique*⁴, *Guillemine Darse*⁵, *Emilie Dassié*⁶ and *Magalie Baudrimont*⁷, (1)EPOC, University of Bordeaux, Pessac, France, (2)University of Bordeaux, France, (3)University of New Caledonia, New Caledonia, (4)BioEko, New Caledonia, (5)CNRS/UMR EPOC, France, (6)Université Bordeaux, France, (7)Université de Bordeaux, France

Anthropic activities such as open pit mining amplifies the natural erosion of soils leading to atmospheric emission of metal particles including nickel (Ni). New Caledonia is particularly affected by Ni mining activities because of the presence of ultramafic soils (30% of its surface), which are highly concentrated in Ni. These particles produced during extraction, by atmospheric transport and soil erosion will end up by deposition or leaching in aquatic ecosystems. These deposits can directly impact living organisms in the rivers downstream the mines, such as eels. Despite alarming freshwater Ni concentrations, no study explained so far the consequences of metals contamination on eels living under mining influence, fish known to be sensitive to this kind of pollution. The aim of this study was thus to determine by different approaches how eels, *Anguilla marmorata*, are impacted by Ni contamination and other associated metals by measuring: (i) morphometric parameters; (ii) expression level of genes encoding proteins implicated in lipid metabolism, oxidative stress, detoxification and apoptosis in liver, kidneys, brain, gills, spleen and muscle and (iii) metal concentrations in liver, kidneys, gills and muscle. The results showed that for eels living in rivers downstream mines, liver seems to be the main affected organ with an oxidative stress, lipid metabolism disruption, mitochondrial dysfunction and carcinogenic markers activated. The organ in which Ni was the most accumulated was the kidney. These results underlined the potential toxic impact of metal contamination from mining activity on eels. This study should allow us to define in an integrated way (i) to what extent the contributions of metals related to the mining activities impact the aquatic organisms and (ii) what would be the levels in natural environment tolerable to preserve the wild fauna.

1.08.P-Tu022 Searching for Novel Biomarkers of Effect of Neuroactive Compounds: A Study on Caged Carp (*Cyprinus carpio*) Exposed to Municipal Wastewaters In Situ

*Sonja Kaisarevic*¹, *Dina Tenji*¹, *Irina Vulin*¹, *Tanja Tomic*¹ and *Ivana Teodorovic*², (1)University of Novi Sad Faculty of Sciences, Serbia, (2)Faculty of Sciences, University of Novi Sad, Novi Sad, Serbia

Contamination of the aquatic ecosystems by neuroactive compounds (NCs), such as neuroactive pharmaceuticals, illicit drugs, stimulants and pesticides with neuroactive action, lately emerged as an important environmental issue. However, assessment and identification of ecological impacts of NCs in aquatic ecosystems still faces challenges and limitations [1]. One of them is the lack of sensitive and reliable biomarkers of effect of NCs, which could be considered as valuable early warning signals of environmental contamination by NCs. In our study, we searched for novel biomarkers of effect of NCs by measurement of expression of selected genes (RQ-PCR analysis), encoding proteins involved in neurotransmitter pathways and exocytosis, myelination, neuroendocrine regulation of reproduction and changes in membrane potential, in brain tissue of caged common carp (*Cyprinus carpio*) exposed *in situ* to untreated municipal wastewater and industrial effluents. Among the tested genes, inhibition of serotonin receptor 1aa (*htr1aa*) and myelin basic protein (*mnp*), and stimulation of tachykinine 3a (*tac3a*) and voltage-gated Ca⁺⁺ P/Q channel $\alpha 1a$ (*cacna1a*) was detected. These elements can be considered as promising novel biomarkers of effect of NCs, whose sensitivity and specificity should be also tested *in vitro* and *in vivo*. To link the observed responses to possible adverse outcomes, they were integrated in the Adverse Outcome Pathways (AOPs) available in AOPwiki database. The corresponding Key Event (KE) was identified only for the inhibition of the serotonin receptor gene expression (serotonin receptor inactivation; AOPs 221, 222, 224, 225) implying to depression and agitation as resulting adverse outcomes. We also stress the importance of synchronisation of biomarker research with further development of the AOP framework database, which should include additional events related to disturbance of neural function, as crucial for development of improved biomarker-based strategy for impact assessment of NCs in the aquatic environment. [1] Kaisarevic S, Vulin I, Tenji D, Tomic T, Teodorovic I (2021) *Environ Sci Eur* 33:115 **Acknowledgements:** The research was supported by the EU FP 7 project SOLUTIONS (Grant No. 603437) and The Science Fund of the Republic of Serbia, PROMIS (Grant No. 6061817), BIANCO. 1.08.P-Tu023 The Ongoing of a Histology Atlas of Normal Medaka Growth As a Future Baseline in Histopathology: Part II

José Enrique García-Mauriño¹, José Luis Calvo Martín¹, Salvador Sastre López² and Miguel Gonzalez-Doncel³, (1)School of Medicine, Complutense University, Spain, (2)Spanish National Institute for Agricultural and Food Research and Technology (INIA), Spain, (3)Environment and Agronomy, National Institute for Agricultural and Food Research and Technology (INIA-CSIC), Madrid, Spain

Medaka (*Oryzias latipes*), a small freshwater teleost, is a versatile vertebrate model in aquatic (eco-)toxicity studies. Numerous reports that describe the internal medaka anatomy have focused on the histopathological analysis of target organs at specific developmental periods disregarding a holistic dynamic vision of their normal configuration. However, a thoughtful search surprisingly indicated limited histological information of normal medaka development. Here we describe a histological study of the orange-red strain of medaka with a general exhaustive description of its normal internal anatomy that focuses on two developmental periods: i.e. immature 10 days post-hatch (dph) and maturing 60 dph, selected from the seven developmental periods considered (i.e. 2, 5, 10, 15, 30, 60, and 110 dph) to complete its development. The two developmental periods included in this presentation are an addition to the 2 and 110 dph periods that we presented at the 19th PRIMO Meeting in Matsuyama, Japan. Specimens were collected at the selected stages, overdosed with anesthetic, whole-fixed in Bouin alcoholic solution, embedded in paraffin blocks to obtain parasagittal, coronal and cross sections (7 µm-thick), and then stained with hematoxylin and eosin. This contribution, as part of the aforementioned series of developmental periods, is aimed to provide a comprehensive reference guide for the three-dimensional organization of internal medaka anatomy along its development offering a baseline from which to compare deviations at specific stages of the medaka life. This work was made possible by Spanish Government Grant RTI2018-096046-B-C21 funded by the MCIN/AEI/ 10.13039/501100011033 and the ERDF.

1.08.P-Tu024 Applying MOLECULAR Tools to Assess Metabolic Characteristics in Wild Marine Tursiops truncatus From Different Subspecies

Bárbara Righetti¹, Karim Hahn Luchmann², Jacó Mattos³ and Afonso Celso Dias Bainy³, (1)Universidade Federal de Santa Catarina, Florianópolis, Brazil, (2)DECT, Universidade do Estado de Santa Catarina, Florianópolis, SC, Brazil, (3)Universidade Federal de Santa Catarina, Brazil

The knowledge of ecological characteristics of cetacean species is crucial to the design of targeted and effective conservation efforts. In Southern Brazil, two subspecies of bottlenose dolphins (*Tursiops truncatus truncatus* and *Tursiops truncatus gephyreus*) present a parapatric distribution, with the first presenting offshore (OF) and the second coastal (CO) habitats. While stable isotopes values suggest a distinct habitat use for the two groups, no studies have evaluated physiological or biochemical characteristics of the two groups. Therefore, this study aimed to investigate if OF and CO *T. truncatus* present distinct molecular profiles regarding lipid metabolism, immune system and xenobiotic detoxification, further elucidating the extent of habitat overlap between the subspecies and their exposure to anthropogenic pollutants. To fill the gap, skin samples were obtained through remote biopsy from *T. truncatus* in the coastal and offshore areas of the Santos Basin. The latter samples were obtained during the sampling efforts of the “Santos Basin Cetacean Monitoring Project”, carried out by PETROBRAS to satisfy environmental constraint of the federal environmental licensing of PETROBRAS’ activities of production and outflow of oil and natural gas in Santos Basin, conducted by IBAMA. The tegument samples were used to evaluate the transcript levels of fatty acid synthase complex 1 (*FASN 1*), ceramide synthase 3 (*CERS3*), and fatty acid elongases (*ELOVL3* and *4*), markers of lipid metabolism, interleukin 1 alpha (*IL-1a*), and major histocompatibility complex II (*MHCII*) as immune markers, as well as *MT2A*, a metal chelator. Among the target genes, only *MHCII* transcript levels did not vary between the subspecies. The transcript levels of *MT2A* were significantly higher in CO dolphins, suggesting higher metal exposure in the coastal areas. Higher *ILa* transcripts of CO dolphins indicates higher immune activity, probably associated to their usage of areas impacted by domestic sewage, a source of pathogenic microorganisms. Regarding genes involved in lipid metabolism, *FASN1* transcript levels were higher in OF dolphins, while *CERS3B* and *ELOVL4* transcript levels were higher in CO animals. Such results suggest differences in the lipid composition of skin/blubber from CO and OF dolphins with a more prominent synthesis of ceramides and very long chain fatty acids in CO dolphins, which might alter the susceptibility for increased bioaccumulation of lipophilic pollutants.

1.08.P-Tu025 Different Responses to Chemical Contamination of Three Flatfish Species in the Bay of Seine (France)

Vincent Roubeix¹, Farida Akcha², Yann aminot², Thierry Burgeo², Tiphaine Chouvelon³, Tiphaine Mille¹, Catherine Munsch², Nathalie Wessel², Tifanie Briaudeau⁴, Urtzi Izagirre⁴ and aourell Mauffret⁵, (1)IFREMER, RBE-BE, France, (2)IFREMER, France, (3)IFREMER, RBE-BE-LBCM, France, (4)University of the Basque Country, Spain, (5)BRGM, France

Flatfishes live in contact with the sediment which accumulates many contaminants. Moreover, they represent an important fishery resource. Their exposure to contaminants and their economic significance justify their use as sentinel organisms in marine ecotoxicology. Flounder and dab are two of the most studied flatfish species in relation to chemical contamination in the North-East Atlantic. Sole is one of the main flatfish species distributed all along the French mainland coast. France is currently implementing a program (SELL) to monitor the effects of chemical contamination on marine organisms for the evaluation of criterion 2 of descriptor 8 in the European Marine Strategy Framework Directive. As part of this program, flatfishes belonging to three different species (sole, dab and flounder) were trawled in September 2018 in the Bay of Seine. The objective was to compare biomarker levels and chemical impregnation in these three species present in the same area. Concentrations of metal trace elements and organic contaminants were measured in fish as well as biomarkers reflecting various biological effects of the contaminants. The comparison of these parameters among species revealed more differences than similarities. Sole often differed from the two other species, e.g. regarding silver concentration in liver, the capacity of metabolism of some organic contaminants and DNA strand breaks (comet assay). These results have to be interpreted in relation to the biological and

ecological characteristics of the species and will serve to make better use of sole in the environmental assessment of marine ecosystems.

1.08.P-Tu026 In Vitro Neurotoxic Effects of Emerging Flame Retardants at Non-Cytotoxic Concentrations on Neuroblastoma Cells

Roser Esplugas¹, Victòria Linares², Montserrat Bellés¹, Jose Domingo¹ and Marta Schuhmacher³, (1)Universitat Rovira i Virgili, Spain, (2)University Rovira i Virgili, Spain, (3)Rovira i Virgili University, Spain

Since 2004, and due to their concern on human health, mainly for neurotoxic effects, some legacy flame retardants (FRs) were restricted or removed from the European markets. Both organophosphorus FRs (OPFRs) and novel brominated FRs (NBFRs) replaced them because they are presumably safer and less persistent emerging FRs. However, as they are included in a commercialized-mixture products, little is known about the potential toxicity and mechanisms of action of individual FRs. Chronic exposure to OPFRs (such as Tris(1, 3-dichloro-2-propyl) phosphate (TDCIPP) and triphenyl phosphate (TPhP)), as well as NBFRs (such as Bis(2-ethylhexyl)tetrabromophthalate (BEH-TEBP) and 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (EH-TBB)) is currently occurring in indoor environments. The present study was aimed at assessing the acute neurotoxicity potential of TDCIPP, TPhP, BEH-TEBP and EH-TBB. Human neuroblastoma SH-SY5Y cells were exposed to non-cytotoxic levels of these 4 FRs from 2.5-20 µM during 2-24h. Reactive oxygen species (ROS) response, immune function and neurodevelopment were studied by the expression of nuclear factor erythroid 2-related factor 2 (NRF2), Matrix Metalloproteinase 9 (MMP-9) and Brain Derived Neurotrophic Factor (BDNF), respectively. Furthermore, Sirtuin 3 (SIRT3) and Cytochrome c oxidase subunit 4 (COX-4) expressions were evaluated to study the mitochondrial damage was assessed. Both the 3-(4,5-dimethyl-thiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) and Adenosine triphosphate (ATP) release assays confirmed the cell viability after exposure to the 4 FRs at selected doses and time-points. The results showed that NBFRs (BEH-TBP and EH-TBB) impair both immune response and neurodevelopment as well as induced mitochondrial damage at 24 hours for selected doses, but not OPFRs (TDCIPP and TPhP) which exhibit slightly modulations. The results of the present study suggests the neurotoxic potential of these 2 NBFRs. In further studies, we will integrate obtained results to *in silico* models that extrapolate data into *in vivo* results to better understanding the neurotoxicity of these FRs.

1.08.P-Tu027 Analysis of MOLECULAR Biomarkers in the Digestive Glands of *Unio Crassus* As a Useful Tool for Assessing Pollution of Aquatic Ecosystems: A Study in the Mrežnica River (Croatia)

Zoran Kiralj¹, Zrinka Dragun¹, Jasna Lajtner², Krešimira Trgovčević³, Tatjana Mijošek¹, Vlatka Filipović-Marijić¹, Damir Valić¹ and Dušica Ivanković¹, (1)Ruđer Bošković Institute, Croatia, (2)University of Zagreb, Faculty of Science, Department of Biology, Croatia, (3)Vodovod i kanalizacija d.o.o., Karlovac, Croatia

The Croatian karst river Mrežnica has been in some parts exposed to pollution from various types of anthropogenic activities, especially from industry. Although most industrial plants now provide proper treatment and discharge of wastewater, pollutants previously accumulated in sediments may still pose a threat to aquatic organisms. Molecular biomarkers are considered the most sensitive and earliest response to pollutants. Therefore, it is useful for pollution assessment to obtain information about the harmful effects of pollutants on biota by analysing different biomarkers. As benthic inhabitants and filter-feeding animals, mussels are capable of accumulating large amounts of pollutants and are therefore considered good bioindicator organisms for assessing water pollution. In order to assess water pollution and evaluate possible effects of pollutants on aquatic biota, a set of molecular biomarkers was analysed in the digestive glands of *Unio crassus* mussels sampled in spring 2021 from two sites at the Mrežnica River: the industrial zone of the Town of Karlovac (contaminated site) and a location upstream from the Town of Duga Resa (reference site). The set included following biomarkers: metallothioneins (MT) for metal exposure, total glutathione (tGSH) and catalase (CAT) for oxidative capacity and malondialdehyde (MDA) for oxidative damage. In addition, cytosolic concentrations of several essential and non-essential (Ag, Cd, Cu, Pb and Zn) elements were determined. Biomarkers were measured spectrophotometrically, and element concentrations were quantified using a high-resolution inductively coupled plasma mass spectrometer. The MDA levels and the activity of CAT were significantly increased in the mussels from the contaminated site, indicating possible overproduction of reactive oxygen species and oxidative stress in these mussels. The elevated levels of these two biomarkers correlated with the increased concentrations of cytosolic Ag, Cu and Pb. Higher tGSH and MTs concentrations at the reference site coincided with higher cytosolic concentrations of Cd, a known inducer of MTs. Cytosolic Zn concentrations were similar in mussels from both sites of the Mrežnica River. The presented results suggest differences in biochemical responses of mussels from two sites with different pollutant loads. Therefore, the application of molecular biomarkers is a very useful tool for diagnosing the effects of environmental conditions on aquatic organisms.

1.08.P-Tu028 Life-Cycle Dietary Exposure to Polystyrene Microplastics on Medaka Fish (*Oryzias latipes*)

Miguel Gonzalez-Doncel¹, José Enrique García-Mauriño², Eulalia María Beltrán³, Carlos Fernández-Torija⁴ and Pilar García⁵, (1)Environment and Agronomy, National Institute for Agricultural and Food Research and Technology (INIA-CSIC), Madrid, Spain, (2)School of Medicine, Complutense University, Spain, (3)Environment and Agronomy, INIA - National Institute for Agricultural and Food Research and Technology, Madrid, Spain, (4)Spanish National Institute for Agricultural and Food Research and Technology (INIA-CSIC), Spain, (5)Environment and Agronomy, National Institute for Agricultural and Food Research and Technology (INIA-CSIC), Spain

The number of published studies evaluating the effects of microplastics (MPs) in fish has increased over the last two decades. However, there is paucity of information on how long-term exposures to secondary MPs may compromise overall fish development. In this study, 6-10 day-old post-hatch medaka (*Oryzias latipes*) fish were exposed to artificially degraded waterborne levels of 50 (i.e. 1X) and 500 (i.e. 10X) µg of polystyrene (PS) MP particles (200-µm range)/L for 150 days. These

concentrations corresponded to respective daily mean values of 247 and 3087 particles/L administered through the diet. The MP dietary exposure resulted in the presence of MP particles in body burdens. The biometric analyses found no incidence of MPs ingestion on fish growth and development. While the histological survey did not reveal severe alterations in potential target organs (i.e. gills and digestive tract), mild alterations in the 10X treatment were seen in other organs and included the kidneys and the thyroid gland. The initial days of the reproductive phase revealed MP-related differences in the number of gravid females, fecundity, and fertilization rates. Overall, these values reverted to normal rates over the succeeding days. The 150-day MP dietary exposure used in this study could not provide conclusive evidence of effects on medaka that could compromise overall growth/thriving and the ongoing reproduction.

This work was made possible by Spanish Government Grant RTI2018-096046-B-C21 funded by the MCIN/AEI/10.13039/501100011033 and the ERDF.

1.08 Understanding and linking effects of contaminants in wildlife across multiple biological levels (Virtual Only)

1.08.V-01 A Multi-Biomarker Approach to Evaluate the EcoToxicological Status of Common Kestrel Populations From Urban and Agricultural Environments

Laura Giovanetti¹, Ilaria Caliani², Tommaso Campani², Gianluca Damiani³, Giacomo Dell'Omo³, David Costantini⁴ and Silvia Casini², (1)Department of physical sciences, earth and environment, University of Siena, Siena, Italy, (2)University of Siena, Italy, (3)Ornis italica, Italy, (4)UMR 7221 CNRS/MNHN Muséum National d'Histoire Naturelle, Paris, France

The Common kestrel (*Falco tinnunculus*) is a small diurnal bird of prey included in the IUCN Red List as Least Concern due to its moderate but steady decline since the 1980s. Agricultural intensification, pesticide use, landscape modification that cause the reduction of foraging areas, and the availability of nesting sites have led to the decline of this species over time. Up today, very few studies evaluated the contaminants sublethal effects on common kestrel populations from areas with different anthropogenic impacts. This study aimed to evaluate the ecotoxicological status of *Falco tinnunculus* from anthropized areas, using a non-invasive multi-biomarker approach to obtain a diagnosis of environmental stressors effects. In 2020 and 2021, 68 blood samples from specimens of common kestrel nestlings were collected. The nest boxes of the animals are installed in an urban and an agricultural area of the Municipality of Rome (Italy) and in a control area. Neurotoxicity (BChE), genotoxicity (ENA assay, comet assay), immunotoxicity (differential WBCs count, SRBC hemolysis assay, bactericidal assay, NBT assay), and oxidative stress (TAS assay) biomarkers were evaluated. Some of these biomarkers were applied for the first time in this study. Moreover, the presence of parasites was also evaluated, and body condition was calculated for each nestling. The specimens from the agricultural area showed the highest level of DNA fragmentation, with statistically significant differences ($p < 0.05$) with respect to control and urban areas. BChE activity was significantly lower in birds from urban area with respect to agricultural area. The specimens from the urban area also showed the lower complement system activity while not showing a significant difference from the kestrels from the control and agricultural area. In conclusion, the kestrel nestlings of agricultural area showed the highest genotoxicity effects, otherwise the immunotoxicity effects were major in specimens from urban area. The results above will be integrated with the contaminant and population dynamics data to obtain more information on the interaction of common kestrel with the environment.

1.08.V-02 Chlorinated Paraffins, Diet and Endocrine Measures in Nestling Peregrine Falcons in the Canadian Great Lakes Basin

Kim J. Fernie¹, Cynthia de Wit² and Bo Yuan³, (1)Environment and Climate Change Canada, Burlington, ON, Canada, (2)Stockholm University, Stockholm, Sweden, (3)Stockholm University, Sweden

Chlorinated paraffins (CPs) are complex mixtures of polychlorinated n-alkanes that are categorized as short-chain (SCCPs, C10-13), medium-chain (MCCPs, C14-17), or long-chain CPs (LCCPs, C?18). The differences in carbon chain length and chlorine content result in a wide range of physical-chemical properties that make them stable for a wide range of industrial applications, including lubricants, flame retardants, plasticizers, among other applications. They are produced in enormous quantities (2009: 1 M metric tons). In 2017, SCCPs were added to Annex A of the Stockholm Convention on Persistent Organic Pollutants. In Scandinavia, SCCPs, MCCPs and LCCPs were present in peregrine falcons (*Falco peregrinus*), with the highest concentrations found for LCCPs, which were the predominant CPs (55%). In the present study, we examine the CP profiles of nestling peregrine falcons sampled across the Laurentian Great Lakes Basin of Canada predominantly in 2017. Our objectives are 1) to compare and contrast exposure levels and profiles of CPs in peregrine falcon nestlings, 2) to determine any effects of diet (inferred from stable carbon, nitrogen and sulfur isotopes), biology (age, sex), and geography (region) on CPs and thyroid hormones, and 3) to examine possible relationships between CP exposure, circulating thyroid hormones, body condition, and size of the nestlings. As with the Scandinavian adult peregrine falcons, the peregrine nestlings in central Canada had circulating concentrations of vSCCPs (C?9), SCCPs, MCCPs that were dominated by LCCPs; Comparatively, the Canadian birds had lower concentrations of SCCPs, similar MCCPs, and higher levels of LCCPs (47%), likely reflecting differences in age and tissues sampled and potentially differences in exposure to CPs between Scandinavia and central Canada. Within southern Ontario, chicks raised within or to the east of Toronto (population: 4 million) had significantly higher concentrations of LCCPs (3245 ng/g lw) than elsewhere in Ontario. Circulating TT4 was significantly associated with vSCCPs ($N = 18$; $r = -0.62$ $p = 0.007$) and SCCPs ($N = 29$; $r = 0.38$ $p = 0.04$) overall. In the southern urban peregrine chicks, SCCPs were associated with estimated thyroid gland function consistent with previous findings involving the related American kestrel.

1.08.V-03 Development of a mRNA Biomarker Tool for Water Quality Monitoring With the Brown Trout *Salmo trutta*
*Anne-Sophie Voisin*¹, *Kristina Rehberger*², *Melanie Fasel*³, *Rébecca Beauvais*⁴, *Helmut Segner*², *Benoit J.D. Ferrari*⁵ and *Inge Werner*³, (1)*Oekotoxzentrum Eawag-EPFL, Switzerland*, (2)*University of Bern, Switzerland*, (3)*Swiss Centre for Applied Ecotoxicology, Switzerland*, (4)*Centre Ecotox, Switzerland*, (5)*Ecotox Centre CH, Switzerland*

Input of pesticides, increased water temperature and pathogens represent a multi-stressor scenario common to many streams flowing through agricultural areas. This can negatively affect fish populations; however, effective methods to detect adverse effects in resident fish are limited. Gene expression biomarkers offer a promising effect-based approach to detect the sublethal effects of chronic exposures in the field. In this context, we aim to build a cost- and time-efficient tool for measuring a set of biomarkers (ca.100) by qPCR. For biomarker selection, we reviewed scientific literature and databases (e.g. AOP-Wiki) focusing on genes involved in specific modes of action as well as general stress responses. To identify further candidates, we carried out a transcriptomic analysis in brain and liver samples of juvenile brown trout exposed to a pesticide mixture (fluopyram, diuron, epoxiconazole, lambda-cyhalothrin and chlorpyrifos) for 14 days in the laboratory, at 12 or 15°C. We performed a second transcriptomic analysis on liver tissues of brown trout infected with *T. bryosalmonae*, the causative agent of the proliferative kidney disease (PKD). To integrate the molecular responses with potential consequences at higher levels of biological organization, we measured physiological health parameters (immune and energy metabolism, parasite infection success) and endpoints at the organism level (organ indices and growth). While no effect was detected on growth and immunoassays, respirometry measurements, reduced condition factor and hepatosomatic index indicated that pesticide exposure may negatively impact the energy status of brown trout. The transcriptomic results showed a massive effect of the 3-degree temperature difference on gene expression with 30 % and 15 % of transcripts being differentially expressed in the brain and liver (differentially expressed genes, DEGs). Pesticide exposure induced 1.26 and 2.29 % of DEGs in the brain, and 0.16 and 1 % of DEGs in the liver, at 12 and 15°C, respectively. The PKD disease caused 1.41% of DEGs in the liver mostly involved in immune pathways. Our results further highlight the importance of considering confounding effects of environmental parameters, such as temperature, when screening for biomarkers.

1.08.V-04 Metabolic Effect of Ocean Acidification on Common Cuttlefish *Sepia officinalis* Early Stages

*Antoine Minet*¹, *Steven Melvin*², *Angus Taylor*³, *Paco Bustamante*⁴, *Marc Metian*³ and *Thomas Lacoue-Labarthe*⁴, (1)*LIENSs, France*, (2)*Australian Rivers Institute, Australia*, (3)*IAEA-EL, Monaco*, (4)*LIENSs CNRS & Université de la Rochelle UMR 7266, France*

Atmospheric carbon dioxide (CO₂) emissions are continuously increasing due to the growing anthropogenic activities, causing a rise in the sea-surface partial pressure of CO₂ (pCO₂). This change in turn leads to decreased ocean pH, named ocean acidification, and affects the carbonate-silicate cycle. Such modification of seawater chemistry also affects the physiology and behaviour of marine organisms, impacting their metabolism, growth and development during vulnerable early-life stages. Among them, the embryo of the cephalopod cuttlefish develops for ~2 months) in encapsulated eggs with harsh conditions of hypoxia and hypercapnia, potentially worsen by the environmental ocean acidification. In this study, the development and the growth of early-life stages of *Sepia officinalis* were followed during the whole embryonic developmental period up to 10 days post-hatchling juveniles. Embryos and juveniles were exposed to five elevated pCO₂ conditions controlled with a continuous pH-stat system (pH 8.08; 7.82; 7.65; 7.54; 7.43). Metabolites were determined in ready-to-hatch embryos, just hatched embryos and 10 d-old juveniles, using a ¹H nuclear magnetic resonance (NMR) spectroscopy as a platform for untargeted metabolomics analysis. Consistent with previous studies, our results showed longer embryonic development and decreased hatching success at the lowest pH, but no effect on juvenile weight upon hatching. Metabolomics analysis revealed a metabolic depression in embryos reared at pH 7.43, non-monotonic changes to pH in 10 d-old juveniles, and no clear pH effect in newly hatched juvenile cuttlefish, likely due to the metabolic stress associated with hatching. Those results reveal possible effect of ocean acidification on the cuttlefish recruitment.

1.08.V-05 Microplastic Effects on Oxidative and Inflammatory Responses in the Japanese Quail

*Laura Monclus*¹, *Eliana McCann Smith*¹, *Tomasz Ciesielski*², *Martin Wagner*² and *Veerle Jaspers*³, (1)*Norwegian University of Science & Technology (NTNU), Norway*, (2)*Norwegian University of Science and Technology, Norway*, (3)*Norwegian University of Science & Technology, Norway*

Plastic pollution is currently recognized as a threat for wild birds. However, the effects of ingesting microplastics in birds are still not well understood. In particular, there are no studies thus far that have investigated the effects of smaller microplastics (< 1 mm). Oxidative stress and inflammatory responses to microplastic exposure have been reported in several species, like crustaceans, fish, and mice, but there is no such information in birds. Therefore, we exposed a laboratory bird model species, the Japanese quail (*Coturnix japonica*), to microplastics and investigated oxidative stress and biomarkers of inflammation (pro-inflammatory cytokines). The aim of this experiment was to compare the toxicity of two different sizes of microplastics, large microplastics (3 mm size) and small microplastics (< 125 µm size) of polypropylene and polyethylene in 55 growing Japanese quails. After 6 weeks of exposure, either to 3 mm particles (T1), powder < 125 µm (T2) or a mixture of both (T3), quails were euthanized, and blood was collected in heparinized tubes. Plasma and red blood cells (RBC) were separated and stored at -80 °C. Four antioxidant enzyme activities were analyzed in RBC samples, including catalase (CAT), glutathione peroxidase (GPx), glutathione-S-transferase (GST) and superoxide dismutase (SOD). Lipid peroxidation was estimated by thiobarbituric acid-reactive substances (TBARS) analysis. Plasma samples were used to analyze cytokine levels, including interleukin-1? (IL-1 ?) and tumor necrosis factor-alpha (TNF-?). Quails from T2 (powder) and T3 (mixture) treatment groups showed higher enzyme activities of CAT, GPx and GST than those in the control group (all *P* < 0.05). SOD activity and TBARS were not significantly different between treatment groups (*P* > 0.05). We did not find any significant differences between treatment groups in TNF-? and

IL-1 ? levels ($P > 0.05$). In this experiment, we provide evidence for the first time that small microplastic ingestion causes an increase of antioxidant enzyme activities in birds and we confirm that microplastic size is important for triggering sub-organismal responses.

1.08.V-06 Mitochondrial Texture of Humpback Whale Fibroblast Cells Upon Chemical Exposure

Hafiz Hosen¹, Stephen Wood², Alex Sykes², Frederic Leusch³, Deanne Whitworth⁴ and Susan M Bengtson Nash⁵, (1)Griffith University, Bangladesh, (2)Griffith University, Australia, (3)Griffith University - Smart Water Research Centre, Australia, (4)The University of Queensland, Australia, (5)Centre of Planetary Health and Food Security, Griffith University, Nathan, QLD, Australia

The bioaccumulative, and often lipophilic nature of many environmental contaminants places cetaceans at a greater risk of accumulating elevated body burdens due to their longevity and high proportion of body fat. Ethical and logistical constraints prohibit *in vivo* toxicological investigation on cetaceans. An important focus of *in vitro* cetacean studies in recent years has involved cell culture. Image-based cell profiling using automated microscopy is a high-throughput and high-content strategy to analyse the effect of chemical exposure on cell morphology and function. Many chemicals and cell organelles can be assayed simultaneously. Its broad application in drug development, revealing subcellular sites of impact, renders it a potentially useful tool for the characterization of contaminant toxicodynamic. This study exposed both human (HF) and immortalised humpback whale (HuWa_{TERT}) skin fibroblast cell lines to 6 priority compounds (1,1-dichloro-2,2-bis(4-chlorophenyl) ethene, lindane, dieldrin, endosulfan, trifluralin and chlorpyrifos) known to accumulate in the Southern Ocean food web. Each cell line was exposed to the same concentration range of each chemical for visualization and quantification of mitochondrial texture effect using a range of stains. Analysis of image-based data on exposure of the cells to selected chemicals demonstrated concentration-, chemical- and species-dependent modulation of mitochondrial texture, with more significant changes observed in HuWa_{TERT} compared to HF. In addition, all 6 compounds were cytotoxic. We observed significant chemical-specific as well as concentration-specific inter-species sensitivity differences. These findings constitute the first fixed mitochondrial images of HuWa_{TERT}. Further, they provide unique insights into the potential toxicodynamics of these chemicals on mitochondria, the cellular 'powerhouses'. Finally, the experiments reveal interesting insights as to relative inter-species sensitivity to selected compounds. Expansion of cetacean *in vitro* toxicity testing is needed for evidence-based conservation and management action.

1.08.V-07 Monitoring the Effects of Contaminants at Different Levels of Biological Organization in Great Tit (*Parus Major*, Linnaeus, 1758) From Rural and Urban Areas of Northern Italy

Silvia Casini¹, Laura Giovanetti², Matteo Griggio³, Matteo Schiavinato³, Matteo Beccardi³, Lia Zampa³, Tommaso Campani¹ and Ilaria Caliani¹, (1)University of Siena, Italy, (2)Department of physical sciences, earth and environment, University of Siena, Siena, Italy, (3)University of Padova, Italy

Pesticides, widely used in agriculture, and other classes of anthropogenic contaminants, can cause reversible alterations or permanent damage to biota, including avian species. Great tit (*Parus major*), the species selected for this research, is ubiquitous, has a good ecological relevance and its territoriality can provide precise information on a given territory due to no variables deriving from migration. Starting from an original idea of Matteo Griggio, in the last four years several nest boxes for great tit, were installed in several areas of Veneto region (northern Italy), characterised by different anthropogenic impact. This work aimed to develop and apply a non-invasive method to monitor, in the selected species, the effects of anthropogenic contaminants at different levels of biological organization. We explored potential interlinkages between effects at molecular and cellular level and effects at behavioural, phenotypic and population level. Nestlings great tit were sampled in urban, agricultural, and wooded environments. We developed and applied a non-invasive protocol on blood and excreta, to test different toxicological responses. Neurotoxicity (esterases inhibition), genotoxicity (ENA assay, comet assay), immunotoxicity (complement system), estrogenic (vitellogenin) and oxidative stress (TAS assay) effects were evaluated in the specimens from the different areas. At higher biological levels, parental care (nest defence and pair coordination over offspring provisioning) of great tits breeding, and cognitive abilities, by problem solving tests, as well as phenotypic endpoints and reproductive success were assessed on the target species. Responses to contaminants at different biological levels were modulated depending on the characteristics of the study areas and interlinkages between responses at different biological levels were found. A strong increase of the total antioxidant system was found in Great tit from agricultural areas, as well as genotoxic effects (Comet assay), present also in urban areas. Body condition index was found altered in the agricultural area. Responses of handling stress, such as tonic immobility showed differences between urban and agricultural sites, while breath rate was affected in urban area. The developed protocol was proved to be a useful tool for the ecotoxicological monitoring of great tit. An integrated approach is fundamental to obtain a complete picture of the health status of the studied species. *Dedicated to the memory of Matteo Griggio.*

1.08.V-08 One Health: Are SARS CoV-2 and Some Chemicals Synergistic?

Jorge Herkovits, Instituto de Ciencias Ambientales y Salud, Fundacion PROSAMA, Argentina

Although the relationship between environmental toxicity and infectious diseases is little studied, it is likely to be more common than is recognized. For instance, some conditions that are known to influence COVID-19 progression could have toxicological causes such as cancer, endocrine, neural and inflammatory disruptions, renal failure, etc. Very early in the pandemic it was noticed that COVID-19 patients from countries/regions with the highest air pollution presented more severe clinical symptoms. As a consequence of the quarantine imposed by the high mortality associated with COVID-19, a significant decrease in air pollution was reported resulting in a reduction of SARS-CoV-2 adverse effects. This contribution is highlighting that SARS-CoV-2 and some high production volume chemicals like Ni, Cd, atrazine, 2,4-D and Bisphenol A could exert dysfunctions on HIF-1 and ACE2 with a potential synergistic effect on COVID-19 severity. By means of early life stages toxicity studies (e.g. AMPHITOX),

among the multiple terato and dysfunction effects, some chemicals like Bisphenol A, 2,4-D and atrazine could produce osmoregulatory disruption resulting in hydropsy that could be associated to ACE2 receptor expressed in early embryonic stages. ACE2 was associated to intra-alveolar edema and is the main multiorgan entrance point of SARS-CoV-2. It is noteworthy that hydropsy was reported in COVID-19 fetus. The same chemicals plus Ni and Cd could be related to COVID-19 severity by means of their effect on oxygen consumption. It is well documented that hypoxia triggers the hypoxia inducible factor (HIF) and hypoxia associated with COVID-19 could implies an over-activation of the HIF system influencing the functionality of 200 genes, including those that regulate apoptosis. It is worth mentioning that the risk of toxicity increases with age which implies higher bioaccumulation and biomagnification of toxics, potentially contributing with the most severe clinical symptoms of COVID-19, including high mortality of the aged people. There is an increasing interest to conduct integrated risk assessment combining the processes of risk estimation for humans, biota and natural resources. Early life stage vertebrate embryos as sentinel organisms with morphological and functional end points for toxicity could represent an optimization toward a holistic approach for toxics control to avoid potential synergistic effect of chemicals with infectious agents.

Track 2: Ecotoxicology becomes stress ecology: From populations to ecosystems and landscapes

2.01 Aquatic and terrestrial plant ecology, ecotoxicology and risk assessment (Part I)

2.01.T-01 Cationic and Anionic Silica Nanoparticles Reduce the Toxicity of the Pesticides Pentachlorophenol, Paraquat and Diflufenican to Algae

Frida Book¹, Michael Persson², Eric Carmona Martinez³, Tobias Lammel¹ and Thomas Backhaus⁴, (1)University of Gothenburg, Sweden, (2)Chalmers Industriteknik, Sweden, (3)Helmholtz Center for Environmental Research - UFZ GmbH, Germany, (4)University of Gothenburg Sweden, Sweden

Colloidal silica shows promising properties as efficient adsorbents for pollutants in water and hence reducing the pollutant's bioavailability to aquatic organisms. To explore this, the present study investigated the toxicity of pesticides in mixtures with colloidal silica towards the freshwater green algae *Raphidocelis subcapitata*. Three spherical silica nanomaterials with different surface charge, weakly anionic, strongly anionic and cationic, were tested in binary mixtures with three differently charged pesticides: cationic paraquat, anionic pentachlorophenol and neutral diflufenican. The hypothesis was that the silica nanomaterials would bind oppositely charged pesticides and hence reduce the toxicity to algae. To test this theory, different nanomaterial concentrations (0.4-50 mg/L) were tested in mixtures with a fixed concentration of the pesticide known to reduce algae growth. The results showed that the strongly anionic silica was able to reduce the growth inhibition of paraquat with up to 60%. The cationic nanomaterial reduced growth inhibition with 30-50 %. The cationic material also reduced the toxicity of diflufenican by 10-20 %. Adsorption of pesticides onto the various nanomaterials was further confirmed by chemical analysis with LC-MS. To conclude, colloidal silica were efficient adsorbents of pesticides, which led to a reduced bioavailability and toxicity to algae.

2.01.T-02 Ecotoxicity, Adaptation and Gene Expression of the Green Alga *Raphidocelis subcapitata* Towards the Herbicide Diflufenican

Daniela Gómez Martínez¹, Anders Nilsson², Rikard Tröger³, Henrik Jernstedt⁴, Adrian Clarke⁵, Henrik Nilsson⁶, Erik Kristiansson⁷ and Natàlia Corcoll², (1)Department of Biological and Environmental Sciences, University of Gothenburg, Gothenburg, Sweden, (2)University of Gothenburg, Sweden, Sweden, (3)Swedish University of Agricultural Sciences (SLU), Sweden, (4)Swedish University of Agricultural Sciences, Sweden, (5)University of Gothenburg Sweden, Sweden, (6)University of Gothenburg, Sweden, (7)Chalmers University of Technology, Sweden

Research on algal ecotoxicology towards herbicides has been mainly focused on short-term responses. However, the development of tolerance via physiological and genetic changes that allows algae to adapt in an ecological time scale to toxic substances, remains poorly understood. This study aims to describe the ecotoxicity and adaptation mechanisms of the freshwater green microalga *Raphidocelis subcapitata* to the herbicide diflufenican, a carotenogenesis inhibitor commonly found in European agricultural streams. To do so, an adaptive laboratory experiment was performed for 90 days. *R. subcapitata* was exposed to three different concentrations of diflufenican with environmental and ecotoxicological relevance (i.e. 0, 10.7 and 310.5 ng/L). During the first week of exposure, a decrease in growth rate up to 55.5%, carotenoid and xanthophylls pigments up to 38.7%, and PSII photosynthetic activity up to 17%, indicated that diflufenican had a negative effect on all these three physiological endpoints. This stress phase was followed by a recovery and an adaptation phase, during which the apical endpoints of the exposed alga returned to similar values compared to their controls. Diflufenican-adapted alga developed tolerance to diflufenican exposure (higher EC50s). However, the adapted alga did not show differences in fatty acids composition, indicating that changes in the lipid composition of the cell membrane were not involved in adaptation processes. *R. subcapitata* showed a removal rate capacity of 10% both at the stress and adaptation phases, suggesting that adaptation mechanisms are not linked with an increase in biodegradation capacity. Our findings reflect the high sensitivity of algae to diflufenican and its ability to adapt, as well as the importance of investigating the effects of herbicides after long-term exposures. Finally, a planned transcriptomic analysis will potentially highlight the genes and enzymes that play a role in bioaccumulation, detoxification and overall adaptation processes that allow the cells to survive under different concentrations of diflufenican (evolutionary ecotoxicology), as well as their implications in ecological functions.

2.01.T-03 Effects of Environmental Parameters and Toxicants on *Lemna minor* Growth: An Integrated Experimental and Modelling Approach

Isabelle Van Dyck, Belgian Nuclear Research Centre (SCK CEN), Belgium

Living organisms can be exposed to radionuclides and heavy metals. Large areas, including surface waters, are contaminated with pollutants and in need for remediation. Phytotechnologies use biological processes of living plants to remove, degrade or stabilise pollutants in environmental compartments such as soil, water and air. Phytoremediation is already known as an efficient site remediation technology for various types of pollutants and can be used as a complementary waste water treatment technique for specific scenarios. *Lemna minor*, commonly known as duckweed, has the possibility to absorb and accumulate pollutants in its biomass and can therefore be used for remediation of contaminated water. It is important to understand the behaviour of *L. minor* to remove pollutants from the aquatic environment, assessing its remediation capability and proposing proper remediation strategies. A mathematical model for *L. minor* growth and transfer of pollutants can help to evaluate and select phytoremediation as appropriate remediation strategy for specific scenarios. Building on a previous growth model, a more comprehensive growth model is developed by incorporating the impact of additional environmental conditions using an experimental and modelling approach. To study growth changes of *L. minor*, experiments are performed under different environmental conditions where temperature, light intensity, photoperiod and nutrient compositions are varied from optimal to very low or high conditions. For each experimental condition, growth curves are created and used to optimise these environmental parameters in the growth model. After an overall optimisation and validation of the global growth model, the model will serve as a basis for the remediation model, where new insights on uptake of radionuclides and other pollutants can be incorporated. For several (mixtures of) pollutants, uptake and dose response curves are being made as well as time-dependent uptake and release curves. In addition, experiments that study the effects of pollutants on photosynthesis and pigment, starch and soluble sugar content of *L. minor* are also performed. Together with the research for the development and optimisation of the growth model, these first (non-published) pollutant results will be presented at the conference. Finally, when the outcome of the *Lemna* based system can be model-predicted, it can be applied as an efficient, cost-effective and eco-friendly water depollution technique.

2.01.T-04 Toxicogenomic Analysis of Ecotoxic Modes of Action in *Lemna minor*

Alexandra Loll¹, Hannes Armin Reinwald¹, Steve Uwa Ayobahan¹, Gabriela Salinas², Christoph Schaefers¹, Karsten Schlich³, Gerd Hamscher⁴ and Sebastian Eilebrecht¹, (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (2)NGS - Integrative Genomics Core Unit, Germany, (3)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallingenberg, Germany, (4)Justus-Liebig-University Giessen, Germany

Due to its high reproduction rate, *Lemna minor* is one of the most frequently used aquatic model organisms in ecotoxicology. As a primary producer, it is an important part of the ecosystem and therefore an indicator for water quality. If the development of the plant is influenced by external factors such as xenobiotics, this will not only have a direct effect on the phenotype of the plant, but also indirectly affect other organisms. Therefore, *L. minor* is commonly used for the evaluation of toxic effects on water plants by newly developed substances such as pharmaceuticals or pesticides. In this study, *L. minor* was used for investigations of ecotoxic modes-of-action (MoA) at the molecular level. Therefore transcriptomics and proteomics methods were applied to a shortened version of the OECD guideline test No. 221 conducted with low effect concentrations of two model substances – the pharmaceutical atorvastatin and the herbicide bentazon. Previous studies have shown that, besides photosynthesis inhibition, bentazon additionally has a similar MoA as atorvastatin, whose action is based on the inhibition of the key enzyme of cholesterol and phytosterol synthesis 3-hydroxy-3-methylglutaryl-CoA reductase (HMGR). The goal of our study was to link the determined molecular fingerprint of each substance with both its hazardous effects on the test organism and its MoA in order to identify possible biomarkers. Therefore, we applied bioinformatics approaches to functionally annotate the previously unannotated reference genome of *L. minor*. Our functional annotation pipeline is in principle applicable to any organism with an available reference genome and thus greatly facilitates the identification of gene functions for poorly annotated organisms. For both test substances, significant changes in gene expression were observed in the context of a shortened ecotoxicity test with low effect concentrations. These molecular changes preceded the physiological effects and may, therefore, be consulted for early predictions.

2.01.T-05 Selecting and Testing Ecologically Relevant Macrophytes and Endpoints in Mesocosm Studies

Marie Brown¹, Nadine Taylor¹, Hanna Samantha Schuster¹, Zoe Leanne Jones² and Katie Smith¹, (1)Cambridge Environmental Assessments, United Kingdom, (2)Cambridge Environmental Assessments, UK

Aquatic macrophytes play an ecologically important role in the ecosystem by providing shelter, food and performing essential biological and ecological functions. Aquatic freshwater mesocosms are designed to represent edge of field water bodies by creating a habitat that will support communities of aquatic macrophytes, algae, zooplankton and macroinvertebrates in a contained system. Therefore the macrophytes included in these systems should reflect the communities found in the natural environment. The EFSA guidance document on tiered risk assessment for plant protection products (PPP) for aquatic organisms in edge-of-field surface waters, makes recommendations for a minimum of 8 sensitive/vulnerable taxa with acceptable minimum detectable difference (MDD) values to be tested. However there is little guidance on selecting representative macrophytes that will survive in these systems, or on the selection of appropriate endpoints that will provide regulatory acceptable data. In addition, the limited number of standard macrophyte laboratory tests makes it challenging to determine which species may be sensitive to any given stressor. The aim of this presentation is to share our expertise on the selection of macrophyte species and techniques for assessing plant growth and health in mesocosm studies. We hope that by sharing our considerations for macrophyte selection and endpoint evaluation in mesocosm studies we can open up the discussion on the relevance of mesocosm studies, particularly within the future of risk assessment for macrophyte communities. We will also demonstrate the CEA sloped mesocosm design as a reference study in order to derive more reliable and robust population and community level endpoints using macrophytes as an example. These results can be used to inform the experimental design of future macrophyte mesocosm studies such that the results meet the EFSA requirements for sensitive/vulnerable taxa with acceptable MDD values for regulatory use.

2.01 Aquatic and terrestrial plant ecology, ecotoxicology and risk assessment (Part II)

2.01.T-06 Combined Impact of Agricultural Run-Off and Warming on Primary Producers and Consumers in Agricultural Streams

*Elisabeth Maria Gross*¹, *Joey Allen*², *Didier Ortiz*², *Vinita Vijayaraj*³, *Vincent Felten*³, *Martin Laviale*⁴, *Nora Kipferler*⁵, *Bastian Polts*⁶, *Grégorio López Moreira Mazacotte*⁷, *Franz Hölker*⁸, *Joséphine Leflaive*⁹, *Mechthild Schmitt-Jansen*¹⁰, *Sabine Hilt*⁸ and *Herwig Stibor*⁵, (1)CNRS UMR 7360 / Université de Lorraine, France, (2)CNRS - LIEC UMR7360, France, (3)Université de Lorraine, France, (4)University of Lorraine, France, (5)Ludwig-Maximilians-University Munich, Germany, (6)UFZ - Helmholtz Centre for Environmental Research, Germany, (7)Institute of Freshwater Ecology and Inland Fisheries (IGB), Germany, (8)Leibniz Institute of Freshwater Ecology and Inland Fisheries, Germany, (9)University of Toulouse, France, (10)UFZ - Helmholtz Ctre Environm. Research, Germany

Ditches or small streams in agricultural landscapes are among the first to be affected by agricultural run-off (ARO) composed of nutrients and pesticides. In artificial streams, we investigated the effects of warming and ARO on the temporal dynamics of different types of primary producers (macrophytes, periphyton, phytoplankton, filamentous blanketing algae) and primary consumers. Our hypotheses were that warming would favour early macrophyte development and that ARO would favour filamentous algae over macrophytes in these systems. The experiment was based on a 2 x 2 factorial-design (warming, ARO) with each 4 replicates. Channels had an upstream compartment containing *Glyceria maxima* and *Dreissena polymorpha*. The downstream channels were planted with root or rhizome sections of three submerged macrophytes, received an inoculum of periphyton, alder leaf litter, *Gammarus roeseli* and *Lymnaea stagnalis*. The effect of ARO on primary producers was very distinct. ARO significantly enhanced the development of blanketing filamentous algae and periphyton, while warming had only minor effects. The high dose of nitrate applied with ARO vanished very fast, probably absorbed by filamentous algae and periphyton. When filamentous algae collapsed towards the end of the experiment, phytoplankton increased, probably triggered by a massive liberation of phosphorus. Macrophytes developed very late in the cold spring in 2021. *Potamogeton perfoliatus* dominated, profiting most from warming. ARO negatively affected its development at a later stage in the experiment, suggesting indirect effects caused by competition with blanketing filamentous algae. All other macrophytes showed no clear response to warming or ARO. ARO had a strong effect on the reproduction of gammarids and snails, likely caused by pesticides and leading to a reduced periphyton control. ARO and warming strongly enhanced mortality of mussels. Leaf litter degradation was enhanced by warming, but not affected by ARO. Submerged macrophytes usually appear only after the water temperature reaches a certain temperature, and often have to compete against a massive development of blanketing algae. Our study aims to determine whether ARO affected this dynamic. Combined nitrate and pesticide effects led to a range of direct and indirect effects on primary producers and consumers, with the most visible being the strong development of filamentous green algae, but also effects on periphyton, gammarids and snails.

2.01.T-07 Uptake, Translocation, and Metabolism of Different Contaminants of Emerging Concern in Radish Crops Grown Under Controlled Conditions

*Nicola Montemurro*¹, *Francesc Labad Roig*² and *Sandra Perez*³, (1)Environmental Chemistry, Jordi Girona 18-26, null, Barcelona, Spain, (2)CSIC - Spanish National Research Council, Spain, (3)CSIC, Spain

The constant search for good quality water for agriculture has meant that water resources are under pressure in many regions, representing the main limiting factor for social welfare and economic development of many countries. Treated wastewater represents a valid alternative to the consumption of good quality water for the irrigation of agricultural crops. However, this practice could contribute to the spread of some organic contaminants in the soil and in the environment. In fact, the presence of contaminants of emerging concern (CECs) is notoriously reported in effluents of wastewater treatment plants (WWTPs), since conventional treatments are not specifically designed for their removal. Their impact is of particular relevance for the disposal and re-use of wastewater in agriculture due to the use and accumulation of CECs in food crops and the consequent spread in the food chain and ecosystems. Radish (*Raphanus sativus*) is often used as a model plant to investigate the fate of organic contaminants in plants given its short growing cycle and its potential ability to accumulate contaminants in the roots. In fact, the contaminants could enter the plants from the soil through the absorption of the roots, and constitute a potential risk to food safety. In addition, to accumulate in the root, these compounds can give rise to phenomena of translocation in the leaf parts or potential metabolism with the formation of a variety of transformation products. However, only a few studies were designed to evaluate the uptake and the potential metabolism of pharmaceuticals in radish and only for a limited range of compounds [1, 2]. This study was therefore planned to evaluate the influence of a wide range of pharmaceutical compounds into radish crops irrigated with artificially contaminated water at 10 and 100 µg L⁻¹. In addition to uptake and translocation, the metabolic transformation of pharmaceuticals was also evaluated. Pharmaceuticals in radish roots and leaf material were extracted by one-step modified QuEChERS method [3], using whereas the detection was performed using the new SCIEX X500R QTOF-MS, a compact hybrid quadrupole time-of-flight mass spectrometer combining advantages of TOF and QqQ systems with accurate mass. In this study, we investigated the use of MRMHR and MS/MS^{All} with SWATH acquisition for the targeted analysis (using reference standards) and non-target screening on a routine basis.

2.01.T-08 Comparative Transcriptomic Analysis of Brassica Napus L. Grown on Soils Contaminated by Metallurgical Industry Reveals New Insights Into PLANTS' Response to Metal Stress

*Marta Jaskulak*¹, *Katarzyna Zorena*² and *Franck Vandembulcke*³, (1)Medical University of Gdansk, Poland, (2)Medical University of Gdansk, Poland, (3)University of Lille, France

Problem with heavy metal-contaminated soils is increasing significantly throughout the world due to industrialization, mining

operations, improper waste, and water treatment. Although the response of plants to single metal contamination in lab condition are extensively researched, the aspect of mixed toxicity, which usually occurs in the natural world, is often overlooked. Our knowledge and understanding of the specific response to synergistic stressors on plants are strictly limited. The main aim of the experiment was to assess the transcriptomic changes in leaves of *Brassica napus* after exposure to soil contaminated with a vast range of heavy metals due to the past metallurgical activity in the area. Specifically, the contaminated soil contained over 20 mg/kg of cadmium (Cd), over 1100 mg/kg of lead (Pb), and over 700 mg/kg of Zinc (Zn). Thus, the purpose was to identify how such actual industrial contamination influences plants on the transcriptome level to broaden our understanding of the actual environmental impact. The experiment was performed in actual field conditions on 6 plots and lasted for the entire vegetative season. All the cDNA libraries of *B. napus* were sequenced using an Illumina HiSeq™ 4000 platform. The sequencing generated 21 688 894 to 29 810 359 raw paired reads for each sample. The soil supplementation with sewage sludge caused 10 025 genes to be differentially expressed with the False Detection Threshold at a level of 0.001. The gene ontology analysis showed that most differentially expressed genes were related, among others, to plants' response to stress, cell death, xenobiotics, hormone production, and transport. The project consisted of a first study dealing with the influence of long-term exposure to mixed metal toxicity application on plant metabolism on a transcriptomic level. *Acknowledgement* - Research was funded by National Science Centre, Poland, 2018/31/N/NZ9/01742

2.01.T-09 Drifting Towards HIGHER Tiers: Developing a Regulatory Greenhouse Test Method for Non-Target Terrestrial PLANTS Mimicking Realistic Drift Exposure to Refine the Risk Assessment of Herbicides

*Rena Jutta Irene Isemer*¹, *Clare Butler Ellis*², *Clive Tuck*², *Andrew Lane*², *Stefanie Nöding*³, *Arne Hantel*³, *Daniela Jans*³ and *Andrew C. Chapple*⁴, (1)Crop Science, Bayer Crop Science, Germany, (2)Silsoe Spray Applications Unit Ltd, United Kingdom, (3)Bayer Crop Science, Germany, (4) Bayer A.G, Crop Science Division, EMEA, Germany

The risk assessment for non-target terrestrial plants (NTTPs) in Europe rests on two pillars: endpoints derived of standard guideline tests and exposure estimations derived from Rautmann drift value tables. Both pillars have been challenged in recent years. Endpoints are criticized as being not realistic enough while drift values will be replaced by more conservative drift values (SETAC DRAW). Accordingly, a more realistic higher tier approach leading to a simultaneous refinement of effects and exposure would be desirable. One possibility could be a recently developed field study design assessing effects of a herbicide on plants after exposure via drift [Moore et al. 2021. Integr Environ Assess Manag]. As the approach is time-, labour- and cost-intensive, a laboratory Plant Intermediate Tier Test (PITT) design is proposed. This study design will follow the guideline protocol for NTTP greenhouse tests but exposure will mimic drift such as the plants would experience in the field. Here, we present the spray cabin set-up as well as results of modelling and measurements used for calibration of the spray cabinet. Spray cabinets will be adapted as follows: (a) volume lowered, (b) use spinning disc nozzle in order to generate a droplet spectrum similar to that of a drift plume, and (c) place plants on a conveyer belt moving them through the spray cloud so that the relative movement of the plant and spray cloud are similar to that of a stationary plant in the field and a drifting spray plume. The SiMoD boom sprayer model was used to predict the quantity and droplet spectrum of drift reaching NTTPs in order to determine how the spray cabinet needs to be calibrated when performing a PITT trial. The quantity of spray deposited is expected to correlate with the quantity of airborne spray. The main factors influencing the droplet size are the wind speed and distance downwind. Interestingly, nozzle design has a very small effect on downwind droplet size distributions. The proposed Plant Intermediate Tier Test (PITT) method could serve as a refinement option for the NTTP risk assessment, refining exposure and effects at the same time while still being labor-, cost- and time-efficient.

2.01 Aquatic and terrestrial plant ecology, ecotoxicology and risk assessment (Virtual Only)

2.01.V-01 Algal Preservation and Enumeration Techniques for Use in Micro and Mesocosm Studies

Zoe Leanne Jones, *Hanna Samantha Schuster*, *Katie Smith*, *Marie Brown* and *Nadine Taylor*, Cambridge Environmental Assessments, United Kingdom

Standard, lower tier, testing strategies for the effects of Plant Protection Products (PPP's) on algae are focused on single species studies and may not provide adequate protection for these important communities. Higher tier approaches, such as micro/mesocosm studies are designed to represent edge of field water bodies by creating a habitat that will support communities of aquatic macrophytes, algae, zooplankton and macroinvertebrates in a contained system. Therefore, these experimental systems offer a more comprehensive analysis of the effects of PPPs on these communities. Whilst definitively more representative of natural systems, this increase in complexity brings further challenges. Freshwater algal communities are very diverse, the taxonomic identification of these species is difficult, and requires trained taxonomists. When designing these studies, consideration needs to be given to the methods employed for sampling, preservation and enumeration to ensure all steps are fit for purpose. The sampling processes need to offer a true representation of the algal assemblages present. One of the major difficulties in sampling freshwater algae is preservation. The need for preservation at all should be considered as they will damage algal morphology over time, however this step is often a necessity in larger, long-term studies. Following sample collection, enumeration is necessary to collect the data needed to derive ecotoxicological endpoints, e.g. MDD's, EC_x and NOEC's. As with the sampling procedures, this process needs to use sub-samples that accurately reflect the whole test system. Here we present and assess different methods that can be used for the sampling preservation and enumeration of freshwater phytoplankton and periphyton. We discuss the pro's and cons of these approaches and present methods for the analysis of microcosm and mesocosm algal samples that have provided the most reliable and robust statistical data from studies conducted at CEA.

2.01.V-02 Assessing the Acute Toxicity of Individual Polycyclic Aromatic Compounds to Furoid Macroalgae (*Fucus vesiculosus*) Using a Germination Assay

Danielle Philibert¹, Rob Holland², Dave Goodwin¹ and Benjamin de Jourdan¹, (1)Huntsman Marine Science Centre, Canada, (2)Oil Spill Response Limited, United Kingdom

Of the 1000s of components within crude oil, polycyclic aromatic compounds (PACs) are thought to be the component of crude oil primarily responsible for toxicity. Due to the complexity of a crude oil spill, stakeholders must rely on mathematical models to predict and assess the impacts of a spill on aquatic life. Oil spill models rely on quantitative structure-activity relationships (QSARs) like the target lipid model (TLM) to estimate the toxicity of different components found within crude oil, as well as species sensitivity distributions (SSDs) to determine species at risk if exposed. Macroalgae play a critical role in both freshwater and marine ecosystems and function as both primary producers and as a habitat for other aquatic life, however very little research has been done to determine the sensitivity of macroalgae to PAC exposure. The aim of the study was to generate toxicity data to determine the sensitivity of *Fucus vesiculosus*, a common intertidal brown seaweed, to PACs, and to assess the impacts of different environmental conditions on observed toxicity. Test solutions were generated using passive dosing with polydimethylsiloxane (PDMS) O-rings left to equilibrate in glass petri-dishes for 24-48 hours. To generate zygotes for the germination assay, the receptacles of sexually mature plants were dissected, sexed, and stored in the dark at 4°C until use. Using previously published spawning protocols, zygotes were generated and allocated to glass slides submerged within the glass petri-dishes. Germination success was assessed at 3 and 5 dpf. Of the compounds tested and assessed at 3 dpf, dibenzothiophene had the most significant impact on germination rate ($EC_{50} = 1.59 \mu\text{mol/L}$), followed by naphthalene, and methylnaphthalene ($EC_{50} = 5.46 \mu\text{mol/L}$, $EC_{50} = 8.07 \mu\text{mol/L}$ respectively). There was a linear relationship between the log (LC_{50}) and log (K_{ow}) of the PACs as described in the TLM, and the critical target lipid body burden (CTLBB) was determined to be $29.1 \pm 12.4 \mu\text{mol/g}_{\text{octanol}}$. The results from this study suggests the zygotes of *F. vesiculosus* are one of the more sensitive species and life stages included in the TLM model and would serve as a good model species to be included in crude oil toxicity tests. The data generated in this study can be used to better understand the sensitivity of macroalgae to PAC exposure, and to assess the impact of shoreline oiling on the germination success of *Fucus* algae.

2.01.V-03 Effects of Tire Fragments Toxicity on the *Vigna radiata*

Lia Kim, Tae-yang Lee, Haemi Kim and Prof. Youn-Joo An, Konkuk University, Korea, South

Tire wear particles, generated from the roads, is one of the main sources of microplastics in the terrestrial environment. This study evaluated the effects of tire particles on mung bean (*Vigna radiata*). Three different types of tire particles (bicycle (B), car (C), and electric scooter (ES)) were exposed to mung bean for 4 weeks and the growth inhibition were measured. Additionally, the tire fragments were leachate for 4 weeks to analyzing the toxicant leaching from the tire fragments. There was some shoot growth inhibition on the exposure group of ES tire fragments. The adverse effects of tire fragments were expected to be induced by the chemical leaching from the tire particles, that the ICP-MS and non-target GC-MS were conducted on three types of leachates to figure out the major toxicants. According to the chemical analysis the tire leachates contained the high concentrations of zinc and benzothiazole in all three leachates, which were used as the additives of plastic-products. Especially in ES leachate, the chrome and lead were detected and showed the dominant correlation with the plant toxicity. Also, there was some size difference between the tire fragments and the ES tire fragments have the small size compared to the others. This finding of this study suggests that tire fragments from the land release the toxic components and the size of tire particles could also induce the plant toxicity.

Acknowledgement - This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT and future planning (2020RIA2B5B02001734).

2.01.V-04 Transfer and Bioaccumulation of Lead and Zinc in Different Tissues of Blackberry

Louisa Steingrüber¹, Catharina Ludolph¹, Johannes Metz², Horst Kierdorf² and Uwe Kierdorf², (1)University of Hildesheim, Hildesheim, Germany, (2)University of Hildesheim, Germany

Plants can accumulate heavy metals from soils, air, and water, which makes them suitable biomonitors. Plant biomonitoring is therefore a useful tool for geochemical risk assessment. Certain plants can also be used for phytoremediation of polluted soils. This study was conducted along a river system (Innerste River) to determine soil-to-plant bioconcentration factors (BCF) and translocation factors (TF) for lead and zinc in naturally occurring blackberries (*Rubus fruticosus* L. agg.). Additionally, we investigated whether heavy metal concentrations in floodplain soils and leaves of blackberries growing in the floodplain and in adjacent regions outside the floodplain decrease with distance from the source region of contamination. The root system of blackberries enters deeply into the soil (some > 1 m), which makes the species suitable as a biomonitor of soil contamination. Consumption of plant parts with an elevated metal content may pose a health risk for humans and animals. As a result of historical mining, processing and smelting processes of metalliferous ores in the Harz Mountains and the associated runoff from tailings and slag heaps, large amounts of heavy metals (Cd, Pb, Zn and Cu) were and still are fluviually transported into the Innerste floodplain. Hence, river sediments and floodplain soils in the immediate vicinity of the point sources as well as floodplains further downstream are heavily contaminated with heavy metals. The soil heavy metal concentration, in the regularly flooded areas (mean of 1457.22 mg Pb/kg and 1365.15 mg Zn/kg), far exceeds the precautionary values of the Federal Soil Protection and Contaminated Sites Ordinance applicable for Germany. It was determined that the concentrations of Pb as well as Zn in the roots and leaves were proportional to the soil heavy metal content. Both studied soil and plant heavy metals differed significantly between the floodplain and its adjacent non-flooded area, while pH and soil organic matter showed no significant difference. With the exception of BCF(Root) Pb, BCFs and TFs were found to decrease exponentially with soil and root heavy metal concentrations. BCF was < 1.0 for both heavy metals and TF was < 1.0 for Pb, but > 1.0 for Zn. Our results indicate that leaves

and roots of blackberry can be used as indicators of soil contamination by Pb and Zn, but that the species is inappropriate for phytoremediation.

2.01.V-05 UV Radiation Modulates the Combined Effects of Depleted Uranium and Gamma Radiation on Aquatic Macrophyte *Lemna minor*

Li Xie¹, Hans-Christian Teien², You Song³, Knut Asbjørn Solhaug⁴ and Knut Erik Tollefsen⁵, (1)NIVA - Norwegian Institute for Water Research, Norway, (2)Norwegian University of Life Sciences NMBU, Norway, (3)Norwegian Institute for Water Research (NIVA), Oslo, Norway, (4)Norwegian University of Life Sciences (NMBU), Norway, (5)Norwegian Institute for Water Research (NIVA), Norway

Elevated concentration of background ionising radiation and radionuclides in the aquatic environment have been observed especially in radioactively contaminated areas such as Chernobyl (Ukraine), Mayak (Russia), Fukushima (Japan) and NORM sites such as mining in Kazakhstan and Canada, and pose a threat to aquatic ecosystems. In addition to ionising radiation and chemical stress from the radionuclides, UV radiation, a common ubiquitous environmental stressor is expected to act as a co-stressor on aquatic organisms inhabiting the upper water layers. All these stressors may interact with each other and cause combined effects that are challenging to predict. The aim of this study was to characterize the combined effects of depleted uranium (DU), ionizing radiation (γ -radiation) and UV radiation on the aquatic macrophyte *Lemna minor*. In the presented study, the aquatic macrophyte *Lemna minor* was used as the model species to assess and exposed to different level of γ -radiation (10-40 mGy h⁻¹), DU (DU ((UO₂(NO₃)₃, 0.2-20 mg L⁻¹) and a fixed UVB radiation (0.5 W m⁻²), either alone or in combination for 7 days. After exposure, the reproduction of *L. minor* was measured to characterize the adverse effects of these stressors at individual level, while the responses of oxidative stress (ROS formation), photosynthetic performance (PSII efficiency) and mitochondrial dysfunction (mitochondrial membrane potential, MMP) were investigated at subcellular and cellular levels. The combined effects were evaluated using a three-way analysis of variance (3W-ANOVA) and a modified Independent Action (IA) model. The results indicated in binary exposure, combination of UVB and γ -radiation induced synergetic inhibition on reproduction, while antagonistic and additive effects were observed in most endpoints at subcellular and cellular level, such as ROS formation, PSII performance and MMP. The combined exposure of DU and high dose rates of γ -radiation (40 mGy h⁻¹) caused significant interactions consistent with synergism on the reproduction of *L. minor*. In ternary exposure, UVB radiation significantly interact the combined effects of DU and γ -radiation on reproduction at high dose rates of γ -radiation (?20mGy h⁻¹). This study demonstrated that γ -radiation, DU and UVB radiation cause combined effects that were both target-specific and concentration (dose rate)-dependent. No interaction and additivity was identified to be the most common effect, whereas synergistic interactions were mainly observed at high levels of γ -radiation and DU. It is anticipated that these results will contribute to inform cumulative hazard and risk assessment for multiple stressors such as ionising radiation and chemical stressors. Additional endpoints and statistical models will be implemented to provide the mechanistic understanding and analytical strategies to identify the most relevant toxicity pathways for the single and multiple stressors tested.

2.01 Aquatic and terrestrial plant ecology, ecotoxicology and risk assessment (Poster)

2.01.P-Tu029 Cigarette Butts Leachates Produce Toxic Effects at the Biochemical and Population Levels in the GREEN Microalgae *Pseudokirchneriella subcapitata*

Frida Aketzali Cano¹, Miriam Hernández Zamora² and Felipe Fernando Martínez-Jerónimo³, (1)Instituto Politecnico Nacional, Mexico, (2)Instituto Politécnico Nacional-Escuela Nacional de Ciencias Biológicas, Mexico, (3)Escuela Nacional de Ciencias Biológicas, IPN, Mexico

Cigarette butts are polluting residues resulting from tobacco smoking, which are present everywhere. It has been estimated that 4.95 billion cigar butts are discarded annually throughout the world. In urban areas, butts are often discarded on the street or anywhere, without any restrictions, so they can accumulate on the ground and can be leached and reach aquatic environments through drainage and sewage system. Microalgae have been used as bioindicators because of their sensitivity to pollutants and their importance as primary producers in aquatic communities. In this study, the toxic effects of leachates from cigarette butts in the green microalgae *Pseudokirchneriella subcapitata* were assessed. Population growth, the concentration of photosynthetic pigments, and the content of proteins, lipids, and carbohydrates were quantified in chronic exposures. The cigarette butts were collected in hermetic containers from voluntary smokers and were selected to study only those of one brand (the most popular); the remains in the butts were manually eliminated. To prepare the extract, 120 butts were placed in 1 L of deionized water and stirred for two hours at room temperature; the leachate was vacuum filtered using autoclaved 0.22 μ m mesh size membranes, under axenic conditions. To determine the 96-h Mean Inhibitory Concentration (IC₅₀), *P. subcapitata* was exposed to the leachate containing the equivalent to 0.012, 0.12, 1.2, 12, and 120 butts L⁻¹, at 25 ° C and continuous illumination. The determined IC₅₀ was 76.9 mg of cigarette butt L⁻¹, equivalent to 0.4 butts L⁻¹. Although toxic inhibitory effects were observed in the population growth of *P. subcapitata*, no significant effects were detected in the content of photosynthetic pigments or the protein concentration. However, a significant decrease in carbohydrate and lipid content was documented. The undiluted leachate caused complete inhibition of growth of *P. subcapitata* since the first exposure hours. Leachate from butts was very toxic to this microalgae, so it is essential to study the effect of this ubiquitous waste due to the environmental consequences in aquatic biota. It is also necessary to regulate the disposal of these wastes to the environment to avoid or reduce biological impacts.

2.01.P-Tu030 A Microwell Plate Based Bioassay for Toxicity Testing Using the Benthic Desmid Species *Closterium ehrenbergii*

Andreas Weber-Theen, University of Applied Sciences RheinMain, Rüsselsheim, Germany

Closterium ehrenbergii is a large unicellular benthic green alga belonging to the class Zygnematophyceae, which represents the closest relatives of land plants. It lives not free floating but attached to filamentous algae and macrophytes in freshwater. With its extraordinary cell dimensions of up to 800 x 100 µm *C. ehrenbergii* is visible with the eye and ideally suited to be observed under little magnification using a simple stereomicroscope. This property enables the use of *C. ehrenbergii* in a miniaturized bioassay for ecotoxicity testing using microwell plates and the absolute cell number as end point without being dependant on surrogate parameters such as absorbance or chlorophyll fluorescence. Cells are transferred in small groups of 10 ± 2 individuals by micropipette to each well of a 24 microwell plate. Subsequently 1 ml of culture medium including the dissolved test substance or pure medium for controls respectively is introduced to the wells. A number of 6 replicates per concentration step ensures high statistical power with variation coefficients of 8 – 12 % on average. The number of cells in every well is counted manually using 10x magnification every 24 hours. No counting chamber is needed since the total amount of cells per sample is recorded. Growth rate is determined from the logarithmic growth function $\mu = \ln(x_t/x_0)/t$. In accordance with OECD 201, test duration is 3 days, whereby illumination may not be continuous since cell division takes place during the dark period. Hence, a light-dark regime of 14:10 h is favourable. Also, light intensity should not exceed $20 \mu\text{mol m}^{-2} \text{s}^{-1}$ to avoid cell damage. C-medium is most suitable for cultivation. Figure 1 shows the results of an ecotoxicity test with *C. ehrenbergii* and 3,5-dichlorophenol as a reference toxin for validation of the new test system: Fig. 1. Dose response curve showing inhibition of growth rate against concentration of 3,5-DCP. The approach of miniaturization for ecotoxicity tests has several advantages: 1. *Closterium ehrenbergii* represents a benthic charophycean alga which has not been standardized in this way yet and is an addition to the chlorophycean planktonic species listed in OECD 201. . 2. The number of living organisms which are sacrificed by a test is dramatically reduced.. 3. The amount of all kinds of chemicals such as toxicants as well as nutrients is reduced to a minimum. . 4. Due to a higher number of replicates without increasing the experimental effort in comparison to traditional test designs using flasks or test tubes, the statistical power is increased. Collaboration between Hochschule RheinMain, university of applied sciences and Georg-August-university Göttingen. 2.01.P-Tu031 Exploring Modes of Action and Concentration-Response Patterns in the High Throughput 96-Well Algae Growth Assay

Daniel Ottosen¹, Mafalda Castro¹, Nina Cedergreen² and Josefine Jensen³, (1)University of Copenhagen, Denmark, (2)Plant and Environmental Sciences, University of Copenhagen, Frederiksberg, Denmark, (3)University of Copenhagen, Frederiksberg, Denmark

The 96 well-plate algal toxicity assay with the green algae *Raphidocelis subcapitata* has been increasingly used for assessing toxicity of samples with complex mixtures of chemicals. This is traditionally done by measuring algae cell density over 48 hours by measuring absorbance at 684 nm, or fluorescence at 440 nm (excitation) and 680 nm (emission). However, we have observed that some water samples with complex chemical mixtures often lead to largely different absorbance and fluorescence response patterns and biphasic concentration-response curves. This raises questions regarding the choice of method and measure, but also leads to questions on which chemicals could be driving the different response mechanisms. To address this issue, in this study, toxicity tests were conducted on individual chemicals, known to be active in this assay. The chemicals are commonly found in water samples and have different modes of action including antibiotics, herbicides, fungicides, antidepressants, metals, among others. In total, 30 compounds were tested, and the best-fitted regression models (Brain and Cousens, Weibull, Log-logistic) were used to estimate effect concentrations and analyse response patterns. Biphasic concentration responses were only present for a few chemicals, and only in the fluorescence assays, leaving the findings of hormesis in absorbance assays on chemical mixtures unexplained. We observed that absolute fluorescence was a more sensitive endpoint for biomass than absolute absorbance for most chemicals. However, this is with few exceptions within the groups of herbicides and antibiotics. This means that the EC50's for fluorescence were mostly lower than for absorbance, varying up to 20%. Furthermore, the relative fluorescence (fluorescence/absorbance) decreases with increasing concentrations after 48 hours for most of the compounds, confirming that fluorescence in general is a more sensitive endpoint compared to absorbance.

2.01.P-Tu032 Reviewing Validity Criteria for *Skeletonema* Sp. Growth Inhibition Studies

Michelle Booth¹, Becky Burden², Dean Leverett³ and Audrey Pearson⁴, (1)Scymaris Ltd, United Kingdom, (2)Ecotoxicology, Scymaris Ltd., United Kingdom, (3)WCA-Environment Ltd, Faringdon, United Kingdom, (4)Environment Agency, United Kingdom

The unicellular marine diatom *Skeletonema* sp. is routinely used to assess growth inhibition often following the ISO 10253 test method. Such data has been compared against the OECD Test Guideline (TG) 201 control validity criteria, which has resulted in inconsistent interpretation regarding whether the data are reliable or not – sometimes in a regulatory context. OECD TG201 is specific to freshwater alga and cyanobacteria - *Skeletonema* sp. is not included as a recommended species. One validity criterion in OECD TG201 (mean coefficient of variation for section-by-section specific growth rates) which is not included in the ISO 10253 standard, is not always achievable for *Skeletonema* sp. The project includes two steps: Task 1: Review of *Skeletonema* sp. control data and culturing techniques to understand the variability in section-by-section specific growth rates and test conditions; and Task 2: Control trials and reference toxicant tests to investigate optimum test design and relevant validity criteria. This project is funded by the Environment Agency, England and undertaken by WCA and Scymaris. Based on the data gathered and generated to date during this project, the mean coefficient of variation for section-by-section specific growth rates in control cultures is found to often exceed the threshold of 35% from OECD TG201, although it clearly can be achieved under certain conditions. This data will help us understand and advise on the best culturing and test conditions for this species, as well as proposing relevant validity criteria for this test. We hope that such an assessment will lead to increased consistency in approaches across different

laboratories and will assist the regulatory review of data submissions. In turn, we hope this will aid evaluation of reliable algal data meaning reducing repeat testing. In addition, the data may be relevant to future test method or guidance document updates which include *Skeletonema* sp. The project completion date is February 2022 and a full review will be available for the SETAC conference in May 2022.

2.01.P-Tu033 Antibiotics in Aquatic Environment: Lemna minor Response to Tetracycline and Recovery After Exposure
*Jurate Zaltauskaite*¹, *Magdalena Krupka*², *Dariusz Michalczyk*², *Gintare Sujetoviene*³, *Katarzyna G?owacka*², *Hanna Grajek*², *Marta Wierzbicka*² and *Agnieszka Piotrowicz-Cie?lak*², (1)Vytautas Magnus University, Lithuania, (2)University of Warmia and Mazury in Olsztyn, Poland, (3)Vytautas Magnus University, Kaunas, Lithuania

The potential environmental risks of antibiotics are of increasing concern. Antibiotics are recognized as an emerging class of environmental contaminants because of their persistence in the environment and wide use for human and animal applications. The intensive use of antibiotics and incomplete removal from wastewater in wastewater treatment plants leads to their continuous release into aquatic environment. *Lemna minor* were exposed to tetracycline (TC, 1-10 mM) and their physiological status was analysed using the following criteria: rate of plant growth, free radical accumulation, antioxidant enzyme activity, chlorophyll content, HSP70 protein content, cell membrane permeability and mitochondrial activity. The potential of *L. minor* to recover following a 7-day exposure to TC was investigated. Mitochondrial activity was the most sensitive of the studied physiological and biochemical endpoints. The study showed that duckweed can considerably recover from the antibiotic-caused damage, within a week after cessation of the stress. After transferring the plants to a tetracycline-free medium, all plant parameters improved significantly except for mitochondrial activity in plants grown on a medium containing the highest dose of tetracycline.

2.01.P-Tu034 Ecotoxicological Assessment of Rare Earth Elements on the Submerged Macrophyte Myriophyllum spicatum

*Nicolas Lachaux*¹, *Sarah Berns*², *Laura Junique*², *Sébastien Cambier*³, *Simon Devin*⁴, *Laure Giamberini*⁵ and *Elisabeth Maria Gross*⁶, (1)LIEC, France, (2)Universite de Lorraine, France, (3)Luxembourg Institute of Science and Technology (LIST), Luxembourg, (4)LIEC - Université de Lorraine - CNRS, France, (5)Université de Lorraine, CNRS UMR 7360, France, (6)CNRS UMR 7360 / Université de Lorraine, France

In the last decades, the increasing use of Rare Earth Elements (REE) in cutting-edge (smartphone, computer...) and green technologies (wind turbine, solar panel...) led to the release of anthropogenic REE into the environment, and especially in aquatic systems. However, still little is known about the potential effects of these emerging contaminants in the aquatic ecosystems, and more particularly on aquatic plants other than algae. Therefore, we investigated for the first time REE effects towards the submerged macrophyte *Myriophyllum spicatum*. The biological effects of neodymium (Nd), gadolinium (Gd) and ytterbium (Yb) were assessed individually and in ternary mixture in a normalised test system (OECD TG 238) and in mesocosms by measuring plant growth, photosynthetic activity, pigment content and elementary stoichiometry. In both test systems, REE induced hormetic effects on *M. spicatum*, by stimulating growth at lower concentrations and inhibiting at higher concentrations. By modifying test medium composition in the OECD TG, we could show that the type of phosphorous used (inorganic or organic) drastically influenced REE toxicity, suggesting a link with REE speciation and bioavailability. Risk assessment should take into account the type of phosphorous used when assessing REE or other metal toxicity towards plants. In mesocosms, an environmental concentration of REE mixture induced harmful effects by significantly inhibiting *M. spicatum* growth after 4 weeks of exposure. Further biochemical analyses for a better understanding of REE toxicity mechanisms towards *M. spicatum* are ongoing.

2.01.P-Tu035 Long-Term Consequences of Exposure to Nuclear Accident Relevant Radionuclides in Lemna minor From (Epi)Genetic to Community Level Effects

Luca Boldrini, *Belgian Nuclear Research Centre (SCK CEN)*, Belgium

It is the purpose of this PhD, which is part of the Marie Curie ITN CHRONIC project [1], to study the long-term effects (over multiple generations) at different levels of biological complexity (from molecular to population and community level) in a duckweed species (*Lemna minor*) exposed to environmental relevant concentrations of different genotoxic radionuclides linked to possible nuclear accidental scenarios (¹³⁷Cs, ⁹⁰Sr). The organism *Lemna minor* was chosen for this project as it is a fast vegetative-growing macrophyte, the only freshwater plant for regulatory toxicity testing for chemicals, and a model organisms within ecotoxicology. Moreover, environmental risk assessment approaches used today mainly focus on short-term acute exposures to environmentally relevant radionuclides, however, in field setting organisms are typically (i) in a multiple stressor context, (ii) in communities in which they interact and compete with other species (iii) and are chronically exposed within or even over generations. Therefore, as these approaches do not appropriately cope with complicated exposures at varying degrees of biological complexity, this project aims at contributing to promote a change in the ERA methodologies and practices required to address existing and future contamination concerns. Thus, by employing molecular biology (gene expression analysis) and epigenetic (chromatin compaction and DNA methylation analysis) techniques, and non-conventional endpoint testing, this project aims at expanding current scientific knowledge on *Lemna*'s stress biology and providing new insights and mechanistic understanding of *Lemna minor*'s molecular physiology with particular regards to epigenetic responses towards ionizing radiation. To this end, *Lemna minor* plants were chronically exposed to ⁹⁰Sr for a period of six weeks and samples were taken on a weekly basis to measure parameters such as growth, ⁹⁰Sr uptake and molecular, biochemical and epigenetic endpoints. The experiments and analysis are currently ongoing and the data will be presented and discussed in this poster with particular regards to the relevance for the ecotoxicology field. [1] H2020-MSCA CHRONIC Innovative Training Network

2.01.P-Tu036 Differences of Semi-Static Systems on Growth and Sensitivity of *Myriophyllum Spicatum* Compared to Static Test in Accordance to the OECD 239

Guido Gonsior, *Aquaculture, Ecotox, Marine Science, GG BioTech Design, Homberg (Ohm), Germany*

The ring-test on the rooted aquatic plant *M. spicatum* in a water/sediment system was conducted under static conditions. However, guideline OECD 239 also mentions to use systems with several water changes in case of degradation of test item. The basic idea behind is to prove a constant exposure for risk assessment. But an influence on the test system was not clarified and the system is more artificial, since natural degradation was not taken into account. This might under or overestimate effects of degrading test items. Further, water changes influence the pH and might increase the amount of nutrients in the water or wash out nutrients from the sediment. This can lead to a higher or lower sensitivity to chemicals. Stabilisation of test items can also be reached by buffering the test system for pH sensitive test items. We present data with buffered and non-buffered test systems and compare growth of control plants from semi-static and static designs.

2.01.P-Tu037 Comparison of Static, Semi-Static and Flow-Through Test Designs With *Myriophyllum spicatum*

Sabine Eser¹, Nathalie Schwalbach² and Katrin Weber², (1)*Aquatics, Eurofins Agroscience Services Ecotox GmbH, Niefer-Öschelbronn, Germany*, (2)*Eurofins Agroscience Services Ecotox GmbH, Germany*

Testing scenarios considered in the OECD guideline 239 for the water-sediment *Myriophyllum spicatum* toxicity test, are static, semi-static and pulsed dose approaches. For the testing of fast degrading substances, it might be necessary to adapt the semi-static approach to a daily renewal of test solutions to keep up the tests concentrations in the medium and to enable the determination of test item concentrations above the detection limit in the aged solutions. However, even with a daily renewal of test solutions, it happens that test item concentrations in the aged test solutions fall below the limit of detection at the end of the renewal period (24h). A solution to overcome this problem, is to use flow-through systems to keep concentrations stable throughout the test. To evaluate whether a test with *Myriophyllum spicatum* under flow-through conditions can be considered a viable option as an addendum to the OECD 239 guideline, a test has been conducted to compare static, semi-static and flow-through test designs. Results will be presented with focus on potential differences between the test systems concerning plant growth and sensitivity.

2.01.P-Tu038 *Glyceria maxima* As an Alternative in Macrophyte Testing

Sabine Eser¹, Nathalie Schwalbach² and Katrin Weber², (1)*Aquatics, Eurofins Agroscience Services Ecotox GmbH, Niefer-Öschelbronn, Germany*, (2)*Eurofins Agroscience Services Ecotox GmbH, Germany*

Glyceria maxima is currently under evaluation to expand the variety of possible test organisms in a water-sediment toxicity test with rooted macrophytes in addition to *Myriophyllum spicatum* (OECD TG 239). A possible testing approach including the obtained control data will be presented.

2.01.P-Tu039 An OECD Test Guideline for *Glyceria maxima* : Results of a Final Ring-Test

Joanna Davies¹, Gertie Arts², Johanna Kubitzka³, Monika Ratte⁴ and Rita Wedeking⁵, (1)*Syngenta, United Kingdom*, (2)*Environmental Risk Assessment, Wageningen Environmental Research - WUR, Wageningen, Netherlands*, (3)*BASF SE, Germany*, (4)*ToxRat Solutions GmbH & Co. KG, Germany*, (5)*Bayer Crop Science, Germany*

Registration of plant protection products in the EU requires assessment of effects on aquatic plants and, for some products, tests are required with the emergent, monocot species, *Glyceria maxima*. Since 2014, a Workgroup affiliated to the SETAC Plant Interest Group, has developed a test method in a water-sediment system, which has been evaluated via three international ring-tests. The first ring-test was completed by 13 laboratories during 2016-2017 with the herbicide, isoproturon, and the objectives of establishing the test duration and defining suitable assessment parameters. Results from this ring-test showed that a test duration of 14 days was preferable to 21 days and that leaf length was a more reliable assessment parameter than shoot height. The protocol was adapted to take account of these findings and introduce further standardization in terms of plant propagation methods and test system specification. The revised protocol was used in a second ring-test with the herbicide, imazapyr, in 11 laboratories during 2018. The objective of this ring-test was to determine the feasibility of assessing effects on root growth. Results showed that shoot parameters are more reliable than root endpoints and that further work is required to reduce test variability by improving the uniformity of starting plant material. In April 2019, an OECD Test Guideline project was initiated and a further ring-test was completed in 2021. This presentation will summarize data generated to date and discuss progress towards delivery of an OECD Test Guideline.

2.01.P-Tu040 Screening Engineered and Natural Nanomaterials for Their Effects on Wheat and Lettuce Seed Germination and Nanomaterial Responses to Exposure

Jessica Chadwick¹, Peng Zhang² and Iseult Lynch³, (1)*GEES, University of Birmingham, Birmingham, United Kingdom*, (2)*University of Birmingham, Birmingham, United Kingdom*, (3)*School of Geography, Earth and Environmental Sciences, University of Birmingham, Birmingham, United Kingdom*

Conventional fertilisers are incredibly inefficient, with up to 60% of nitrogen fertiliser lost to the environment on average, as leachate (e.g. nitrate, ammonia, etc.) and volatilized gases (e.g. NO_x, N₂O) (FAO, 2002). Identifying alternative fertilisation strategies, like use of biochar and engineered nanomaterials (NMs), that are able to minimise environmental losses and prevent long-term effects such as soil acidification, eutrophication, and ozone depletion, while maintaining or improving crop yields is of global significance. Seed treatments are a common method to minimise entry of fertilisers into soil and to prime seeds for better germination and initial growth. Seed germination tests are used to determine NM suitability for agricultural application by assessing the doses at which they display phytotoxicity. We explored *in vitro* the impacts of a broad panel of natural and engineered NMs, including zeolites, hydroxyapatites, biochar, and metal-based NMs, on lettuce and wheat seeds. These seeds

differ in size significantly, which alters their exposure to the NM suspensions, and represent dicotyledonous and monocotyledonous crop plants, respectively. By screening a broad range of NMs with different chemistries it is hoped that more effective comparisons can be drawn between germination rates and NM properties and that NMs' effects can be grouped, and in due course predicted computationally. Only root growth was affected by NM treatment in wheat, with no significant differences found between NM treatments and control for rate of emergence. Lettuce seeds showed a very different pattern of response, having their shoot length affected by NM treatment, and with several NMs that promoted wheat root growth inhibiting lettuce shoot growth. The dose-response seed germination experiment is accompanied by analysis of changes in the composition of the seed exudate and on the impacts of the seed exudate on the NMs, in terms of corona formation and physico-chemical transformation of the NMs, which will help to elucidate the mechanism of effect (enhancing water uptake, intensifying sugar metabolism/energy production, inducing antioxidant defences, and/or remodelling membrane lipids). Results from these seed priming experiments will inform future work to explore the NMs interactions with the two crops, their impacts on nutrient cycling, and changes in the NM characteristics in both hydroponic media and agricultural soils.

2.01.P-Tu041 Multi-Endpoint Toxicity Evaluation of Rare Earth Elements in Terrestrial PLANTS

Isidora Gjata¹, Costantino Paciolla² and Franca Tommasi², (1)Biology, University of Bari, Bari, Italy, (2)University of Bari, Italy

Rare earth elements (REE) are a group of 15 elements, the lanthanides and Yttrium and Scandium, with similar chemical and physical properties. They are naturally present in the environment, where accumulation can occur following anthropogenic inputs, altering their biogeochemical cycle. These elements were extracted from complex minerals, and until 30 years ago, they were scarcely investigated. REEs are now considered 'critical' or 'strategic' substances because they are crucial to a wide range of modern technologies such as catalytic additives, hybrid vehicles, wind turbines, oil refining, lighting technologies and, in recent years, have caused widespread concerns about their persistence in the environment and bioaccumulation in the biota. Few data in the literature concern the effect (beneficial or toxic ones) induced by REE application in terrestrial vascular plant species and at different physiological stages. Therefore, the aim of this study was to improve the knowledge on ecotoxic responses to different REEs in terrestrial plants on the basis of their bioavailability in soil and water. To evaluate this, a set of experiments with exposure to different REEs were performed on plant organisms. Preliminary data of investigations focused on the exposure of *Lens culinaris Medik.* seedlings and *Allium cepa L.* bulb to cerium chloride (CeCl_3) and neodymium chloride (NdCl_3) at various concentrations. These acute toxicity tests lasted for 72 hours and results showed alteration of the growth rate and the levels of some parameters considered as biomarkers of stress (reactive oxygen species and antioxidant systems). Some aberrations of the mitosis were also observed in the root tissues of both species. All these analyses are being performed through techniques of spectrophotometry, microscopy, and electrophoresis. Preliminary results indicate that the sensitivity of *L. culinaris Medik.* in this bioassay is higher for lower concentrations compared to *A. cepa L.* Also, lower concentrations of REE had a positive effect on the growth rate of lentils. We will further elaborate on this study and present the first results in the poster.

2.01.P-Tu042 Improving the Interpretation of Terrestrial Plant (NTTP) Toxicity Studies by Considering Crop Tolerance

Klaus Swarowsky¹, Carmen Schweikert², Steffen Matezki³ and Jörn Wogram⁴, (1)German Federal Environment Agency (UBA), Germany, (2)German Environment Agency (UBA), Germany, (3)German Environment Agency UBA, Germany, (4)German Federal Environment Agency UBA, Germany

Plant Protection Product (PPP) risk assessment to non-target terrestrial plants (NTTPs) needs to account for the rich diversity of the plant kingdom by testing a wide range of potentially sensitive species. Especially herbicides carry a high potential to affect NTTPs and therefore require a careful choice of test species. 6-10 species of different taxonomic groups are usually tested to represent the sensitivity distribution of NTTP communities off-field, mainly crop species. In many cases, labelled crops (i. e. crop plants where herbicide use is intended) need to be tolerant to adverse effects to exclude damage to the crop. Therefore, focusing testing on labelled crop species would severely bias the toxicity estimate. Nevertheless, this case sometimes occurs. As an example, we present the case of a herbicide. It primarily inhibits the seedling emergence/establishment of weeds, but not the crop, which must be tolerant. We show that regulatory studies submitted during the current EU evaluation of the active substance focused on labelled crops and thus on species known to be insensitive to this herbicide. We want to share this assessment to make sure that sensitive species are tested in the studies used to evaluate the PPP risk to NTTPs. A way forward will be presented how to check the tolerance of tested NTTP species exposed to a herbicide to support the design and evaluation of such tests for PPP risk assessment.

2.01.P-Tu043 Identifying Suitable Non-Crop Species for the Potential Use in Guideline Plant Protection Product Testing for the Risk Assessment of Non-Target Terrestrial PLANTS

Sebastian Fellmann¹, Petra Koehler¹, Rena Jutta Irene Isemer², Christine Mihan¹ and Daniela Jans¹, (1)Bayer Crop Science, Germany, (2)Crop Science, Bayer Crop Science, Germany

To assess the risk of plant protection products (PPP) to non-target terrestrial plants (NTTP), official guidelines provide test designs. A homogeneous germination and seedling growth is of high importance to allow for statistically reliable and reproducible results, accordingly the specified validity criteria of the guidelines require germination rates of at least 70% and a rate of 90% for the survival of emerged control plants. Crops are preferred over non-crop species for testing as they typically show the desired properties. In the past it has been discussed, whether non-crop species are more or less sensitive than crop species and whether the non-crop species are adequately covered within the current PPP risk assessment. At the last SETAC conference (2021), we presented a list of non-crop species which have the potential to fulfil the validity criteria and could be used in guideline testing. However, many of those species (e.g. *M. chamomilla*, *S. media*) can be defined as target species considering the efficacy spectra of common PPP. Target species are not suitable for testing the risk of PPP towards non-target plant species. Thus, this work aims

to identify non-crop species from different plant families which (i) are expected to occur adjacent to agricultural fields in Germany (ii) are not target species, and (iii) can fulfill the validity criteria specified in the guideline. Plant communities (e.g. grass meadows) which would be expected in close vicinity of agricultural fields in Germany were identified. Species from those plant communities were excluded when they were found to be within the efficacy spectrum of common PPP. In total 27 species meeting these criteria were available at seed suppliers. Germination rates and growth stage assessments (BBCH) of species from two suppliers were compared. Two different sowing depth (1 cm of soil and a shallow layer of sand) were applied to identify optimum conditions. Preliminary results showed that depending on the supplier and the sowing depth several species can fulfill the validity requirements for guideline testing. Challenges were seen regarding identifying representative non-crop species, availability as well as quality of seeds and the need for specific sowing conditions.

2.01.P-Tu044 Challenges and Regulatory Relevance of Statistically Assessing Visual Injury As Additional Endpoint in EcoToxicological Testing of Non-Target Terrestrial Plants (NTTP)

Andreas Duffner¹, Dominik Ripperger², Sebastian Fellmann³ and Christine Mihan³, (1)Eurofins Agroscience Services Ecotox GmbH, Niefern-Öschelbronn, Germany, (2)Eurofins Agroscience Services Ecotox GmbH, Germany, (3)Bayer Crop Science, Germany

The main refuges for Non-Target Terrestrial Plants (NTTPs) in intensively used agricultural areas are field margins representing semi-natural habitats. Ecotoxicological testing to assess the effects of plant protection products on NTTP's under greenhouse conditions is conducted according to standard guidelines (e.g. OECD 208 and OECD 227). In addition to the quantitatively assessed endpoints mortality or shoot dry weight, visual injuries such as chlorosis, necrosis as well as leaf and stem deformation are also assessed. However, as in most studies for ecotoxicological testing, no statistical estimations (e.g. determining ER_x values) are done for visual injuries. The technical report of EFSA (2019) stated that the ER_x for visual injuries should be reported and used for the risk assessment if this endpoint is the lowest of those available/assessed. However, there are several challenges which have to be addressed before a reliable determination and interpretation of ER_x values for visual injuries could be considered. The objective of this poster is to create awareness for the topic and to discuss the challenges of deriving a reliable endpoint based on visual injury as well as potential solutions. In comparison to quantitatively assessed endpoints such as mortality or shoot dry weight, visual injuries are determined based on different qualitative rating systems (e.g. A-E, 1-4, 10-100%) and a subjective estimation of the assessor. The comparability of visual injury between different studies is therefore challenging. A consistent rating system in combination with a clear guidance would need to be developed for the assessment of visual injuries and to transfer already assessed visual injury data in a comparable scale. From a statistical point of view, the evaluation of visual injury data is challenging because they are neither continuous data like shoot dry weight nor quantal data like survival and they do not allow to account for variability of responses between individual plants from the same replicate. Nonetheless, if it were possible to develop procedures for a reliable estimation of ER_x values for visual injury, the regulatory relevance could be evaluated by comparing it with the currently assessed endpoints shoot dry weight, shoot height or mortality. Currently running initiatives addressing this topic will also be presented on this poster.

2.01.P-Tu045 Protectivity Check of the Tier 1 Pesticide Risk Assessment for Aquatic Primary Producers

Sarah Hartmann¹, Andreas Solga², Sibylle Eck³, Gertie Arts⁴ and Eric Bruns¹, (1)Bayer Crop Science, Germany, (2)Ecotoxicology, Bayer Crop Science, Germany, (3)Bayer AG, Germany, (4)Environmental Risk Assessment, Wageningen Environmental Research - WUR, Wageningen, Netherlands

In Europe, the aquatic Tier 1 environmental risk assessment (ERA) of plant protection products (PPPs) for herbicides and plant growth regulators requires the performance of chronic studies with at least two different algae species and one aquatic macrophyte species. These data requirements for active substances are laid down in the Commission Regulation (EU) No 283/2013. According to the Aquatic Guidance Document (EFSA PPR, 2013), the ERA should be based on growth rate related values (i.e., E₁₀C₅₀ for primary producers, with an AF=10), which raised the question whether the ERA for primary producers is still protective after moving from the biomass related endpoints (E_b/E_yC₅₀) to growth rate related endpoints. To further investigate this question, several authors compared the regulatory acceptable concentrations (RACs) resulting from the Tier 1 risk assessment with the Tier 3 RACs resulting from micro/mesocosm studies in the last years. The evaluations available so far have come to different conclusions. Several authors found that, in the majority of cases (van Wijngaarden & Arts, 2018, ET&C 37), the risk assessment is protective while at SETAC Rome the German EPA (oral presentation: Duquesne et al. 2018) presented an evaluation with a different result. In order to investigate this inconsistency, the present study investigated the protectiveness of 18 herbicides and 2 fungicides where primary producers are the most sensitive species. The compounds were chosen considering their use for data comparison in the past and, at least in most cases, Tier 1 and Tier 3 data pairs were available. The Tier 1 and Tier 3 endpoints were extracted from publicly available EFSA conclusions and, if needed, from papers and the resulting RACs compared with each other. For the derivation of the Tier 1 RACs from laboratory studies, the most sensitive species were considered in combination with an assessment factor of 10. To derive Tier 3 RACs from micro/mesocosms, the endpoints were used in combination with assessment factors published in EFSA conclusions, where available on the EFSA website. For some cases, where this evaluation resulted in a Tier 1 RAC being higher than the Tier 3 RAC, and thus giving a hint for non-protectiveness of the Tier 1 risk assessment, we had a closer look on the observed effects in the Tier 3 studies. The in-depth evaluation of the underlying data was used to further increase the understanding about potential risks related to current procedures in the environmental risk assessment of primary producers.

2.02 Arthropods at Risk? Current and Future Perspective on Insect Ecotoxicology

2.02.T-01 Development of an Ecotoxicological Testing Method to Assess Side-Effects of Plant Protection Products on Herbivorous Lepidopteran Larvae Under Laboratory Conditions

Lena Böhrs¹, Christoph Walter² and Andreas Duffner³, (1)Goethe Universität Frankfurt am Main, Germany, (2)Eurofins Agrosience Services Ecotox GmbH, Germany, (3)Eurofins Agrosience Services Ecotox GmbH, Niefern-Öschelbronn, Germany

In the current environmental risk assessment of Plant Protection Products (PPP), the exposure route via food ingestion by herbivorous arthropods is not considered and therefore, no standard test protocols for non-target arthropods are available. In the EFSA opinion on non-target arthropods, testing of lepidopteran larvae is suggested to cover this methodological gap, as this group of organisms play an important role in the ecosystem and are widely distributed across Europe. The objective of this study was the development of an ecotoxicological testing method to assess the side-effects of PPP to herbivorous lepidopteran larvae. The presented research was divided into two steps: 1) establishment of *Aglais io*, *Aglais urticae* and *Vanessa atalanta* lepidopteran species rearing under controlled laboratory conditions; a 4th species *Pieris brassicae* was bought from a commercial source as eggs and 2) the assessment of acute and chronic endpoints of these four herbivorous lepidopteran species exposed to two PPP with a different mode of action. Lepidopteran adults and larvae of *A. io*, *A. urticae* and *V. atalanta* were reared under laboratory conditions at 25±2°C, 60-70% relative humidity and a photoperiod of 16:8 (L:D) h. During their larvae stage until pupation, all 3 species were provided with at libitum nettle leaves as food source. Adults were provided with sugar solutions. *P. brassicae* eggs were bought from a commercial source and kept in an environmental chamber at 25±2°C, 60-70% relative humidity and a photoperiod of 16:8 (L:D) hours. Larvae of *A. io*, *V. atalanta* and *P. brassicae* within the age range of 24 to 48 h were used for testing. The test design consisted of a control and seven treatment groups, with 15 replicates each. The test substances were sprayed on the surface of nettle or savoy cabbage leaves, depending on the lepidopteran species tested. Test organism larvae were exposed to treated leaves and kept in test units under controlled environmental conditions (25±2°C, 60-70% relative humidity and a photoperiod of 16:8 (L:D) h). Mortality was assessed 24 and 48 hours after the application of the test substance. Afterwards pupation rate and reproductive performance were assessed. Acute and chronic endpoints will be statistically evaluated and the respective ER_x values will be calculated and presented. It can be concluded that a reliable rearing of the herbivorous lepidopteran species *A. io* and *V. atalanta* can be established as well as the assessment of acute and chronic endpoints of these species is feasible. Challenges of testing herbivorous lepidopteran larvae and the relevance for the risk assessment will be discussed.

2.02.T-02 Evaluation of the Risks of Hydroxymethylfurfural (HMF) for Honey Bees: Results of a Guts-Based Modelling Approach to Assess the Potential for Time-Reinforced Toxicity

Andreas Focks¹, Alessio Ippolito² and Salomon Sand³, (1)University of Osnabruck, Germany, (2)EFSA - European Food Safety Authority, Italy, (3)Swedish Food Agency, Sweden

Hydroxymethylfurfural (HMF) is a degradation product of particular sugars and can be present in bee feed. HMF is of low acute toxicity in bees but causes increased mortality upon chronic exposure. Within the frame of an EFSA risk assessment of HMF in bee feed the toxicity of HMF in bees was investigated. Two studies, Gregorc et al., (2020) and Jachimowicz and El Sherbiny (1975) have investigated chronic effects of HMF on the survival of honeybees. Experimental analyses indicated that HMF has potentially time reinforced toxicity (TRT) characteristics. However, the experimental data on HMF in bees might not adequately cover the full life span of summer and winter bees, i.e., the impact related to bee health may be underestimated if the environmentally relevant length of exposure exceeds the duration of laboratory tests. A novel approach was developed, that allows to assess TRT characteristics based on toxicokinetic-toxicodynamic modelling of survival using the GUTS framework. A modified GUTS-RED-SD model was used where everything was standard ([4,5]), except the model for the control mortality, where we used the cumulative distribution function of the log-normal distribution as 2-parameter background mortality model. The parameters of the probability distribution function, p_1 and p_2 , were fitted to the decline in survival over time of the tested bees in the control by minimization of the negative log-likelihood value (see [5]). The remaining 3 parameters of the GUTS-SD-RED model were fitted to the survival over time by minimization of the negative log-likelihood function value. For each data set, the calibrated GUTS was used to calculate survival for a series of 36 exposure levels and exposure durations between 2 and 180 days. Background mortality was not considered for these extrapolations, but alone the toxic effect. The slope of linear regressions of the logarithm of extracted LD50 values for extrapolated exposure duration, and the duration of (simulated) exposure was estimated to a value of -1.89 based on data from Gregorc et al., (2020). The corresponding slope value based on Jachimowicz and El Sherbiny (1975) is -1.96. The TRT characteristic is shown for HMF for both datasets with slope factors s very close to -2; according to the TRT theory, HMF is thus an almost “ideally accumulative toxicant”, independent of the specific dataset, and the sensitivity of the test. The developed methodology provides a methodology to analyse the TRT property from data from prolonged ecotoxicological testing by using a modelling approach based on the GUTS modelling framework.

2.02.T-03 Predicting solitary bee pollen consumption and its relevance for pollinator risk assessment

Tobias Pamminer, Dr.¹, Christof Schneider², Raffael Maas² and Matthias Bergtold², (1)Bayer Crop Science, Germany, (2)BASF SE, Germany

In recent years there is growing concern that some solitary bee populations are in decline, potentially compromising pollination security in agricultural and non-agricultural landscapes. Among the numerous causes associated with this trend bee exposure to plant protection products in agricultural landscapes has been discussed. Bees can be exposed to plant protection products directly resulting from overspray and/or to residues in pollen and nectar. In the case of solitary bee larvae, the main exposure route is likely pollen and the amount consumed depends on the size of the bee larvae and the pollen composition and (e.g. pollen protein concentration). So far exposure estimates for wild bee larvae for risk assessment purposes have been based on a limited information making their robustness uncertain. In an attempt to tackle this question we combine published information on solitary bee ecology (plant preference), plant pollen quality (pollen protein concentration), bee larvae weight and pollen consumption to

build a inter species correlation model to estimate the protein needs of solitary bee larvae. By combining this model with known pollen protein content, we predicted the expected pollen needs of a developing red mason bee (*Osmia bicornis*) a regulatory relevant pollen generalist (polylactic). In summer 2020 we tested the model predictions in a field experiment in central Germany. These results support the validity of the model framework. We discuss our findings in the context of current EU risk assessment framework and highlight the potential of using scaling models to support pollinator risk assessment.

2.02.T-04 Concept for a Geospatial Landscape Model to Estimate the Site Specific Forage Supply for Pollinators

Silvana Hudjetz¹, Leonie Breidenbach¹, Jana Gerhard¹, Volker Grimm², Juergen Groeneveld³, Monika Hammers-Wirtz⁴, Gottfried Lennartz¹ and Andreas Toschki¹, (1)gaiac - Research Institute for Ecosystem Analysis and Assessment, Germany, (2)Ecological Modelling, Helmholtz Centre for Environmental Research - UFZ, Leipzig, Germany, (3)Helmholtz centre for environmental research - UFZ, Germany, (4)Research Institute gaiac, Germany

Key pollinators, such as honeybees, face multiple stresses (food shortage, pesticides, diseases). To address these problems, the landscapes complexity needs to be regarded as a whole. Vegetation and especially (semi-natural) elements such as grassy field margins and hedges play a key role. They need to be considered to understand temporal and spatial resource availability and to assess potential resilience and/or recovery of pollinator populations. Process-based modelling techniques are recommended to cope with the high complexity of the landscape. We here present a spatially explicit modelling approach that estimates the forage availability for pollinators in an existing agricultural landscape throughout the year. In addition to the amount of forage provided by agricultural crops, the supply by semi-natural vegetation in off-crop areas is estimated based on existing GIS (geoinformation system) data. To this end, we set up a data base with GIS data for the given landscape (e.g. cadastral maps, landscape elements), phytosociological data on vegetation units, and plant trait data (e.g. forage supply, flowering time), estimated the present vegetation units based on the GIS data, estimated the species cover for the vegetation units based on the phytosociological literature data, calculated the nectar and pollen supply of the given vegetation unit throughout the year and created a forage supply map of the considered landscape. We used this map as input data for the simulation model BEEHAVE, which simulates the development of a honeybee colony and its foraging of nectar and pollen in different landscapes. The developed modelling approach can be added as a modul to the dynamic GraS-Model to allow for a process-based plant community modelling including the forage supply for pollinators. The presented research is part of the ongoing project VIBee (establishing digital indicators of bee vitality in the agricultural landscape, <https://vibee-project.net/>). Further research will include the analyses of the following collected data: counting of a colony's flight activity using electronic counters (BeeCheck), the weight of the beehives (5 minutes resolution), weekly analyses of the collected pollen, field data of surrounding vegetation including flowering plants over the vegetation season. The here presented modelling approach can be adjusted for other pollinators and other landscapes.

2.02.T-05 Variability in Chemical Sensitivity of Arthropod Communities Across Europe

Ralf Bernhard Schaefer¹, Jonathan Jupke², Sebastian Scheu³, Tomás Duque², Javier Diaz², Frederik De Laender⁴, Martin Entling², Lorraine Maltby⁵ and Paul van den Brink⁶, (1)University Koblenz Landau, Germany, (2)University of Koblenz-Landau, Germany, (3)University Koblenz-Landau, Germany, (4)Université de Namur ASBL, Belgium, (5)The University of Sheffield, United Kingdom, (6)Wageningen Environmental Research, Netherlands

Current chemical risk assessment with respect to chemical effects on non-target organisms largely follows a one-size-fits-all approach, focusing on sensitive single species tests or multispecies test systems. However, real world species assemblages vary in their composition over space and time and so may their sensitivity towards a chemical. Depending on the variability in sensitivity, the use of a single effect threshold can result in over- and underprotection. Hence, knowledge on this variability is pivotal for an efficient risk assessment. We examined the sensitivity of selected aquatic (freshwater invertebrates) and terrestrial (spider) arthropod communities towards four chemicals with different modes of action (herbicide, insecticide, metal, pharmaceutical) across Europe. We compiled related monitoring data covering major macroecological gradients in Europe and used biogeographical and habitat classification systems to derive typical assemblages for freshwater invertebrates and spiders. Subsequently, we estimated the chemical sensitivity based on statistical models and derived sensitivity distributions for the different assemblages. Our results show that assemblage sensitivity can vary considerably, in particular in freshwater invertebrates. We discuss the implications of our results for arthropod conservation and chemical risk assessment.

2.02 Arthropods at Risk? Current and Future Perspective on Insect Ecotoxicology (Virtual Only)

2.02.V-01 Estimating the Range Shift of Beetle Occurrence Using Species Distribution Modeling - an Application in the Climate-Change Perspective

Gerco Hoogeweg¹, Brenna Kent¹, Chiara Accolla², Jennifer Jackson¹, Amelie Schmolke¹ and Amy Ritter¹, (1)Waterborne Environmental, Inc., United States, (2)Waterborne Environmental, Inc, United States

With a changing climate, many species, including agricultural pests, are likely to shift their geographical ranges. This has important implications for pest management and crop yields. How could this shift look like for major pests? To get an idea for a specific example, we analyze the occurrence data of the spotted cucumber beetle (SCB), a significant pest to cucurbit crops in the US. The purpose is to (i) explore the presence of suitable habitat in the USA and (ii) project the habitat suitability to the future, considering different climate change scenarios. The work is performed using a flexible and open platform for modeling species niches and distributions. To build a species distribution model, data on species occurrence (locations where the species was observed) and environmental conditions relevant to the species across the US have to be retrieved and processed. For our analysis, we used the dataset of the SCB occurrences from the Global Biodiversity Information Facility and the environmental data from WorldClim. After processing these datasets, we performed a partition of occurrence data to test the accuracy of the predictive

model. Subsequently, we ran the species distribution model which is based on a machine-learning algorithm that estimates the species response to the environment. Model outputs show the relative abundance or probability of occurrence over space (the USA) and time (projections to 2070). We tested two different scenarios of climate change using the intermediate RCP4.5 scenario and the worst-case RCP 8.5 scenario. Results suggest that there will be areas of estimated range loss of SCB (Southeast US, Southern Texas) and areas of estimated range expansion (Northeast, Northern parts of the Midwest, Eastern regions of CA, and the Pacific North West) in both climate scenarios, suggesting that the species could become a major pest in regions where it is currently absent or occurring at low abundances.

2.02.V-02 Evaluating the Effects of Fungicide and Herbicide Alone and in Binary Mixture on *Apis mellifera* by a Multi-Biomarker Approach

*Agata Di Noi*¹, *Silvia Casini*², *Tommaso Campani*², *Marco Romi*², *Giampiero Cai*² and *Ilaria Caliani*², (1)Department of Life Sciences, University of Siena, Siena, Italy, (2)University of Siena, Italy

Apis mellifera plays an important role in agriculture and in the conservation of plant biodiversity. This species is disappearing globally due to parasites infestations and diseases, habitat loss, beekeeper management issues and to the widespread use of pesticides. Honeybees could be exposed not only to single pesticides but also to their mixtures that may cause synergistic or antagonistic effects. Insecticides and their sub-lethal effects have been widely studied in this species, while fungicides, herbicides, and pesticide mixtures, are not equally investigated. The main objective of this work was to investigate the sub-lethal effects in *Apis mellifera* after the exposure to two doses of a commercial fungicides (having as active principles 15.86% bromuconazole + 10.17% tebuconazole), of a commercial herbicide (2,4 D), and to the combination of them, by applying a multi-biomarker approach. A control with acetone was used for each experiment. The specimens were exposed topically to two concentration of the fungicide (200 g/L and 400 g/L), of the herbicide (225 g/L and 450 g/L), and of the binary mixtures of pesticides (200 g/L fungicide + 225 g/L herbicide and 400 g/L fungicide + 450 g/L herbicide). The experiment lasted 4 days. AChE, CaE, GST, ALP, and lysozyme activities, hemocytes differential count and NA assay were evaluated. CaE was inhibited in both fungicide treatment groups. Since AChE did not show a neurotoxic activity, it is possible to hypothesize that fungicide may act at metabolic level. GST showed an induction at the lowest dose respect to control, while at the highest dose the activity decreased; fungicide may activate organisms' biotransformation systems response. Herbicide highest dose showed an increase in GST and a dose-dependent inhibition in ALP. It is possible to hypothesize that herbicide modulates organisms' biotransformation and metabolic responses. CaE showed an inhibition at the highest mixture dose while GST showed an increase at the same dose. Mixture lowest dose showed a slight decrease in ALP activity respect to the control. Mixture highest dose showed an increase in the granulocytes number. The results obtained after the treatments with these commercial pesticides alone and in binary mixtures showed that they can modulate the detoxification and metabolic responses. Moreover, the multi-biomarker approach proved to be a useful tool for the ecotoxicological evaluation of xenobiotic compounds effects in pollinator species.

2.02.V-03 New Method for Evaluation of Damaged Digestive Tract in *Collembola Folsomia candida*

Jin Il Kwak, *Lia Kim* and *Prof. Youn-Joo An*, Konkuk University, Korea, South

Folsomia candida is widespread arthropods and commonly used test species in soil ecotoxicology, therefore the test guidelines for *F. candida* have been developed to assess the survival and reproduction. However, there are limited method for evaluation of toxicity of chemicals in individual level even though collembola are becoming an increasingly important subject in soil ecotoxicology area. The purpose of this study was developing a new method into soil ecotoxicological evaluation of chemicals using *F. candida*. This study hypothesized that damaged digestive tract of *F. candida* can be visualized by trypan blue which staining dead cell. To find the optimum staining media, staining duration and dye concentration, necessity for agar, sugar, various staining duration (5 to 120 minutes), and dye concentrations (0.1% and 1%) were investigated and compared. Subsequently optimum test conditions using trypan blue were applied to metal exposed *F. candida* to confirm applicability of this new method. As results, we found that a new method supported to evaluate and visualize the digestive tract damages in *F. candida* after metal exposure. We expect this new method for evaluation of damaged digestive tract using trypan blue can contribute to expand the test endpoints for collembola *F. candida*. *Acknowledgement*-This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT and future planning (2020R1A2B5B02001734, 2021R1C1C2012628)

2.02.V-04 Sensitivity of Bee Species to Pesticides: A TK/TD Perspective Using the GUTS Modelling Framework

*Jan Baas*¹, *Benoit Goussen*², *Mark Miles*³, *Thomas Preuss*⁴, *Vanessa Roeben*⁴ and *Ivo Roessink*⁵, (1)Wageningen Environmental Research - WUR, Netherlands, (2)IBACON GmbH, Germany, (3)Bayer Crop Science, United Kingdom, (4)Bayer Crop Science, Germany, (5)Wageningen Environmental Research, Netherlands

Although empirical data on non-apis species is being generated lately, risk assessment for bees is still for a large extent based on data for honey bees. This raises the question whether or not data for honey bees are a good proxy for other bee species. This question is not new and has resulted in several publications where the sensitivity of bee species is compared. In all publications, comparisons are based on 48 *LD*₅₀ values from acute contact test results. In such a test, a drop of fluid containing the compound of interest is placed in the neck of the bee and subsequently effects on survival of the test subjects are observed, the test result of which is summarised in the 48 hr *LD*₅₀. However, previous research showed that during this observation period, the exposure concentration declines over time. This in itself raises questions on the validity of the *LD*₅₀ value and in addition, the decline over time is likely to be different for different species, depending on the characteristics of the bee. Therefore an assessment of bee sensitivity based on 48 hr *LD*₅₀s is problematic. These issues can be taken into account by the use of a Toxicokinetic/Toxicodynamic (TK/TD) model that can handle time-varying exposure concentrations. The endpoint then becomes a time- and test-

independent measure for the toxicity; the effect threshold. This approach was tested and validated for honey bees in the so-called BeeGUTS framework, but so far the approach has not been applied to species other than honey bees. This framework was now calibrated and validated for different species of bees (*Osmia*, *Bombus*, *Megachile*) and a variety of different pesticides allowing for the comparison of bee sensitivity and the evaluation on whether or not the honey bee is a good proxy for bee sensitivity in environmental risk assessment.

2.02.V-05 Temperature Sensitive Effects of the Neonicotinoid Clothianidin on Bumblebee (*Bombus terrestris*) Foraging Behaviour

Pawel Kolano¹, Katrine Borga² and Anders Nielsen³, (1)CEES, University of Oslo, Oslo, Norway, (2)UiO, Norway, (3)Norwegian Institute of Bioeconomy Research (NIBIO), Norway

Currently, 46% of European bumblebee species have declining populations. Pesticide usage has been pointed out as one of the drivers behind the decline of wild bee populations. Globally, neonicotinoids are one of the most commonly used insecticides. Studies have shown that exposure to neonicotinoids at sublethal concentrations can alter foraging behaviour of pollinators. Bumblebees are social insects with a complex colony structure and division of labour. Any disturbance of these intricate activities might negatively affect bumblebee colony survival and reproduction. As there is still little knowledge about how interactions between anthropogenic stressors such as neonicotinoids and natural drivers such as ambient temperature affects bumblebees, the aim of this study was to assess if foraging bouts were affected by clothianidin, and if this effect was modulated by the ambient weather conditions (i.e., temperature and precipitation). Using a custom-made bumblebee colony monitoring system, we examined how the number and duration of foraging bouts of bumblebees on an individual level was affected by exposure to low (6.5 µg/L) and high (10.6 µg/L) sub-lethal concentrations of the neonicotinoid clothianidin via nectar. We also examined possible interaction between clothianidin exposure and abiotic factors (temperature and precipitation), and its impact on foraging bout number and duration. Exposure to sublethal concentrations of clothianidin increased foraging bout duration in bumblebees. Furthermore, the foraging bout duration decreased with increasing temperature at both exposure concentrations, whereas the unexposed control group was not affected by temperature. Neither number of foraging bouts nor the daily rhythm of foraging bout duration was affected by clothianidin exposure or temperature. The foraging bout duration decreased with increasing precipitation in both exposed and non-exposed groups. However, we did not find any interaction between precipitation and exposure, suggesting that precipitation does not affect toxicity. Our study shows the importance of semi-natural experiments and accounting for ambient factors when assessing the risk that pesticide exposure may present to pollinators. We conclude that the effect of clothianidin exposure on bumblebee foraging behaviour is temperature sensitive and that local climatic conditions and future climate change scenarios should be considered in risk assessments of clothianidin and other insecticides.

2.02 Arthropods at Risk? Current and Future Perspective on Insect Ecotoxicology (Poster)

2.02.P-Mo061 A Chronic Toxicity Test With the Mayfly *Cloeon dipterum*, Results of a Ringtest

Silke Claßen¹, Eric Bollinger², Eric Bruns³, Kirsten Germing⁴, Katrin Gergs¹, Sara Kolbensschlag⁵, Katrin Kuhl³, Zoe Leanne Jones⁶, Hanna Samantha Schuster⁶, Maria Vogt⁴ and Ivo Roessink⁷, (1)gaiaac - Research Institute for Ecosystem Analysis and Assessment, Germany, (2)University of Koblenz-Landau, Germany, (3)Bayer Crop Science, Germany, (4)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (5)University Koblenz Landau, Germany, (6)Cambridge Environmental Assessments, United Kingdom, (7)Wageningen Environmental Research, Netherlands

In recent years, the interest of testing non-standard species for environmental risk assessment of pesticides has increased. Particularly, mayflies gained interest due to their relevance in aquatic ecosystems and sensitive response to chronic exposure to certain pesticides. In this context, we developed and refined a chronic test system for the mayfly *Cloeon dipterum*. To evaluate the validity of the test procedure among laboratories, a ring test comprising six participants was carried out. The participating laboratories performed the test according to the same protocol with local larval wild catches of *C. dipterum*. Larvae were exposed to at least five concentrations of Imidacloprid in a semi-static test design. The larvae were preferably fed with lab grown periphyton on unglazed tiles. Tiles were exchanged at least once a week ensuring provisioning of food ad libitum food. In some labs additional experiments with artificial fish food were performed. The experiments were terminated when almost all larvae had emerged or died. The larval development was monitored two to three times a week by the determination of the developmental stage. All laboratories were able to determine the developmental stages as well as immobility. In four of the five laboratories that carried out experiments with periphyton, the test duration and thus the development rates of the larvae were comparable with control mortalities not exceeding 30% at test termination. Here, mortality was observed predominantly for older larvae and nymphs. Larvae fed with artificial fish food developed slower and showed higher control mortality relative to the provisioning of periphyton as food source. Also, the effect data show a clear dose-response and are comparable between the laboratories. Thus, the results give good indications for further development of the test protocol. Overall, the results are very promising and represent an important step forward in the development of a robust test method for mayflies. **Acknowledgement** - The authors thank Julius Alberti, Margret Arnold, Marie-Claire Boerwinkel, Marie Brown, Mirco Bundschuh, Noel Diepens, Alexander Feckler, Jutta Hager, Laura Koster, Charlotte Krapp, Sophie Oster, Sebastian Pietz, Joe Reiser for their assistance in performing the tests.

2.02.P-Mo062 Behavioural Ecotoxicology: A Novel High-Throughput Approach to Quantify Sublethal Effects

Laura Johanna Soose¹, Kim Hügl¹, Jorg Oehlmann², Andreas Schiwy³, Henner Hollert³ and Jonas Jourdan¹, (1)Johann Wolfgang Goethe-Universität Frankfurt am Main, Germany, (2)Johann Wolfgang Goethe-Universität Frankfurt, Germany, (3)Goethe University Frankfurt am Main, Germany

There is an increasing demand for the implementation of sublethal effects in chemical risk assessment over the last years, not at last because sublethal endpoints are considered more sensitive than traditional endpoints in acute or chronic toxicity tests. However, the assessment of sublethal endpoints faces the problem of standardisation. To address this problem, we apply an approach that uses high-throughput data collection and allows us to quantify behavioural changes in real-time time with an optical behaviour monitoring tool. Our promising approach has the potential to contribute significantly to the understanding, standardisation and incorporation of sublethal behavioural effects into risk assessment. In our pilot study, we used *Gammarus* spp. due to their important ecological role in European freshwater systems and quantified their behavioural patterns under chemical exposure. Behavioural measures included locomotion activity, mating or foraging behaviour, which are elemental to the survival of the individual or the persistence of the population. Identifying abnormalities in these essential behavioural traits is a major challenge, especially in the context of multiple interacting stressors such as climate change, anthropogenic chemical pollution and the competition with invasive species. In our study, we have simulated a pollution wave and recorded the swimming activity of the individuals for 90 min while they were exposed to different pharmaceuticals and pesticides in sublethal concentrations. Additionally, an acetylcholine esterase inhibition assay was conducted to differentiate between a stress reaction and neurotoxic activities of the compounds. Our experiments revealed that even in low concentrations of ibuprofen (1ng/L), methiocarb (1.88 µg/L) and dichlorvos (1.56 µg/L), the test substances affected the behaviour of the gammarids. Our approach shows the enormous potential of behavioural ecotoxicology and the need to develop high-throughput and standardized assessment tools. With the right tools it is feasible to create a comprehensive, inter-disciplinary, multiscale approach to systematically identify behavioural endpoints and implement them in the risk assessment of substances. In this presentation, we give an overview of the method using the two pesticides dichlorvos and methiocarb as examples, the insights and our plans for future research on behavioural ecotoxicology of amphipods in the evolving Anthropocene.

2.02.P-Mo063 Ecological Significance of a Pesticide-Induced Geotaxis Reversal in Mosquito Larvae (Culicidae)

Patricks Voua Otomo¹, Simangele Mazibuko², Ngitheni Nyoka¹ and Nomasonto Dlamini¹, (1)University of the Free State, South Africa, (2)University of South Africa, South Africa

Fourth instar *Culiseta longiareolata* larvae were exposed to imidacloprid (0, 1 and 2 mg/L) and filmed for 10 minutes. The time spent in negative geotaxis was the cumulative time the larvae spent breathing at the water surface and moving upward within the water column. The time spent in positive geotaxis was the cumulative time the larvae spent moving downward below the water surface or resting at the bottom of the water column. We also assessed the larvicidal effects of imidacloprid after exposure to 0, 0.5, 1, and 2 mg/L for 24 hours. In the control, the larvae spent significantly more time in negative geotaxis, assuming the breathing stance 75% of the time ($p < 0, 01$). In the presence of imidacloprid, a reversal of geotactic behaviour occurred, with a significant decrease in negative geotaxis in all treatments ($p < 0,05$) and a significant increase in positive geotaxis in the 1 mg/L treatment ($p < 0,05$). Fitting the geotaxis data onto polynomial functions, helped estimating the duration of exposure (i.e., 300 s) and imidacloprid concentration (i.e., 0,523 mg/L) beyond which the behaviour of the larvae switched from negative to positive geotaxis. The 0,523 mg/L (concentration at the behavioural tipping point) was similar to the 24h LC₃₁ of 0,519 mg/L. Considering the mode of action of imidacloprid, in nature such a reversal in behaviour could cause greater mortality than 31%. More research is needed to establish whether these preliminary findings and testing framework could find applications in mosquito control programmes.

2.02.P-Mo064 Common Practices to Promote Beneficial Insects and Biodiversity in Vegetables Producers in Almeria

Salvador Salvatierra¹, Magdalena Delgado Cerezo¹, Esther Garcia¹ and Anne Alix², (1)Corteva Agriscience, Spain, (2)Corteva Agriscience, Abingdon, United Kingdom

The cultivated area of Almeria consists of ca 33,000 hectares dedicated to the cultivation of pepper, tomatoes, zucchini, cucumbers, watermelons, melons and aubergines, under greenhouses. Greenhouses are typically considered artificial environments where biodiversity is highly reduced, and where biocontrol is usually provided by the grower. However, measures can be implemented to bring biodiversity back into these cultivated areas, which are supported by national and European programs. The regional research centers IFAPA de La Mojonera (Junta de Andalucía), Las Palmerillas (Cajamar) and farming associations COEXPHAL (fruits and vegetables growers association of Almería) and APROA (fruits and vegetables growers association of Andalucía) foster the implantation of these new techniques. One of these techniques consisted in the implementation of ca 200 km of new green perimeter around greenhouses, making a total of 5-7 % of the greenhouses holding exterior vegetation. These hedges act as a refuge and source of feed (nectar, pollen and other preys) for auxiliary fauna, as well as a barrier against pests and finally improving the agricultural landscape. To ensure diversity and sequential flowering seasons, at least five different species are typically used chosen from lavender, rosemary, mastic, sea parsley, thyme, matagallo, broom, esparto, myrtle, daisies or wild olive. In some cases, these bushes will become orchards, where small birds and reptiles will establish. Inside the greenhouses, appropriate plants acting as reservoirs or multiplication spaces for auxiliary insects are installed, such as fennel, sage, corn, yarrow, calendula, marigold, sunflower or lobularia. The objective is to get a non-stop flowering vegetation that can be used as feed or as hosts for different auxiliary insects. It is estimated a 15 % of the greenhouses already use these reservoir plants inside. Additional tools have been developed as the mobile app, PlantEN, designed to identify the most convenient plants to be used as natural reservoirs. Additional applications such as IPM Pro are available that guide farmers on the crop protection products that are compatible with beneficial insects and biological control. This poster will illustrate in situ implementations of the technique and results in terms of biodiversity gains.

2.02.P-Mo065 Feeding Effects of a Systemic Insecticide on Ant Workers and Larvae

Marius Pohl¹, Sebastian Eilebrecht², Bernd Göckener³, Udo Hommen⁴, Judith Klein², Christoph Schaefers², Jürgen Gadau⁵ and

Mathias Otto⁶, (1)Institute for Evolution and Biodiversity, University of Münster, Muenster, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (3)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (4)Fraunhofer IME, Germany, (5)University of Münster, Germany, (6)Federal Agency for Nature Conservation, Germany

Neonicotinoids are highly effective insecticides. Due to their high solubility in water, they are absorbed by the treated crops and move within the plants vascular system which can result in their presence in all parts of the plant. Neonicotinoids are known for high toxicity to bees which can result in sublethal effects also at relatively low exposure levels. Due to their close taxonomic relatedness to bees, presence in or close to agricultural areas and similar social organization, ants (Formicidae, Order Hymenoptera) might also be sensitive. Many European ant species are omnivore and general scavenger. Thus, their exposure routes might be different from bees as exposure via food chain is more relevant for ants. Using pest insects, which were killed by an insecticide, as food source could lead to the uptake and distribution of the insecticide in the whole colony because many ants use trophallaxis, a method to share stomodeal fluids with nestmates. Hence, brood and queens are possibly affected. They depend on more resources than adult workers due to growth, development and (for queens) reproduction. We will present the first results of experiments using a systemic insecticide, imidacloprid, to test the effects of exposure via the diet on workers and larvae of *Camponotus maculatus* (carpenter ants) as surrogate test species. *C. maculatus* is an omnivore species and belongs to the subfamily Formicinae, which is the dominant ant subfamily in Europe (e.g., *Formica*, *Lasius*, *Camponotus*). Colonies can be easily maintained in the laboratory over many years and thus, test organisms are available all over the year. The test item will be applied to the workers solved in sugar solution. In a first test, acute effects on workers will be tested. In a second study, we will investigate the transfer of the test item to the larvae via trophallaxis. Therefore, behaviour and survival of worker as well as growth, development and survival of larvae will be assessed.

2.02.P-Mo066 How Can Ants Be Exposed to Plant Protection Products and Transgenic Plant Toxins?

Udo Hommen¹, Marius Pohl², Sebastian Eilebrecht³, Judith Klein³, Christoph Schaeffers³, Jürgen Gadau⁴ and Mathias Otto⁵, (1)Fraunhofer IME, Germany, (2)Institute for Evolution and Biodiversity, University of Münster, Muenster, Germany, (3)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (4)University of Münster, Germany, (5)Federal Agency for Nature Conservation, Germany

Ants occupy different ecological niches and provide important ecosystem services as waste decomposition, soil formation, and feed provision for other animals. They live in many different types of habitats, including agricultural areas. However, up to now ants are not explicitly assessed in the environmental risk assessment for plant protection products or transgenic plants. Because it is not feasible to test all taxonomic groups on a routine basis, the risk assessment is based on surrogate species and it is assumed that by the use of safety factors, also not tested taxa are sufficiently protected in the field. Honey bees, bumble bees and wild bees, can be principally considered to be suitable surrogate test species for ants in ecotoxicological tests since they belong to the same insect order of Hymenoptera and are (partly) also social insects. Nevertheless, the exposure routes of ants and bees might be different. For example, ants might collect pest insects killed by plant protection products or toxins produced by transgenic plants and use these to feed larvae or queens. Thus, the aim of this project is to explore the relevant exposure routes for ants in agricultural areas in the EU, to identify suitable test species and to conduct tests of different complexity as case studies with plant protection products, toxins produced by plants or transgenic plant material itself. We will discuss which ant species are expected to be present in agricultural areas in the EU and thus, are potentially exposed and which exposure routes to plant protection products and toxins of transgenic plants can be relevant for ant species with different feeding strategies.

2.02.P-Mo067 Reproduction of Chrysoperla and Coccinella - Only Qualitative or Ready to Use for the Risk Assessment?

Thomas Schmidt¹, Stephen Vinal², Russell Vaughan³ and Stefan Hoger⁴, (1)IES Ltd, Switzerland, (2)Mambo-Tox, Southampton, United Kingdom, (3)Mambo-Tox, Southampton, UK, (4)Innovative Environmental Services (IES) Ltd, Witterswil, Switzerland

As summarised in the EFSA Scientific Opinion addressing the state of the science on risk assessment of plant protection products for non-target arthropods (2015), the ladybird beetle species *Coccinella septempunctata* and the lacewing species *Chrysoperla carnea* are foliage dwelling predators already selected as relevant test species in the ESCORT 1 guidance document (1994). In the IOBC approved test guidelines, both species are listed and published by Schmuck et al. (2000) and Vogt et al. (2000). Whereas the statistical evaluation of the endpoints of mortality and reproduction are required for many selected non-target arthropod species (e.g. *Typhlodromus pyri*, *Aphidius rhopalosiphii*, *Aleochara bilineata*), for *C. septempunctata* and *C. carnea* only mortality is the endpoint to be statistically analysed. In contrast, reproduction is defined as a “qualitative” endpoint for these two species without the need of statistical testing, as “for the time being, the reproductive performance is evaluated only qualitatively due to the high species-inherent variability in egg-laying performance” (IOBC 2000). From our point of view, reproduction as sublethal parameter can be highly valuable and would increase the significance of the assessment of possible effects of a plant protection product. It is acknowledged that the limited number of replicates in the reproduction phase in *Coccinella* and *Chrysoperla* tests does not allow a valid testing of statistically significant differences between the treatments and the control. However, the establishment of a rate-response relationship allows the determination of the effect rates with 10 % effect (ER₁₀) and 20 % effect (ER₂₀) which supplement the No-Observed-Effect-Rate (NOER). Based on the data sets of two independent laboratories, the significance of the rate-response approach for the potential risk of plant protection products on reproduction of the foliage dwelling predators *C. septempunctata* and *C. carnea* is evaluated.

2.02.P-Mo068 Fitness and Life History: Incorporating Sublethal Effects on Invertebrates Into Risk Assessment of GMO Toxins

Lena Kosak¹, Udo Hommen², Lidiya Shemotyuk², Maria Vogt³ and Mathias Otto⁴, (1)Ecotoxicology, Fraunhofer IME - Institute

for Molecular Biology and Applied Ecology, Schmalleberg, Germany, (2)Fraunhofer IME, Germany, (3)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (4)Federal Agency for Nature Conservation, Germany

The release of genetically modified organisms (GMOs) is regulated in the EU (Directive (EC) 2018/350) and potential risks to the environment must be assessed depending on the type of genetic modification and before a release of GMO into the environment. Many transgenic crops express proteins with biocidal properties, e.g. to protect the crops against insects, other pests or pathogens. The main route of exposure of non-target organisms (NTOs) to such toxins is uptake via the diet, either directly by feeding on living or dead plant material or indirectly by biomagnification within the food chain. Ecotoxicity tests are central to identify hazards for NTOs and most tests focus on lethality. At lower doses, stressors may also cause sublethal effects which can be biologically meaningful and negatively affect the sustainability of populations. From this perspective sublethal effects should, and in fact are foreseen to be included in the overall risk assessment. However, the number of test methods to assess sublethal effects, especially resulting from uptake with the diet, is limited. With the current project we focus on non-target invertebrates and want to screen how methods for the assessment of sublethal effects used for other stressors such as plant protection products, may be applied or modified to the assessment of GMO for the oral exposure route. The second aim is to evaluate how life-history theory, including the importance of constraints and trade-offs, may be informative for the assessment of sublethal effects. The results of the literature review will be used to develop a first proposal how sublethal effects on invertebrates could be better included in the risk assessment of transgenic crops.

2.02.P-Mo069 Bee-Longing Together - Using BEEHAVEecotox for a Better Understanding of (semi-)field-studies and Testing of Mitigation Strategies

Vanessa Roeben¹, Annika Agatz², Liubov Zakharova² and Thomas Preuss¹, (1)Bayer Crop Science, Germany, (2)IBACON GmbH, Germany

Insect pollination is an important ecosystem service and pollinators play an essential role in providing important pollination services to most wild plant species and cultivated crops. Thus, pollinators and as such honeybees, are a crucial part of the environmental risk assessment of pesticides in the European Union. In this context, mechanistic modeling offers a powerful tool to predict the exposure and effects on bees in the field. The BEEHAVE_{ecotox} model is the first model to mechanistically link the realistic exposure in the field with subsequent effects on different levels of the bee colony. We use the BEEHAVE_{ecotox} model which is implemented as an extension of the honeybee colony model BEEHAVE in NetLogo. BEEHAVE_{ecotox} consists of 4 modules: the exposure module, the water foraging module, the in-hive fate module, and the effect module. The model was setup to represent the conditions of (semi-)field studies in terms of number of adult bees, brood, honey and pollen stores, forage availability, and weather conditions. For this case study an insecticide application was simulated and the effects on the colony strength were assessed based on different mitigation strategies and (semi-)field conditions. The results show how BEEHAVE_{ecotox} can be used to help better understand effects and dynamics observed in (semi-)field studies. The model can be used to assess the cascading effects on different cohorts, such as foragers, on the longterm dynamics of the honeybee colony. The case study further investigates how BEEHAVE_{ecotox} can be used to test different mitigation strategies. Strategies can include application timing, such as application during day or night to avoid contact exposure. Furthermore, the BBCH stadium of a plant can be taken into account, e.g., via pre- or post-flower applications. Bees play a crucial role in the pollination of our agricultural products and thus it is important to be able to predict the exposure and effects on bee colonies in the field. The BEEHAVE_{ecotox} model is a suitable and validated tool to predict the effects of plant protection products on bees. It is the first model to mechanistically link exposure and effects and predict PPP exposure both outside the hive to foragers and within the hive from several routes of exposure. In this study we will show how such a model can be used to better understand (semi-)field studies and to test different mitigation strategies in the context of environmental risk assessment of honeybees.

2.02.P-Mo070 Predicting the Outcomes of Honey Bee Semi-Field Studies Using BEEHAVEecotox

Liubov Zakharova¹, Annika Agatz¹, Benoit Goussen¹, Vanessa Roeben² and Thomas Preuss², (1)IBACON GmbH, Germany, (2)Bayer Crop Science, Germany

Factors affecting honey bee health are manifold (including diseases, parasites, pesticides, environmental and socio-economic factors). The deriving complexity for the environmental risk assessment (ERA) of plant protection products (PPPs) for bees is currently assessed at the higher tier using semi-field and field experiments often conducted with honey bee colonies. The inability to conduct such studies for all plant protection products, their different use patterns, and at different climatic zones makes coherent availability of data and their interpretation and the use for higher-tier risk assessment challenging. There is a consensus amongst different stakeholders that mechanistic modelling can strengthen the ERA for pollinators. Currently, the BEEHAVE model is a freely available and potentially suitable candidate. Its potential suitability has recently been increased by the addition of a mechanistic ecotoxicological module. We present the results of a BEEHAVE_{ecotox} evaluation study conducted by comparing model simulations with observations made in three semi-field studies with tunnel setup. These semi-field studies were carried out to assess the impact of spirotetramat applied on different crops on bee colonies. The general tendency of the model predictions across the studies was to overestimate the impact of the PPP on the total colony strength. This observation is in line with the desired conservatism enforced into the conceptual development of the ecotoxicological module for BEEHAVE. Overall, the observed discrepancy between model predictions and experimental observations can be explained by the lack of empirical data on the food availability for model parameterisation, particularly in the post-exposure phase (landscape characterisation). The lack of information on food availability affects the model prediction for pollen and nectar resources in the hive, which causes the discrepancy in the abundance of bees. Additionally, standard semi-field studies lack precise information on the colony structure, which might cause additional inaccuracy in the model prediction. The addition of a mechanistic toxicological module that accounts for toxic impacts on adult and larva survival amplifies the potential use of BEEHAVE_{ecotox} for higher-tier ERA. The

parameterisation of the combined model can be lengthy and challenging. However, parameterisation of the ecotoxicological module is straightforward as standardised experimental data are available and no other information is required. Parameterisation of the combined BEEHAVE_{ecotox} model is only required for model evaluation studies. Once there is abundant evidence that the model serves the purpose for ERA, standardised simulation scenarios can be developed. Further, BEEHAVE_{ecotox} parameterisation for ERA purposes will no longer be a challenge.

2.02.P-Mo071 BEEHAVE and Brood Termination Rate - a Modelling Study How Magnitude and Duration of Effects Determine Colony Strength

Johannes Lückmann¹, Alexander Singer², Oliver Jakoby¹, Marcus Metz¹ and Daniel Ruf², (1)Rifcon GmbH, Germany, (2)RIFCON GmbH, Hirschberg, Germany

The brood termination rate (BTR) investigated in OOMEN and OECD GD 75 studies for pesticide risk assessments is the determinant of honey bee (*Apis mellifera* L.) mortality during development from egg to adult and thus influences colony strength. Colony strength as the number of worker bees per colony affects pollination services, yield of hive products and colony viability. In this context, a honey bee colony is regarded as viable and strong enough for successful overwintering and subsequent development to a vital colony in the following year, if at least 5000 worker bees are recorded prior to hibernation according to the respective EFSA Bee Guidance Document of 2013. The EFSA bee guidance gives levels of forager mortality due to pesticide exposure at which colony strength is assumed to fall below this threshold. Impacts of pesticides on honey bee brood are commonly investigated under semi-field, worst-case exposure conditions according to OECD GD 75 with the BTR as one key endpoint. Until now it remains unclear how magnitude and duration of effects on the BTR affect the strength of honey bee colonies before overwintering and thereby the hibernation ability and viability in the following season. Using the honey bee colony model BEEHAVE, we simulated how BTRs of different magnitude and duration affected colony strength prior to overwintering. Our results show how different BTR values influence the colony size, aiding the interpretation of experimentally observed BTRs in terms of consequences for colony strength and viability.

2.02.P-Mo072 BEEHAVE_{ecotox} - a Mechanistic Effect Model for Honeybees

Thomas Preuss¹, Annika Agatz², Benoit Goussen², Vanessa Roeben¹, Jack Rumke³, Liubov Zakharova² and Pernille Thorbek⁴, (1)Bayer Crop Science, Germany, (2)IBACON GmbH, Germany, (3)Syngenta, United Kingdom, (4)BASF SE, Germany

Insect pollination is an essential ecosystem service. Thus, pollinators and as such honeybees, are a crucial part of the environmental risk assessment of pesticides in the EU. Here, we introduce BEEHAVE_{ecotox}; an ecotoxicological model that mechanistically links exposure of bees in the field with the hazard profile for individual honeybees, leading to emerging colony effect. It is an addition to the extensively tested and widely used BEEHAVE colony model. The mechanistic link allows the translation of results from standard laboratory studies to processes and parameters relevant for simulating bee colony dynamics. The BEEHAVE_{ecotox} model includes 4 submodules: an external exposure module, in-hive fate module, water foraging module, and effect module. The external exposure module incorporates the concentration of PPPs in the bee-relevant matrices such as nectar, pollen, and water. When foragers forage on these matrices, they receive an oral dose of the PPP. Foragers can also be exposed via contact on the day of application. The water foraging module incorporates the water need for dilution of stored honey and cooling of the hive, including potential exposure to PPPs. The in-hive fate module simulates the entry and mixing of the PPP into the hive, through nectar, pollen, or water. The effect module includes the mortality due to exposure for the different cohorts. It uses the slopes and LD50 values of standard acute contact, oral, chronic oral, and larvae studies as inputs. The BEEHAVE_{ecotox} model was validated against two semi-field studies with a tunnel setup with two PPPs with different modes of action (dimethoate and fenoxycarb). The validation showed that the BEEHAVE_{ecotox} model captured the initial effects on colony strength and the subsequent colony dynamics well for both substances. The model predicted the relative magnitude of effect at colony level directly after application, as well as the long-term reduction in colony strength in the post-exposure phase after the tunnel and the lack of recovery of the colony. The BEEHAVE_{ecotox} model is a suitable tool to predict the effects of PPPs on bees. It is the first model to mechanistically predict PPP exposure to foragers and within the hive from several different routes of exposure. For the regulatory risk assessment the model can potentially be used to extrapolate from laboratory to semi-field and field studies, study the effects in different crops and regions, and to test different mitigation strategies.

2.02.P-Mo073 Impact of Plant Protection Products and Nutritional Resources on Bumble Bee Colony Development and Their Microbiome

Denise Castle¹, Abdulrahim Alkassab², Falk Gerdes², Silvio Erler², Hannes Beims³, Michael Steiner⁴, Ingolf Steffan-Dewenter⁵ and Jens Pistorius², (1)Julius-Kuehn-Institute, Braunschweig, Germany, (2)Julius Kühn-Institute, Germany, (3)Institute for Apiculture, Germany, (4)Technical University Braunschweig, Germany, (5)University of Würzburg, Germany

Bumble bees are exposed to multiple stressors, including exposure to agrochemicals, low food resource quality and parasites and pathogens. These stressors can affect bee health and vitality. In conventional agriculture application, plant protection products (PPP) play an important role to ensure production quality and quantity. During their foraging flights, bees and other pollinators are exposed to PPPs, either to single products or mixtures of PPPs. The objective of this study is to investigate the interaction between different stressors (different nutritional status and exposure to a mixture of PPPs) and the related impacts on bumble bee colonies and their microbiome under semi-field conditions. The semi-field study was realized with twenty tunnels: ten tunnels planted with the bee attractive sweet lupine (*Lupinus albus*) and ten tunnels planted with lupine and a flowering strip. Additionally, half of the tunnels were sprayed with a tank mixture of the fungicide prochloraz and the insecticide chlorantraniliprole. In every tunnel we placed two small queen-right colonies with the bumble bee *Bombus terrestris*. Various parameters were investigated such as mortality of adults, colony development and the composition of the microbiome in larvae,

adult guts and involucrem. Overall, mortality of adults in the treated variants (lupines and flower strips) was significantly higher compared to the control. The median mortality in the controls three days after application was 2 bees/colony compared to 12 bees/colony in the treated variants. In treated lupine, we found in median 6 dead bees/colony whereas in treated lupine with flower strips we found 21 dead bees/colony. The different mortalities in flower strips and lupine might be explained by a higher flight activity in flower strips. Number of young brood (eggs and larvae) did not differ between variants. However, the number of pupae in lupine was significantly lower compared to variants with flower strips. In combination with PPPs, the number of pupae shows significantly negative interaction effects. Our results show that the mixture of chlorantraniliprole and prochloraz has a negative effect on worker mortality, but not on brood, except for the combination with a diet containing monofloral lupine. Further studies should be conducted under realistic field conditions to evaluate the potential risk on bee health.

2.02.P-Mo074 Development and Validation of a Method by UHPLC-MS/MS in 'Multiresidue' Pesticides From Honey From Bees of the Genus *Tetragonisca angustula*

Rafael Sardeli de Oliveira, IQSC-USP, Brazil

The increasing for the demand of more sensitive methods also requires an improvement of the quality of chemical measurements, traceability, and reliability. To provide a safe new analytical method, with trustable results, and precise report of the sample characteristics, it must consider an evaluation called validation. The process of validating an analytical method must pass through the planning and execution of the method, to assure the method is reliable. One of the largest groups of tropical pollinators are the indigenous stingless bees, being the main pollinators of several ecosystem, some of them with a directly dependence of the bees. Seeking increase the production, the use of pesticides is a common measure to eliminate insects that devastates the crops. Whoever, these substances also reach non-target species, mostly pollinators that are gainful for the crop. The Tiamethoxam is an insecticide of second-generation neonicotinoids, largely used in crops in Brazil and worldwide. Mostly found in lettuce, cotton, potato, and bean, are also used in highly pollinator dependent crops like strawberry. Like the other neonicotinoids studied, Imidacloprid and clothianidin, its toxic effects on the pollinating agents have been described in the literature and associated with disorders and collapse of entire population of bees, being harmful to agriculture and endangered species. Abamectin is an avermectin insecticide that acts on the gamma-aminobutyric acid (GABA) receptors in both vertebrates and invertebrates, compromising the nervous system and is also largely used and not selective, reaching bees. The fungicide Difenconazol hasn't direct effect in invertebrates but, like the other four, are associated with Colony Collapse Disorder and must be studied. The present work aimed to determine and validate an analytical method for pesticides detection in honey from the indigenous bees *Tetragonisca angustula* in a way to contribute with studies of chronic effects of the exposure in bees and larvae. The modified QuEChERS extraction method was used to prepare samples, which were then analyzed by UHPLC-MS/MS. The validation parameters method must include a linear range between 0.05 and 0.0100 $\mu\text{g mL}^{-1}$ and precision values greater than 80%, accuracy less than 20% and three-level recovery satisfying the international validation guidelines. The Matrix effect was bellowing the allowed limits for honey. The method can be applied in further studies, becoming a useful tool determinate these pesticides and contribute to environmental risk assessment involving.

2.02.P-Mo075 Historical Control Data (HCD) in Non-Target Arthropod Field Studies: A Way Forward?

Melanie Hagen-Kissling¹, Bogdan Dehelean², Livia De Felici² and Josep Roig³, (1)Eurofins-MITOX B.V., Amsterdam, Netherlands, (2)Eurofins MITOX Group, Netherlands, (3)Eurofins MITOX Group, France

Non-target arthropod (NTA) off-field studies measure biological responses to test item exposure in highly complex natural systems. The settings usually include a control and multiple treatment groups. By design, the controls are not controlled systems as in laboratory studies, but untreated natural groups with a number of biotic and abiotic factors increasing the variability in the system (e.g. soil moisture, humidity, temperature, species interactions). In addition, these factors and their interaction with the NTA communities are not stable but can vary over time. It is critical to distinguish between this background variability and treatment related effects. Therefore, understanding the variability and optimising the statistical precision is critical. Due to several reasons (e.g. field size constraints), it is usually not possible to increase the number of replicates within studies, which would support statistical precision. Historical control data (HCD), which consist of pooled control group responses from previous (comparable) studies could help to distinguish between true treatment related effects from chance findings, as they can represent the extent of background variability (e.g. in abundance of NTA taxa). HCD data could be used to check if a control population, to which the test population is compared, shows a population development as expected from previous studies, or if this particular control population shows some specific features, which could lead to either masking of effects, or the appearance of an effect in the test item group, where indeed no such effect exists. Historical control data (HCD) are used in a variety of contexts already (e.g. mammalian toxicology studies), and recently, Brooks et al (2019) discussed, if and how HCD could be used in higher Tier studies (e.g. mesocosm studies). Here, we investigate, if HCD could be used in NTA off-field studies. We especially focus on the extent of variation in abundance data of NTA between years and if these differences can be explained by selected abiotic factors (e.g. weather data). Our data set comes from a (spatially constrained) meadow landscape in South-western France where NTA were collected over several years.

2.02.P-Mo076 Pyrethrin As a Toxic Reference for Field Studies With Non Target Arthropods (NTA)

Stefan Dehelean¹, Aude CAZANAVE², Brian Pater³, Koen Verhoogt⁴, Melanie Hagen-Kissling⁵ and Josep Roig², (1)Eurofins-Mitox, Netherlands, (2)Eurofins MITOX Group, France, (3)Wageningen University, Nederland, (4)Eurofins MITOX Group, Netherlands, (5)Eurofins-MITOX B.V., Amsterdam, Netherlands

In ecotoxicology, especially terrestrial field studies, the use of a toxic reference substance is a key validation tool. It is required to show that exposure of the non-target arthropod (NTA) community occurred and that the sampling was adequate to show effects.

Historically, pesticides such as organophosphates were the status quo choice to achieve the two goals and to ensure the regulatory validity of the studies. Their toxicity and persistence in the environment resulted in a Europe wide ban in 2020. This brought several challenges to the conduct of NTA studies due to a lack of a good replacement reference-substance. Other insecticides like synthetic pyrethroids, pyridines or insecticides from the ryanoid class have specific mode of actions, and thus, do not affect certain taxonomic groups, such as mites, springtails or Hymenoptera. Considering the importance of the toxic reference, we asked the following questions: Can we find a good replacement reference substance, for the organophosphate insecticides, which is less persistent and still achieves the goals of a toxic reference? To answer the question a field trial started in autumn 2021 in France. The trial was located in a natural meadow and had a randomized block designed with three treatments: water control, Pyrethrin and an organophosphate insecticide were applied. The NTA communities were sampled a few days before the application and at three days, one week, four weeks and six months after the application. The effects of the application of the two types of insecticides will be compared in terms of magnitude and duration of effects on a range of arthropod taxa, typically occurring in off-crop meadow habitats. Based on these results we will discuss the potential of pyrethrin as a more sustainable and environmentally friendly toxic reference in terrestrial ecotoxicology studies.

2.02.P-Mo077 Brood Termination Rate in Honey Bees: Comparison of BTRs Obtained Under Semi-Field Vs Open Full Field Conditions

Johannes Lückmann¹, Wally Bluhm¹, Stefan Kimmel², Thomas Steeger³ and Selwyn Wilkins⁴, (1)Rifcon GmbH, Germany, (2)Corteva Agriscience, Germany, (3)U.S. Environmental Protection Agency, United States, (4)Fera Science Ltd, United Kingdom

The potential impact of pesticides on honey bee (*Apis mellifera* L.) brood is often investigated under higher-tier semi-field, worst-case exposure conditions, according to OECD GD 75, with the brood termination rate (BTR) as one of the key measurement endpoints to be considered. Historical data from such semi-field studies, where brood cells with eggs are marked out and the 7-day exposure period takes place under tunnel conditions, show a high variability in the BTRs within the untreated control groups. In contrast, control BTRs obtained under full-field conditions with free-flying honey bees are substantially lower and less variable. The current analysis by the ICP-PR Bee Brood Working Group investigated the magnitude and variability in BTRs for a negative control and a reference chemical (*i.e.*, fenoxycarb) at two subsequent brood cycles, the first started under semi-field conditions (*i.e.*, while colonies are confined in the tunnels), while the second started under full-field conditions after completion of the first brood cycle when colonies were in the post-exposure monitoring phase of the study and colonies are no longer confined. In addition, the results obtained for the reference chemical fenoxycarb provide insight on the duration of effects on brood caused by an active substance with known insect growth regulating (IGR) properties. These results will be compared and discussed regarding the interpretation of BTRs gathered from bee studies.

2.02.P-Mo078 Honey Bee Brood Studies Under Semi-Field Conditions: Evaluation of Effects Mitigation With the Test Item Application During Evening in Absence of Bee Flight

Benedetta Ponti¹, Erica Tediosi², Francesca Noè¹, Silvia Messinetti¹ and Maria Chiara Neri², (1)ChemService s.r.l., Italy, (2)ChemService srl (Labanalysis Group), Italy

Honey bees (*Apis mellifera*) are important pollinators of major agricultural crops around the world. Populations of honey bees have been reported to be in decline in the EU and USA since 1961, and pesticide exposure has been suggested as one of the non-disease factors for this decline. Therefore, regulatory authorities around the world are paying close attention to this issue. A three-tier assessment scheme consisting of laboratory studies, semi-field studies, and field studies is a common approach for evaluating pesticide risks in honey bees. The decision-making scheme used in pesticide assessment in the EU and USA requires that a semi-field test is undertaken if effects on bee brood development cannot be excluded. In the present study the impacts of an insecticide belonging to the pyrethroid family was evaluated in a semi-field test. The application was performed during the full flowering of *Phacelia tanacetifolia* both during daily bee flight and during the evening without bee flight to evaluate the possibility of mitigation of the effects. The OECD No. 75 guidance document with some method improvements (use of bigger colonies, start in spring, use of large tunnels size) were followed with the aim to reduce the variability of the replicates and reducing the Brood Termination Rate (BTR, failure of individual eggs or larvae to develop) in the negative control. A honey bee semi-field test was successfully carried out: at the end of the test the BTR of the negative control was < 30 % and clear adverse effects were observed in the brood development after treatment with the reference item (BTR > 90 %) confirming the sensitivity and reliability of the test method. No statistical difference was observed between the BTRs calculated from the treatment during the flight activity and during evening without flight activity, and respect to the negative control. These results indicated that the test item could not represent a potentially unacceptable risk for honeybee.

2.02.P-Mo079 How to Feed the Mason Bee *Osmia bicornis* -Establishing a New Feeding Technique for the Acute Oral Bioassay With Solitary Bees

Timm Knautz¹, Christian Berg², Annika Barme¹ and Tatsuya Sekine¹, (1)Ibacon GmbH, Germany, Germany, (2)Eurofins Agrosience Services Limited, Germany

The loss of insect biodiversity in agricultural landscapes during the past decades indicates a need to extend the current risk assessment applied for pesticides from honey bees to other pollinators. One candidate species for establishing a new acute bioassay is the Red Mason Bee *Osmia bicornis*. Currently, an acute oral toxicity test for the solitary living Mason Bee (*Osmia* spp.) is under development by the OECD ring test group. Some of the major challenges observed during the initial trials were low food consumption, low number of feeders and a tendency towards elevated control mortality in the test (? 15 %). Hence, objective of this study was to improve the applied feeding methodologies to increase the acceptability of the treated feeding solution to the

test organisms and to reduce the control mortality. The experimental set-up of the ring test group was used introducing the single bees after 24 hours starvation in queen cages with queen cups containing sucrose solution. The weight of the queen cup was determined before and after exposure to assess the ingested amount of feeding solution. In a first trial, balls with different colours were added to the queen cups. The feeding solution was added afterwards. The introduction of coloured balls in the queen cups increased the relative amount of feeders up to 20 % compared to the queen cups containing only feeding solution. In a second trial, an adaption period was included to enable the mason bees to learn from each other how to feed from the queen cups ('advanced feeders'). The bees were held together in groups of the same sex beforehand and were fed the same way as in the following application. The number of feeders in the 'advanced feeder' group was 13 % higher compared to the 'first time feeder' group. Taking these measures a series of acute oral tests with *Osmia bicornis* resulting in low control mortalities (0 to 11 %) and representative amounts of feeders (54 – 90 %) were conducted. Conclusively, an improved feeding methodology and the inclusion of an adaptation period provided evidence that the challenges of the low food consumption could be solved, although further experiments should be conducted to confirm the inter-laboratory reproducibility of the results

2.02.P-Mo080 Interactive Effects of Agrochemicals on Survival of the Red Mason Bee (*Osmia bicornis*)

Anna Misiewicz¹, Maryellen Zbrozek², Ryszard Laskowski² and Agnieszka Bednarska³, (1)Institute of Nature Conservation, Polish Academy of Sciences, Cracow, Poland, (2)Jagiellonian University, Poland, (3)Polish Academy of Sciences, Poland
In agricultural landscapes, bees may be exposed to many plant protection products applied to crops that are attractive to pollinators. Apart from direct effects of individual active ingredients or their formulations actually used in the field, which are evaluated following legal requirements, agrochemicals applied in mixtures or sprayed consecutively in short time intervals may potentially interact with each other, causing unpredictable effects on bees. The mixture effects of agrochemicals are, however, poorly recognized, especially for non-*Apis* bees which, in contrast to honeybees, are not included in any standard procedures for ecological risk assessment of pesticides but may respond differently because of differences in physiology and ecology. We tested the impact of the following agrochemical formulations on survival of *Osmia bicornis* females: Dursban 480 EC (with the organophosphate chlorpyrifos), Sherpa 100 EC (with the pyrethroid cypermethrin), Mospilan 20 SP (with the neonicotinoid acetamiprid), Karate Zeon 050 CS (with the pyrethroid lambda-cyhalothrin) and Closer (with sulfoxaflor from the sulfoximine class of systemic insecticides). The agrochemicals were applied topically in three binary mixtures using a full factorial design with five concentrations. The concentrations were selected based on literature data for residues of their active substances recorded in the field and were expressed as the Recommended Application Concentrations (RAC). We found a strong negative effect of Dursban 480 EC ($p < 0.001$), with LT50 of 1 day at 0.7 and 1 RAC (LT50=30 days for control), a much weaker but significant effect of Sherpa 100 EC ($p = 0.02$) at 0.25 to 5 RAC (LT50 from 10 to 30 days), and no effect of their interaction on bee survival. In the case of Sherpa 100 EC × Mospilan 20 SP mixture, the effect of Sherpa 100 EC ($p = 0.02$) on bee survival was surprisingly lower with the presence of Mospilan 20 SP ($p = 0.001$ for interactive effect), even at 5 RAC. We also found a negative effect of Closer ($p < 0.001$), which was especially strong at RAC₇₅, and smaller effect of Karate Zeon 050 ($p < 0.001$) (visible mostly at RAC=25) and their interaction ($p < 0.001$) showing that at high Closer concentrations (RAC₇₅) the effect of Karate Zeon 050 on bee survival disappeared due to the high toxicity of Closer. This study was supported by National Science Centre, Poland (UMO-2017/26/D/NZ8/00606) and the EcoStack project (Grant Agreement 773554 - H2020-SFS-2016-2017/H2020-SFS-2017-2).

2.03 Biomonitoring of legacy and emerging contaminants in wildlife (Part I)

2.03.T-01 Quantification of the Sources of Lead Exposure in the Bearded Vultures From the French Alps

Rafael Mateo Soria¹, Lidia Giménez-Lozano², Rosa Rodríguez Martín-Doimeadios³ and Ilka Champly⁴, (1)IREC (CSIC- UCLM), Spain, (2)IREC Instituto de Investigación en Recursos Cinegéticos, Spain, (3)Universidad de Castilla-La Mancha, Spain, (4)ASTERS, France

In order to perform a risk assessment of lead ammunition on the conservation of bearded vultures in the Alps, we have estimated the contribution of the different sources and routes of Pb exposure in the bearded vultures, like soil ingestion during soil bathing, soil ingestion during feeding, ingestion of bones and soft tissues of prey and the ingestion of Pb shot pellets and fragments of Pb bullets. We also evaluated the contribution of these sources by the analysis of their stable Pb isotope signatures. Moreover, Pb analysis along sections the feather rachis was used to detect the pulses of abnormal exposures, which together with the ptylochronology may help to estimate the incidence of lead poisoning in the bearded vultures. Based on energetic (food) requirements of bearded vultures, we calculated the Estimated Daily Intake with regard to the mean concentration of Pb detected in food. The concentration of Pb, excluding two outliers in liver values, give mean values of 0.15 ppm for muscle, 0.22 ppm for liver and 0.40 ppm for bone. We may estimate and intake of less than 0.025-0.036 mg/day when feeding on soft tissues and 0.157 mg/day feeding on bones. Pb levels in bathing and feeding sites were relatively low (< 60 ppm), but soils from or around Pb mines showed elevated levels of Pb (10,000-20,000 ppm) that are well above the threshold of highly contaminated soils (>300 ppm) and comparable with polluted sites. Pb isotopic composition differed between primary sources (soil or ammunition), but also among different types of ammunition (bullets). The prey samples with highest Pb levels (potential contamination with bullets) showed a trend towards some of the bullet types and golden eagle samples and faecal samples with high Pb levels also showed lower 208/207 ratios. However, soil samples tend to show higher 208/207 ratio than ammunition (bullets). From feather analysis, we may conclude that the estimated prevalence of lead ammunition ingestion could be 5% and the monthly incidence 2.5%. In principle, as found in other vultures, lead from soil may contribute to the elevation of lead levels in the food chain and in the chronic exposure in the avian scavengers, but the extremely levels in some birds can only be explained by the ingestion of ammunition.

2.03.T-02 First Diclofenac Intoxication in a Wild Avian Scavenger in Europe

Marta Herrero Villar¹, **Émilie Delepoulle**², **Laura Suárez Regalado**², **Carlos Solano Manrique**³, **Carles Juan-Sallés**⁴, **Juan José Iglesias Lebrija**², **Pablo R. Camarero**⁵, **Fernando Gonzalez**², **Ernesto Álvarez**² and **Rafael Mateo Soria**⁶, (1)University of Castilla La Mancha, Ciudad Real, Spain, (2)Grupo de Rehabilitación de la Fauna Autóctona y su Hábitat (GREFA), Spain, (3)Centre de Fauna Vallcalent, Spain, (4)Noah's Pat, Spain, (5)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (6)IREC (CSIC- UCLM), Spain

Diclofenac is a non-steroidal anti-inflammatory drug (NSAID) extremely toxic for old world vultures after ingestion of domestic animals tissues previously treated with it. Diclofenac intoxication was responsible of dramatic population declines of three native South Asian *Gyps* vulture species two decades ago. Even so, this NSAID was authorised in 2013 for veterinary use in Spain, which hosts the biggest vulture populations in Europe. Including cinereous vultures (*Aegypius monachus*), which is classified as “near threatened” by the International Union for Conservation of Nature (IUCN). Cinereous vulture has been the target species in reintroduction and monitoring programs developed in Catalonia (NE Spain), achieving a stable population composed by 61 individuals and 15 breeding pairs in 2020. In September 2020, GPS-GSM movements from one tagged fledgling suddenly ceased and the individual was found dead in the nest. Data obtained from GPS device permitted to estimate the time of death, onset of poisoning signs and the potential time and location of diclofenac exposure. Post-mortem examination of the fledgling revealed severe visceral and articular gout, which was confirmed by histopathological findings that indicated that visceral gout was caused by a toxicant. In fact, diclofenac was detected at concentrations of 26.5 ng/g in the liver and 51.4 ng/g in kidney, respectively. Diclofenac levels are in the range of toxic concentrations for *Gyps* vultures, suggesting similar vulnerability of other genus of avian scavengers, such as *Aegypius*. In addition to diclofenac, tissues were subjected to a wider screening for other NSAIDs and chemicals commonly detected in poisoning events in Spain (carbamates, organophosphates...) obtaining negative results. Post-mortem examination findings, together with the toxicological and histopathological results, provide evidence that this individual died of diclofenac intoxication. This is the first case of diclofenac poisoning in Spain (and Europe), and the first report of diclofenac poisoning in cinereous vultures. The detection of one confirmed case of diclofenac intoxication in a closely GPS monitored vulture is of particular concern, due to it could indicate diclofenac intoxication can remain undetected in a high number of birds, underestimating its potential impact in vulture populations. This case report supports the need to closely monitor vulture populations and implement strict regulatory measures to prevent diclofenac poisonings.

2.03.T-03 Effect of Moulting Patterns on the Elimination of Hg in Seabirds' Feathers: Implications for Hg bioMonitoring

Paco Bustamante¹, **Alice Carravieri**², **Céline Albert**², **Fanny Cusset**², **Jérôme Fort**² and **Yves Cherel**², (1)La Rochelle University, France, (2)University of La Rochelle, France

As they occupy high positions in the food webs, seabirds are relevant bioindicators of biomagnifying contaminants such as mercury (Hg), one of the most toxic metal, which is now regulated by the UN Convention of Minamata. Feathers can be non-lethally sampled during the reproduction period, and constitute an interesting tissue to implement Hg biomonitoring programs at large spatial and temporal scales. After its bioaccumulation in the body, Hg is excreted in feathers during their synthesis because of its strong affinity for the sulphur residues of keratins. The elimination of Hg in body feathers depends largely on moulting patterns, which are variable depending on seabird species/group. For example, penguins have a catastrophic moult, with all body feathers being replaced in a highly synchronous manner once a year. Species such as alcids and larids have an asynchronous moult of the whole plumage or parts of it (e.g., nuptial moult). Finally, other species such as albatrosses have a prolonged, continuous moult. By studying Hg body feather concentrations of seabirds from the Arctic and the Southern Ocean, we propose to define different strategies from the “capital seabirds”, which bioaccumulate Hg over long periods to the “income seabirds”, which eliminates the Hg as it is incorporated. Our objective here is to show the fundamental principles which must be considered to use body feathers during Hg biomonitoring studies in the light of recent studies. Indeed, understanding the temporal integration of Hg in feathers is necessary to obtain reliable information for Hg biomonitoring, especially in the context of the Minamata Convention. It is thus crucial to know precisely the biology (moulting patterns) and ecology (distribution range, migration patterns) of seabird species in order to use body feathers for Hg biomonitoring, and identify areas where birds are most exposed.

2.03.T-04 Contaminant-Specific Power Analysis for the Common Buzzard, *Buteo Buteo*, for Cost Effective Monitoring

Lee Walker¹, **Nikiforos Alygizakis**², **Alexander Badry**³, **Ralph Buij**⁴, **Alessandra Cincinelli**⁵, **Rene Dekker**⁶, **Guy Duke**⁷, **Georgios Gkotsis**⁸, **Natalia Glowacka**², **Jan Koschorreck**⁹, **Tania Martellini**⁵, **Maria-Christina Nika**⁸, **Varvara Nikolopoulou**⁸, **M. Gloria Pereira**¹⁰, **Jaroslav Slobodnik**², **Nikolaos Thomaidis**⁸, **Gabriele Treu**³, **Nico van den Brink**¹¹ and **Paola Movalli**⁶, (1)UK Centre for Ecology & Hydrology, United Kingdom, (2)Environmental Institute, Slovak Republic, (3)German Environment Agency (Umweltbundesamt), Germany, (4)Wageningen University & Research, Netherlands, (5)University of Florence, Italy, (6)Naturalis Biodiversity Center, Netherlands, (7)University of Oxford, United Kingdom, (8)National and Kapodistrian University of Athens, Greece, (9)Umweltbundesamt, Umweltbundesamt, Berlin, Germany, (10)Centre for Ecology & Hydrology, United Kingdom, (11)Toxicology, Wageningen University, Wageningen, Netherlands

Raptors as apex predators are suitable sentinel species for contaminants in the environment. In particular, monitoring of contaminants in raptors may be used to assess the effectiveness of chemical risk mitigation measures and to assess the effectiveness of chemicals regulations more generally in their aim of protecting environmental (and human) health. It is important when interpreting monitoring data or planning such studies that we have an understanding of whether the number of samples used enables us to detect changes in exposure of the desired magnitude. This study used recently generated contaminant data for the common buzzard, *Buteo buteo*, to explore the relationship between the numbers of samples used the power to detect temporal changes in specific contaminants. To investigate the effects of bulk sampling, the Sum PCB, Sum PBDE, Sum SGARs, total mercury, and lead residues values was used as a reference data set, providing a guide as to the inherent variability of these

concentrations. We simulate the impact that within-year pooling of samples (of 2, 3, 4 or 6 individuals) has on the provision of representative country-scale data on the detection of changes over time in average residue concentrations with a view to assessing the power of monitoring with pooled samples. Power here means the size of change that can be detected with a certain statistical probability over a specified time period. We examine trade-offs between extent of sample pooling, number of pooled samples that are analysed, and projection of the magnitude of change in environmental concentrations that would be detectable if monitoring were continued for 5 and 10 years.

2.03.T-05 Chemical Contamination in the Muscle of Several Fish Marine Species: Comparison Between the Four Regional Areas of the Marine Strategy Framework Directive

Tiphaine Mille¹, Nathalie Wessel², Melanie Brun², Tiphaine Chauvelon³, Pierre Cresson², Marc Bouchoucha² and aourell Mauffret⁴, (1)IFREMER, RBE-BE, France, (2)IFREMER, France, (3)IFREMER, RBE-BE-LBCM, France, (4)BRGM, France

The European Marine Strategy Framework Directive (MSFD) aims to achieve or maintain the “Good Environmental Status” (GES) of European marine waters. To implement efficient monitoring programs, the contamination levels on target substances are required. The main objective of this study is to explore the potential differences of contamination levels among several marine fish collected in the four regional areas covered by the MSFD in France, for several family of inorganic and organic substances. Four economically important fish species (the European hake *Merluccius merluccius*, the whiting *Merlangius merlangus*, the mackerel *Scomber scombrus* and the spotted dogfish *Scyliorhinus canicula*) were sampled during the annual Data Collection Framework surveys, namely CGFS in the English Channel and Celtic Seas in 2018, EVHOE in the Bay of Biscay in 2018 and MEDITS in the Mediterranean Sea (Gulf of Lion and east of Corsica) in 2017. The concentrations of four families of chemical substances including both inorganic contaminants (trace metal elements) and organic contaminants (chlorobiphenyls, dioxin and furans and polybrominated diphenyl ethers), were measured in the muscle tissue of studied species. Variations in contamination levels among species and regional areas were assessed by permutational multivariate analysis of variance, based on distance matrix of contaminants concentrations. In addition, profiles of contamination were performed for chlorobiphenyls and polybrominated diphenyl ethers, according to the number of halogen atoms. According to substances families, variations in species and/or French subregional areas of MSFD have been detected and we will link them with subregion characteristics and fish biology. Preliminary results showed that higher levels of metals, especially in As and Hg, were observed in Mediterranean seas than in Atlantic ones and in spotted dogfish than the other fish species and higher levels of PCB were found in Bay of Biscay and English Channel. However, the fish species presented similar concentrations excepted the spotted dogfish from English Channel and Mediterranean Sea that showed lower PCB concentrations. In addition, PCB profiles were similar among species within the same regional area with the predominance of penta, hexa and heptachlorobiphenyls.

2.03 Biomonitoring of legacy and emerging contaminants in wildlife (Part II)

2.03.T-06 Anticoagulant Rodenticides in Birds of Prey From Western Canada: Exposure and Toxicity

John E. Elliott¹, Veronica Silverthorn², Sofi Hindmarch³, Sandi Lee⁴, Victoria Bowes⁵ and France Maisonneuve⁴, (1)Research Scientist, Environment and Climate Change Canada, Canada, (2)Department of Environment and Climate Change, Canada, (3)Fraser Valley Conservancy, Canada, (4)Environment and Climate Change Canada, Canada, (5)BC Ministry of Agriculture and Lands, Canada

As the dominant means for control of pest rodent populations globally, anticoagulant rodenticides, particularly the second generation compounds (SGARs), have widely contaminated non-target organisms. Here we present data on hepatic residues of anticoagulants in 748 raptorial birds found dead or brought into rehabilitation centres in British Columbia, Canada, 1988 to 2018. The incidence and extent of exposure varied by species, geographic area, and over time, with at least one SGAR residue detected in 74% of all raptor livers sampled. Hepatic SGAR concentrations varied from < 0.005 to 1.83 mg/g wet wt. By comparison, first generation compounds (FGARs), typified by warfarin, were detected in just 5% of the raptors analyzed. Highest rates of exposure were in larger owl species with diverse diets, that can include targeted rats, and that have inhabited suburban and intensive agricultural habitats, particularly Barred (*Strix varia*) and Great Horned (*Bubo virginianus*) owls. Overall exposure to at least one SGAR in those two species in the study area was 95% and 81%, respectively. Barn owls (*Tyto alba*), mainly a vole (*microtus*) eater, had a lower incidence of exposure of 66%. Concentrations of SGARs were highly variable, for example in Barred owls, the geometric mean total SGAR = 0.12, with a range < 0.005 to 1.81 mg/g wet wt (N = 208). Putatively bird-eating raptors also had relatively high incidence of exposure with Cooper’s hawks (*Accipiter cooperii*) at 75% (n = 36), Sharp-shinned hawks (*Accipiter striatus*) 60% (n = 15), and Peregrine falcons (*Falco peregrinus*) at 75% (n = 8). Analysis of the spatial trends and patterns revealed that exposure of Barred Owls occurred in landscapes with a high proportion of residential land use. Mean concentrations of brodifacoum and difethialone decreased in Barred and Great Horned owls, while bromodialone increased coincident with implementation of regulatory restrictions on their usage commencing in 2012, and which followed a trend among commercial applicators to move from brodifacoum to bromodialone about 2008.

2.03.T-07 Detection of Enrofloxacin and Ciprofloxacin in Domestic Animal Carcasses and Eurasian Griffon Vultures (*Gyps fulvus*) in Spain

Marta Herrero Villar¹, Patricia Mateo-Tomás², Ines Sanchez-Barbudo³, Pablo R. Camarero², Mark Taggart⁴ and Rafael Mateo Soria⁵, (1)University of Castilla La Mancha, Ciudad Real, Spain, (2)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (3)Institute for Game and Wildlife Research, IREC (CSIC-UCLM), Spain, (4)Environmental Research Institute, United Kingdom, (5)IREC (CSIC- UCLM), Spain

Veterinary pharmaceuticals are commonly used to treat livestock and therefore, residues can remain within their carcasses after

death with potentially risky consequences for scavengers. One example are antibiotics, which have already been detected in plasma of vultures. The presence of quinolones may be used as a contamination indicator to elucidate antibiotic contamination and potential effects in higher vertebrates. Griffon vultures (*Gyps fulvus*) are good sentinels. We present data regarding exposure to quinolones and residues in carrion supplied for their consumption in Aragon, NE Spain. Griffon vultures (n = 656) were captured at 19 feeding sites in Aragon (NE Spain) between 2008 and 2011. Besides, carrion samples from pig (n = 114), sheep (n = 25), cow (n = 2) and goat (n = 1), were taken during supplementary alimentation procedure in 10 feeding sites during 2011, 2017 and 2018 in Aragon and Castellon (close to Aragon border). Selected tissue samples were muscle and liver. Quinolones were detected in plasma from 13% (85/656) griffon vultures captured in Aragon. Enrofloxacin was detected in 11% (n = 73), while ciprofloxacin was detected in 6% (n = 38) and both could be detected in 4% (n = 27). Concentrations found ranged between 0.14 and 36.68 ng/mL for enrofloxacin and between 1 and 66 ng/mL for ciprofloxacin. Prevalence differed between feeding sites, showing up to 66% enrofloxacin and/or ciprofloxacin prevalence in feeding stations sampled in Teruel province. In addition, Pb concentrations detected also differ among feeding sites, suggesting exposure to antibiotics or Pb depending on carrion species ingestion. Enrofloxacin and ciprofloxacin were detected in 18% (26/142) of the total animal tissues supplemented at feeding stations in Aragon, mostly in pig (n = 24). We detected higher average concentrations in liver (1578 ng/g and 355 for enrofloxacin and ciprofloxacin, respectively) than in muscle (642 ng/g and 185 ng/g for enrofloxacin and ciprofloxacin, respectively). Moreover, we used Generalized Linear Mixed Models (GLMM) with multiple environmental variables to explain the presence of antibiotics in vulture plasma, which correlated positively with livestock related activity and negatively with gaming. Low levels of fluoroquinolones were detected in the plasma of griffon vultures, and prevalence varied depending on the feeding site where the vultures were trapped. These results indicate that vultures are regularly being exposed to quinolones through the carrion supplied at feeding sites.

2.03.T-08 Assessment of Per- and Polyfluoroalkyl Substances in an Arctic Seabirds Through Non-Invasive Sampling

Ignacio Martínez¹, Laurent Peluher², Patrick Pardon³, Alice Carravieri⁴, Jérôme Fort⁵, Pierre Labadie², Paco Bustamante⁶ and Hélène Budzinski⁷, (1)University of Bordeaux, France, (2)CNRS, France, (3)University of Bordeaux, CNRS, France, (4)LIENSs UMR 7266 CNRS-University of La Rochelle, France, (5)University of La Rochelle, France, (6)Université de La Rochelle, France, (7)Université de Bordeaux, France

The monitoring of pollutant trends in areas of high ecological relevance, such as the Arctic that is assumed to be a pristine environment, is an increasingly important issue. Areas with lower direct inputs of pollutants than populated areas are subjected to the transport of pollutants through atmospheric and ocean circulation. Emerging pollutants, such as per- and polyfluoroalkyl substances (PFAS), which are present in the composition of a large number of consumer products, may reach remote locations in the Arctic. PFAS are considered ubiquitous pollutants due to their occurrence at global scale in the environment, including biota. PFAS are found in high concentrations in Arctic birds, but their physiological and ecological effects remain almost unknown. The aim of the present study was to measure concentration levels and pollutant trends in the little auk (*Alle alle*), a seabird with an ecology and habitat that have been affected by global change and environmental pollution. The specific objective of this work was to assess the contamination levels of selected PFAS in the plasma of little auk at different life stages, to investigate potential maternal transfer and dietary exposure. Results showed a significant decrease in plasma concentration of total PFAS (?PFAS) was observed between 2018 and 2019 in both life stages of little auk. Linear perfluorooctane sulfonate (L-PFOS) was the main pollutant in seabird plasma, with the highest concentration found in chicks in 2018 (2919±792 ng/g - 27%; mean ± SD - RSD), followed by adults in 2018 (2661±1752 ng/g - 66%). As expected, the PFAS pattern was dominated by perfluorooctane sulfonate (PFOS), followed by even-chain carboxylates. Regarding parental transfer, chicks presented similar values to their corresponding parents from the same nest. Adult males presented greater variability of ?PFAS plasma concentration than either the females or chicks; nevertheless, males and females presented concentrations similar to those founded in chicks. PFAS were detected in all little auk samples collected from East Greenland; L-PFOS (linear and branched isomers) and PFUnDA were predominant. Results indicate decreasing concentrations from 2018 to 2019 in the plasma of those seabirds, which may be attributed to ecological factors (currently under investigation). PFAS levels were similar between adults and chicks, thereby suggesting the predominance of dietary exposure.

2.03.T-09 Comparative Study of Polycyclic Aromatic Hydrocarbons and Alkylphenols in Plasma of Seabird Chick Species From the English Channel

Laurence Poirier¹, Aurore Zalouk-Vergnoux², Abderrahmane Kamari², Jérôme Fort³ and Paco Bustamante⁴, (1)Nantes Université, France, (2)Nantes University, France, (3)University of La Rochelle, France, (4)LIENSs CNRS & Université de la Rochelle UMR 7266, France

Coastal ecosystems and particularly the estuaries of large river such as the Seine river, are contaminated by a multitude of chemicals, released by domestic, industrial and agricultural activities. Despite international restrictive regulations, polycyclic aromatic hydrocarbons (PAHs) and alkylphenols (APs) are still widely used or released in the environment and are targeted in the Water Framework Directive list of priority substances and priority hazardous substances. In aquatic ecosystems, long-lived species at the top of food webs, such as seabirds, are particularly relevant for monitoring the extent of trophic contamination by contaminants. The aim of the present study is to describe PAH and AP impregnation in seabirds from the Seine estuary, in comparison to a reference site with limited anthropogenic pressure (Chausey Islands). The role of the dietary ecology (inferred from stable isotopes of ¹³C, ¹⁵N and ³⁴S) was also investigated. Seabird blood samples were collected on chicks of 4 seabird species: Great black-backed gull (n=81), European herring gull (n=72), Lesser black-backed gull (n=25) and Common cormorant (n=12), collected from different sites (Antifer, Le Havre, Ratier Island) in the Seine Estuary (Eastern English Channel) and from the Chausey Islands (Western English Channel), between 2015 and 2017. Over the three years of study, we showed that gull and

cormorant chicks are exposed to both pyrogenic and petrogenic sources of PAHs as well as to APs. PAH signatures are dominated by low molecular weight congeners, reflecting an atmospheric exposure above the city of Le Havre. Feeding habitat seems to have an influence on AP concentrations: the individuals preferentially feeding on the mainland being highly exposed to APs. Correlation with physiological variables will be further investigated to estimate the impacts on the fitness of individuals.

2.03 Biomonitoring of legacy and emerging contaminants in wildlife (Virtual Only)

2.03.V-01 Invasive and Non-Invasive Heavy Metal Pollution Assessments in Wildlife: A Comparative Review

Catarina Vinhas Jota Baptista, DVM (Degree in veterinary Medicine)¹, Fernanda Seixas¹, José M. Gonzalo-Orden² and Paula A. Oliveira¹, (1)Universidade de Trás os Montes e Alto Douro, Portugal, (2)Universidad de León, Spain

Pollution by heavy metals and metalloids is a matter of concern in wildlife conservation and a current One Health problem. Using animal species in toxicology assessments (i.e. biomonitoring studies) positively contributes to a better understanding of health and environmental hazards in many aspects. For instance, to find out the most critical geographical regions or to evaluate their specific toxic effect in each organism. While some organs or tissues are ideal to evaluate pathological lesions as a result of the direct contact with these substances, others are more suitable to perform longitudinal studies in animals suspected of suffering from a long-time exposure. In general, non-invasive samples (as hair, feathers or faeces) represent easier ways of obtaining information on heavy metal exposure, but invasive samples (as internal tissues) provide a more complete and detailed perspective of this health problem. Thus, samples (either invasive or non-invasive) must be selected and interpreted according to the species involved, and also with the aims and conditions of the study. This review aims to compare invasive and non-invasive sampling in wildlife studies, providing a brief comparative resume. **This work was funded by National Funds through FCT under the PhD scholarship 2021.04520.BD.**

2.03.V-02 Linking Legacy Organic Contaminants to Maternal Foraging Areas in the Critically Endangered Kemp's Ridley Sea Turtle: Results From Sampling of Salvaged Eggs

Bethany K. Kunz¹, Donna Shaver², Kristen Hart¹, Jennifer Walker², David Alvarez¹, Michael Hooper¹, Danielle Cleveland¹, Craig Stricker¹, David Walters¹, Michael Iacchetta³ and Christopher Schmitt¹, (1)U.S. Geological Survey, United States, (2)US National Park Service, United States, (3)US Geological Survey, United States

Biomonitoring studies are particularly challenging for wide-ranging, rare species, such as sea turtles. Typically, female sea turtles are only encountered on land during brief windows of nesting. Sea turtle nests, however, are present for longer periods of time and can be easier to access, especially for closely monitored populations such as those of the critically endangered Kemp's ridley sea turtle (*Lepidochelys kempii*) in Texas, USA. Sampling of non-viable eggs may therefore be an effective, non-destructive tool for establishing baseline contaminant concentrations. In addition, because differences in maternal diet are reflected in eggs, chemical profiles of eggs may be useful indicators of where female turtles foraged. In the current study, we are examining legacy organic contaminants such as polychlorinated biphenyls (PCBs) and organochlorine pesticides (OCPs) in eggs of satellite-tracked female Kemp's ridley sea turtles. Thirty-nine turtles that nested in Texas from 2010 to 2013 were tracked after leaving nesting beaches and their foraging areas in the Gulf of Mexico were determined through state-space modeling. Composite samples (n=48) of non-viable eggs salvaged from the nests of these turtles were analyzed by dual-column gas chromatography with electron-capture detection. Preliminary results indicate that concentrations of many analytes were below the limit of quantitation (LOQ). However, detections above the LOQ were frequent for total PCBs, as well as OCPs formerly used in agricultural production (DDT and chlordane constituents) and fire ant control (mirex). Concentrations tended to be highest in eggs from turtles tracked to the northern Gulf of Mexico. These results demonstrate that sea turtles are still being exposed to legacy contamination, and that the presence of organic contaminants in eggs can be used to differentiate foraging areas. These results also support the analysis of non-viable eggs as a useful, non-destructive sampling strategy for biomonitoring studies of rare or endangered sea turtles.

2.03.V-03 Mercury Bioaccumulation in the East Himalayas of China: Elevational Patterns in Soils and Non-Volant Small Mammals

Yanju Ma¹ and Yiming Hu², (1)The Southern University of Science and Technology, China, (2)Guangdong Key Laboratory of Animal Conservation and Resource Utilization, Guangdong Public Laboratory of Wild Animal Conservation and Utilization, Institute of Zoology, Guangdong Academy of S, China

Mercury (Hg) is a global pollutant. Due to the “grasshopper effect” and “mountain cold-trapping effect” Mercury (Hg), as a global pollutant, its contamination has been documented in environmental compartments of the Himalayan region. However, little research exists regarding to Hg accumulation in terrestrial wildlife, as well as its driving factors. In this study, surface soil and small mammals were collected in the Lebu Valley, East Himalayas of China, in order to measure the uptake of the long-distance transported Hg along an elevational gradient approximately from 2300 to 5000 m a.s.l. The soil Hg concentrations were measured and predicted mostly by vegetation type as well as soil organic matter, while the Hg in hair of small mammals (Muridae and Cricetidae) showed deeply influenced by soil Hg. Notably, combined with the field survey data, soil and hair Hg were both enhanced in low and mid-elevations, which overlapped the distribution ranges of a majority of mammals. Overall, this indicates that Hg contamination in low- and mid-elevations poses a potential threat to the top predators that consuming small mammals directly or indirectly. Furthermore, our data advances the understanding of Hg dynamics in remote, high mountain ecosystems and provides baseline data for biomonitoring for reduction of Hg emission globally.

2.03.V-04 Mercury Content of Guano As a Proxy for Hg Exposure in Bat Colonies Located in Northwestern Italy

Davide A.L. Vignati¹, Laura Garzoli², Frédéric Gimbert³, Emanuele Ferrari², Paolo DeBernardi⁴, Elena Patriarca⁴, Roberta

Bettinetti⁵ and Angela Boggero², (1)CNRS, France, (2)National Research Council-Water Research Institute (CNR-IRSA), Italy, (3)University of Bourgogne Franche-Comté, France, (4)S.Te.P. Stazione Teriologica Piemontese, Italy, (5)University of Insubria, DISUIT, Italy

Bats provide important ecosystem services but are subject to several anthropogenic pressures including exposure to potentially toxic trace elements and organic microcontaminants. Species such as *Myotis blythii*, *M. capaccinii*, *M. emarginatus* and *Rhinolophus ferrumequinum* (all mentioned in annexes II and IV of the Habitats Directive 92/43 EC) form colonies in low-altitude sites and are particularly exposed to human-induced pollution (e.g., trace elements and other chemicals). In bat colonies, guano accumulates in large quantities and may be used as a proxy of organisms' exposure to chemicals (non-invasive biomonitoring). Among legacy contaminants, mercury (Hg) is of pivotal interest because of its tendency to biomagnify along the food webs and its possible transfer from aquatic to terrestrial ecosystems, notably through the emergence of insects with an aquatic larval stage. In the present study, samples of guano were collected in sixteen bat colonies located in Piedmont and Aosta Valley (northwestern Italy), freeze-dried, homogenized, and analysed for total Hg content. Thirteen sites are normally used by the previously mentioned species, while three sites host species belonging to the genera *Hypsugo* and *Pipistrellus*. Measured Hg levels ranged from 0.089 to 0.597 mg/kg, with the highest Hg concentration measured in a colony of *M. emarginatus* near a rice field agro-ecosystem. High levels (0.449 ± 0.021 mg/kg) were also observed in a mixed colony (dominated by *M. capaccinii*) roosting at Lake Maggiore, where Hg pollution of industrial origin occurred throughout the twentieth century. Our analyses did not detect preferential Hg accumulation neither for individual bat species nor for specific land uses or foraging habitats. Additional analyses (e.g., diet characterisation via metagenomics approaches) are needed to better understand the relationship between land use and Hg accumulation in different bat species and ecosystems.

2.03.V-05 Occurrence of Current Use Pesticides in Bumblebees and Environmental Matrices Under Different Land Uses Scenarios in the Southeast Pampas, Argentina

Franco Cecchetto¹, Agustina Villalba², Tomás Mac Loughlin³, Damián Marino⁴, Matias Maggi⁵ and Karina Miglioranza⁶, (1)IIMyC, CONICET-UNMDP, Mar del Plata, Argentina, (2)Instituto de Investigaciones Marinas y Costeras (IIMYC) CONICET, UNMDP, Argentina., Argentina, (3)Universidad Nacional de La Plata, Argentina, (4)Centro de Investigaciones del Medio Ambiente, Universidad Nacional de la Plata - CONICET, Argentina., Argentina, (5)Instituto de Investigación en Sanidad, Producción y Ambiente (IIPROSAM), CONICET, UNMDP, Argentina, Argentina, (6)University of Mar Del Plata, Argentina Bees (Apidae) are crucial in global biodiversity, ecosystems stability and crops production. In the last years, they have been threatened by several factors, such as agricultural intensification and excessive use of pesticides. In Argentina, the native bumblebee, *Bombus pauloensis*, is one of the most prevalent species of the genus, and could be useful for pollution biomonitoring. The aim of this study is to assess the impact of land use on the levels of Current Use Pesticides (CUPs) in workers and drones of *B. pauloensis*, flowers and soil from foraging sites near Mar del Plata City. Sampling sites included a conventional agriculture area (A1), an ornamental plants field next to a municipal waste landfill (A2), natural reserve with agroecological agriculture (A3) and urban area (A4), and were carried out during application (P1) and post-application (P2) periods of pesticides. 50 compounds were assessed by QUECHERS-LC-MS/MS. The highest pesticides levels were found in A1 for flowers and soils and general higher levels during P1 was seen in flowers. Ten compounds were detected in flowers, four in soil and one in bumblebees. The ?CUPs in flowers during P1 were found to be 10,70 (A1), 4,93 (A2), 1,55 (A3) and 3,07 ng/g (A4), while in P2 were 6,72 (A1), 1,77 (A2), 4,83 (A3) and 127,57 ng/g (A4). Soils showed ?CUPs levels of 3,00 (A1) and 0,9 ng/g (A3) during P1 (no detections in A2 and A4), while in P2 were 34,50 (A1), 5,13 (A2), 1,67 (A3) and 1,47 ng/g (A4). Metolachlor, Azoxystrobin, Imidacloprid co-occurred in flowers and soil. In flowers, Chlorpyrifos predominated (100% of samples(s.)) with a maximum of 7,90 ng/g (A1-P1) and a minimum of 0.67 ng/g (A3-P2), followed by Azoxystrobin (50% of s.) with a maximum of 0,69 ng/g (A1-P1). Curiously, Atrazine and Flurochloridone were found in A3 during P1, and remarkably, Cypermethrin was identified in A4 (P2) at 123,77 ng/g. In soil, Azoxystrobin prevailed (37.5% of s.) with a maximum of 1,67 ng/g (A3-P2). However, in bumblebees only Dimethoate was found in workers from A2 (P2), thus further research is necessary to re-evaluate pesticides impacts on this pollinator. The pesticide pattern seen in all matrices and periods highlights the impacts that conventional agriculture could have on bumblebee's habitat, which represents a key pollinator for many plant species in the area. To our knowledge, this work represents the first analysis of CUPs bioaccumulation in wild bees and related environmental matrices in Argentina.

2.03.V-06 Potential Adverse Effects of Organochlorines on Caretta CARETTA (Linnaeus, 1785) Hatchling Success: First Assessment in Tuscan Nesting Events (Italy)

Iaria Ceciari¹, Cecilia Mancusi², Guia Consales¹, Lorenzo Minoia³, Carlo Amico¹, Marco Zuffi⁴, Giuliana Terracciano⁵, Enrica Franchi¹, Alessia Prestanti¹, Francesco Bonucci¹, Fabrizio Cancelli⁶ and Letizia Marsili¹, (1)University of Siena, Italy, (2)Environmental Protection Agency of Tuscany Region, Italy, (3)Department of Physical Sciences, Earth and Environment, University of Siena, Siena, Italy, (4)University of Pisa, Italy, (5)Istituto Zooprofilattico Sperimentale Lazio Toscana, Italy, (6)Accademia dei Fisiocritici Siena, Italy

Among the three species of sea turtles that regularly live in the Mediterranean Sea, the loggerhead turtle (*Caretta caretta*, Linnaeus, 1785) is the most abundant and the only one nesting along the Italian coasts. Nesting events are reported in Tuscany only from 2013 where they are monitored from the deposition to the hatching. After hatching, in order to collect biological material such as unhatched eggs, pipped and hatchlings, the chamber nest is open. These samples collected during the digging can give valuable information about genetic, pathological, parasitological, toxicological aspects. In this study, for the first time in Italy, are reported the concentrations and the fingerprints of some chlorinated xenobiotics analysed in the unhatched eggs sampled from four Tuscan nests: Marina di Cecina (Li), Rimigliano (Li), Le Marze (Gr) and Riva del Sole (Gr). The toxicological analyses revealed the presence of HCB, 29 congeners of PCBs and the *op'* and *pp'* forms of DDT, DDE and DDD in all 52 samples (13

eggs for each nest). Even if the mean values of contaminant class in the four nests are different, all samples show the same following pattern: *PCBs*>*DDTs*>*HCB*. Levels of contaminants found in our study are lower than those found in the fewer available studies worldwide and they cannot be correlated to the hatching failure. Despite this, the research of these contaminants is still a priority especially in the Mediterranean basin, because even if they were banned many years ago their levels are still high in the marine biota. This reptile, a very long living species, can be considered an integrator of the pollution of Mediterranean basin and, for this reason, the scientific community suggest to consider *C.caretta* a bioindicator in the Good Environmental Status (GES) of Marine Strategy Framework Directive, not only for Descriptor 1 (Biodiversity) and 10 (Marine Litter), but also for Descriptor 8 named Contaminants

2.03.V-07 Risso's Dolphin (*Grampus griseus*) and Persistent Organic Pollutants (POPs): Preliminary Assessment in Stranded Specimens Along the Italian Coasts

*Lorenzo Minoia*¹, *Guia Consales*², *Ilaria Ceciari*², *Sandro Mazzariol*³, *Cecilia Mancusi*⁴, *Giuliana Terracciano*⁵, *Antonella D'Agostino*⁶ and *Letizia Marsili*², (1)Department of Physical Sciences, Earth and Environment, University of Siena, Siena, Italy, (2)University of Siena, Italy, (3)University of Padua - Italy, Italy, (4)Environmental Protection Agency of Tuscany Region, Italy, (5)Istituto Zooprofilattico Sperimentale Lazio Toscana, Italy, (6)Parthenope University of Naples, Italy

Both globally and in the Mediterranean Sea, ecotoxicological studies on Risso's dolphin (*Grampus griseus*, Cuvier 1812) are scarce. In general, we can say that there is still little knowledge about this species and, in fact, in the Mediterranean Sea, this cetacean has been classified within the *International Union for Conservation of Nature (IUCN)* as "Data Deficient". To fill these gaps at least in a small part, in this study, toxicological analyses were performed in 20 specimens of *Grampus griseus* stranded along the Italian coasts between 1998 to 2021. In the biological material (blubber, liver, muscle and brain) the presence of some Persistent Organic Pollutants (POPs): hexachlorobenzene (HCB), polychlorinated biphenyls (PCBs), dichlorodiphenyltrichloroethane and its metabolites (DDTs) were assessed. Through the biomagnification process, these contaminants can be found in much high levels at the top of the food chain and then, Risso's dolphin that is a top predators of marine food chain. These contaminants were evaluated, both quantitatively and qualitatively. The blubber is the biological material with the higher levels, followed from liver, muscle and brain, confirmed the results found in this species and in other cetaceans in the world. The results were discussed according to sex, age and stranding areas. No statistically significant differences were found between genders, age and stranding areas. The levels of POPs found in these specimens were the highest recorded among this species, except for two specimens stranded in 1995 in Ligurian and Tyrrhenian Sea.

2.03.V-08 Roe Deer Antlers As Monitoring Units to Assess Lead Exposure in a Floodplain Polluted by Historical Mining Activities in the Harz Mountains, Germany

*Catharina Ludolph*¹, *Uwe Kierdorf*² and *Horst Kierdorf*², (1)University of Hildesheim, Hildesheim, Germany, (2)University of Hildesheim, Germany

The Harz Mountains (Germany) are one of the oldest Central European industrial areas, and the pollution resulting from more than 3500 years of mining-related activities reaches far into the Harz foreland. Lead concentrations in hard antlers of 105 adult (? 2 years) roebucks (*Capreolus capreolus*) killed between 1939 and 2018 were analysed to assess lead exposure within the floodplain of the Innerste River, which is known to be strongly influenced by historical mining activities in its upper catchment area within the Harz Mountains. Antlers of 50 roebucks killed during a similar time period (1957 - 2018) in a control area not influenced by this river system were also examined. Antler lead concentrations of roebucks killed within or close to the Innerste floodplain ranged between < 0.17 mg Pb/kg (limit of detection, LoD) and 51.48 mg Pb/kg. Median lead concentration in antlers of roebucks killed within the floodplain was 11.12 mg Pb/kg, compared to 2.26 mg Pb/kg in antlers of bucks killed in the floodplain vicinity ($P < 0.01$). Variability of antler Pb concentrations in bucks killed in the floodplain vicinity (CV = 149.8%) almost doubled that of the bucks killed within the floodplain (CV = 75.1%), indicating a more heterogeneous Pb exposure of the former. Lead concentrations in antlers of roebucks originating from the control area, ranged between values < LoD and 5.56 mg Pb/kg, with a calculated median concentration also below the LoD. Lead isotope ratios of antlers from the Innerste downstream area (²⁰⁶Pb/²⁰⁷Pb: 1.179 - 1.181; ²⁰⁸Pb/²⁰⁶Pb: 2.083 - 2.085) overlapped with those established for hydrothermal vein deposits from the Upper Harz Mountains. Sampling year had no significant effect on antler lead concentrations in the bucks shot within and close to the Innerste floodplain ($F_{(1, 78, 444)} = 0.1402$, $P = 0.748$), which highlights the overriding role of lead from wastes of former mining activities in the Harz Mountains on the exposure situation of resident biota in downstream areas. This study demonstrates the long-lasting impact of the historical metal ore mining, processing, and smelting in the Harz Mountains on lead pollution in floodplains of rivers draining this area and the lead exposure of wild herbivores inhabiting these frequently inundated areas. Furthermore, it highlights the suitability of roe deer antlers for monitoring environmental lead levels and the usefulness of lead isotope signatures in antlers for source apportionment of lead pollution.

2.03.V-09 Thirteen Years After: Dynamics of Trace Metals in Free-Ranging Small Mammals Related to Soil Aging 2006-2019

*Shinji Ozaki*¹, *Francis Douay*², *Sébastien Détriché*², *Francis Raoul*³, *Renaud R Scheifler*⁴ and *Clémentine Fritsch*⁵, (1)University of Franche-Comte, BESANCON, France, (2)LGCgE - EA 4515, France, (3)University of Franche-Comte, UMR UFC/CNRS 6249, France, (4)University of Franche-Comte, France, (5)CNRS, France

In terrestrial ecosystems, persistent contaminants such as trace metals (TMs) are accumulated in soils and can be transferred to wildlife through food webs. The lability of soil TMs is time-dependent, and state changes over time are known as "soil aging." It has been reported that soil aging significantly affects the fractionation of TMs in soils that controls their environmental availability and bioavailability. Nonetheless, no study has dealt with the long-term effects of soil aging on the trend of

bioaccumulation of TMs in wild mammals. Therefore, it remains poorly known whether and how soil aging could be involved in the dynamics of TMs transfer in food webs. Based on long-term monitoring in a metal-contaminated site, we assessed the temporal change in (bio)availability of TMs in soils and the trends of TMs in a small mammal species. In this study, soil sampling was carried out in 2006 and 2019 over a 40 km² study area in the surroundings of a smelter located in northern France (Metaleurop Nord) which ceased operation in 2003. In both years, soil samples were taken in the same 37 woody patches located along a soil contamination gradient. The total concentration and sequential extraction of cadmium (Cd) and lead (Pb) in soils were measured. Wood mice *Apodemus sylvaticus* were sampled in the same woody patches in either or both spring and autumn from 2006 to 2019. The total concentrations of Cd and Pb in their liver and kidneys were measured as a proxy for bioaccumulation of TMs. Our primary analysis showed that the total concentrations of Cd and Pb in soils did not significantly change between 2006 and 2019. However, the most mobile fraction of Pb generally decreased, whereas less mobile fractions of Pb increased in many of the patches. These results suggest that Pb in soils became less available during the period. Concentrations of Pb in the tissues showed a decreasing trend, and this trend was more prominent in high contaminated habitats. Meanwhile, no general temporal trend was observed for Cd in the tissues. Overall, our results indicate that soil aging over 13 years played a role in the dynamics and transfers of metals. Changes in availability of TMs in soils probably modified bioavailability and transfers of metals in diet items of wood mice. Our results have strong implications on risk assessment, remediation strategies, and management of polluted sites, which should be implemented according to the spatial and temporal dynamics of TMs.

2.03.V-10 Use of Road-Killed Owls for Contaminant Monitoring

Maria Dulsat-Masvidal¹, Rui Lourenco², Rafael Mateo Soria³ and Silvia Lacorte⁴, (1)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (2)Universidade de Evora, Portugal, (3)IREC (CSIC- UCLM), Spain, (4)IDAEA-CSIC, Spain

In the present study we investigated the exposure of legacy compounds such organochlorine pesticides, PCBs, PAH, and emerging compounds such PFAS, pharmaceuticals, and currently used pesticides in road-killed nocturnal raptors. The purpose of the present study is to evaluate the effectiveness of using road-killed owls as a source of valuable samples to monitor environmental contaminants. We proposed owls as sentinel species to monitor contaminants because of their position in the top of the food chain and because of their likeliness to be found road-killed. Working on road-killed animals could be an effective way to establish monitoring programmes in areas without active sampling activities on raptors to obtain valuable tissues for chemical analysis in a non-invasive way. During a decade, road-killed owls found in Southern Portugal rural area were collected and stored from 2010 until 2019. 47 livers suitable for analysis were obtained from five different owls' species: *Bubo bubo*, *Asio otus*, *Athene noctua*, *Strix aluco*, and *Tyto alba*. Necropsies were practiced obtaining liver samples and individuals were sexed and aged. Liver samples were analysed for a total of 91 target compounds. The analytical procedures consisted in three different extraction methods and three different analytical methods based on liquid and gas chromatography coupled with mass spectrometry detection. The results showed the exposure of 20 persistent compounds including PAH, PCBs, and Organochlorine pesticides in all five species analysed. However, residues of emerging compounds were not detected in any sample. Organochlorine pesticides were the most prevalent group of compounds, specially 4-4'DDE present at high concentration levels in all analysed individuals. Age was found as an important factor to take into consideration for POPs bioaccumulation. Meanwhile no differences were observed between sex of individuals. Among the species, *Bubo bubo* and *Asio otus* presented high concentrations levels of legacy contaminants indicating their effectiveness as sentinel species. However, these species were not frequently found road-killed, so other species as *Strix aluco* could be more suitable to establish a monitoring scheme based on road-killed owls. Finally, the multi-contaminant monitoring is proposed to assess the impact of emerging compounds in livers from dead animals found in more anthropogenic landscapes.

2.03 Biomonitoring of legacy and emerging contaminants in wildlife (Poster)

2.03.P-Mo082 Assessment of Exposure to Anticoagulant Rodenticides in Wild Mesocarnivores Linked to Freshwater Ecosystems of the Region of Murcia (Spain) Using Faeces As Alternative Samples

Andrés-Esteso Mercedes¹, Pedro Jiménez¹, Livia Spadetto², Silvia Espin¹, Alicia Montano³, Judit Castellví-Xaus¹, Almudena Méndez¹, Antonio Juan Garcia-Fernandez¹ and Pilar Gomez-Ramirez¹, (1)University of Murcia, Spain, (2)Health Sciences, University of Murcia, Murcia, Spain, (3)Consejería de Agua, Agricultura y Medio Ambiente de la Región de Murcia, Spain

In spite of EU restrictions for the use of anticoagulant rodenticides (ARs), they still may pose a risk to non-target wildlife, either by the consumption of baits, but also indirectly by ingestion of exposed rodents. This study aims to evaluate the exposure to ARs in different mesocarnivores inhabiting freshwater systems in the Region of Murcia, as well as the factors that determine such exposure by collecting faeces as a non-invasive sampling method. For this purpose, 36 samples were collected in different localities from the following species: Eurasian otter (*Lutra lutra*), marten (*Martes foina*), fox (*Vulpes vulpes*) and genet (*Genetta genetta*). Different variables were categorised according to the land use of each habitat (forest, agricultural or peri-urban) and whether there were extraordinary sources of pollution such as wastewater treatment plants, agricultural activity, or the presence of artificial water reservoirs. Sample analysis was performed by HPLC-QTOF-MS after extraction using acetone. All ARs were detected, being coumatetralyl and difenacoum (25%) the most frequent, possibly due to their high persistence and the fact that they are mainly excreted via faeces. Warfarin and flocoumafen showed significant differences between species, being more frequently detected in genets. Genet was the species with the highest frequency of residue detection (75%), followed by marten and otter (47.06% and 44.44% respectively) and fox (33.33%). On the other hand, the fox which has great ecological plasticity showed the highest concentrations of brodifacoum, a widely used compound. The otter is the species in which the greatest variability of 6 compounds has been detected, probably due to their ecological habits. Coumatetralyl and coumafuryl were the

most commonly detected compounds in the agricultural habitat. The use of coumatetralyl is possibly associated with the existence of moles in home gardens. In conclusion, further studies are needed to know what causes the detection of warfarin in genet faeces and it is suggested that this non-invasive sampling method is a suitable tool for the detection of ARs residues. In addition, exposure is found to be influenced by factors such as interspecific feeding variation and habitat type. On the other hand, risk mitigation strategies are needed for application in all habitat types. Acknowledgements: Funded by Seneca Foundation (20945/PI/18). SE supported by IJCI-2017-34653. LS supported by 21413/FPI/20. Fundación Séneca.

2.03.P-Mo083 Occurrence of Per- and Polyfluoroalkyl Substances (PFAS) in Baikal Seals

Shannen Sait¹, Silje Fiskum Rinø¹, Susana Gonzalez¹, Mikhail Pastukhov², Vera Poletaeva², Julia Farkas³, Tomasz Maciej Ciesielski¹, Bjorn Munro Jenssen⁴ and Alexandros Asimakopoulos¹, (1)Norwegian University of Science and Technology (NTNU), Norway, (2)Vinogradov Institute of Geochemistry, Russia, (3)SINTEF Ocean, Norway, (4)Norwegian University of Science and Technology, Norway

The Baikal seal (*Pusa sibirica*) is an endemic freshwater seal species in Lake Baikal, Russia. As a top predator, the Baikal seal may be vulnerable to biomagnification of persistent organic contaminants. PFAS have proven to be bioaccumulative and associated with immunotoxic effects. Plasma, liver, brain and blubber from 18 Baikal seals (16 pups and 2 adult females, sampled 2011) were analysed for 36 PFAS using a rapid Hybrid[®]SPE extraction technique followed by ultraperformance liquid chromatography tandem mass spectrometry (UPLC-MS/MS) analysis. A total of 10 different PFAS were quantified across all matrices. Concentrations of PFAS (PFAS) in seal plasma were in the range of 10.1 - 88.7 ng/g ww (median; 25th - 75th percentile: 38.1; 28.9 - 39.5 ng/g ww) with PUnA and PFOS as the dominant PFAS with median concentrations of 11.1 and 8.52 ng/g ww, respectively. Hepatic concentrations of PFAS were in the range of 17.0 - 112 ng/g ww (53.1; 38.0 - 69.4 ng/g ww), similarly PFOS and PUnA showed highest median concentration in liver at 17.3 and 11.3 ng/g ww, respectively. Concentrations of PFAS in seal brain were in the ranges of 58 - 210 ng/g ww (65.7; 89.5 - 97.2 ng/g ww), and similarly PFOS and PFNA were detected at highest levels with median concentrations of 27.6 and 27.2 ng/g ww. However, detection rates were low for these compounds (less than 10% of individuals) and when considering only compounds that were detected in >50% of individuals, perfluorotetradecanoic acid (PFTDA), and PUnA were detected in highest median concentration at 6.61 and 1.85 ng/g ww, respectively. The lowest number of PFAS were detected in blubber with concentrations in the range of 25.8 - 37.5 ng/g ww (31.0; 28.1 - 33.6 ng/g ww) with 7H-Dodecafluoroheptanoic acid (PFHeA) and perfluoro-1-octanesulfonamidoacetic acid (FOSAA) showing highest median concentrations at 15.9 and 7.02 ng/g ww, respectively. PFAS concentrations were present in a similar magnitude of concentration regardless of sex or age (adult and pups). Levels of PFAS in this study were similar to those quantified in Baikal seals previously (sampled 2005) and other pinnipeds, with the exception of PFOS which was lower than reported in other pinnipeds. Geographic differences are likely attributed to different sources of local pollution. To our knowledge, this is the first study to quantify perfluorotridecanoic acid (PFTriDA), PFTDA and perfluoro-3,7-dimethyloctanoic acid (P37DMoA) in Baikal seals.

2.03.P-Mo084 Application of a Tiered Green Toxicology Approach During the Development of Alternative Surfactants

Marc Wollenweber¹, Jacob Ouellet², Carina Lackmann³, Jade Tessien⁴, Marina Sebastian⁵, Olga Linker⁵, Stefan Eichwald⁶, Niklas von der Assen⁶, Thomas-Benjamin Seiler⁷ and Henner Hollert⁸, (1)Evolutionary Ecology & Environmental Toxicology (E³T), Goethe University Frankfurt, Frankfurt am Main, Germany, (2)Goethe University Frankfurt, Germany, (3)Goethe-Universität Frankfurt, Germany, (4)Goethe University Frankfurt, Germany, (5)Covestro Deutschland AG, Germany, (6)RWTH Aachen University, Germany, (7)Directorate, Hygiene-Institut des Ruhrgebiets, Gelsenkirchen, Northrhine-Westphalia, Germany, (8)Goethe University Frankfurt am Main, Germany

For decades, large quantities of chemicals have been released into aquatic environments, leading to long-term damage to aquatic ecosystems and biota. These chemicals include not only known toxic substances, but also supposedly harmless compounds, so-called emerging pollutants, whose potential impacts on the environment have long been insufficiently studied and potentially underestimated. Emerging pollutants, used by everyday consumers (detergents, personal care and pharmaceuticals), can enter the environment both due to improper use and disposal as well as due to inadequate purification steps in wastewater treatment plants. In order to limit the development, production and use of emerging pollutants the so called Green Toxicology concept was developed. The aim of Green Toxicology is to identify potentially toxic products early during the development of new products and therefore shifting production and use towards products that are less toxic. In this context, Green Toxicology is essential for the identification of harmful substances and the development of environmental friendly alternatives ("benign by design"), but additionally enables resource- and cost-efficient development ("fail early, fail cheap"). Here, we apply Green Toxicology to the prototype study DreamResourceConti (DRC). DRC is a joint project between chemical industry and academia that aims to develop environmental friendly surface-active substances (surfactants) using CO₂ as a substitutional compound within the polymeric chain and replacing fossil raw materials. For DRC we developed a tiered approach that increases in complexity and selects possible prototype substances based on their environmental impact. This approach separates Green Toxicology into 3 phases: (1) Biodegradability and mechanism-specific screening (endocrine disruption, mutagenicity), (2) acute toxicity screening (algae, daphnia, fish) and (3) chronic toxicity screening (reproduction toxicity) and biomarker assessment (oxidative stress, multi-xenobiotic resistance). Phase 1 and 2 follow the proposed framework of the EU project SOLUTIONS (NORMAN bioassay battery). Based on the successful application and feasibility, we propose the tiered Green Toxicology approach as a novel tool for the development of sustainable and environmental friendly products.

2.03.P-Mo085 Chemical Analysis of Legacy and Emerging Pollutants in the Emblematic Arctic Bird, Ivory Gull

Ignacio Martinez¹, Laurent Peluhet², Patrick Pardon³, Jérôme Fort⁴, Guillaume Evanno⁵, Olivier Glig⁶, Glenn Yannic⁷, Pierre

Labadie² and H el ene Budzinski⁸, (1)University of Bordeaux, France, (2)CNRS, France, (3)University of Bordeaux, CNRS, France, (4)University of La Rochelle, France, (5)Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France, (6)Universit e de Bourgogne Franche Comt e, France, (7)Universit e Savoie Mont Blanc, France, (8)Universit e de Bordeaux, France

Pollutant trends are changing in the Arctic due to the sea ice shrinking, which causes a new threat to biota in this area. Some Arctic birds are closely linked with sea ice cover and have suffered significant global population loss. Therefore, they represent key organisms for understanding current impacts on the Arctic ecosystem. The present study is part of a larger project to assess the impacts of Global Change on an emblematic Arctic bird, the Ivory Gull (*Pagophila eburnea*). The specific objective of this work was to investigate the levels of legacy (polychlorinated biphenyls (PCBs) and organochlorinated pesticides (OCPs)) and emerging (per- and polyfluoroalkyl substances (PFAS)) pollutants in the plasma of Ivory Gulls. Fieldwork was carried out in 2018 and 2019 in northeastern Greenland (81.60  N, 15.57  W). A total of 22 individuals were caught in July 2018 (n=6) and July 2019 (n=16) and blood was sampled from the brachial vein on each bird. After collection, blood samples were immediately centrifuged for plasma acquisition. For PCBs/OCPs, analyses were performed on relatively small plasma amounts (100  L) by solid phase extraction (SPE) and gas chromatography-mass spectrometry (GC-MS). In the case of PFAS (25  L), we used online SPE coupled to high performance liquid chromatography tandem mass spectrometry (HPLC-MS/MS). Results indicated that OCPs were the most abundant compounds in bird plasma in 2018 (?OCPs = 209 180 ng/g) followed by ?PCBs (160 118 ng/g). In 2019, concentrations were similar: 97 37 ng/g for ?OCPs and 103 32 ng/g for ?PCBs. Of the 7 and 13 target PCBs/OCPs compounds, 5 and 8 were detected, respectively (limits of quantification in the range of 0.05 to 1.61 ng/g). The most abundant OCP was 4,4'DDE, accounting for 87% and 93% of ?OCPs in 2018 and 2019, respectively. CB-153 was the most abundant PCB, i.e. 46% in 2018 and 52% of ?PCBs present in 2019. In contrast to the results observed for PCBs and OCPs, the mean concentration of total PFAS (?PFAS) in plasma increased over time from 45 27 ng/g in 2018 to 97 35 ng/g in 2019. Out of the 17 target PFAS, 14 were detected (LOQ: 0.003 to 2.756 ng/g). The molecular pattern was dominated by PFOS and an increase of PFTTrDA concentration was observed between 2018 and 2019 from 2.5% to 7.9%. In summary, we showed the widespread occurrence of organohalogens in this Ivory Gull population. Preliminary results may suggest time trends that should be further investigated on a larger number of samples.

2.03.P-Mo086 Organochlorine Pesticides in Blood of Wild and Captive African Leopards, *Panthera Pardus Pardus*

Michelle van As¹, Nicholas J Smit², Nico Wolmarans³ and Victor Wepener⁴, (1)North West University, South Africa, (2)NorthWest University, South Africa, (3)North-West University, South Africa, (4)North-West University - School of Biological Sciences, South Africa

Compared to aquatic ecosystems, limited information exists on organochlorine accumulation in terrestrial ecosystems and this is specifically true for terrestrial carnivores that have received limited attention in terms of studies on pollutant bioaccumulation. The African Leopard, *Panthera pardus pardus* (Linnaeus, 1758), is a popular focal species for research by ethologists and ecologists, but a noticeable knowledge gap exists with regards to toxicological aspects. To address this gap, the aim of this study was to determine baseline organochlorine pesticide (OCP) concentrations in blood of live wild and captive leopards in South Africa, and to explore the relationship between OCP levels and different conservation management strategies. Peripheral blood samples of captive and wild leopards, representing regular and melanistic individuals within the captive population, were collected while under sedation. The  OCP concentrations in blood serum were detected by means of GCECD. Statistical relationships among pesticide content in leopards from three geographical areas, different sexes, age groups and conservation status were examined. Captive leopards from this study had a slightly higher mean  OCP concentration (901 ng.ml⁻¹) than wild leopards (768 ng.ml⁻¹), and captive females had lower mean levels of  OCPs (797 ng.ml⁻¹) than males (1058 ng.ml⁻¹). Melanistic leopards had higher mean  OCP concentrations (1038 ng.ml⁻¹) than their regular counterparts (810 ng.ml⁻¹) and adult individuals had higher concentrations of  OCPs (856 ng.ml⁻¹) than sub adults (838 ng.ml⁻¹). OCPs accumulated in the following order DDTs (27%) > HCHs (21%) > Heptachlors (15%) > CHLs (15%) > Drins (14%) > HCBs (8%). Differences in OCP composition profiles of resampled captive individuals were also found. This is the first report on OCP concentrations from leopards in Africa and highlights the need for this parameter to be considered in terms of the conservation management of healthy populations.

2.03.P-Mo088 Temporal Trends of Pollutants in Black Guillemot From the Faroe Islands

Katrin Hoydal¹, Birgitta Andreassen², Halla Weihe Reinert³, Sjurdur Hammer³ and Maria Dam⁴, (1)Environment Agency, Argir, Faroe Islands, (2)Fiskaaling, Faroe Islands, (3)Faroe Environment Agency, Faroe Islands, (4)Environmental Agency, Faroe Islands

Contaminants such as persistent organic pollutants (POPs) and mercury (Hg) are transported to the Arctic and sub-arctic area with long-range transport, and high concentrations can accumulate in biota. Seabirds can be used as a monitoring organism for pollution since they are relatively high in the food chain and high concentrations of contaminants have been reported in seabirds. Environmental pollutants have been monitored in Black guillemot (*Cepphus grylle*) on the Faroe Islands in connection with the Arctic Monitoring and Assessment Programme (AMAP) for the last couple of decades. The results from the monitoring studies can be used for analyses of time-trends for these contaminants in the area. Temporal trends of Hg in liver, feather and eggs, and PCBs and chlorinated pesticides in eggs of Black guillemot were analysed, and the possible influence of a changing diet was measured by analysis of naturally occurring stable isotopes of nitrogen (¹⁵N/¹⁴N). The time trends in black guillemots generally showed an increasing temporal trend for mercury in birds and eggs and a decreasing or non-changing trend for POPs in eggs from the Faroe Islands, indicating an increased deposition of Hg in the area, whereas the deposition of POPs is decreasing or stationary.

2.03.P-Mo089 Spatial Differences in Toxic Elements in Svalbard Reindeer Faeces From Central Spitsbergen, Svalbard
Malin Andersson Stavridis¹, Susanne Brix Røed², Brage Bremset Hansen³, Tomasz Maciej Ciesielski⁴ and Bjorn Munro Jenssen², (1)Department of Biology, The University Centre in Svalbard, Trondheim, Svalbard And Jan Mayen, (2)Norwegian University of Science and Technology, Norway, (3)Norwegian Institute for Nature Research, Trondheim, Norway; Centre for Biodiversity Dynamics, Dept. of Biology, Norwegian University of Science and Technology, Trondheim, Norway, Norway, (4)Norwegian University of Science and Technology (NTNU), Norway

The Arctic is considered an accumulation zone of long-range, oceanic, and atmospherically transported pollution. In addition, local anthropogenic activities could further contribute to the regional pollution level. The Svalbard reindeer (*Rangifer tarandus platyrhynchus*) is considered an ideal organism to use for monitoring studies in the Arctic. They are key components in Arctic terrestrial food webs and non-migratory, meaning that they reflect local pollution levels. Faeces have in particular been used as non-invasive means of biomonitoring as it reflects the diet of the reindeer, and thus their potential exposure to pollutants. This study aimed to compare the elemental levels and composition in reindeer faeces between two separate sites in central Spitsbergen, Svalbard, to assess the possible contribution of local anthropogenic pollution to the overall elemental concentrations, while also evaluating reindeer dietary elemental exposure. Elemental analysis was carried out (using HR-ICP-MS) in 97 faecal samples collected from Kapp Linné and Adventdalen (n=32 and n=65, respectively). Kapp Linné represents a pristine location, far away from local pollution sources, while there are more human activities (e.g., coal power plant and vehicles) occurring in areas around Adventdalen. The overall elemental composition in the faecal samples differed significantly between the two studied locations. Levels of copper, iron, zinc, and aluminium were higher in the faecal samples from Adventdalen ($p < 0.0001$), while concentrations of the non-essential elements lead (Pb) and cadmium (Cd) were higher at Kapp Linné ($p < 0.005$). Mercury (Hg) levels did not differ significantly between the two sites but showed tendencies to correlate with levels of selenium. The results indicated that Cd levels increased with increasing distance to the ocean (in Kapp Linné), while levels of Hg and Pb correlated with the snow depth (i.e., precipitation) at the location where the excrements were sampled. These results support that oceanic input and atmospheric deposition are important pathways for certain elements to reach Arctic terrestrial ecosystems. It further suggests that reindeer are exposed to a range of toxic elements through their diet. We can however not conclude whether these elements are absorbed in the gastrointestinal tract and distributed to other tissues based on solely faecal samples.

2.03.P-Mo090 Trace Element Distribution Within and Across Ungulate Species and the Potential of Hair As Non-Invasive Long-Term Biomarkers of Wildlife Health

Sophia V. Hansson¹, Åshild Pedersen², Niels Martin Schmidt³, Monica Lønborg Frederiksen⁴, Floris M. van Beest³, Heidi Huus Petersen⁵, Lars Holst Hansen³, Brage Bremset Hansen⁶, Mathilde Le Moulllec⁷ and Jesper Bruun Mosbacher², (1)CNRS, CASTANET TOLOSAN Cedex, France, (2)Norwegian Institute of Polar Research, Tromsø, Norway, Norway, (3)Department of Ecoscience, Aarhus University, Roskilde, Denmark, Denmark, (4)Vet Consult, Charlottenlund, Denmark, Denmark, (5)Centre for Diagnostics, Technical University of Denmark, Kgs. Lyngby, Denmark, Denmark, (6)Norwegian Institute for Nature Research, Trondheim, Norway; Centre for Biodiversity Dynamics, Dept. of Biology, Norwegian University of Science and Technology, Trondheim, Norway, Norway, (7)Centre for Biodiversity Dynamics, Dept. of Biology, Norwegian University of Science and Technology, Trondheim, Norway, Norway

Monitoring the health and trends of wildlife populations is an essential component of informed conservation management and can serve as an early indicator of ecosystem response to rapid environmental changes induced by e.g. climate or anthropogenic perturbations. However, detailed monitoring in remote areas such as the high-Arctic can be logistically and financially challenging. Additionally, the use of traditional sampling methods to infer wildlife health (i.e. collection of liver or serum samples) are often constrained as they require invasive approaches or rely on hunted animals or carcasses (either of which is impractical for remote, endangered, or declining populations). As such, there is a need for developing novel, non-invasive methods to serve as an indicator of individual health and population demographics/dynamics. While the use of hair/wool as a non-invasive monitoring tool to evaluate wildlife health certainly has potential, knowledge of the within individual chemical distribution, i.e. the distribution and coherence in concentrations of essential and non-essential elements in various tissues (e.g. blood, liver, muscle, spleen, hair) and its linkages to the overall health status of the animal are still largely unexplored. A better understanding of the linkages between trace elements in hair, internal tissues, and wildlife health is therefore needed before this non-invasive diagnostic tool can be used reliably to monitor the health status of wildlife populations. Drawing on iCap TQ-ICP-MS data from different ungulates; muskoxen (*Ovibos moschatus*), Svalbard reindeer (*Rangifer tarandus platyrhynchus*), red deer (*Cervus elaphus*) and fallow deer (*Dama dama*), we will present preliminary results on the trace element composition (e.g. Se, Cu, Zn, Mo, Pb, Cd, Hg) in hair and how this links to other internal tissues (e.g. blood) as well as to the general health status of the animal. By including and comparing results from a range of species and locations (i.e. Greenland, Svalbard and Denmark) our results will also form the foundation of a much-needed reference data base on the range of chemical composition in hair and wool from ungulate species. The end-goal of the project and this presentation is to assess the use of hair and wool as a novel, non-invasive long-term tool for monitoring the status and trends of wildlife populations, which in turn can inform and help shape wildlife management practices, especially in remote and logistically challenging areas such as the high-Arctic.

2.03.P-Mo091 Differences in Metal Compositions and Concentrations of Sympatric Predatory Fish and Squid From the South Atlantic Ocean

Ryan Uren¹, Francois Bothma², Carl van der Lingen³ and Hindrik Bouwman⁴, (1)Environmental Science and Management, North-West University - Potchefstroom Campus, Potchefstroom, South Africa, (2)North-West University Potchefstroom, South Africa, (3)Department of Environment, Forestry and Fisheries, South Africa, (4)North-West University, South Africa
Organisms at higher trophic levels may contain metals at elevated concentrations due to accumulation from various sources,

potentially making them more susceptible to detrimental effects, as well as passing them on to consumers. The concentrations of thirty metals were quantified in hake (*Merluccius capensis*), kingklip (*Genypterus capensis*), monkfish (*Lophuis vomerinus*) and chokka (*Loligo reynaudii*) from the South Atlantic Ocean of South Africa, using inductively-coupled plasma mass spectrometry. Nekto-benthic chokka differed significantly ($p < 0.05$) in metal concentrations and composition compared with the three demersal fish predators (hake, kingklip, and monkfish). Demersal fish metal concentrations and relative pattern compositions (fingerprints) were similar. Since the samples were collected within an 80 km radius, the differences are likely due to a combination of factors such as diet, habitat (depth), and differences in the physiological regulation of metals between cephalopods and fish rather than location. This study is the second of its kind, providing information on commercially important marine species of South Africa. Based on South African estimated daily intake, total hazard quotient, and European Union limits for Hg, Cd, and Pb, these four economically important species from the South Atlantic Ocean are safe for human consumption.

2.03.P-Mo092 A Multi-Tissue Investigation for Levels and Trophic Transfer Potential of Toxic Trace Elements in Cattle Egret (*Bubulcus ibis*)

Muhammad Hamza Zaman¹, Muteeb Ahmed Sheikh¹, Ghulam Mustafa¹, Syed Umair Shahid¹, Abdul Qadir¹ and Naeem Akhtar Abbasi², (1)University of the Punjab, Pakistan, (2)CEES, University of the Punjab, Lahore, Pakistan

Exposure to toxic trace elements in birds has become a matter of concern as they transfer through food chain and bioaccumulate in varying concentrations in different tissues posing serious health risks. Therefore, current study is designed to investigate to compare tendency of toxic trace elements viz. Cd, Cr, Pb, Cu, As, Hg to bioaccumulate in liver, kidney, blood, pelvic and pectoral muscles of Cattle Egret (*Bubulcus ibis*). Further, the trophic transfer potential (TTF) of these elements was also evaluated using prey/food samples of Cattle Egret. All of the selected trace elements except Hg and As were detected with varying concentrations in different tissues of Cattle Egret. In general, toxic trace elements followed the pattern as $Cu > Pb > Cd > Cr$. The maximum mean (Min-max) concentrations ($\mu\text{g/g ww}$) of Cu 0.58 (0.11-0.93) and Pb 0.46 (0.40-0.54) were recorded in blood. Whereas highest mean (min-max) concentrations ($\mu\text{g/g ww}$) of Pb 0.46 (0.40-0.54) was observed in liver. The greatest equal mean (min-max) concentration ($\mu\text{g/g ww}$) of Cr 0.17 (0.09-0.25), 0.17 (0.12-0.21) were recorded in pectoral muscle and liver, respectively. Blood and liver were found as the most contaminated tissues followed by kidney, pectoral and pelvic muscles. Differences of trace elements was found non-significant (all $P > 0.05$) among tissues of Cattle Egret reflecting their homogenous distribution in body. Principal component analysis (PCA) corroborated no strong association of any elements with any of the tissue. All the metals except Cr showed considerable higher tendency of trophic transfer potential through food chain in all the tissues of Cattle Egret ($TTF > 1$). The constant exposure of toxic trace elements which have potential to transfer through the food chain can adversely affect the already declining birds population throughout the globe.

2.03.P-Mo093 Bioaccumulation and Effects of Selenium From Surface Coal Mining on an Aquatic Songbird

Christine Bishop¹, Simon English², John E. Elliott³, Helmi Hess⁴ and Kim Cheng⁴, (1)Wildlife Research Division, Environment and Climate Change Canada, DELTA, BC, Canada, (2)University of Toronto, Canada, (3)Research Scientist, Environment and Climate Change Canada, Canada, (4)University of British Columbia, Canada

In birds, Selenium can induce non-reproductive chronic effects, impaired productivity through decreased fertility, and reduced egg hatchability and fatal embryo deformity. Here we examine the impacts on the American Dipper (*Cinclus mexicanus*) in fast-flowing mountain streams within the Elk Valley, BC, where the coal mining industry poses a variety of long-lasting impacts, including Selenium contamination, to surrounding aquatic ecosystems. The Elk Valley in southeastern British Columbia which is currently host to five active open-pit coal mines and there are plans for substantial expansion. To minimize adverse effects in aquatic organisms, the British Columbia Ministry of Environment has set a selenium concentration guideline in the water column at 2?g/L. In 2016, water directly downstream of active mines, in their standard operation, shows high levels of selenium up to 39.8?g/L. However, the water concentration guideline is inadequate to quantify risk to the ecosystem, as it is greatly complicated by wide variation in biological uptake and selenium speciation. We describe the reproductive status and contaminant levels in American Dippers in this system in the context of risk assessments for these birds and other species here and elsewhere.

2.04 Bringing together exposure and effects: towards a mechanistic understanding of the environmental risk of chemicals in aquatic ecosystems

2.04.T-01 Does Temperature Influence Pesticides' Toxicokinetics and Toxicodynamics Alike? An Investigation With the Full-Guts Model for *Gammarus pulex*

Annika Mangold-Doring¹, Anna Huang², Egbert van Nes³, Andreas Focks⁴ and Paul van den Brink⁵, (1)Aquatic Ecology and Water Quality Management, Wageningen University & Research, Wageningen, Netherlands, (2)Wageningen Environmental Research - WUR, Wageningen, Netherlands, (3)Wageningen University and Research, Netherlands, (4)University of Osnabruck, Germany, (5)Wageningen Environmental Research, Netherlands

As global climate change continues, environmental risk assessment (ERA) needs to consider the potential influence on pesticides' toxicity by temperature. However, the underlying physiological mechanisms of temperature effect on the toxicity of pesticides are poorly understood. To address this knowledge gap, mechanistic or process-based effect models based on toxicokinetic (TK) and toxicodynamic (TD) processes, like the general unified threshold model of survival (GUTS), are powerful tools. However, temperature is not integrated into GUTS models per default, limiting its application in ERA for future climates. Thus, we investigated how to consider temperature in GUTS models for pesticides explicitly. For this, we examined the chronic toxicity of imidacloprid (IMI) and flupyradifurone (FPF) and their TK in the freshwater shredder *Gammarus pulex* at different temperatures. With the results of these experiments, we performed a modeling study to investigate the influence of temperature on the TK and

TD of FPF and IMI in *G. pulex*. Model calibrations for the GUTS?FULL models were done in two configurations. In the first, we only corrected the TK parameter for temperature with the Arrhenius equation. In the second, both TK and TD parameters were corrected with the Arrhenius equation. Finally, we compared the performance of the models by using Akaike's information criterion. We found that model calibrations of both model configurations resulted in a good fit of the survival data of *G. pulex*. However, the second configuration performed significantly better than the first. Furthermore, the Arrhenius temperatures for TK and TD parameters differed for both chemicals. Thus, our results demonstrate that GUTS models perform better when temperature is considered for both TK and TD parameters and that both processes are affected by temperature differently. This study indicates that applying mechanistic effect models to experimental data gains insights beyond the standard toxicity information, i.e., which model processes are affected by temperature. Furthermore, explicitly accounting for temperature in GUTS models will reduce uncertainties in its application for ERA and allow a temperature neutral comparison for various contaminant's TKTD parameters between species.

2.04.T-02 Speed It up: How Temperature Drives Toxicokinetic Processes in Aquatic Invertebrates

Johannes Raths¹ and Juliane Hollender², (1)Uchem, Eawag, Zürich, Switzerland, (2)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland

Studies for the environmental risk assessment of chemicals are generally conducted under highly standardised laboratory conditions. However, environmental parameters and external stressors are known to exert a strong influence on organism fitness. The ongoing climate change draws a lot of attention towards the parameter temperature. Many studies found a higher sensitivity of aquatic invertebrates towards contaminants with increasing or dynamic exposure temperature. However, the exact mechanisms do remain unravelling. Few studies have been carried out to achieve a more structured and in depth understanding of this link. This study aimed to investigate the influence of temperature on toxicokinetic parameters in *Gammarus pulex* and *Hyalella azteca*. Bioconcentration experiments at four different temperatures (6, 11, 16 and 21°C) with a mix of 12 compounds were carried out using the two amphipod species. Tissue and medium samples were taken in regular intervals and analysed by online-SPE LC-HRMS/MS. From these data toxicokinetic rate constants were modelled and analysed in dependence of the exposure temperature using the Arrhenius equation. A positive relationship between uptake, elimination and biotransformation rates versus temperature was observed. Nevertheless, the kinetic bioconcentration factors (BCFs) of the compounds were generally similar between the different temperatures due to a similar Arrhenius temperature of the uptake and elimination rate constants. However, in some cases BCFs were decreasing towards higher temperatures. The later observation could potentially be explained by the influence of temperature on biotransformation rates, which was supported by high biotransformation product concentration. The present study demonstrated that temperature can be an important driver of toxicokinetic processes and provides data and methods for risk assessment implications. The obtained results help understanding the mechanisms of temperature on chemical uptake, biotransformation and elimination and their interaction resulting in different sensitivity towards chemicals. Further, generated toxicokinetic rate constants can support modelling of environmental exposure as well as toxicodynamic laboratory studies under different temperature conditions.

2.04.T-03 Developmental Insecticide Exposure of Zebrafish Induces Transient Locomotor Effects Mediated by Neuromuscular Alterations

Sarah Könemann¹, Melissa von Wyl¹ and Colette Michèle vom Berg¹, (1)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland

Among a variety of different modes of action, several classes of insecticides target the cholinergic system. Cholinergic signalling plays an essential role in critical developmental processes of the nervous system such as axon development or synapse formation. Thus, early developmental stages of organisms are particularly vulnerable to chemical exposure. Considering the high number of chemicals with neurotoxic potential, there is an urgent need for new developmental neurotoxicity test strategies involving alternative methods. One such method is the zebrafish light-dark transition (LDT) test, which measures the larvae's locomotor reaction to light changes. Although the LDT is widely applied, it is not yet fully understood whether detected alterations in locomotion reflect structural changes of the nervous system and how persistent these alterations are. This study investigated insecticide-induced locomotion effects in zebrafish and underlying structural changes in neuromuscular components required for locomotion. Therefore, locomotor behaviour of zebrafish larvae was measured after 6-day exposure to non-toxic insecticide concentrations. Additionally, heart rate and body length of each larva was determined. To analyse effects on motor axons and neuromuscular junctions, fluorescence labelling was applied. Reversibility of effects was assessed by exposing zebrafish for 6 days followed by a 3-day depuration phase in chemical-free medium. To monitor the recovery process, locomotion was measured daily during depuration, while body length and heart rate were measured only on day 9. Exposure to the tested organophosphate, carbamate, and neonicotinoid insecticides led to reduction in locomotion, while no effect was observed for the pyridine-derivates. The other tested endpoints showed a different effect pattern for almost all insecticides, while strong locomotor effects could be linked to defects in muscle fibres. The recovery experiment showed that most insecticide-induced behavioural effects recovered within 24 hours of depuration. However, larvae exposed to methomyl, pirimicarb, and thiacloprid, required more time to recover. The results underline that locomotion is a more sensitive endpoint than structural changes. Overall, by investigating the effects underlying alterations in locomotion, this study helps to improve the mechanistic understanding of insecticide-induced neurobehavioral effects.

2.04.T-04 Interpretation of Aquatic Risks at Landscape Scale Using a CASE Study of Pyrethroid Use in Belgium

Bas Buddendorf¹, Hans Baveco², Wim Beltman³, Maarten Braakhekke⁴, Louise Wipfler³, Sascha Bub⁵, Andre Gergs⁶, Sebastian Multsch⁷ and Thorsten Schad⁶, (1)Wageningen UR, Nederland, (2)Wageningen University and Research, Netherlands,

(3)Wageningen Environmental Research, Netherlands, (4)Wageningen Environmental Research, Nederland, (5)University of Koblenz-Landau, Germany, (6)Bayer Crop Science, Germany, (7)knoell Germany GmbH, Germany

The disregard of spatial-temporal dynamics of both pesticide exposure and organisms is a flaw in the current risk assessment methodologies. Additionally, guidance on how to assess environmental risks at the landscape scale in the regulatory context is lacking. Therefore, a framework is needed to i) link specific protection goals to landscape scale assessment endpoints, and ii) develop a common language among stakeholders. For this, example studies with concrete model outcomes are considered helpful. In this study we present such an example for aquatic organisms, with the final aim to feed into the discussion on the use of landscape scale models in ERA. For the example study, an integrated modular model system (xAquaticRisk) was developed that includes spatially explicit simulation of hydrology, pesticide application, fate, and effect models. The application of the xAquaticRisk landscape model to the Rummen catchment area in Belgium, is presented and risk to aquatic organisms is quantified. The Rummen catchment is dominated by the cultivation of fruit orchards. The use of PPPs in these orchards may impact aquatic communities by spray drift deposition onto water bodies. Spray drift resulting from annual single application of 12.5 g/ha insecticide (K_{oc} 1,024,000 L/kg) was simulated over a 20-year period from 1998-2017. Realistic mitigation measures were simulated, assuming 75% drift reduction and a 10 m buffer strip. The effect module Landscape-GUTS (based on the GUTS TKTD models for survival) simulates a GUTS model in all reaches of the Rummen catchment over the same 20-year period for *Asellus aquaticus*, *Cloeon dipterum*, and *Gammarus pulex*. Outputs from the LGUTS module were used to determine LP50 values (multiplication factor for the exposure profile that results in 50% mortality) per year and per reach.

2.04 Bringing together exposure and effects: towards a mechanistic understanding of the environmental risk of chemicals in aquatic ecosystems (Virtual Only)

2.04.V-01 Effect of WATER Exchange Rate in Spiked-Sediment Toxicity Tests With *Hyaella azteca* on Behavior and Bioaccumulation of Hydrophobic Organic Chemicals

*Kyoshiro Hiki*¹, *Fabian Fischer*², *Takahiro Nishimori*¹, *Satoshi Endo*¹, *Haruna Watanabe*² and *Hiroshi Yamamoto*², (1)National Institute for Environmental Studies (NIES), Japan, (2)National Institute for Environmental Studies, Japan

Spiked-sediment tests are widely used to assess the toxicity of hydrophobic and persistent chemicals to benthic organisms. During the test, overlying water is usually exchanged with clean water to supply oxygen and to remove excretes (e.g., ammonia). The frequency and volume of water exchange vary between laboratories and standardized protocols using the same test species, however, little is known about the effects of water exchange methods on temporal and special concentrations and observed toxicity in spiked-sediment tests. We performed 10-day sediment toxicity tests with the freshwater amphipod *Hyaella azteca* using three polycyclic aromatic hydrocarbons (PAHs; phenanthrene [Phe], pyrene [Pyr], and benzo[a]pyrene [BaP]) as model chemicals at five commonly applied water exchange scenarios. The five scenarios were: (i) static (i.e., no exchange), (ii) 3x/week at 2 volumes per day (i.e., semi-static), (iii) every day at 2 volumes per day, (iv) continuous at 1 volume per day (i.e., flow-through), and (v) continuous at 2 volumes per day. The total dissolved concentrations (C_{diss}) of PAHs in overlying water increased gradually in the static scenario (scenario i), whereas those in the other scenarios decreased at the timing of exchange and remained low as compared to scenario i. The difference in time-averaged C_{diss} in overlying water among scenarios was up to 3.7 times (Phe), 6.8 times (Pyr), and 35 times (BaP), whereas the difference in freely dissolved concentrations (C_{free}) was 1.6 times (Phe), 2.7 times (Pyr), and 1.5 times (BaP) at most. Mechanistic modeling revealed that slow chemical diffusion in the upper sediment could not compensate for the fast chemical outflux by water exchange, resulting in a chemical gradient from pore to overlying water. In contrast to overlying water, C_{diss} and C_{free} of PAHs in pore water did not differ among scenarios. In particular, the difference in C_{free} in pore water was within a factor of 1.5 for all the chemicals tested. The 10-day survival rate was above 70% in all the scenarios and the dry weight of amphipods ranged from 0.06 to 0.09 mg, both of which did not differ among scenarios. In addition, the bioaccumulation of three PAHs did not differ among scenarios; the body concentrations were within a factor of two. These results suggest that water exchange scenarios have a substantial effect on C_{diss} in overlying water but not on other concentrations and thus the bioaccumulation and toxicity of *H. azteca*.

2.04.V-02 Effects of Atrazine on the Breeding Activities and the Antioxidant Enzyme Activities of the Aquatic Snails *Lymnaea natalensis*

*Norah Basopo*¹, *Donald Ndebele*² and *Nomathemba Moyo*², (1)Applied Biology and Biochemistry, National University of Science & Technology, Bulawayo, Zimbabwe, (2)National University of Science and Technology, Zimbabwe

Adoption of modern farming methods has increased drastically the usage of the herbicide atrazine in Zimbabwe. Most farmers including small scale farmers have shifted from manual removal of weeds to spraying of herbicides to effectively kill weeds and promote growth of crops. Literature has shown that only small quantiles of the sprayed herbicide reach target weeds, the majority of the herbicides find their way to natural water bodies via, aerial drifts, and runoffs after heavy rains where they affect non target organisms. We investigated the effects of atrazine on the breeding activities as well as on the antioxidant enzyme activities of the water snail *Lymnaea natalensis*. Groups of 20 snails were exposed to water containing different environmentally relevant concentrations (0?g/L, 3?g/L and 30?g/L) of atrazine. The time taken for the snails to lay eggs and for the eggs to hatch were observed. After 3 months of exposure both adults and juvenile snails were sacrificed and homogenates prepared for analysis of superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase GPx and glutathione S-transferase (GST). The reproduction and the hatching of eggs significantly decreased in snails exposed to atrazine ($p < 0.05$). The activities of SOD, CAT, GPx and GST were enhanced (between 1.125 to 8 fold depending on the enzyme) in snails exposed to atrazine compared to enzyme activities in unexposed snails. These results showed that atrazine affected the wellbeing of the snails and the activated antioxidant enzyme activities observed were defense mechanisms in snails used for protection against the antioxidant effects of atrazine.

2.04.V-03 Toxicity of Selenium Nanoparticles on *Poteroiochromonas Malhamensis* Algae in Waris-H Culture Medium and Lake Geneva WATER: Effect of Nanoparticle Coating, Dissolution, and Aggregation

Wei Liu¹, Yuying Chen², Xiaojing Leng² and Serge Stoll¹, (1)University of Geneva, Switzerland, (2)China Agricultural University, China

Understanding the algal toxicity of selenium nanoparticles (SeNPs) in aquatic systems by considering SeNPs physicochemical properties and environmental media characteristics is a concern of high importance for the evaluation and prediction of risk assessment. In this study, chitosan (CS) and sodium carboxymethyl cellulose (CMC) coated SeNPs are considered using Lake Geneva water and a Waris-H cell culture medium to investigate the effect of SeNPs on the toxicity of algae *Poteroiochromonas malhamensis*, a widespread mixotrophic flagellate. The influence of surface coating, z-average diameters, ζ -potentials, aggregation behavior, ions release, and exposure medium properties on the toxicity of SeNPs to algae *P. malhamensi* was investigated. It is found that SeNPs are 5–10 times more toxic in Lake Geneva water compared to the culture medium, suggesting that the traditional algal tests in Waris-H culture medium currently underestimate the toxicity of NPs in a natural water environment. Despite significant dissolution, it is also found that SeNPs themselves are the toxicity driver, and dissolved ions have only a marginal influence on toxicity. SeNPs diameter is found a minor factor in toxicity. Based on a principal component analysis (PCA) it is found that in Lake Geneva water, the nature of the surface coating (CMC versus CS) is the most influential factor controlling the toxicity of SeNPs. In the culture medium, surface coating, ζ -potential, and aggregation are found to contribute at the same level. These results highlight the importance of considering in details both NPs intrinsic and exposure media properties in the evaluation of NPs biological effects.

2.04 Bringing together exposure and effects: towards a mechanistic understanding of the environmental risk of chemicals in aquatic ecosystems (Poster)

2.04.P-Tu046 Algae TKTD Modelling for Tier 2C Risk Assessment: Ring Testing the Validation Studies Using Flurtamone and the Alga *Raphidocelis subcapitata* (Korshikov, Nygaard, Komárek, Kristiansen & Skulberg 1987)

Cecilie Rendal¹, Roman Ashauer², Johannes Witt³, Thomas Preuss³, Ian Sims¹, Roger Baetscher², Sibylle Eck⁴, Eric Bruns³ and Andrea Alonsoramos⁵, (1)Syngenta, United Kingdom, (2)Syngenta Crop Protection AG, Switzerland, (3)Bayer Crop Science, Germany, (4)Bayer AG, Germany, (5)CropLife Europe, Belgium

For the purpose of validating TKTD modelling of algal growth tests, during 2021 two methods for testing of variable exposure regimes for algal growth tests were subjected to ring-testing using the test item flurtamone and the alga *Raphidocelis subcapitata* (Korshikov). The variable exposure algae growth tests aim for validation and calibration of TKTD models according to the EFSA Scientific opinion on TKTD modelling. Two methodologies were the subject of the laboratory comparison test performed, funded by CropLife Europe: Method A: a flow through method Method B: a semi-static method Nine laboratories from Europe and the United States of America participated in the ring-test: Fraunhofer Institute for Molecular Biology and Applied Ecology*, gaic Research Institute, Innovative Environmental Services (IES) Ltd, Witterswil, Switzerland*, Eurofins EAG Agrosience, Easton, MD*, Cambridge Environmental Assessment (CEA), Bayer AG_Division CropScience*, Scymaris, ECT Ecotoxicology GmbH* and Eurofins Agrosience Services Ecotox GmbH (Europe)*. All nine laboratories undertook the semi-static method, while the six participants, indicated with *, agreed to run the flow-through method. Here we concentrate on the semi-static method. The semi-static method used filtration to separate the algal cells from their growth medium and re-suspend them in fresh medium. Three concentrations were used for two exposure patterns. Each pattern employed two 24-h exposure periods, separated by a 24-h non-exposure period in the case of pattern 1 and by a 48-h non-exposure period for pattern 2. In both patterns, after the final exposure period, the algae were grown for a further 6 days to assess their growth over this period. The tests were initiated in November 2021 and the results for both exposure patterns will be presented. Their implications for TKTD algal growth modelling and potential uses in the aquatic risk assessment using Tier 2C will be discussed.

2.04.P-Tu047 Modelling the Contribution of Metabolites in the Overall Aquatic Toxicity of Imidacloprid

Anna Huang¹, Annika Mangold-Doring² and Paul van den Brink³, (1)Wageningen Environmental Research - WUR, Wageningen, Netherlands, (2)Aquatic Ecology and Water Quality Management, Wageningen University & Research, Wageningen, Netherlands, (3)Wageningen Environmental Research, Netherlands

The Environmental Risk Assessment (ERA) of pesticides is important for aquatic systems because pesticides used in farmland usually end up in the water system and may persist in the environment. However, the concentrations of these pollutants are usually not static because these compounds may be biotransformed by exposed organisms or abiotically degraded. Over time, a mixture consisting of the parent compound and metabolites will be produced, making risk assessment difficult. To understand the toxicity of pesticides and their biotransformation products and predict the effects of such mixtures during pulsed exposure, toxicokinetic-toxicodynamic modelling (TK-TD) is considered a promising tool. The TK-TD model quantifies the time course of internal concentration, which is defined as uptake, elimination, and biotransformation (TK), as well as damage and repair processes leading to toxic effects (TD). Imidacloprid is one of the widely used pesticides and has a delayed effect on various non-targeted species. This delayed or so-called time cumulative effect can be explained by the production of the biologically active metabolite imidacloprid-olefin as it has been demonstrated for two aquatic species, *Cloeon dipterum* and *Gammarus pulex* [1]. However, the exact contribution of the parent compound and the metabolite on the overall toxicity has not been distinguished. This study will use the published toxicity and toxicokinetic data of IMI and IMI-ole in two species to calibrate the parent-metabolite-TK-TD model. First, the TK parameters such as IMI uptake rate, elimination rate, biotransformation rate, and IMI-ole elimination rate are estimated. Next, we will obtain compound-specific TD parameters based on the acute toxicity data set of IMI and IMI-ole. Thirdly, we will use the obtained TK and TD parameters to calibrate the damage caused by IMI-ole by simulating

the effects of the internal concentration of IMI-ole only which is generated during IMI exposure. In addition, the parent-metabolite-TKTD model will be validated by pulse exposure experiments with the same species. The selection of the model fits will be based on the AIC value from the same dataset. Our results will deepen the understanding of the toxicity of pesticides in the context of biotransformation and better predict their effects. 1. Huang, A., et al., *The toxicity and toxicokinetics of imidacloprid and a bioactive metabolite to two aquatic arthropod species*. *Aquat Toxicol*, 2021. **235**: p. 105837.

2.04.P-Tu048 Novel MOLECULAR Tool for Monitoring Aquatic Quality

Marlea H.A.B. Wagelmans¹, Jari Claassen¹ and Aleida de Vos van Steenwijk², (1)Rijkswaterstaat, Netherlands, (2)Orvion, Netherlands

Due to industrial processes and (domestic) wastewater discharges all kinds of chemicals enter the environment. This has an effect on the water quality in all types of waterways. The Netherlands is a delta of a total of four international rivers. Rijkswaterstaat is responsible for the aquatic quality in the large rivers, lakes and the coastal areas. In the rivers Meuse and Rhine Rijkswaterstaat has border laboratories for continuous measurements using GC-MS and HPLC-UV which cover volatile and non-volatile, polar and non-polar organic compounds, as well as measurements of metals, nutrients and environmental conditions. Biological monitoring is also performed using an in-situ flow-through daphnid system and an algae flow-cytometer. In case of incidents the potential effect on the ecosystem is assessed by means of chemical analyses and some bioassays. However, this doesn't take into account the aquatic system itself! Therefore a pilot has started in order to assess the applicability of Next Generation Sequencing to monitor the effects on the aquatic ecosystem itself as well as the resilience of the aquatic system in case of incidents. The pilot is being performed at the border laboratory in the Meuse. Each month a water sample is taken and analyzed by means of NGS. This characterizes all known bacteria and archaea and gives a clear overview of the biodiversity. The biodiversity is compared with the results of the chemical analyses and the flow-through bioassays. During the pilot we will gain insight in the annual fluctuations of the biodiversity. In case of a highly increased value of a chemical compound either at the border laboratory or elsewhere in the river, additional samples will be taken in order to assess the effect of the compound on the biodiversity in the water as well as the resilience. On the poster the results of the pilot will be shown. Ing. M.H.A.B. Wagelmans MSc, National Water management Centre, Rijkswaterstaat, the Netherlands Ing. J. Claassen BSc, National Water management Centre, Rijkswaterstaat, the Netherlands A.A. de Vos van Steenwijk MSc, Orvion, the Netherlands

2.04.P-Tu049 How DO You Quality Control the Natural Environment?

Nadine Taylor, Marie Brown, Zoe Leanne Jones, Hanna Samantha Schuster and Adrian Terry, Cambridge Environmental Assessments, United Kingdom

The tiered risk assessment approach for plant protection products (PPPs) for aquatic organisms allows for the increasing complexity of studies, with increased realism of the experimental systems. Laboratory-based, lower-tier studies are easily implemented since all studies are performed to strict guidelines, under controlled conditions and have strict validity criteria to allow for standardised, reliable results and reproducibility of studies and their associated data. However, higher tier studies are purposefully uncontrolled to reflect the natural environment. So, how do you implement quality control processes, and generate reliable, reproducible, and robust data from a natural test system? Here we discuss the challenges involved in controlling the uncontrollable and present our findings, to date, on how we manage mesocosm studies to increase data robustness in the face of such intrinsic variation of the test system. Our approaches cover test design, the importance of pre-application phases and homogeneity, replication, sampling techniques, frequencies and representativity, and improving data robustness.

2.04.P-Tu050 Modified Exposure Studies in Aquatic Risk Assessments: How Useful Are They?

Katie Smith, Hanna Samantha Schuster, Nadine Taylor, Zoe Leanne Jones, Marie Brown and Amy C. Brooks, Cambridge Environmental Assessments, United Kingdom

Modified exposure studies are included as a refinement option (Tier 2C) for aquatic risk assessments for plant protection products (PPPs) under the current guidance (EFSA 2013). They can be a useful refinement option for scenarios where the predicted exposure profile indicates that exposure will not be continuous, and therefore ecotoxicity endpoints based on constant exposure may be over conservative. The overall aim of modified exposure studies is to more closely align the exposure profiles used in the ecotoxicity study with that predicted by the exposure profiles, such that we are assessing the more realistic risk from the proposed use of the PPPs. Although Tier 2C refinements are permitted under the current aquatic guidance, some EU Member States have indicated that they will not readily accept such an approach; for example, the central zone MSs recently concluded that Tier 2C refinements 'should generally not be supported at zonal level, considering that implementation in ERA is complex and linked to high uncertainties'. No further detail is provided regarding what 'complexities' and 'uncertainties' are being referred to. The aim of this poster is review active substance dossiers submitted and evaluated at the EU level in the last 6 years (allowing 2 years implementation of the EFSA (2013) guidance) to determine how many substances have attempted to use a modified exposure approach in the risk assessment and, of those, how many have been successful (and why), and where rejected, what were the reasons provided by regulators. Where concerns have been raised by regulators, we will discuss ways in which these could be addressed, aiming to conclude whether or not there is still a role for modified exposure studies in PPP aquatic risk assessments. We will also consider the usefulness of modified exposure studies beyond Tier 2C refinements e.g. supporting the use of TWA PEC_{sw} by demonstrating no latency of effects and linear reciprocity.

2.04.P-Tu051 Protection Goals and Associated Endpoints for Environmental Risk Assessment of Pesticides at Landscape-Scale, As Addressed by Spatial Population Models

hans haveco¹, Wim Beltman², Bas Buddendorf³, Maarten Braakhkke⁴, Louise Wipfler², Sascha Bub⁵, Thorsten Schad⁶ and Andre

Gergs⁶, (1)Wageningen University and Research, Netherlands, (2)Wageningen Environmental Research, Netherlands, (3)Wageningen UR, Nederland, (4)Wageningen Environmental Research, Nederland, (5)University of Koblenz-Landau, Germany, (6)Bayer Crop Science, Germany

Assessment at landscape scale is considered in Europe as an option to improve the realism and relevance of regulatory Environmental Risk Assessment (ERA) for pesticides. Spatially explicit population models quantifying effects at the spatial population level, are part of the extensive modelling toolbox dealing with all steps from application and fate of pesticides to effects at landscape scale. Population models are used to quantify endpoints allowing evaluation of to what extent protection goals at the population level are met. For landscape level ERA, additional endpoints might be needed, addressing specifically the larger spatial scale. Current assessment for aquatic systems focusses on the edge-of-field scale. Landscape level assessment should be more than an upscaled local assessment: not only accounting for a large number of spatially distributed edge-of-field situations, but also address the essential ecological aspects (and complexity) of spatially structured populations. For aquatic species this means explicitly accounting for spatial structure of habitat in e.g., an entire catchment, where some parts may be more exposed than others, account for the role of spatial processes (movement, dispersal, migration) providing functional connectivity and thereby playing an important role in e.g., local recovery, and accounting for larger temporal scale associated with spatial processes including local extinction and recolonization. A new endpoint in landscape level assessment may be the conservation of the spatial distribution (spatial integrity) of a target species population. Therefore, we explore a number of spatially implicit and -explicit endpoints for spatially structured populations, taking inspiration from e.g., metapopulation theory and the concept of source-sink dynamics. For an entire catchment, over a long period (>20 years) we apply a state-of-the-art individual-based population model for *Asellus aquaticus*, with individual sub-models for pesticide impact (reduced GUTS model for TKTD processes affecting survival and DEB - dynamic energy budget - for individual growth and development). The study is part of an extensive case-study for the Rummen catchment.

2.04.P-Tu052 Development of Sampling Methods to Facilitate Community Level Assessment of Chemical Impacts in Mesocosm Experiments for the Use in Aquatic System Models

Juergen Schmidt¹, Ann-Kathrin Loerracher², Tanja Wilke², Tido Strauss³, Damian Preziosi⁴, Nele Schuwirth⁵, Steven Bartell⁶, Isabel O'Connor⁷, Amelie Schmolke⁸, Nika Galic⁹, Roman Ashauer¹⁰, Roman Ashauer¹⁰, Peter Ebke² and Peter Ebke², (1)MESOCOSM GmbH, Institut für Gewässerschutz, Homberg Ohm, Germany, (2)MESOCOSM GmbH Institut für Gewässerschutz, Germany, (3)gaia Research Institute, Germany, (4)Integral Consulting Inc., United States, (5)Systems Analysis and Modelling, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland, (6)Cardno Inc., United States, (7)EBP Schweiz AG, Switzerland, (8)Waterborne Environmental, Inc., United States, (9)Syngenta Crop Protection LLC, United States, (10)Syngenta Crop Protection AG, Switzerland

Mesocosm experiments are well established and regularly used as higher-tier test systems in environmental risk assessment and the authorization of chemicals. Due to their complexity, it is possible to assess the effects of stressors on multiple phylogenetic and zoological taxa from different trophic levels of aquatic communities. Study designs, endpoints and sampling techniques of mesocosm studies are mainly driven by e.g. the type of test item and its exposure, but also by requirements of general guidance documents and regulatory acceptance. For sampling methods in particular, this results in a focus on reproducible samplings over a relatively long period, with an emphasis on capturing a consistently high number of taxa and individuals for statistical evaluation. Therefore, results of these methods are well suited to follow and compare populations of each species over time and thus identifying direct and indirect effects. In recent years, modelling approaches in ecotoxicology have been developed and applied in the context of environmental risk assessment. Considerable efforts are currently being made to gain a deeper mechanistic understanding of the processes and effects of chemicals that lead to observed patterns at the community level. In a comprehensive ring study, control data from seven mesocosm studies are used connected with four aquatic system models (ASM) with the intent of evaluating their potential to explain observed effects on population dynamics and to inform future risk assessment. Arising from this ring study is the need for the development of new sampling approaches and techniques to produce representative mesocosm system level information suitable for model input and validation. Mesocosm studies are currently aimed to sample sufficient numbers of organisms for statistical analysis, and area- or volume-based quantification has not been a focus of method development. In addition, enrichment methods designed for comparison of treatment and control make it difficult to estimate the abundance of organisms for the entire system. In this study, we present a series of sampling approaches in untreated mesocosms to evaluate extrapolation factors and variances of different traps for common endpoints. This serves as a necessary link between information from mesocosm studies for regulatory purposes and modelling approaches, opening the opportunity to use huge amounts of available high-quality data for the refinement of ASMs to assess potential effects of chemicals or exposure patterns.

2.04.P-Tu053 Identification of Structural and Functional Endpoints in Fluvial Biofilms for Ecosystem-Service Approaches in Ecotoxicology

Nuria Isabel Rubio Morales¹, Amina Khalid², Berta Boner³, Anna Romani⁴ and Helena Guasch⁴, (1)Centro de Estudios Avanzados de Blanes, Blanes (Girona), Spain, (2)University of Girona (UdG), Spain, (3)Centro de Estudios avanzados de Blanes (CEAB), Spain, (4)University of Girona, Spain

Rivers provide a wide range of benefits for human populations while also being one of the most impacted ecosystems worldwide, particularly regarding chemical pollution. Within rivers, microbial biofilms are especially connected to the capacity of the river to provide supporting environmental services, including nutrient and carbon cycling, and pollutant mitigation. As part as the PRORISK-ITN, the aim of this work is to improve Environmental Risk Assessment (ERA) by incorporating functional and structural endpoints in fluvial biofilms as early warning signs of ecosystem service loss and ecosystem damage. To do so, we installed simplified fluvial systems to study the effects of benzotriazole-1H (a commonly used anticorrosive) in fish (*Gambusia*

holbrooki) with and without the presence of epilithic biofilms; in the composition and viability of the biofilms themselves (*i.e.*, algal and bacterial biomass, diversity, photosynthetic activity), and their potential as ecosystem service providers (ESPs) (*i.e.*, nutrient uptake, carbon cycling, toxicant removal). This experiment will facilitate the translation of chemical pollution effects in wild fish populations and ecosystem services associated with biofilms.

2.04.P-Tu054 Characterization of Biofilms From Microbial Fuel Cells With Raman- and Scanning Electron Microscopy-Based Techniques

Irina Beer¹, Sarah Brunschweiler², Karl Glas², Martin Elsner² and Natalia Ivleva², (1)Institute of Hydrochemistry, Institute of Hydrochemistry - Technical University of Munich, Garching, Germany, (2)Technical University of Munich, Germany

Microbial fuel cells (MFC) are an innovative approach in wastewater treatment aiming to reduce the pollution of greenhouse gases, to minimize the energy costs for wastewater treatment by generating bioelectricity and, consequently, to enhance the self-sufficiency of small- and middle-sized enterprises [1]. The process of electricity production of such exoelectrogenic biofilms is studied in many scientific fields, e.g., electrochemistry, biology, and biochemistry. Different strategies have been recognized of how a microbial consortium can transfer electrons to an electrode surface. One of the mechanisms can be the direct transfer of the electrons through outer membrane proteins or proteins that are aligned to a pilus. These proteins mainly contain heme-groups for conducting redox-processes. Another possible way is to transfer electrons via mediators such as humic substances, flavin molecules or carotenoids that can be easily oxidized and reduced. Electrons can also be transferred via interspecies contact from one cell to another as an electron transport chain to a conductive surface [2]. This work focuses on the characterization of microbial biofilms with imaging methods such as scanning electron microscopy (SEM) and Raman microspectroscopy (RM) to get a better insight into the complex structure of a biofilm that is used in MFCs for the anaerobic treatment of brewery waste. This includes the visualization of the allocation of inorganic compounds, as well as cellular components such as proteins, lipids, and polysaccharides and their characterization. SEM provides information on the three-dimensional structure of biofilms and their heterogeneity to complement findings obtained by three-dimensional Raman imaging. Both techniques help to shed a light on the underlying mechanisms of electricity production. [1] Gude, V. G.: "Wastewater treatment in microbial fuel cells – an overview", *Journal of Cleaner Production* 122, p. 287–307, 2016. [2] Semenc, L., Aracic, S., Mathews, E. R., Franks, A. E.: "Electron transfer between bacteria and electrodes", *Functional Electrodes for Enzymatic and Microbial Electrochemical Systems*, p. 93–170, 2017.

2.04.P-Tu055 Effect of Emerging EDCs on Crustacean Amphipod Behaviour

Susanne Vogeler¹, Matthew Parker², Samuel Robson² and Alex Ford², (1)School of Biological Science, University of Portsmouth, Portsmouth, United Kingdom, (2)University of Portsmouth, United Kingdom

Environmental pollution is still one of the biggest man-made threats to freshwater and marine environments. Of particular concern are emerging contaminants, anthropogenic chemical pollutants that have recently been detected in aquatic ecosystems but have not been assessed or regulated sufficiently. Effects of emerging pollutants on marine life are often unpredictable. Many of these compounds are targeting the endocrine system of an organism (endocrine disrupting chemicals, EDCs), and they impact not only survival but also behaviour, reproduction and development. Risk assessments of these emerging EDCs are difficult, given the lack of appropriate standardised tests and types of species tested. Here, we use the marine amphipod, *Echinogammarus marinus*, as a non-model species to assess the impact of three emerging EDCs on behaviour, measured in distance travelled over a time period after different light stimuli (alternating 2 min light off, light on) in crystallising dishes. Our results showed that dexmedetomidine, the active ingredient of novel antifouling paints for boats and a proposed EDC for octopamine receptors in crustaceans, significantly increased locomotion in amphipods after 4 days exposure (1-100 µg/L), while long term exposure up to 2 weeks suspended this effect. Triphenyl phosphate, a modern plasticiser and flame retardant used extensively around the world, did not affect distance travelled during the first few days of exposure, but significantly reduced locomotion in all concentrations (0.1 µg/L – 1 mg/L) after 2 weeks. Thiram, an agricultural fungicide, also used in personal care products and antifouling paint, had a significant effect on mortality with an LC₅₀ of 562 µg/L after 7 days. Effects on locomotion were clearly observed after 4 days with a significant decrease in distance travelled at higher concentrations (10-500 µg/L) and a further decrease after 2 weeks even in low concentrations (1-500 µg/L). While it is difficult to predict the ecological impact of those exposures on amphipods, an altered locomotive behaviour often comes with severe costs, e.g., in terms of ability of predator avoidance or energy consumption. Nevertheless, our results provide crucial information for future regulatory assessment of these commercially used compounds by authorities, while also promoting crustacean behavioural tests as part of the risk assessments process in the future.

2.04.P-Tu056 Crustacean Behaviour As an Assessment Tool for Emerging Environmental Pollutants

Susanne Vogeler¹, Matthew Parker², Samuel Robson² and Alex Ford², (1)School of Biological Science, University of Portsmouth, Portsmouth, United Kingdom, (2)University of Portsmouth, United Kingdom

With environmental pollution still a present threat to our marine environments, accurate and rigorous assessments of emerging chemicals are crucial to protect aquatic ecosystems. The marine amphipod, *Echinogammarus marinus*, and the common shore crab, *Carcinus maenas*, are key ecological species along marine coastal shores. Marine amphipods are top mesograzers, feeding mostly on macroalgae and reducing algal biomass, while also providing a food source for various predatory invertebrates, fish and birds. Although being essential to their ecosystem, amphipods are not commonly used as model organism for risk assessment of environmental pollutants. The common shore crab is more frequently used, but research is often focused on diseases and genetics. However, assessments of the effects of potential contaminants on the behaviour of invertebrates are rare due to insufficient information available for standardised protocols, suitable endpoints and controls. Here, we present information about crustacean behavioural assays using the marine amphipod and shore crab as model species to assess their behaviour using different endpoints

(distance travelled, activity) and behaviour stimuli (light, vibrations). The Zantiks behavioural measurement system was used to quantify and automate the crustacean's behaviour by tracking each animal in a crystallising dish and record their movement and activity. Many environmental pollutants, in particular pharmaceuticals, ingredients of personal care products as well as additives in plastics are known to act on the endocrine system of non-target species by mimicking or interfering with endogenous hormone functions or production. To make adequate assessment of future potential endocrine disrupting chemicals, appropriate positive controls are necessary, but are currently not well-established. In an attempt to provide such controls, we tested a variety of neurotransmitter and neurohormones such as serotonin, dopamine and octopamine on our crustacean models to assess their potential as controls alongside exposure experiments. Our results will provide better understanding of crustacean behaviour assays as well as promote their usage in assessments of environmental pollutants.

2.04.P-Tu057 Behavioural and Reproductive Effect of Plastic Additives on a Marine Amphipod

Bidemi Green-Ojo¹, Marina Tenório Botelho², Gisela Umbuzeiro³, Vicente Gomes², Lena Grinstead⁴, Matthew Parker⁴ and Alex Ford⁴, (1)University of Portsmouth, Portsmouth, United Kingdom, (2)University of São Paulo, Brazil, (3)School of Technology-UNICAMP, Brazil, (4)University of Portsmouth, United Kingdom

Plastic additives are known for their endocrine disrupting properties even at low concentrations, which are suspected of causing behaviour and reproduction alterations in humans and animals. This study aimed to evaluate the impact of di-ethylhexyl phthalate (DEHP) and dibutyl phthalate (DBP) on locomotive activity and sperm count of a coastal marine amphipod *Echinogammarus marinus*. The second aim was to compare intraspecies variability from the behavioural data. Amphipods were exposed to five concentrations (0, 0.5, 5, 50 and 500) $\mu\text{g/l}$ of DEHP and DBP for 14 days. Behavioural analysis using an 8-min alternating dark and light protocol was performed on day 7 and day 14. Sperm count was analysed at the end of the 14 days exposure. DEHP exposure at all tested concentrations did not significantly affect the mean distance moved at the end of the experiment. DBP however resulted in a decline in the mean distance moved on day 14. The variability around the mean analysis suggests that animals exposed to DBP were more likely to react to a stimulus (light) during the 8 mins tracking time while DEHP had no significant variations. DEHP did not affect sperm counts; however, DBP significantly reduced sperm counts by 41.7% and 58.3% in 50 and 500 $\mu\text{g/l}$ respectively. In conclusion, DBP impacted the locomotion of amphipods but not the same for DEHP, and DBP significantly reduced amphipods sperm counts. The variations in a behavioural dataset can potentially provide new information that might be lost or hidden. This has implications for marine ecologies and underscores the continued necessity for continuous review of plastic additives to combat negative effects transferable to the population levels.

2.04.P-Tu058 Exposure of *Mytilus Trossulus* to Oxytetracycline: Immunological Effects and Histological Alterations

Anna Hallmann¹, Katarzyna Smolarz², Dagmara Leszczyńska¹, Justyna Świeżak², Magda Caban², Aleksandra Czumaj¹ and Alicja Michnowska², (1)Medical University of Gdansk, Poland, (2)University of Gdansk, Poland

Potentially harmful or harmful compounds including pharmaceuticals are commonly found in marine waters and sediments. Among those, antibiotics and their metabolites are detected worldwide in relatively high concentrations, posing a risk to non-target free living species. In the current presentation, based on obtained experimental results, we encounter the hypothesis that oxytetracycline (OTC) exposure induces oxidative stress in marine invertebrates, activates cellular detoxification processes including Phase I and Phase II xenobiotic biotransformation enzymes and multixenobiotic resistance pumps (Phase III). Performed exposure experiment in which a model *Mytilus trossulus* was exposed to 100 $\mu\text{g/L}$ of OTC resulted in no traces of cellular markers of the oxidative stress and no changes in expression of genes involved in detoxification processes (NADPH-CYP450 oxidoreductase CYP11L1, glutathione transferase GST γ 3, P-glycoprotein). Our results highlighted increased activity of phenoloxidase, a tissue-dependent activation of major vault protein (MVP) gene expression and a decrease in the nuclear factor kappa B-1 (NF- κ B) gene expression in OTC exposed mussels. OTC-related endocrine disrupting effect was only confirmed at the gonadal tissue level (atresia of female gonads), but not on the aromatization efficiency in mussels. We therefore believe that the above-mentioned results together with an elevated number of regressive changes and inflammatory responses in tissues such as gills, digestive system and mantle (gonads) underline OTC effects on bivalves immunocompetence and general health, yet without markers of oxidative stress being detectable.

2.04.P-Tu059 Does Norfluoxetine Impact the Blue Mussel *Mytilus Trossulus* at Early Developmental Stages?

Katarzyna Smolarz¹, Justyna Świeżak¹ and Anna Maria Gennaraki², (1)University of Gdansk, Poland, (2)Uniwersytet Gdanski, Poland

In the last decade pharmaceutical pollution, due to their ubiquitous character and potential persistence, became an emerging concern in aquatic environment. It is acknowledged that pharmaceuticals entering freshwater and marine environments are derived from human activities based on daily usage of prescribed medication and their main source are treated water disposal from various sewage treatment plants. While environmental concentrations of various pharmaceutical compounds and their derivatives are continuously being detected in the water column, sediments and biota, their mode of action on non-target organisms are still insufficiently explored. Also, studies addressing the effects of pharmaceutical metabolites on aquatic organisms are still scarce. Norfluoxetine is an active metabolite of fluoxetine, a common antidepressant belonging to the group of drugs called selective serotonin reuptake inhibitors (SSRIs) used worldwide. Its presence has been found in many freshwater and marine environments adjacent to highly urbanized and densely populated areas. Particularly limited is the knowledge on the effects of SSRIs on early life stages of invertebrate benthic animals which are usually more sensitive to environmental stress. Thus, the aim of the present study was to elucidate potential effects of norfluoxetine on the early embryos and larvae of the model Mytilidae species inhabiting coastal areas of the Gulf of Gdańsk (the Baltic Sea). Early embryos and gametes of the blue mussel *Mytilus trossulus* were exposed to environmentally relevant concentrations of norfluoxetine (100 ng/L) in laboratory conditions. Fertilization success,

embryo development rates and morphological features of trochophore larvae treated with this compound were investigated against control conditions to better understand the effect of norfluooxetine on early life stages of these marine ecosystem engineers. The preliminary results showed significant effects of norfluooxetine on the bivalve *M. trossulus* embryos during first 24 hours post exposure pronounced in delayed development of early pre-trochophore stages. We therefore believe that the presence of pharmaceutical compounds of that type in the natural aquatic environments may have repercussions on embryo development, larvae growth and morphology, and eventually fitness of this ecologically and economically important species.

2.04.P-Tu060 Acute and Mechanism-Specific Toxicity of Coastal WATER Extracts From Swedish Industrial Cluster in Zebrafish and Marine Medaka Embryos

Nastasia Schmitt¹, Jakob Pfefferle¹, Henner Hollert², Pedro Inostroza³, Thomas Backhaus⁴, Riccardo Massei⁵, Werner Brack⁶ and Sarah Johann⁷, (1)Goethe University Frankfurt am Main, Germany, (2)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (3)Biological and Environmental Sciences, University of Gothenburg, Gothenburg (Sweden), Sweden, (4)University of Gothenburg, Sweden, (5)University of Antwerp, Germany, (6)Helmholtz Centre for Environmental Research – UFZ, Germany, (7)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany

Estuaries and coastal aquatic environments are daily threatened by the input of high levels of anthropogenic contaminants such as pesticides, industrial chemicals and pharmaceuticals. For a concrete risk management, it is of major relevance to examine the impact of complex chemical pollution within representative case studies. In this context the present study investigates the adverse effects of coastal water samples from Stenungsund and nearby freshwater streams in Western Sweden. Stenungsund hosts the largest petrochemical hub in Scandinavia and a middle city, which are expected to contribute into the pollution load and therefore play a role affecting aquatic organisms. This work had the overall aim to quantify adverse effects on marine and freshwater fish model species *Oryzias melastigma* (medaka) and *Danio rerio* (zebrafish) using multi-level endpoints on acute and mechanism-specific toxicity. Particularly, our study contributes to identify the ecotoxicological drivers of toxicity in this well-studied region, highly impacted by chemical industry, and will support the practical applicability of *O. melastigma* as a standard model species in marine ecotoxicology. To this end, fish embryo acute toxicity (FET) tests were performed at marine (*O. melastigma*) and freshwater (*D. rerio*) conditions. Embryos were exposed to large volume solid phase extraction (LVSPE) extracts in MeOH (marine: relative enrichment factor (REF) 5–80, 0.2 % solvent; freshwater: REF 5–40, 0.1 % solvent) shortly after fertilization. Embryos development was monitored every 24 h up to 192 (medaka) and 120 (zebrafish) hours post fertilization according to OECD 236. To investigate mechanism-specific endpoints on neuro- and cardiotoxicity with enzymatic biomarkers (EROD, AChE, CAT) and motor behavior alterations (spontaneous tail coiling, light dark transition test), embryos were exposed to sublethal concentrations of the extracts (EC5-20). Preliminary results with zebrafish indicated concentration-related increases of (sub)lethal effects and mortality for freshwater samples. In contrast, none of the marine water samples showed a distinct concentration-related increase in sublethal and/or lethal effects. In both species, most frequent effects were the impairment of the cardiovascular system as well as a reduced pigmentation. For a comprehensive interpretation of the current findings, the biological effect data will be compared with findings from chemical analysis which is currently in progress.

2.04.P-Tu061 Effect of Pesticide Prochloraz on Embryo-Larval Development of Common Carp (*Cyprinus carpio*)

Denisa Medková¹, Pavla Lakdawala², Jana Blahová², Aneta Hollerová³, Zdenka Svobodová² and Jan Mareš¹, (1)Mendel university in Brno, Czech Republic, (2)University of Veterinary Sciences Brno, Czech Republic, (3)Department of Infectious Diseases and Preventive Medicine, Veterinary Research Institute, Brno, Czech Republic

In the few past decades, water pollution caused by pesticides has become a commonly discussed issue including many scientific studies published on the presence of pesticide residues in the environment and their negative effect on non-target species. Pesticides are commonly used in agriculture and in households. Since they are persistent and might have bioaccumulation potential, they have been detected in surface water. Their residues can have a negative effect on aquatic biota, such as fish and other non-target organisms. Prochloraz is widely used imidazole fungicide, among other toxic properties it is also considered a potential endocrine disruptor. The aim of this research study was to describe the effects fungicide prochloraz on development of common carp early life stages using the Early-live Stage Toxicity Test according to the Guideline for Test No. 210. Five different concentrations of prochloraz (0.1 µg/L, 1 µg/L, 10 µg/L, 100 µg/L and 1 000 µg/L) were applied to water for 31 days with fresh solution replacements twice a day. In the study, statistically significant changes were observed at high tested concentrations. The results of the study showed that fungicide prochloraz had a negative effect on fish development at some tested concentration. This research was supported by project PROFISH – Mendel University in Brno, CZ.02.1.01/0.0/0.0/16_019/0000869 and IGA VETUNI 223/2021/FVHE.

2.04.P-Tu062 Assessing Critical Windows of Insecticide Exposure During Zebrafish Development

Melissa von Wyl¹, Sarah Könnemann¹ and Colette Michèle vom Berg¹, (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland

During its development, the nervous system is most vulnerable to chemical exposure. Particularly, neuroactive chemicals, designed to target the nervous system, can interfere with tightly orchestrated developmental processes. Any disturbance of these processes can lead to impaired neuronal functioning, which severely reduces the fitness of the organism. Among others, insecticides represent a large group of neuroactive chemicals, which are inevitably released into the environment. Insecticides are applied primarily during spring and early summer such that insecticide application coincides with spawning season of many aquatic species, including fish. It is therefore unavoidable that fish and other species are exposed during early development. This study aimed to investigate which stages of the early development of zebrafish were most susceptible to sub-lethal insecticide

exposure. To cover different periods of neuronal development, zebrafish were exposed to two organophosphate (OP), two carbamate (CBM), and two neonicotinoid (NIC) insecticides in eight exposure scenarios. The latter included exposure from 0-1 days post fertilization (dpf), 1-2 dpf, 2-3 dpf, 3-4 dpf, 4-5 dpf, 5-6 dpf, 0-6 dpf, and unexposed control. After each exposure, except for the continuous, larvae were transferred to chemical-free medium and were raised until 6 dpf. Effects on the nervous system were assessed based on three behavioural assays. At 1 dpf, spontaneous movements of embryos within the chorion were measured with an automated tracking device. At 3 dpf, the touch-evoked response was tested by touching the tail of hatched larvae with a needle and measuring the distance moved. From 4 to 6 dpf, the locomotion in response to changing light conditions was assessed using the light-dark transition assay. Briefly, the OP dimethoate and the CBM pirimicarb significantly increased the number of spontaneous movements, while for thiacloprid (NIC) a significant reduction was observed. In the touch-evoked response assay, almost all insecticides, except imidacloprid (NIC), induced a reduction in distance moved. However, this effect predominantly occurred immediately after exposure, while larvae seem to have recovered from earlier exposure. Similarly, the locomotion at 4 to 6 dpf only was reduced when larvae were exposed shortly before. Although none of the exposure windows seemed to be critical when looking at locomotion, there is a tendency that earlier exposure leads to longer lasting effects.

2.04.P-Tu063 Implementation of Novel Methods in Ecotoxicology Assessment of Nanoparticle Toxicity to Aquatic Model Organisms (*Chironomus riparius*)

*Jelena Slavisa Stojanovic*¹, *Perica Vasiljevic*², *Jelena Vitorovic*², *Dimitrija Savic-Zdravkovic*², *Nikola Stankovi*^{2,3} and *Djuradj Milošević*², (1)Biology and Ecology, Faculty of Sciences and Mathematics, University of Niš, Niš, Serbia, (2)Faculty of Sciences and Mathematics, University of Niš, Serbia, (3)Department of biology and ecology, Faculty of Science and Mathematics, University of Niš, Serbia

Excessive production of nanoparticles has led to their accumulation in environment. Studies have shown that the current concentrations of nanoparticles in aquatic environment are only sublethal. For this reason, developing novel biomarkers that can detect negative effects of nanoparticles even at very low concentrations is very important. This way, appropriate remedial actions could be taken on time to prevent severe damage to aquatic ecosystems. Geometric morphometrics has a great potential to be used in ecotoxicology assessment, because of its ability to detect changes in fine structures on organisms and quantify them for statistical analyses. Tissue architecture alterations are very important indicators of toxic effect of pollutants. Histopathology analyses can present tissue morphology changes qualitatively as well as quantitatively. It is shown that nanoparticles could induce oxidative stress by generating ROS and comet assay is a simple method for detecting level of DNA damage that it causes. We have shown that sublethal concentrations of TiO₂, CeO₂ and Fe₃O₄ nanoparticles induce changes in *Chironomus riparius*. Using geometric morphometrics, alterations in mouth structures and wings in treatment with all three metal oxide nanoparticles was observed. Changes were noticed at a tissue level as well. Histology analysis of *C. riparius* larvae revealed vacuolization of digestive cells and Malpighian tubule epithelial cells in groups treated with nano-CeO₂ and nano-Fe₃O₄, as well as morphology changes of digestive system epithelial layer and fat body tissue in group treated with nano-TiO₂. DNA damage was observed by comet assay in groups treated with CeO₂ and Fe₃O₄ nanoparticles, where the severity of damage was concentration and particle size dependent. Geometric morphometrics and histopathology analyses revealed the structures that were the most sensitive to the presence of pollutants and could serve as potential biomarkers of nanoparticle toxicity. Harmful effect of nanoparticles on DNA molecule has indicated the importance of the comet assay method usage in ecotoxicology assessment. Our study showed that sublethal concentration of nanoparticles could have detrimental effect on aquatic environment and defining biomarkers of their toxicity is a very important step in taking actions to reduce risk of nanoparticle exposure.

2.04.P-Tu064 Assessment of the Effects of Cadmium, Samarium and Gadolinium on the Blue Mussel (*Mytilus edulis*): A Biochemical and Lipidomic Approach

*Binbin Cai*¹, *Romarc Moncrieffe*¹, *Abderrahmane Kamari*², *Samuel Bertrand*¹, ***Laurence Poirier***³ and *Aurore Zalouk-Vergnoux*⁴, (1)Université de Nantes, France, (2)Nantes University, France, (3)Nantes Université, France, (4)Université de Nantes, France

Rare earth elements are a group of 17 metallic elements. Their electronic configuration gives them particular properties which make their use in the composition of many products of our daily life essential. Their worldwide popularity disrupts natural biogeochemical cycles and enrichments in lanthanum (La), gadolinium (Gd) and samarium (Sm) are already observed in rivers. This study was carried out to assess the bioaccumulation and potential effects of 2 rare earth elements, Gd and Sm, in comparison with cadmium (Cd), on a marine sentinel species: the blue mussel (*Mytilus edulis*), combining biochemical marker analyses and a global lipidomic approach. Laboratory exposures were carried out at low doses of 50 and 500 µg/L in 13-L tanks of artificial seawater. Three tanks per element – Cd, Sm, Gd – each containing 13 mussels, were maintained in parallel with 3 other tanks without contamination. At the end of an 8-day exposure, during which the water and contamination were renewed every 2 days, the mussels were dissected, and a battery of biomarkers were performed on digestive gland, gills and mantle. Superoxide dismutase (SOD), catalase (CAT), and glutathione S-transferase (GST) activities served to monitor the oxidative stress. The neurotoxicity was analysed through the acetylcholinesterase activity (AChE). Acid Phosphatase (AcP) measures were used as a biomarker for immunotoxicity in haemolymph. Moreover, lipidomic analyses were performed using flow injection analysis coupled to high resolution mass spectrometry (FIA-HRMS) on lipid extracts from the digestive glands of mussels. Finally, the metal bioaccumulation was measured on exposed organisms by ICP-MS. All the metals were bioaccumulated by the mussels. Concerning the effects, Sm led to oxidative stress – induction of GST – in both gills and digestive glands. No significant effect was observed on the other biomarkers, *i.e.* phosphatase acid, CAT and AChE. Concerning lipidomics, no significant unsupervised discrimination between the conditions of exposure was highlighted by PCA. But, the exposures to Cd, Sm and Gd led to a total of 31 compounds up- or downregulated compared to the controls in the supervised analysis, using PLS-DA. Among them, one

compound was upregulated by the mussels exposed to the 3 metals and it would correspond to PIP3, which is involved in cell growth and survival. To conclude, biochemical and lipidomic approaches are complementary tools in ERA.

2.04.P-Tu065 Integrative Ecotoxicological Assessment of Rare Earth Element Effects on a Model Aquatic Community

Nicolas Lachaux¹, Laura Junique², Sébastien Cambier³, Benedicte Sohm⁴, Danièle Pauly², Marie Zaffino², Simon Devin⁴, Elisabeth Maria Gross⁵ and Laure Giamberini⁶, (1)LIEC, France, (2)Université de Lorraine, France, (3)Luxembourg Institute of Science and Technology (LIST), Luxembourg, (4)LIEC - Université de Lorraine - CNRS, France, (5)CNRS UMR 7360 / Université de Lorraine, France, (6)Université de Lorraine, CNRS UMR 7360, France

In the last decades, the increasing use of Rare Earth Elements (REE) in cutting-edge (smartphone, computer...) and green technologies (wind turbine, solar panel...) led to the release of anthropogenic REE into the environment, and especially in aquatic systems. However, still little is known about the potential effects of these emerging contaminants in the aquatic ecosystems. Therefore, we investigated REE aquatic fate and toxicity in indoor mesocosm exposure systems. A model food web was established with primary producers (macrophyte and microalgae), primary consumers (bivalve and crustacean) and a secondary consumer (fish). The organisms were exposed during four weeks to a mixture of REE (neodymium, gadolinium and ytterbium) at environmental concentrations. An integrative approach was implemented studying the speciation, bioavailability, bioaccumulation and toxicity of REE at the sub-individual and individual levels in a community context. This poster focuses on the effects on the bivalve *Corbicula fluminea*, a key filter-feeding benthic invertebrate of freshwater aquatic systems. A battery of biomarkers was measured by automated spectrophotometer in order to examine oxidative stress (glutathione peroxidase, superoxide dismutase, total antioxidant capacity), detoxification (glutathione S-transferase, acid phosphatase activities), cellular damages (lipid peroxidation, caspase-3 activity), energy metabolism (electron transport system, lactate dehydrogenase activities) and reserves (triglyceride, cholesterol, protein content) in the digestive gland and the gills of the bivalves. The results show a higher response of the biomarkers in the digestive gland with a significant increase of antioxidant and detoxification activities in the exposed bivalves relatively to controls. Moreover, an increase of lipid peroxidation was observed at the highest concentration. This work demonstrates that REE, at environmental concentrations, can induce toxic and oxidative stress and even cellular damages towards this key species in freshwater ecosystems.

2.04.P-Tu066 Ecotoxicological Effects of Closed Loop Scrubber WATER on Stickleback and Blue Mussel

EL Joachim Sturve¹, Alice Mellring¹, Christina Jonander², Bethanie Carney Almroth³, Ingela Dahllöf² and Ida-Maja Hassellöv⁴, (1)University of Gothenburg, Sweden, (2)University of Gothenburg, Sweden, (3)Goteborg University, Sweden, (4)Chalmers University of Technology, Sweden

The shipping industry is responsible for the release of numerous contaminants, including sulphur oxides and polyaromatic hydrocarbons (PAHs), to the air and the marine environment. To reduce airborne pollution, a global 0.5 % sulphur limit for marine fuels was implemented in January 2020. The new lower sulphur limits can be reached via two different methods, by the use of low sulphur fuel or by installing an Exhaust Gas Cleaning System (scrubber). Today a large number of ocean-going ships have installed scrubbers to avoid using more costly low sulphur fuels. In a scrubber, the exhausts are led through a fine spray of water thereby “washing“ out particles and pollutants. There are different types of scrubbers, where the closed loop type recirculates the water to minimize discharge to the sea. Despite the name, a closed loop scrubber typically discharges 3-5 m³/h of polluted water. To study the effects of scrubber water, sticklebacks (*Gasterosteus aculeatus*) and blue mussels (*Mytilus edulis*) were exposed to water from a closed loop scrubber, in controlled laboratory experiments. Fish were exposed to 1% and 10% of the scrubber water for 4 and 14 days in a semi-static system, while the mussels were exposed to the same concentrations for 14 days. A battery of hepatic biomarkers on gene and protein levels were analysed in the fish while lysosomal membrane stability and byssus thread formation were analysed in the mussels. In addition, micronucleus analyses of fish blood cells were performed. Chemical analysis of the scrubber water showed the presence of several PAHs and metals. Results in fish show an induction of genes involved in detoxification (CYP1a), metals homeostasis (metallothionein), and oxidative stress (glutathione reductase, superoxide dismutase, glutathione S-transferase). Increased EROD activity and antioxidant enzyme activities show that upregulated gene expression led to increased enzyme function. Identification of 4-ringed and 5/6-ringed PAH in the bile samples of the fish confirmed the uptake of PAHs. However, no DNA damages were detected using micronucleus analysis. In mussels, no effect on lysosomal membrane stability was detected but it was clear that animals exposed to high levels of scrubber water had problems anchoring to the surface with byssus threads. Overall, results confirm that scrubber water carries pollutants capable of causing adverse effects in marine organisms.

2.04.P-Tu067 Effect Profile Characterisation of Complex Chemical Mixtures in a Wwtp-Affected Stream Using Effect-Based Methods

Fabian Weichert¹, Jörg Ahlheim², Werner Brack², Mario Brauns², Patrick Fink³, Sarah Johann⁴, Martin Krauss⁵ and Henner Hollert⁶, (1)Goethe University Frankfurt am Main, Germany, (2)Helmholtz Centre for Environmental Research – UFZ, Germany, (3)University of Cologne, Germany, (4)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (5)Helmholtz centre for environmental research - UFZ, Germany, (6)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany

Contemporary water pollution patterns are characterised by a steadily growing number of contaminants that are present in complex mixtures. The ecological consequences of these mixtures are often difficult or impossible to assess. Thus, it is important to conduct effect-based *in situ* studies – considering realistic scenarios – in biological systems to analyse the ecologically relevant effects of the combined exposure to pollutant mixtures. The present study, as part of a large case study within a well-studied low mountain stream in Central Germany (Holtemme River), is designed to (1) characterise the ecotoxicological potential along the

stream course, (2) identify hot spots of pollution and thus, (3) allow for an effect-based decision-making on suitable locations for subsequent experiments with caged fish. The case study aims to determine whether effect-based methods can be combined with established biomarkers, transcriptomics and genomics in feral fish to offer a diagnostic tool to assess ecologically relevant effects of anthropogenic stress in freshwater ecosystems. Water will be sampled, using Large-Volume Solid Phase Extraction (CHROMABOND HR-X) at 6 sampling sites along the Holtemme River. After enrichment, each sample will be analysed using a selected bioassay battery. The bioassays will comprise the Ames fluctuation test and micronucleus test to identify mutagenic and genotoxic potentials, respectively. Furthermore, ER-, AR- and Nrf2-CALUX assays will help to determine oestrogenic, androgenic and oxidative stress-related effects. The prolonged zebrafish embryotoxicity test (up to 120 hours post fertilisation, hpf) will be carried out to examine (sub)lethal effects and thus fish-specific toxicity. Moreover, locomotor behaviour of zebrafish larvae (96 hpf) at low sublethal concentrations will be analysed. These bioassays are complemented by targeted chemical analysis, using high-resolution LC-MS techniques to calculate toxic units and identify compounds strongly contributing to total toxicity. With this approach, a longitudinal characterisation of the ecotoxicological potential will be established and most importantly, hot spots of chemical pollution will be identified for the subsequent caging experiments. This study will help connect chemical pollution and ecological effects, fostering the understanding of causal links between environmental contamination and ecological impacts. This is considered a crucial input for future sustainable use of water resources.

2.04.P-Tu068 Multigenerational Exposure of *Daphnia magna* to Diazinon: Physiological and Molecular Responses

Floriane Tisserand, Federica Gilardi, Micaela Faria, Elodie Melo de Almeida, Aurélien Thomas and Nathalie Chevre, University of Lausanne, Switzerland

Most of the ecotoxicological studies on daphnids are carried out on short to middle duration (48h/21 days). These classical tests are not adequate to evaluate the toxicity of environmentally relevant concentrations of chemicals. Indeed, organisms in surface waters are chronically exposed to pollutants, i.e. on several generations. These chronic exposures to low concentrations can induce subtle changes in health and physiology. Those can have negative ecological consequences on population levels and biodiversity. Life cycle exposures (continuous exposure from embryo to maturity) and multi-generational exposures (exposures extended beyond a life cycle) are therefore necessary to evaluate the ecotoxicological effects of compounds. In this study we aim in assessing sensitive makers such as physiological changes (reproduction, mortality and size) and biomarkers (acetylcholinesterase, Glutathione-S-Transferase and Cytochrome P450), over two generations exposed to diazinon, an insecticide regularly detected in surface waters. The concentrations range from 0.1 to 6 ng/L, which are realistic concentrations. In our study, we only exposed the first generation to diazinon (about 15 days) to mimic agricultural pollution, that is seasonal. The first results showed observable effects from 6ng/L, and this on the adults' size, the number of offspring and the egg laying time in the mothers exposed to diazinon. In the second generation, unexposed and therefore representing the consequences of parental exposure, only a slight trend was observed with increasing pesticide concentrations. The effects on biomarkers are currently under measurement.

2.04.P-Tu069 Assessing Anti-Androgenic ACTivity in Pond Water Using a Tropical Clawed Frog (*Silurana tropicalis*) Androgen Receptor Transactivation Assay

Catherine Helen Whatley¹, Charles Tyler², Shinichi Miyagawa³ and Frances Orton⁴, (1)School of Science and Sport, University of the West of Scotland, Glasgow, United Kingdom, (2)University of Exeter, United Kingdom, (3)University of Tokyo, Japan, (4)Health and Life Sciences, UWS, Glasgow, United Kingdom

Abstract – 300 words (2085 characters with spaces) Many amphibian populations are experiencing rapid global declines, with pollution being cited as a major cause. Of particular concern are pollutants that act as endocrine disrupting chemicals (EDCs). Laboratory exposure to various EDCs have been shown to induce a wide array of adverse reproductive effects in amphibians, particularly feminisation in males, including features of their morphology (e.g. secondary sexual characteristics) and physiology (e.g. changes in hormone levels and feminised gonads). These effects can occur through both oestrogenic and anti-androgenic activity of pollutants. Anti-androgenic activity is one of the most commonly detected endocrine disrupting activity recorded for environmental pollutants, however, very little is known on this activity in freshwater ponds where amphibians typically reside during breeding. Reports of anti-androgenicity – both for individual chemicals in the laboratory and derived from the testing of water samples – typically use transactivation assays which contain the human androgen receptor (AR). While there is a high sequence homology in the ligand binding domain between the human and amphibian AR (88 % or 82 % alignment between *Homo sapiens* and *Xenopus laevis* or *Rana catesbeiana*, respectively), the relative sensitivity of the amphibian AR compared to the human AR is not known. This is important in order to assess potential risk of anti-androgenic pollutants on the reproductive health of wild amphibians. With this purpose in mind, here we describe the development of a transactivation assay using tropical clawed frog (*Silurana Tropicalis*) AR transfected into immortalised liver cancer cells (HepG2). We also present preliminary data describing the activation of this receptor upon exposure to water extracts collected from common frog (*Rana temporaria*) breeding ponds in the UK. Results from this assay will be combined with sex determining gene expression data in common frog tadpole gonads to investigate for any relationships between anti-androgenic activity and the expression of selected target genes.

2.04.P-Tu070 Assessing the Impacts of Organic and Inorganic Contaminants on British Rivers: From Sediments to Otters

Calum Ramage¹, Lisa Yon², Matthew Johnson³, Liz Bailey², Chris Vane⁴, Raquel Dos Santos⁴ and Elizabeth Chadwick⁵, (1)School of Veterinary Medicine and Science, University of Nottingham, Sutton Bonington, United Kingdom, (2)University of Nottingham, United Kingdom, (3)The University of Nottingham, United Kingdom, (4)British Geological Survey, United Kingdom, (5)Cardiff University, United Kingdom

A substantial proportion of British rivers are in poor ecological and chemical condition. Trace metal pollution has been a longstanding issue in the England and Wales, and recent reports also suggest that many British rivers are suffering from chronic

pesticide pollution. Both classes of pollutants have the potential to accumulate in the aquatic environment and in its inhabitants, and both can be highly toxic to aquatic life. Many rivers are still seeing catastrophic declines in freshwater fish, and chemical pollution is likely playing a role in this. However, there is a lack of knowledge of the general health status of fish populations, other than across population-level changes, and very few in-depth health assessments have been carried out in the UK. In addition, few pollutants are routinely monitored in sediments, and the exposure to biota is rarely assessed. To accurately evaluate and manage the risk to rivers, water and sediments pollution should be characterised in conjunction with effect-based monitoring methods. Of these methods, multibiomarker approaches across multiple levels of organisation have been developed to better characterise the physiological status of organisms. In this study, we have sampled water, sediments, invertebrates, and fish from across two contrasting agri-urban catchments in England. We will test our samples for a range of 31 trace elements and 64 current-use pesticides using ICP-MS and UPLC-MS/MS to map their distribution across the catchments and assess their bioaccumulation in the local aquatic fauna. The fish will undergo an in-depth health assessment using a series of biochemical, cellular, and histopathological assays. The gut microbiome of selected fish will also be sequenced using HiSeq to assess the implications of pollution on the microbiome and to examine the presence of antimicrobial resistance genes. In addition, and in collaboration with the Cardiff Otter Project, over 700 otter bones collected from four regions over two decades, including from two of the regions sampled in by our project, will be analysed for lead (Pb) accumulation, and potential Pb sources determined using stable isotope analyses. Concentrations will be mapped against background geology and anthropogenic sources, and a time-series analysis will determine whether bone Pb concentrations have decreased with reduced Pb emissions. Overall, this combined approach allows for a comprehensive ecotoxicological assessment of two typical British rivers.

2.04.P-Tu071 Effects of Leachates From Tyre Wear Particles on Marine Copepods

*Evanthia Bournaka*¹, *RODRIGO ALMEDA*², *Thomas Page*³, *Rebecca Andreani Mejholm*⁴, *Marja Koski*⁵ and *Torkel Gissel Nielsen*⁵, (1)DTU Aqua, DTU Aqua, Kgs. Lyngby, Denmark, (2)Danish Technical University, Spain, (3)National Institute for Aquatic Resources, DTU (Technical University of Denmark), Kgs. Lyngby, Denmark, (4)DTU Technical University of Denmark, Denmark, (5)Technical University of Denmark DTU, Denmark

Tyre wear particles (TWP) contribute a significant proportion to the microplastic pollution in the ocean, but the knowledge of their potential effects on marine organisms is still limited. This study aims to address some of this knowledge gap focusing on marine copepods, which are important organisms with a significant role in marine food webs and the biological carbon pump. The main objective of this project was to investigate the acute effects of TWP leachates on multiple zooplankton species including the cyclopoid *Oithona davisae*, the harpacticoid *Amonardia normanni* and the calanoids *Temora longicornis*, *Centropages hamatus* and *Acartia tonsa*. These copepod species differ in size, feeding mode and reproductive strategies. Acute toxicity experiments were carried out in the laboratory by exposing adult copepods of each species to a range of leachate concentrations (0.005 - 5 g L⁻¹) and using mortality (median lethal concentration, LC₅₀) as endpoint. All species exposed to the highest leachate concentration experienced 100% mortality within 72hrs, besides *A.normanni* (96.2%). Generally, the toxicity increased with increased leachate concentration and exposure time, therefore LC₅₀ values decreased over time for all species. Calanoids exhibited higher sensitivity, especially the small *A.tonsa* (728 ± 58 µm) and *T.longicornis* (672 ± 54 µm) which showed mostly 100% mortality in concentrations > 1.25 grL⁻¹, while the larger (853 ± 74 µm) *C. hamatus* exhibited higher tolerance (LC₅₀=1.5 grL⁻¹). The ambush feeder *O. davisae*, the smallest of the tested copepod species, was less affected than the larger calanoids (LC₅₀ for *O. davisae*=1.6 grL⁻¹). The harpacticoid copepod, *A.normanni*, showed a remarkable tolerance to TWP leachates (LC₅₀ = 3.2 grL⁻¹). Our results indicate that toxic effects of TWP leachates vary among different copepods taxonomic orders and that toxicity is most likely related to feeding/swimming strategies and species-specific defense mechanisms against pollutants.

2.04.P-Tu072 Impact of Tyre Wear Particle Leachates on Marine Phytoplankton

*Thomas Page*¹, *RODRIGO ALMEDA*², *Evanthia Bournaka*³, *Rebecca Andreani Mejholm*⁴, *Marja Koski*⁵ and *Torkel Gissel Nielsen*⁵, (1)National Institute for Aquatic Resources, DTU (Technical University of Denmark), Kgs. Lyngby, Denmark, (2)Danish Technical University, Spain, (3)DTU Aqua, DTU Aqua, Kgs. Lyngby, Denmark, (4)DTU Technical University of Denmark, Denmark, (5)Technical University of Denmark DTU, Denmark

Recent studies suggest that tyre wear particles (TWP) are abundant microplastics (MPs) in the environment. Once TWPs enter the aquatic systems, these particles leach out plastic additives that can be toxic to aquatic biota. However, little is known about the impact of TWP leachates on marine phytoplankton. The aim of this study was to determine the acute effect of leachates derived from TWP on three phytoplankton species: the cryptophyte *Rhodomonas salina*, the diatom *Thalassiosira weissflogii* and the dinoflagellate *Heterocapsa steinii*. Specifically, the effect concentration (EC50) for specific growth rate of each species was determined. Leachates were obtained by incubating < 250 µm TWP (1 g/L) in artificial seawater following a standard protocol. To be more environmentally realistic, we use a lower solid to liquid ratio compared to other standard protocols (50-100 g/L). Phytoplankton was exposed to leachates at different concentrations, and cell concentrations were measured every 24 h over 3 days. The dinoflagellate *H. steinii* was the most sensitive species to TWP leachates, with an EC50 of 23% leachate concentration after 72 h. *R. salina* and *T. weissflogii* exhibited EC50 values of 64% and 73%, respectively. These results indicate that leachates from TWP are toxic to marine phytoplankton. More field data is needed to evaluate the potential environmental impact of TWP leachates, particularly in coastal areas with close proximity to roads.

2.04.P-Tu073 Microplastics in Diet Affect Liver and Gills Function of Rainbow Trout (*Oncorhynchus mykiss*) Juveniles

*Aneta Hollerová*¹, *Nikola Hodkovicová*², *Denisa Medková*³, *Jana Blahová*⁴ and *Martin Faldyna*², (1)Department of Infectious Diseases and Preventive Medicine, Veterinary Research Institute, Brno, Czech Republic, (2)Veterinary Research Institute, Czech Republic, (3)Mendel university in Brno, Czech Republic, (4)University of Veterinary Sciences Brno, Czech Republic

Plastic waste pollution is considered to be one of the most serious issues of our planet. Decades of increasing production and improper recycling caused that huge amounts of plastic waste enter the aquatic environment. Moreover, the widespread use of protective equipment due to Covid-19 pandemic, which is mainly made from various plastic materials, pollute the aquatic environment even more. In external environment, these plastic objects in large size may initiate creation of so-called microplastics (< 5 mm), which may be consumed by non-target organisms and could have negative effect on their health. The main task of this project was the evaluation of polystyrene (PS) microparticles effects on indicators of inflammation in rainbow trout (*Oncorhynchus mykiss*) juveniles. Tested fish were divided into four groups – with 0.5%, 2% and 5% concentration of PS microparticles in diet concurrently with the control group without the addition of microplastics in their feed pellets. Fish were fed with this diet for six weeks and the experiment ended with the blood and selected tissues sampling. In the highest tested PS concentration (5%), the inflammatory alterations were detected via changes in expression of selected cytokines in liver and gills and were confirmed by histopathological analysis of these tissues. In addition, the biochemical analysis found a decrease in ceruloplasmin activity and ammonia concentration in the same PS group. In conclusion, PS microparticles can affect health indices of *O. mykiss* and thus the potential risk for aquatic environment and even human consumption should be considered. Project was funded by the ERDF/ESF “PROFISH” [no. CZ.02.1.01/0.0/0.0/16_019/0000869].

2.04.P-Tu074 Variability of Tolerance to Methylisothiazolinone Among Independent Lines of *Daphnia pulex*

*Margot Wagner*¹, *Marie-Agnes Coutellec*² and *Scott McCairns*³, (1)INRAE, Rennes, France, (2)INRA, France, (3)INRAE, Institut Agro, IFREMER, Rennes, France

Isothiazolinones are a family of broad-spectrum biocides widely used in industry and consumer products. These compounds are recognised as strong irritants, with the first cases of contact allergies being reported in 1984, resulting in their restriction by EU legislation. The less harmful of these molecules – methylisothiazolinone (MIT) – is still being used in cosmetics, household cleaners, hygiene products and various industrial applications. Despite this widespread use, the release of MIT from urban sources to aquatic environments and its potential impacts on aquatic organisms have received little attention. Few studies have reported the toxicity of MIT to non-target species. The present work addressed this current knowledge gap by evaluating acute MIT toxicity to *Daphnia pulex* (Cladocera), as well as its sublethal effects on fertility and growth under environmental concentrations. To account for intraspecific genetic variation in sensitivity, the design involved six clonal lines of *D. pulex* stemming from distinct natural populations or commercial strains. Clones exhibited strong variation in their responses, which points to the need to incorporate genetic diversity into ecological risk assessment procedures.

2.04.P-Tu075 Acute and Chronic Toxicity in the Cladoceran *Daphnia Curvirostris* Exposed to Inorganic Turbidity and Glyphosate

*Maricruz Quintero-Serrano*¹, *Miriam Hernández Zamora*² and *Fernando Martínez-Jeronimo*³, (1)Zoology, Instituto Politécnico Nacional-ENCB, Mexico City, DF, Mexico, (2)Instituto Politécnico Nacional-Escuela Nacional de Ciencias Biológicas, Mexico, (3)Mexico Regional Chapter, Mexico

Intensive agriculture is actually one of the most widely techniques to satisfy the food claims in the world, which among other things makes increasing use of herbicides like glyphosate. In countries like México, other type of agriculture is extensive, realized commonly in slopes and in sites with grades, promoting the loss of soil and dragging sediments to the catchment basins. Pesticides and inorganic particles are introduced to water bodies by runoffs causing increased inorganic turbidity and negative effects in aquatic organisms, specifically on the filtering zooplankton. This study evaluated the glyphosate toxic effect, in presence and absence of inorganic turbidity, on reproduction, survival and the biomolecules in the cladoceran *Daphnia curvirostris*. The acute toxicity (48 h) of glyphosate (FAENA[®]) was determined applied both individually and in combination with clay presence (0.1 mg/L). For the chronic bioassay (life cycle) were used the following sublethal concentrations: LC_{0.1}: 1.34 mg/L, LC₁: 1.95 mg/L, LC₅: 2.72 mg/L y LC₁₀: 3.25 mg/L, each one with 0.1 mg/L of clays, one control and a control with 0.1 mg/L of clays; these were feed with the microalgae *Pseudokirchneriella subcapitata* (800,000 cel). The calculated LC₅₀ for FAENA[®] was 4.92 mg/L without clays and 6.10 mg/L with clays. Chronic bioassay (FAENA[®] with clays) results showed that the LC₁₀ affected the survival of the 80% of the cladocera at the 32th day; both controls completed their life cycle at the day 43th; chronic bioassay (FAENA[®] without clays) results showed that the LC₁₀ and LC₅ affected the survival of the neonates the first few days. There was a significant reduction in the number of neonates and litters, mainly those exposed to the highest concentrations of glyphosate + 0.1 mg of clay. The highest percentage of abortions (total of neonates: 6%) was recorded in LC₁₀ with clay. According to macromolecules, adults of *D. curvirostris* had high protein content, followed by carbohydrates and lipids in all FAENA[®] with clays concentrations; lipids were significantly reduced in all treatments. In neonates were registered highest lipid contents, followed by proteins and carbohydrates. Results of this study indicated that the clays modify significantly the glyphosate toxicity, moreover, the exposure of *D. curvirostris* to glyphosate and clay caused damage to survival, reproductive and macromolecule content, specially the decrease of lipids, which are important for the reproduction.

2.05 Lab and field based experimental approaches to investigate ecosystem integrity under multiple stressors

2.05.T-01 The Effects of Stressor Dominance at Environmentally Relevant Levels on the Freshwater Gastropod, *Lymnaea stagnalis*"

*Emily M Moore*¹, *Claus Svendsen*² and *Frances Orton*³, (1)Centre for Environmental Research, University of the West of Scotland, Glasgow, United Kingdom, (2)CEH, Wallingford, United Kingdom, (3)Health and Life Sciences, UWS, Glasgow, United Kingdom

Human activity is driving biodiversity loss at an alarming rate and multiple interacting stressors are recognised as driving many of

these declines. However, due to the practical limitations associated with multifactorial experimental designs, a new approach to investigate the effects of environmental stressors is needed. Here we assess combined effects of three ubiquitous environmental stressors (pollutant mixture, invasive predator and global warming) utilising a novel testing paradigm based on the ‘dominance’ theory. The central tenet of this theory is that when one or more stressors are present at sufficiently high levels, this drives the observed effects. Under this scenario, the addition of co-stressors at lower levels will have little impact on the level of response. In order to test this theory, stressors were combined with each stressor at a ‘dominant – EC30’ level, either alone or in combination with additional stressors at ‘negligible – EC10’ levels and the selected levels encompassed environmentally relevant exposures. Effects on survival, growth, reproduction and behaviour in *Lymnaea stagnalis* upon long-term exposure (~ 5 months) were recorded. When stressors were applied singly at the ‘dominant’ EC30 exposure level, negative effects on reproduction (embryo viability) were observed in response to pollution, avoidance behaviour was observed in response to predator cue and stimulatory effects on reproduction (accelerated egg production) was observed in response to temperature. Supporting our hypothesis, there were no differences in these effects when compared with co-exposure with other stressors at negligible levels. However, additional effects were observed for all stressors under the multiple stressor exposure scenario when compared with their respective single EC30 exposure. Observed effects were similar between the different multiple stressor exposure scenarios, and therefore, the overall stressor levels appeared to have more importance than the individual stressor identities. This could be due to a general stress response leading to changes in energy budget allocations. Findings from this study will provide crucial information on how combinations of stressors interact to affect aquatic organisms, reflecting how human activities are contributing to biodiversity loss within natural systems.

2.05.T-02 Combined Effects of Droughts and Pesticides Cocktail on the Biomass and ACTivity of Aquatic Biofilms

Lluís Bertrams Tubau¹, Yoann Menard², Lorenzo Proia¹, Mertixell Abril¹, Sergio Ponsá¹ and Joan Artigas², (1)BETA Technological Center - UVic, Spain, (2)Université Clermont Auvergne, France

The potential adverse effects of mixing different pesticides (pesticide cocktail) in freshwater ecosystems subjected to extreme hydrological events such as droughts has been poorly explored. For this reason, there is an urgent need to increase our knowledge in this field to propose suitable pesticide mitigation strategies in the context of future global change scenarios affecting aquatic ecosystems. In this study, a microcosm experiment was performed to assess the effects of two types of drought events caused by hydropeaking (short and highly frequent drought episodes- HF_SD) and agricultural practices (long and low frequent drought episodes- LF_LD), with an immersed control (IC), on aquatic biofilm performance before and after the exposure to a cocktail of pesticides (composed by fungicides, insecticides, and herbicides). Different biomass and functional parameters were analysed in biofilm to determine the combined impact of droughts and pesticides. Results showed that lower bacterial densities in biofilms were measured after the cocktail application. In contrast, the proportion of live bacteria was higher after the application of the pesticides cocktail in the three hydrological conditions. Algal biomass measured as chlorophyll-*a* concentration was significantly lower under drought conditions comparing to the IC and these differences were more remarkable after the application of the cocktail of pesticides. Microbial respiration corrected by organic matter content in the biofilm was strongly lower in the LF_LD condition compared to the IC in the overall experiment ($F=25.972$, $p<0.0005$). Moreover, an interaction between droughts and pesticides ($F=2.738$, $p=0.043$) revealed that respiration rates increased in LF_LD and IC after the cocktail application. Besides, results from community-level physiological profile analyses revealed significant differences between drought treatments, especially in biofilms exposed to LF_LD with stronger contribution to polymers degradation ($F=24.211$, $p<0.0005$) causing a shift in biofilm heterotrophic behaviour. Fundamental knowledge to determine the effects of multiple stressors such as a combination of pesticides impact and droughts exposure on microbial biofilm communities will help to improve the management of freshwater ecosystems under the global change.

2.05.T-03 Dietary Effect Pathway in *Gammarus fossarum* (Crustacea; Amphipoda): Influence of Land-Use and Leaf Substrate

Sara Isabel Bastos Goncalves¹, Annika Pollitt¹, Alexander Feckler² and Mirco Bundschuh³, (1)University of Koblenz-Landau, Germany, (2)University Koblenz-Landau, Germany, (3)Institute for Environmental Sciences University of Koblenz-Landau, Germany

Ecosystem functions provided by microbes in low-order streams, such as microbial colonization of allochthonous leaf litter that increases the leaf palatability for macroinvertebrate leaf-shedders, maybe globally be threatened by increasing chemical stress due to an intensified agricultural activity. The observed bottom-up directed effects on leaf-shredders may, however, depend on a previous stress exposure of microbes that shaped the microbial community and favored more or less palatable microbial species. To test this, we studied how the feeding rate and egestion of the leaf-shredder *Gammarus fossarum* (Crustacea; Amphipoda) are modulated when feeding on two types of leaf substrates (black alder, European beech, and a combination thereof) that were colonized by microbial communities with distinct exposure histories (pristine vs. vineyard runoff [VYRO]), using a fully-crossed 2x3-factorial test design over 21d (n=40). Additionally, we assessed the exoenzyme activity and community composition of the leaf-associated microbial communities (currently being performed). *Gammarids* fed slightly more (~10%) on alder conditioned in the pristine stream than on leaves conditioned in VYRO. The same pattern was observed for the combination of alder and beech. In the case of beech, the opposite trend was observed, namely *gammarids* fed more (~30%) on leaves conditioned in VYRO than at pristine sites. The *gammarids*' feeding rate thus showed an effect of the substrate ($p=0.015$) and interaction of community history with the substrate ($p=0.005$). A similar pattern to the feeding rate was also observed for the egestion ratio, however, the effect was only significant for substrate ($p<0.05$). The higher consumption of beech conditioned in VYRO might be a mechanism of compensation due to microbial community shifts that reduced the nutritional value of the leaf litter and forced *gammarids* to consume more in order to meet their energetic requirements. Against this background, energy reserves will be analyzed to better

understand physiological consequences at the consumer level. A very distinct pattern of the enzyme activity was found on the differently conditioned leaves, with peroxidase showing a significant interaction between community history and substrate ($p=0.016$). Together with the pending data, we will discuss the consequences for gammarids, a keystone organism in stream ecosystems converting leaf material to particulate organic matter and serving as prey for higher trophic levels.

2.05.T-04 Metabolomics Insights in the Response and Tolerance of Stream Biofilms to Chemical Stress in Urban Context

Nicolas Creusot¹, Louis Carles², Eon Mélissa³, Simon Wullschleger⁴, Soizic Morin⁵, Nicolas Mazzella³, Christian Stamm⁴ and Ahmed Tlili⁶, (1)INRAE BORDEAUX, Gazinet-Cestas, France, (2)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (3)INRAE BORDEAUX, France, (4)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (5)Irstea, France, (6)Eawag, Switzerland

Recent evidences highlighted the effect of urban effluent on the structure and functions of downstream biofilms associated to increased tolerance to further chemical stress. Nevertheless, the underlying (molecular) mechanisms of these responses remain poorly understood while usual descriptors provide a partial picture of the phenotype of the communities under chemical stress. In this context, the present study aims to gain knowledge about the molecular/biochemical responses of stream biofilms under urban stress through the implementation of untargeted metabolomics approach. To do so, following exposure in indoor channels connected to a urban effluent, the metabolomic responses of the biofilms were characterized in parallel of structural and functional responses. First, no significant effects were noted on the photosynthesis, respiration, primary/secondary production, as well as on biomass whereas exposure to the unfiltered effluent led to tolerance acquisition to further chemical stress likely associated to significant shift in the microbial diversity. Then, the metabolomic profiles showed discrepancies between all the tested conditions demonstrating a clear effect of the effluent on the molecular phenotype of the biofilms. Moreover, the clear separation between unfiltered and ultrafiltered conditions highlighted the potential contribution of the microbes from the effluent in the response. Such pattern paralleled with microbial diversity one. The strong influence of the microbes was further confirmed through HCA showing that control and ultrafiltered conditions were clustered together. Further trends analysis combined with pathways analysis revealed potential impact on porphyrin and chlorophyll metabolism, among others. Finally, statistical comparison between the metabolomic profiles of raw vs ultrafiltered conditions highlighted that only 11% down- and 18% up-regulated signals contributed to the tolerance of the biofilm. Overall, this study demonstrates that the metabolomic response is more sensitive than usual descriptors through its ability to discriminate all the experimental conditions. Moreover, our results showed that microbes strongly contribute to these various molecular/biochemical responses, as well as to tolerance acquisition. Further investigations are ongoing to confirm the identity of the candidate metabolites and pathways and discriminate their link to urban microbes vs chemicals associated to the tolerance acquisition to chemical stress.

2.05.T-05 Interactive Effects of Metals and Carbon Nanotubes in a Microcosm Agrosystem

Mathieu Leroy¹, Benjamin Pey¹, Vincent Jassey², Clarisse Liné¹, Arnaud Elger³, Anne Probst², Emmanuel Flahaut⁴, Jerome Silvestre¹ and Camille Larue⁵, (1)Université de Toulouse INPT, France, (2)CNRS, France, (3)University of Toulouse, France, (4)CIRIMAT UMR CNRS 5085 UPS INPT, France, (5)CNRS, Castanet Tolosan, France

Agricultural soils are exposed to multiple contaminants through the use of agrochemicals or sewage sludge, introducing in the environment metals and nanomaterials among others. Among nanomaterials, carbon nanotubes (CNTs) are known for their large specific surface area and adsorption capabilities, possibly modifying the behavior of other element. However, to date, very little is known about the impacts of such interactions in agrosystems. In this study, we aimed at understanding the transfer and toxicity of contaminants (Cd, Pb, Zn and CNTs) in microcosms configuration including native soil bacteria, earthworms and lettuce. After a 6 week exposure, no effect of the addition of CNTs to metal-contaminated soils was detected on bacterial concentration or earthworms growth. However, in plants, an interactive effect between CNTs and metals was evidenced: the addition of CNTs led to a biomass loss (-22%) together with a flavonoid concentration increase (+27%). In parallel, the addition of CNTs led to differential impacts on elemental uptake in lettuce leaves possibly related to soil matter content. For earthworms, the addition of CNTs resulted in an increased body elemental transfer in the soil with the highest organic matter content (Pb: + 34% and Zn: + 25%). The results of this experiment provide evidence of interactions between CNTs and metals and show the potential for synergistic and antagonistic interactions depending on the organism considered. Finally, the results of this study raise the issue for authorities to review the current model by which contaminant risk is currently assessed. It is necessary to include the impact of contaminant interactions (cocktail effects).

2.05 Lab and field based experimental approaches to investigate ecosystem integrity under multiple stress (Virtual Only)

2.05.V-01 Great Pond Snail (*Lymnaea stagnalis*) As Sentinel Species for Biomonitoring Anthropic Pressure Impact in Two Algerian West Rivers

Imene Benali¹, Laurent Boualiti², Laetitia Monbaron³, Floriane Tisserand³, Mohammed Bouderbala⁴ and Nathalie Chevre³, (1)Laboratoire Réseau de Surveillance Environnemental, oran, Algeria, (2)Institute of Earth Surface Dynamics, University of Lausanne, Lausanne, Switzerland, (3)University of Lausanne, Switzerland, (4)University of Oran I Ahmed Ben Bella, Algeria

Most of the rivers in the North-West of Algeria have a catchment considerably influenced by localities and agricultural activities, which can generate discharges of various pollutants and weaken biodiversity. This study aims in assessing the risk of two rivers submitted to anthropic pressure: El Malah river (EM), and Sidi Djelloul river (SD), using a gastropod species *Lymnaea stagnalis* as a bioindicator. To reach this goal, we selected 09 sites along both rivers, and we analyzed the following parameters: 1) abundance of the population, 2) biomarkers activities (Acetylcholinesterase (AChE), Glutathion-s-Transferase (GST), Lipid Peroxidation (LPO)), 3) concentration/bioaccumulation of trace metals (Cd, Pb, Cu, Zn, Cr, Ni), in the sediment and specimens.

Sampling was done for four seasons during 2020/2021. The ecological distribution study demonstrated a longitudinal decrease in the abundance of the population along both rivers from upstream to downstream. Moreover, no specimen was recorded in the areas submitted to wastewaters discharge, to discontinuous drying out due to the lack of rain, or to a high irrigation rate. The results also showed a significant increase in GST activity and a significant decrease in AChE activity in the snail from SD river, suggesting greater exposure to insecticides at this site. Indeed, many insecticides are cholinesterase inhibitors. An increase in GST activity could indicate general oxidative stress. However, no statistically significant variation was observed in LPO activity. In site 2 of EM river, high concentrations of trace metals in sediment were recorded in fall coupled with high bioaccumulation in the specimens, especially for lead (Pb) 33.44 µg/g d.w., 14.94 µg/g d.w., respectively. Lead could originate from chemical fertilizers or wastewaters. This study represents a first step in the risk assessment of rivers highly influenced by anthropic pressure in Algeria. It allowed demonstrating that there is a high and chronic risk for invertebrate communities and the fluvial ecosystems in general. Measures must be implemented, such as urban wastewater treatment and the promotion of extensive agriculture.

2.05.V-02 Microscale Climate Exposure System for Assessing the Effect of CO₂, Temperature and UV on Microalgae
Li Xie¹, Ailbhe Macken², Odd Arne Skogan³, Marit Norli⁴ and Knut Erik Tollefsen⁵, (1)NIVA - Norwegian Institute for Water Research, Norway, (2)Norwegian Institute for Water Research, NIVA, Norway, (3)NIVA, Norway, (4)Norwegian Institute for Water Research, Norway, (5)Norwegian Institute for Water Research (NIVA), Norway

Due to the intense anthropogenic activities and accelerated climate change, marine ecosystems are facing enormous challenges to survive the effects of rising temperatures, ocean acidification and changes in background Ultraviolet (UV) radiation. To better characterize the effects of changing environmental factors on marine ecosystems, a small-scale exposure system that can effectively simulate multiple climate change effects using high-throughput bioassays is desirable. In the presented study, a multiple stressor exposure system based on micro-climate units that can fit into traditional laboratory incubators was constructed to assess the effects of climate relevant stressors such as CO₂, temperature and UV radiation on small marine organisms. The performance of the exposure system was tested using a chronic toxicity test with the diatom *Skeletonema pseudocostatum* (NIVA BAC 1) exposed to varying levels of CO₂, different temperatures and UVB radiation for 72 hours. Changes in physical parameters, including pH, dissolved inorganic carbon (DIC), total alkalinity (TA), temperature and salinity in the medium, as well as several toxicity endpoints such as reduction in growth, photosynthetic efficiency and content of chlorophyll a were characterised. The results verify that the exposure system can maintain a stable CO₂, temperature and UVB irradiance for extended durations of time, suggesting that the system can successfully simulate changes in ocean acidification, global warming and UV exposure. Toxic responses measured in the bioassays were typically dose-dependent, which is comparable to other exposure systems, and suggested that the multiple-stressors exposure system has utility for assessing both effects and climate adaptation to single and multiple stressors. Acknowledgment – This project was financed by the Norwegian Ministry of the Environment through the Norwegian Institute for Water Research basic funding (SIS-program on Ocean Acidification), the Research Council of Norway project 223268: Centre of Excellence funding scheme, and NIVAs Computational Toxicology Program (www.niva.no/nctp).

2.05 Lab and field based experimental approaches to investigate ecosystem integrity under multiple stress (Poster)

2.05.P-We021 Aquatic Ecotoxicology Testing : Methodological Adaptation of Mesocosms for Complex Substances Like Paraffin Oils

Clementine Gelber¹, Philippe Lemaire², christian laemmer², Philippe Adrian³ and Sylviane Gony³, (1)TOTAL ONE TECH S.E., France, (2)Total Special Fluids Division, France, (3)CEHTRA SAS, France

Paraffin oils, used as insecticide and acaricide for crop protection, can be challenging when they have to be tested for effects towards specific aquatic organisms in mesocosms systems : indeed, as for the same type of substance, their physico-chemical properties, hydrophobicity and very low solubility in water with a density less than 1 in particular, requires to use specific equipment and facilities. A customized experimental system was run in 2020 to assess the environmental impact of paraffin oils: open-stream outdoor fresh water mesocosm i.e. 16 channels artificial open streams rivers (max. 200 m³/h in total and 7,5 m³/h each) fed by Gave de Pau (southwest France) allowing to test different exposure conditions. The injections of the tested substance occurred through a shearing valve directly into the stream. The shearing valves generate an intimate emulsion which micro-disperses the formulated active substance in water and allows a homogenous dissolved concentration in the streams. Two concentrations have been tested in accordance with the Good Agricultural Practices, as well as a negative and positive control (pentahydrated Copper sulfate) control. Details of the design are presented in this poster, including the different monitored parameters. Results of the 28 days experiments are subject to another poster.

2.05.P-We022 Honey Bee Lifecycle Assessment and Homing Success in Field Observations With the Help of Visual Bee Monitoring Technology

Silvio Knaebe¹, Frederic Tausch², Katharina Schmidt² and Gundula Gonsior³, (1)EAS Ecotox GmbH, Germany, (2)apic.ai, Germany, (3)Eurofins Agrosience Services Ecotox GmbH, Germany

At the moment there are fast advances in the technology available for bee monitoring. There is a strong desire to enhance the knowledge creation on bee health and to get a better understanding of how available feed resources contribute to bee health. New technologies such as bee counters and other monitoring devices/equipment carry a vast potential to gain insights into these questions. They make it possible to move from assessments of individual time points to continuous observations. A new technology besides counters to observe survival, and/or behavior are RFID chips. The chipped bee's homing flight behavior can also be observed to find out if there is an influence of a plant protection product on the orientation of the bees (OECD GD 332).

To increase the amount of information on colonies it would be advantageous to include information about the life cycle of individual bees with bee counters. Field testing of plant protection products is already very labor-intensive. If homing behavior would be included in a field study with RFID chips additional hives would be needed. But hives use landscapes in different ways so effects observed on a hive equipped with RFID readers are not necessarily relevant for the other hives placed in the same landscape. Since apic.ai and EAS Ecotox are partners in the improvement of a visual bee monitoring technology in the research project OCELI (FKZ 281C307B19), a proof-of-concept experiment was performed. The apic.ai monitoring systems with computer vision technology were used to observe individual bees. Queen markers were attached to bees to identify them individually. This approach could enable the inclusion of life cycle, homing success, and individual behavior in studies where visual monitoring technology is already in use to assess other behavioral endpoints like activity, pollen collection or share of foragers. For the study, two colonies were marked in one interval of one week with a different color. At each marking, young and forager bees were marked. The aim of the experiment was to find out if the OCELI bee monitor could distinguish individual bees moving in and out of the hive. It was assessed whether there are colors that work better than others and how well the identification of the numbers printed on the plates would work. Furthermore, the success of the marking was determined for an experienced and inexperienced group to see how easy the methodology would be transferable. This work was supported by grants from the German BMLE.

2.05.P-We023 Trophic Dynamics of Mercury in the Baltic Archipelago Sea Food Web

Riikka Vainio¹, Veijo Jormalainen², Rune Dietz³, Toni Laaksonen², Ralf Schulz⁴, Christian Sonne³, Jens Søndergaard³, Jochen Zubrod⁴ and Igor Eulaers⁵. (1)Biology, University of Turku, Turku, Finland, (2)University of Turku, Finland, (3)Aarhus Universitet, Denmark, (4)University of Koblenz-Landau, Germany, (5)Norwegian Polar Institute, Norway

At the present day, mercury (Hg) exceeds its natural environmental concentrations with well-documented biomagnification and toxic consequences for biota. The present study, therefore, investigated trophic Hg dynamics in the benthic and pelagic food chains of the Baltic Archipelago Sea, known for its high pollution. While traditional biomagnification (BMFs) and trophic magnification factors (TMFs) were used, special attention was paid to the influence of ecological (food chain, trophic position) and ecophysiological traits (thermoregulatory capacity). The study species, composing of 3 seabird, 17 fish, 10 invertebrate and 4 primary producer species, were categorised based on their habitat (benthic, pelagic or benthopelagic) and thermoregulatory capacity (homeotherm, poikilotherm), and ¹⁵N-based trophic position (TP) calculations were carried out according to their habitat. Hg concentrations (mean \pm SD μ g g⁻¹ dry weight: seabirds 1.21 \pm 1.18; fish 0.20 \pm 0.278; invertebrates 0.023 \pm 0.0208; primary producers 0.029 \pm 0.071) increased significantly with TP in the species of both benthic and pelagic food chains, with all TMF exceeding one (benthic food chain [range] 3.0-3.2; pelagic food chain 4.4-5.6), indicating biomagnification. In the models excluding seabirds, TMFs were significantly higher in the pelagic food chain, possibly due different in species biology, such as metabolic differences and narrower niche width of pelagic species, causing more efficient transfer of Hg in the food chain. Most BMFs were >1, further demonstrating Hg biomagnification. There was higher variation in the BMFs when normalising for the TP difference between the prey and predator (mean \pm SD: 14.0 \pm 44.5, range: 0.1 – 508.4) than when not (mean \pm SD: 10.7 \pm 10.3, range: 0.05 – 82.2). The highest BMFs corrected for TP were not caused by a large difference in Hg concentrations between prey and predator, but rather by a small difference in TP, showing how a small difference in TP can artificially inflate the BMF. Currently, there is not one single waterproof BMF calculation and different formulas each present trade-offs between ecological reality and statistical applicability. Our results demonstrate Hg biomagnifying in both benthic and pelagic food chains of the Baltic Archipelago Sea. Trophic magnification of Hg seems to be more efficient in the pelagic food chain, highlighting the important role different ecological pathways can have in contaminant exposure of the species.

2.05.P-We024 Characterization of the Metabolomic Response of Freshwater Biofilms to Urban Wastewater Effluents

Eon Mélissa¹, Manon Karolkowski², Adeline Arini³, Soizic Morin⁴ and Nicolas Creusot⁵. (1)INRAE BORDEAUX, France, (2)INRAE BORDEAUX / UR EABX, France, (3)Universite de Bordeaux., France, Metropolitan, (4)Irstea, France, (5)INRAE BORDEAUX, Gazinet-Cestas, France

Urban wastewater treatment plants (WWTPs) release large amounts of pollutants (e.g. chemicals, microbes) into aquatic environments that may impact exposed organisms. Among these organisms, aquatic biofilms, as a complex assemblage of microorganisms with a short life cycle (e.g. microalgae, bacteria, etc.) and by their key role in aquatic ecosystems (e.g. primary production), are relevant and increasingly used to investigate the impact of chemical contamination at the community level. Despite increasing knowledge on the impact of chemical stress on these communities, the underlying (molecular/biochemical) mechanisms remain poorly described while usual descriptors provide a partial picture of the phenotype. To tackle this issue, untargeted metabolomics approach is relevant through the simultaneous characterization of chemical exposure and the global response of the whole biofilm. In this context, this study focuses on the characterization of the potential impact of urban WWTPs on aquatic periphytic microbial communities by implementing an untargeted metabolomic approach. To do so, biofilm colonization/exposure was carried out during 4 weeks at upstream and downstream sites from three WWTPs along the main tributary of Arcachon Bay (Belin Béliet: upstream, Salles: intermediate; Mios: downstream). First, multivariate analyses (PCA and HCA) showed discrepancies in the metabolomics profile between the three WWTPs and between upstream and downstream site of each WWTP. This difference is more marked at the downstream site (Mios), likely because of increasing disturbances along the tributary (e.g. detection of pesticides only on the downstream site). Moreover, the strong discrimination between upstream and downstream sites at Mios suggested that this WWTP is a source of pollutants. At this site, further univariate analysis combined to pathways analysis allowed preliminary annotation (i.e. based only on MS1) that highlighted a potential impact on the respiration and photosynthesis pathways. Further investigations are ongoing to improve the annotation through the analysis of

MS² spectra and by using an internal database. Overall, this study confirms the relevance of untargeted metabolomics to highlight potential impact of urban discharges on aquatic microbial communities.

2.05.P-We025 Preservation of Environmental DNA (eDNA) in WATER Using Cationic Detergents

Viresh Thamke¹, Berkay Paylar², Jana Jass³ and Per-Erik Olsson³, (1)The Life Science Center-Biology, School of Science and Technology, Örebro University, Sweden, (2)Biology, Örebro University, Sweden, (3)School of Science and Technology, Örebro University, Örebro, Sweden

Abstract: Environmental DNA (eDNA) techniques are gaining attention as cost-effective, non-invasive strategies for the detection of many types of animals, especially in aquatic ecosystems. These include common, invasive, indicator and endangered species in ponds, lakes, rivers, streams, and oceans. Filtration of water using glass fibre and nitrocellulose filter paper are commonly used to extract eDNA from the water and later used for the sequencing or quantification. As eDNA is more prone to degradation immediate filtration is usually needed and can be done by onsite filtration. However onsite filtration can be difficult in remote areas and sometimes the quality of water challenges filtration rate. To overcome these difficulties, we have analysed the efficacy of using different water preservation methods utilizing addition of cationic detergents. Four different cationic detergents, Benzalkonium chloride, Benzethonium chloride, Cetylpyridinium chloride and Cetyltrimethylammonium bromide have been tested for their eDNA preservation efficiency in water. A mesocosm study (5 days) was conducted using zebrafish (*Danio rerio*) as a test organism. The water was then treated with and without the addition of 0.01% cationic detergents. To test the efficiency of the additions the water was collected and filtered from 0 to 96 h after collection. The results showed that all cationic detergents were equally effective at preserving zebrafish eDNA in water while untreated samples showed substantial degradation. At present eDNA studies have adopted on-site filtration followed by filter fixation. Addition of cationic detergents can protect eDNA in water samples allowing for transport to the laboratory for extraction as they prevent the loss of eDNA in water samples. In the ongoing work with development of the eDNA method we will establish a ddPCR protocol to improve the sensitivity of the assay and validate the method using environmental lake water with and without addition of cationic detergents.

2.05.P-We026 Periphyton Communities Under Multiple Stress - Detecting Community Shifts Via Dna-Metabarcoding

Sophie Oster¹, Mugilvannan Sivagnanam², Verena Christina Schreiner³, Sabine Filker⁴ and Mirco Bundschuh⁵, (1)Institute for Environmental Sciences, University of Landau, Germany, Germany, (2)University of Koblenz-Landau, Germany, Germany, (3)University of Koblenz-Landau, Germany, (4)University of Technology Kaiserslautern,, Germany, (5)Institute for Environmental Sciences University of Koblenz-Landau, Germany

Assessing the effects of multiple stressors in surface waters is currently an important topic in ecotoxicology research. Multiple stress may include combinations of chemicals or excessive input of nutrients, hydromorphological degradation, temperature increase or salinization. Due to the increasing effect complexity associated with the occurrence of multiple stressors, e. g. as a result of global climate change, a better understanding of the interactive effects of stressors on communities and their responses is required. In freshwater systems, periphyton communities contribute to primary production, represent an important food source for grazing animals and host a large biodiversity including bacteria and algae. Thus, chemical stressors, such as antibiotics or herbicides, can directly interfere with these communities. Species turnover in the periphyton community composition (horizontal interaction) could in turn indirectly affect the food webs depending on primary production and grazers (vertical interaction). The aim of our study, therefore, was to investigate the combined effects of chemical stress and nutrient enrichment on the community composition of freshwater periphyton. Using artificial indoor streams as microcosms, we set up experiments by colonising natural periphyton on ceramic tiles and exposed them to four different concentrations of the antibiotic ciprofloxacin and the herbicide propyzamide (i.e., chemical stress; 0, 1, 10, 100 and 1000 µg/L), as well as nutrient poor or nutrient rich media (i.e., nutrient stress; modified Borgmann and KUHL, respectively). As periphyton communities underlie seasonal changes, we performed two experiments during winter and two during summer. Via DNA-Metabarcoding, we evaluated the species composition of microeukaryotes and prokaryotes within chronically exposed periphyton (14 days). The data is currently being analysed and the results will be the focus of this poster.

2.05.P-We027 Link Between Glyphosate Exposure and Teratological Forms in Freshwater Benthic Diatoms

Sarah Chéron¹, Vincent Felten², David Heudre³, Aurélie Moreira⁴, Débora Millan-Navarro⁴, Nicolas Mazzella⁴, Soizic Morin⁵, Simon Devin⁶ and Martin Laviale⁷, (1)CNRS UMR 7360 / Université de Lorraine, France, (2)Université de Lorraine, France, (3)DREAL Grand Est, France, (4)INRAE BORDEAUX, France, (5)Irstea, France, (6)LIEC - Université de Lorraine - CNRS, France, (7)University of Lorraine, France

The Water Framework Directive stipulates that water bodies must achieve “good ecological status” in the EU. Although many indicators exist, they are not always able to reveal the subtle effects of low episodic pressure over long exposure times. It is therefore essential to develop early warning indicators of the surface water quality. For this purpose, the study of phototrophic biofilms seems particularly relevant because of their major role in aquatic ecosystems. The Cleurie river (Vosges, North-eastern France) constitutes an ideal study site for testing the sensitivity of indicators and their relevance in the WFD context. Due to industrial activities (textiles), this forested headwater stream is exposed to a complex cocktail of molecules characterized by relatively high concentrations of glyphosate (i.e close to environmental quality standards) and aminomethylphosphonic acid (AMPA), its main degradation product but also dyes and optical brighteners. A preliminary study on the watercourse indicates that teratological forms in the diatoms seem to be more abundant downstream of the discharges. The purpose of this study was to determine if the deformities of benthic diatoms would constitute an early and more sensitive marker than the traditional structural indices. In this context, our objective was to estimate *in situ* the ecotoxic potential of this complex contamination on the diatoms morphology and to identify if these effects can be related to the release of glyphosate and AMPA in the Cleurie river. For this

purpose, diatom community structure, presence of deformations and water physicochemistry were monitored on five sampling sites along the river, at seven occasions along the year. In parallel to this field approach, bioassays were performed in 96-well microplates to evaluate the toxicity of glyphosate and AMPA on diatoms under standardized conditions. Short-term (7 days) exposure of the model species *Nitzschia palea* was conducted to determine the concentrations of contaminants inhibiting 5, 10 and 50% of their growth (IC₅, IC₁₀ and IC₅₀ values). These concentrations and an environmental concentration were then used to expose diatoms under semi-static conditions for 28 days to assess the teratogenic potential of glyphosate and AMPA on diatom morphology. In both experiments, observed deformations were analysed qualitatively (type of deformations) and quantitatively (relative abundance, severity) using morphometric measurements.

2.05.P-We028 Indications of Pollution-Induced Community Tolerance (PICT) of Microphytobenthic Communities in Small Agricultural Streams

Franziska Fiolka¹, Martin Krauss², Hannah Schäfer³, Floriane Larras⁴, Bastian Polst³, Olof Berglund⁵ and Mechthild Schmitt-Jansen⁶, (1)Aquatic Ecology, Lund University, Lund, Sweden, (2)Helmholtz centre for environmental research - UFZ, Germany, (3)UFZ - Helmholtz Centre for Environmental Research, Germany, (4)Helmholtz Center for Environmental Research - UFZ GmbH, France, (5)Lund University, Sweden, (6)UFZ - Helmholtz Ctre Environm. Research, Germany

Small streams harbour a variety of communities in agricultural landscapes and are frequently polluted by chemical mixtures from agricultural run-off. The characterisation of these mixtures and their effects on microphytobenthos (MPB) have rarely been studied in agricultural streams. This work suggests a combined approach for analysing chemical mixtures in MPB from field samples and the evaluation of effects on the structural and functional, i.e. photosynthetic performance as well as tolerance patterns of photosynthetic biofilms. 15 streams from agricultural and non-agricultural landscapes were investigated for their chemical and non-chemical stressor profiles (i.e. nutrients, light climate) and MPB was sampled from autochthonous stones as well as from artificial substrates incubated for 6 weeks on site. About 400 chemicals were analysed within the biofilms with a therefore developed chemical extraction protocol using LC-HRMS. The diatom community assembly was assessed by metabarcoding, both from natural substrate as well as from artificial substrate on site. Pollution-induced community tolerance of the biofilms was assessed in a short-term exposure experiment. Our study will present results illustrating biological effects of pollution on photosynthetic biofilms. It could be shown that biofilm communities from 9 out of 10 agricultural sites showed an up to 20 times increased community tolerance. This is one of the effects illustrated in this study deriving from chemical pollution on site. Up to 324 individual chemicals were found in biofilms from agricultural sites, with a significantly higher chemical load in biofilms from agricultural streams than non-agricultural streams. The detailed characterisation of pollution within the biofilms may give further insights into the effect drivers. Our results further open the perspective of biofilms to be used as a cheap and universal tool for effect- as well as for refined exposure assessment.

2.05.P-We029 Clogging LED to Stronger Effects Than Environmental Copper Contamination on Hyporheic Microbial Communities

Laura Kergoat¹, Aymeric Dabrin², matthieu masson², Thibault Datry² and Chloe Bonnineau³, (1)INRAE, Villeurbanne, France, (2)Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France, (3)UR RiverLy, INRAE Lyon, Villeurbanne, France

The hyporheic zone can be defined as the water saturated sediments below and beside the riverbed. This zone plays a key role in the ecological and biogeochemical river processes such as organic matter decomposition or pollutant degradation. However, anthropogenic activities leading to physical river alterations (e.g. hydroelectric dam) and chemical pollution (e.g. pesticides, heavy metals) can disturb the hyporheic zone functioning. Clogging caused in particular by the erosion of cultivated soils and copper used as a fungicide are generally concomitant in agricultural river catchments. The impacts of these two stressors have been explored independently on microbial communities of the hyporheic zone, but their combined effects are still unexplored. In this study, (1) the effects of clogging on copper distribution in the hyporheic zone and (2) the combined effects of clogging and copper on hyporheic microbial community structure and function were investigated. To this end, we set up a mesocosm experiment using columns filled with sediment and continuously supplied with water during 32 days under controlled conditions to mimic the hyporheic zone and study cause-effect relationships between combined stressors and microbial responses. Four treatments were tested in a full factorial design: (1) control, (2) exposed to copper ([Cu]_{nominal}=191µg.L⁻¹), (3) clogged, (4) clogged and exposed to copper. At the end of the experiment, sediments were collected at four depths of the columns (0-3cm, 4-7cm, 10-13cm, 25-28cm) to determine vertical profiles in copper concentration and microbial structure and functions (e.g. microbial community structure, respiration, denitrification, extracellular enzymatic activities, copper induced tolerance). The results of this experiment showed that copper was filtered mainly in the first few centimeters of the columns, independently of clogging, protecting the microbial communities in deeper layers. In this first centimeters, clogging had greater effects than environmental copper concentration on microbial communities. Whatever the treatment, the interface between surface and hyporheic zone was characterized by a particular microbial community in term of structure, functions and acquisition of tolerance to copper. The information provided by this experiment contribute to a better understanding of the impacts of combined stressors on the hyporheic zone.

2.05.P-We030 Physiological Traits As Biomarker to Assess the Chronic and Acute Exposure of Zn on Mediterranean Barbel

Amina Khalid¹, Cristina Galobar², Guluzar ATLP³, Helena Guasch⁴ and Anna Vila Gispert⁵, (1)Institute of Aquatic Ecology, University of Girona, Girona, Spain, (2)Centro de Estudios avanzados de Blanes (CEAB), Spain, (3)Cukurova University, Turkey, (4)Centre d'Estudis Avançats de Blanes, CSIC, Blanes, Spain, (5)GRECO, Institute of Aquatic Ecology, Universitat de

Girona, Girona, Spain, Spain

The responses to the stress caused by anthropogenic alterations and environmental extreme conditions are compensated by the energy trade-offs of an organism to maintain homeostasis. Physiological traits related to metabolism and locomotor behavior are often overlooked to be used as a biomarker of effect in ecotoxicology. In our study we employed metabolic traits (SMR, MMR) and swim capacity (Ucrit) in combination with a battery of antioxidant enzymes (AE). Mediterranean barbel were sampled from Osor river (NE Spain). The concentration of Zn in different reaches of the river ranges from 36 $\mu\text{g L}^{-1}$ to 450 $\mu\text{g L}^{-1}$ implying that its essentiality to act as a micronutrient diminishes. Therefore, chronic test was conducted on wild fish, sampled close to mine effluent (high Zn) and controls were taken from upstream (low Zn). Acute toxicity however was investigated after giving 1 mg L^{-1} of Zn in a controlled environment for 96h. The results of swimming performance showed that chronic exposure did not impact the SMR, but it significantly reduced the MMR. However, Ucrit and AAS were not significantly affected. On the contrary, acute exposure lowered MMR, Ucrit and AAS significantly. The AE response depicted that Zn induced tissue specific and duration dependent AE activities with a higher effect on chronic exposure than the acute. This could be the cumulative effect of Zn in fish tissues followed by oxidative stress due to the long duration, even at lower Zn concentrations. Lipid peroxidation (TBARS) only occurred in the gill and liver in wild fish despite the oxidative stress modulation to avoid it. GSH responses varied with tissue type and exposure duration. It seems that Zn hampered the electron transport chain thus decreased the cellular metabolism and energy acquisition capacity. As a result, the ability of fish to carry out energy intensive activities reduced (low MMR) with a pronounced effect of acute concentration. This in turn gives competitive advantage to the fish from less polluted areas compared to fish from polluted waters, as the studied traits are crucial to determine the energy available to escape predators, capture prey, migrate, select habitat and to reproduce. Our study infers that the use of metabolic traits and locomotor behaviour as a biomarker of ecotoxicity has an ecological value. It is indispensable to understand the role of energy dynamics to understand the repercussion of pollution on the efficiency of functional group to serve the ecosystem.

2.05.P-We031 Laboratory Observations of Oil Induced Sublethal Toxicity Are Reflected in Survival and Reproduction of Tagged Wild Mahi-Mahi (*Coryphaena hippurus*)

Martin Grosell¹, Lela Schlenker², Robin Faillettaz³, John Stieglitz¹, Justin Greer⁴, Chi Hin Lam⁵, Rachael Heuer⁶, Christina Pasparakis⁷, Charles McGuigan¹, Daniel Schlenk⁸, Daniel Benetti⁹ and Claire Paris¹⁰, (1)University of Miami, United States, (2)East Carolina University, Coastal Studies Institute, United States, (3)IFREMER - Station de Lorient 8, rue François Touleuc 56100 Lorient, France, France, (4)U.S. Geological Survey, United States, (5)University Of Massachusetts Boston, United States, (6)University of Miami, RSMAS, United States, (7)University of California Davis, United States, (8)University of California, Riverside, United States, (9)RSMAS University of Miami, United States, (10)University of Miami (RSMAS), United States

Environmental regulations and impact assessments are based primarily on simplified and controlled laboratory experiments. While such experiments are practical and reproducible, the link between their outcomes and the impacts on wild individuals and populations are rarely verified. To address this shortcoming, we compared laboratory oil-exposures to in-situ observations of wild tagged mahi. Wild mahi were angled from a sport fishing vessel and transferred to a research vessel where oil exposures were performed. In total, 50 wild mahi were tagged with pop-up satellite archival tags (PSATs), with 24 exposed to the water accommodation fraction of Deepwater Horizon source oil and 26 exposed to uncontaminated seawater for a 12-24-hour period prior to release of the tagged fish. Earlier laboratory experiments demonstrated that brief 24-hour exposures in early life stage (ELS) and juvenile mahi led to sublethal impacts on visual acuity, behavioral responses to olfactory cues, and cardiovascular function with consequences for aerobic scope and swimming performance at 1-30 $\mu\text{g?50PAHs/L}$. Notably these effects were predicted from RNAseq experiments on ELS. RNAseq analyses on fin clips obtained from adult tagged mahi prior to release confirmed gene expression changes after exposure to $35.0 \pm 3.4 \mu\text{g?50PAHs/L}$ which were similar to those observed in fish exposed under laboratory conditions, suggesting impairment of cardiovascular function. Wild mahi released after exposure to $35.0 \pm 3.4 \mu\text{g?50PAHs/L}$ for 12-24 hours showed a significantly greater predation mortality during the first 7 days post release. Detection of spawning events from acceleration data documented spawning in control mahi at rates comparable to previous studies. However, over similar periods and locations, wild oil-exposed mahi did not participate in any spawning event. We observed no mortality in tagged mahi during exposure and prior experiments on captive mahi revealed no impact of tagging on spontaneous swimming activity, before, during and after feeding, and showed no reduction in feeding efficiency. The PSAT experiments on wild mahi suggest that sublethal effects observed in laboratory experiments translate to reduced survival and reproduction in wild mahi and further, that even brief low-dose oil exposures of adult fish can cause long term changes that potentially impact population dynamics. This research was made possible by a grant (SA-1520) from The Gulf of Mexico Research Initiative.

2.05.P-We032 Different Biotic and Abiotic Environments Change the Responses of *Lumbriculus variegatus* to Long-Term Exposures to Chemicals

Jacqueline Hilgendorf¹, Diogo Filipe Nunes Cardoso², Jesper Sørensen³ and Susana Loureiro⁴, (1)CESAM & Department of Biology, Universidade de Aveiro/CESAM, Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)Aarhus Universitet, Denmark, (4)Universidade de Aveiro, Portugal

Environmental risk assessment (ERA) is nowadays based on high acute exposures to a small number of model species in the laboratory using lethal endpoints as observed effects. However, these experiments can hardly simulate the complex conditions of natural environments, where low-level and long-term exposure to chemicals is the day?to?day life. These exposures cause several subcellular changes within the organisms, leading to adverse effects in the long run, which short-term experiments can not detect. For the implementation of chronic exposures in the ERA, new non-standard endpoints need to be investigated. This is the aim of the Marie Curie International Training Network CHRONIC. As part of the CHRONIC network, the present work aims to evaluate

the consistency of chemically induced initiating events (lower level of biological organisation) and individual-level responses (physiology and behaviour) in *Lumbriculus variegatus* under long-term, low-level exposures, along with combined stressors' exposures (chemical, abiotic and biotic stressors). For this purpose, a chemical model will be chosen based on a first screening approach using standardised short term technical guidelines. Physiological markers represent a useful tool in ERA, as they represent initiating key effects measured at the subcellular level to sublethal exposure. Biomarkers can show effects before irreversible changes occur within the organisms and are considered fast and sensitive responses. The chosen biomarkers for the present study represent the xenobiotic metabolism (e. g. glutathione-S-transferases, sulfotransferase) and the defence response (e. g. catalase, lipid peroxidation rate). Additionally, biomarkers representing the general condition of the organisms, including the energy budget (e. g. glycogen, carbohydrate, lipid contents), will be used for the approach to link subcellular effects to higher biological levels. All biomarkers will be combined in an Integrated biomarker response (IBR). The behavioural response of the organisms and genotoxicity, as well as the dynamic energy budget model and adverse outcome pathways, will be used to link the subcellular response to higher biological levels.

2.05.P-We033 Comparative Study of the Ecotoxicity in Water and Soils of 4 Hydrolates and 2 Natural Products of Plant Origin

*M Rosa Pino*¹, *Diego Ballester*², *Cristina Gan-Oria*², *Natalia Ferrando Lázaro*², *Guillermo Abajo*², *Antonio Valenzuela*², *Eva Terrado*², *Elisa Langa*² and *Ana Mainar*³, (1)San Jorge University, Zaragoza, Spain, (2)Universidad San Jorge, Spain, (3)Universidad de Zaragoza, Spain

Plant-based products are frequently considered as efficient and more environmentally friendly alternative against synthetic products for many applications such as biopesticides or antimicrobials. In fact, many of them are already commercialized under “green” labels. Nevertheless, few research have analysed their ecotoxicity when they are released and accumulate in the environment. We conducted a comparative study of the ecotoxicity in water and soil for four hydrolates obtained by semi-industrial vapor-pressure extraction from three selected aromatic plant species: (domesticated *Artemisia absinthium* (Teruel, Spain), *Dittrichia graveolens* (Ciudad Real, Spain), and experimentally pre-domesticated *Lavandula luisieri* (Toledo, Spain)); two plant-based products (citronellol and tannic acid) and a commercial synthetic pesticide (fipronil). In order to determine ecotoxicity in the environment, four indicator organisms were selected: the invertebrate *Daphnia magna* and the bacterium *Vibrio fischeri* as aquatic organisms and the earthworm *Eisenia fetida* and the plant *Allium cepa* as soil organisms. In addition, the study of mesocosms samples exposed to the tested products allowed to evaluate the global impact in fluvial periphyton and microbial communities of both aquatic and soil ecosystems. Our results concluded that the *S. montana* hydrolate is the most toxic for *V. fischeri* and *A. cepa*, being also the one that most affects to the fluvial periphyton and the mesocosm of water and soil microorganisms (on which pesticide fipronil has no effect). *A. absinthium* hydrolate is was especially harmful to *D. magna* and *E. fetida*; while *D. graveolens* hydrolate mainly affects *E. fetida* and *A. cepa*. Finally, citronellol and tannic acid showed higher LC₅₀ values for *D. magna* and fluvial periphyton than fipronil, although they have had higher antimicrobial activity against microbial communities in rivers and soil than the synthetic pesticide. Without denying the reasonable possibility that plant-based products biodegrade more easily than synthetic pesticides, and they might generate less bacterial resistance, systematic monitoring of their ecotoxicity should be required before they are proposed as viable alternatives to synthetic products since it has been shown that their natural origin does not imply harmlessness to the environment. *The authors thank the financial support of Gobierno de Aragón: Departamento de Ciencia, Universidad y Sociedad del Conocimiento (Group E39_20R).*

2.05.P-We034 First Look Into the Use of Fish Scales As a Medium for Multi-Hormone Stress Analysis

*Emily Kennedy*¹ and *David Janz*², (1)Toxicology, University of Saskatchewan, Saskatoon, SK, Canada, (2)University of Saskatchewan, Canada

Cortisol (F) is the main glucocorticoid and a primary mediator of the physiological stress response in fishes. While the quantitation of secreted cortisol provides some indication of the state of stress within an organism, the use of multi-hormone analyses may be capable of uncovering further information. Dehydroepiandrosterone (DHEA) is an androgen and precursor steroid with actions that oppose those of cortisol in mammals. Currently, the potential role of DHEA in the stress response in fish is unclear; however, in humans and other vertebrates high ratios of cortisol to DHEA are considered indicative of chronic stress and an increased allostatic load. The means by which DHEA negates the effects of cortisol in mammals is thought to occur in part via changes in the metabolism of cortisol to its inactive metabolite cortisone (E). The quantitation of F as well as DHEA and E could therefore provide a more complete picture of the overall state of stress in fishes. While the quantitation of glucocorticoids to assess stress in fishes is often accomplished using plasma or serum, the use of fish scale hormone concentrations in the evaluation of long-term stress presents some unique and useful features. Scales incorporate steroid hormones as they grow and thus present an integration of hormones secreted over lengthy periods of time rather than a single time point as is characteristic of other media. Additionally, scale hormone concentrations are most likely unaffected by brief increases in stress incurred upon capture, a problem often encountered when sampling blood. As DHEA and E have yet to be quantified within the fish scale the first objective of this study was to develop a sample processing protocol for the extraction and quantitation of F, E and DHEA. Following this, we induced a state of long-term stress in goldfish (*Carassius auratus*) and rainbow trout (*Oncorhynchus mykiss*) to determine changes in scale and circulating F, E and DHEA concentrations. After 14 days of randomized daily physical stressors, scale concentrations of F, E and DHEA were elevated compared to unstressed controls in both fish species, however these elevations were not reflected in all serum samples. This study thus supports the use of fish scales in place of other media when assessing long-term stress in teleost fish.

2.05.P-We035 Potential Impacts of Sacrificial Anodes on the Health Status of the Black Scallop *Mimachlamys Varia*: Laboratory and Field Study

Marine Barbarin¹, **Emmanuel Dubillo**², **Carine Churlaud**³, **Clément Genin**⁴, **Angelique Fontanaud**⁵, **Nicolas Menard**⁶, **Philippe Refait**⁴ and **Helene Thomas**², (1)LIENSs, La Rochelle, France, (2)LIENSs UMR7266, France, (3)LIENS UMR7266, France, (4)LaSIE UMR7356, France, (5)Port de Plaisance de La Rochelle, France, (6)Port Atlantique La Rochelle, France

Coastal areas are important interface environments between marine and terrestrial ecosystems and are populated by abundant living communities. They are generally areas with high levels of economic activity, particularly linked to the presence of ports areas (seaport, fishing and marina). These port areas have developed marine ecosystems in their basins, which may be subject to various forms of contamination resulting from port activities. Heavy metals in particular may be at issue. Indeed, they may come from roadways, river discharges, careening stations, but also from cathodic protection equipment. To date, few biomonitoring studies have examined the potential impact of cathodic protection on biodiversity in port areas. This phenomenon slows down the corrosion of steel structures caused by sea water thanks to sacrificial anodes. In fact, these anodes will corrode in place of the structure they protect and thus release the metals they contain (aluminum, zinc and indium-based alloys) into the water. Large quantities of anodes are therefore necessary to protect submerged infrastructures, and consequently the quantity of corrosion products resulting from the degradation of anodes seems considerable. Studies were therefore carried out in 2021, both in port areas and in the laboratory, in order to observe whether sacrificial anodes have an impact on the health status of black scallops through several biomarker responses. Described in the literature as a sentinel species in the marine environment, the black scallop is a filter feeder with a sedentary lifestyle, allowing it to bioaccumulate and tolerate large quantities of contaminants in its body. It thus seemed the most suitable species for this study. A first study was set up in the seaport and the marina of La Rochelle, on sites with old anodes and sites with new anodes, accompanied by a reference site without anodes and without influence from port activities. A second study, carried out in the laboratory, aimed to reproduce the same conditions as the first study with regard to anodes, but without the influence of port activities. The first results showed that in a port areas the different activities (trade, careening) and the meteorological conditions greatly influence the data and that the potential effect of sacrificial anodes is not visible. The study in a controlled environment, the results of which are still being analyzed, should make it possible to overcome these constraints and provide new answers.

2.05.P-We036 Methodological Adaptation of Mesocosms for Complex Substances Like Paraffin Oils : Results of Environmental Impact Assessment for Insecticide and Acaricide Uses in Crop Protection

Clementine Gelber¹, **Philippe Lemaire**², **christian laemmer**², **Philippe Adrian**³, **Sylviane Gony**³ and **Julien delderenne**³, (1)TOTAL ONE TECH S.E., France, (2)Total Special Fluids Division, France, (3)CEHTRA SAS, France

In order to assess the environmental impact on aquatic ecosystems of paraffin oils (used as insecticide and acaricide for crop protection), specific experimental facility and equipment must be used to overcome the challenge of the hydrophobicity/low solubility of that kind of substances. A study was conducted between July and December 2020 at the Pilot Rivers platform at Lacq (France) in outdoor freshwater open-stream mesocosms, fed with 200 m³/h by Gave de Pau, which are a very ecologically relevant system. The principle of this experimentation was to expose colonized ecosystems from artificial streams during 28 days (followed by 28 more days of recovery) to defined concentrations of formulated paraffin oil, in order to observe and measure the biological responses in time of different organisms and communities of organisms (chlorophyll-a, milfoil growth, diatoms, litter breakdown, benthic macro invertebrates, Gammarus), and to determine the magnitude and significance of the effects in comparison to control ecosystems. The continuous treatment was applied at higher concentrations than recommended for paraffin oil applications at full scale for plant protection, so that the results of the study can be considered as overconservative. This study was not designed to build a full dose-response relationship, but to assess 2 concentrations of the paraffin oil and determine the highest tested concentration with No Effect. From the results regarding the experimental design, it is concluded that there is no risk for aquatic environment at the tested concentration of 5 mg/l for the formulated product (EC, 97% paraffin oil). The evaluation of the data was conducted in agreement with the EFSA guidance including Minimum Detectable Differences calculation (Guidance on tiered risk assessment for plant protection products for aquatic organisms in edge-of-field surface waters EFSA Journal 2013;11(7):3290).

2.05.P-We037 Interactive Effects Between Light and Temperature During Glyphosate Degradation in River Biofilms

Selma Abdelhak¹, **Yoann Menard**¹, **Florence Donnadiou**² and **Joan Artigas**¹, (1)Université Clermont Auvergne, France, (2)Clermont Auvergne University, France

Global change is expected to alter environmental conditions driving the structure, diversity and functions of biological communities in aquatic ecosystems. Among ecological functions, we investigated how temperature and light variations affected biofilm's capacity to attenuate the herbicide glyphosate from running waters. With this aim, natural biofilm communities were acclimated to two water temperature regimes (Ambient = 19-22 °C, Warming = 21-24 °C) and three light conditions (Dark = 0 Lux, Intermediate = 600 Lux, High = 1600 Lux) in a factorial design experiment in the laboratory. After four-weeks acclimation, all biofilms were contaminated with glyphosate (50 µg/L final concentration) and their capacity for glyphosate dissipation was monitored during 21 days. The transformation of glyphosate in the warming condition was faster at high light ($DT_{50} = 6.36$ days) comparing to intermediate light and dark conditions (8.53 and 9.49 days, respectively), though differences in light effects were not observed at the ambient temperature condition (11.35, 10.13 and 8.41 days, respectively). Biofilms transformed glyphosate into aminomethyl phosphonic acid (AMPA), but were not capable to completely mineralize the molecule suggesting that the latter will tend to accumulate in the environment. Light was a structuring factor of bacterial communities diversity subjected to warm temperatures, *Burkholderiaceae* taxa were characteristic of this condition (IndVal = 0.98, $P < 0.005$). Light also influenced the structure of eukaryotic communities subjected to both ambient and warm conditions. Protozoan (*Flamella* sp.) and diatoms

(*Fistulifera sp.*) were indicator taxa from high light conditions in eukaryotic communities. Light and temperature variations are important factors regulating microbial communities capacity for glyphosate removal in river ecosystems.

2.06 Multi-stressor ecotoxicology in aquatic ecosystems in a rapidly changing climate (Part I)

2.06.T-01 The Impact of Consecutive Heat Wave and Pesticide Exposure on Two Congeneric Damselfly Species and Their Gut Microbiome

Charlotte Theys¹, Julie Verheyen¹, Nedim Tüzün², Lizanne Janssens² and Robby Stoks³, (1)Biology, KU Leuven, Leuven, Belgium, (2)KU Leuven, Belgium, (3)University of Leuven, Belgium

Freshwater organisms are often exposed to both toxicants and natural stressors, whereby it is key to assess the combined impact of toxicant exposure under warming. Both heat waves and pesticides are frequently occurring stressors in aquatic ecosystems and are expected to increase under global warming. Since their transient nature, and because organisms are often sequentially exposed to these stressors, it might be expected that negative effects of a pesticide could be increased due to previous exposure to a heat wave, if the heat wave reduces the energy budget to deal with the pesticide. Therefore, we examined the effect of consecutive exposure to a heat wave (absent and present) and a pesticide (solvent control and 2 µg/L chlorpyrifos) on two life history traits (mortality and growth rate) and three physiological variables (acetylcholinesterase activity, malondialdehyde and cellular energy allocation) in two congeneric *Ischnura* damselfly species (*I. elegans* and *I. pumilio*). Of a subset of larvae, the gut microbiome was dissected to analyze the effects of the stressors on the microbiome community composition and whether these differed between species, and covary with the response patterns observed for the life history and physiological variables (analyses in progress). Larval life history was only negatively impacted by exposure to the heat wave, whereas the physiological variables were altered by both stressors. Moreover, we found that *I. pumilio* had a higher energy budget than *I. elegans*, which allowed them to be better able to cope with the increased energetic demands under stressor exposure. We did not find any evidence of higher negative effects of the pesticide after exposure to a heat wave. Potentially, cross-tolerance occurred: by activation of the defense system under heat wave exposure, larvae might have been able to better withstand subsequent pesticide exposure, and thus do not show an increased negative response to the second stressor. Our results highlight that life history traits may not always show the combined impact of stressors on organisms, and that physiological variables may be more sensitive biomarkers.

2.06.T-02 Ecotoxicological and Biochemical Effects of Two Pesticides, Single and Combined, on the Marine Diatom *Thalassiosira weissflogii* - the Impacts of Climatic Changes

Andreia Filipa Mesquita¹, Fatima Jesus¹, Fernando J. M. Gonçalves¹ and Ana Marta Goncalves², (1)CESAM & University of Aveiro, Portugal, (2)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Coimbra, Portugal

In the last decades, climatic changes have been a great concern among the scientific and political communities. Nowadays, climatic changes effects have been reported associated to extreme climatic events like the raise of temperature, floods and droughts with impacts in several activities and in the ecosystems. The exponential increase in world population and growth in food consumption are placing unprecedented demands on agriculture and natural resources, what enforces to an intensive use of fertilizers and pesticides to suppress food production requirements. So, it is crucial to understand the harmful effects of pesticides in aquatic systems, in a context of climatic changes. In this work was considered the effects of the pesticides copper sulphate and oxyfluorfen on the marine diatom *Thalassiosira weissflogii*, at three temperature scenarios (15°C, 20°C and 25°C). This work intends to: a) evaluate the growth rate of *T. weissflogii* exposed to both pesticides, single and combined, at 15°C, 20°C and 25°C; and b) determine the biochemical impacts, namely the fatty acids (FA) profiles, after the exposure to both pesticides at 15°C, 20°C and 25°C. Results showed that this species is highly sensitive to oxyfluorfen, with EC50 values in the µg/L range. A greater growth rate of *T. weissflogii* was found at higher temperatures (20°C and 25°C) than at lower temperatures (15°C). However, increased temperature leads to increased sensitivity of the species to both compounds (at 25°C, EC50_{Copper sulfate}=98µg/L; EC50_{oxyfluorfen}=2.46 µg/L). Interactions between compounds showed a marked antagonism at 20°C and 25°C, but at 15°C a synergistic effect was observed at low concentrations of oxyfluorfen and at high concentrations of copper sulphate. Regarding on the effects on FA profiles, the organisms exposed to highest temperatures (20°C and 25°C), showed to be more affected by the pesticides (dissimilarity between control and combined pesticides at 20°C=92 % and at 25°C=79%), than the ones exposed to the lowest temperature (15°C) (dissimilarity between control and combined pesticides=14.98 %). These results raise concern over the potential effects of climate change, considering the predicted increase in temperature and the presence of mixtures of these pesticides in the environment. Under these conditions, this species will face decreased growth rate and impaired nutritional value, which will likely impact the trophic food webs and, thus, the structure of marine communities.

2.06.T-03 Long-Term Effects of Warming and Pyrene on *Calanus hyperboreus*

Khuong V. Dinh¹, Josefín Titelman², Janne Søreide³, Ketil Hylland² and Katrine Borga⁴, (1)Department of Biosciences, Department of Biosciences, University of Oslo, Oslo, Norway, (2)University of Oslo, Norway, (3)The University Centre in Svalbard, Norway, (4)UiO, Norway

The copepod *Calanus hyperboreus* is a key species in the Arctic marine ecosystems being vital lipid-rich food for Arctic fish, birds, and mammals. However, cumulative long-term effects of warming and pollutants on *C. hyperboreus* population success are of concern. To address this issue, we conducted a one-year experiment using *C. hyperboreus* collected in March 2021 from the upper 400 m in the deep Arctic Ocean northeast of Svalbard. *C. hyperboreus* females were assigned individually in 250-ml glass bottles filled with 200 ml of the filtered seawater at 1 or 5°C (n = 40 for each temperature). After two weeks, 20 females of each temperature treatment were exposed to one pulse of pyrene (200 nM). In May, which was the algal bloom period, females were fed six times per week (Mon-Fri) with *Rhodomonas salina* (~500 µg C L⁻¹). The survival, egg production, hatching success, and

grazing rate (faecal pellet production) were quantified through the productive season from 31 March to 30 September 2021. The lipid content was measured in May, July, August, and September to assess how females recovered from reproduction. No short term treatment effects were detected on survival or egg production after just 14 days, but over the longer course of the year, the long-term experiment females exposed to pyrene had both lower survival and lower faecal pellet production than controls, particularly at 1°C. Survival and grazing rate was generally higher at 5°C than at 1°C, suggesting that a +4°C warming is not critical for *C. hyperboreus*. Surviving females were kept and are currently overwintering at 1°C in filtered seawater, starting from November 2021 until February 2022. Survival and gonad development of females is checked weekly. Final egg production and potential egg hatching success will be quantified in January-March 2022. This study will provide unique information on long-term oil pollution and warming effects on *C. hyperboreus*, a key species in high-Arctic marine food webs.

2.06.T-04 Influence of Salinity on Pyrethroid Toxicity: An Analysis of Neurotoxicity and Osmoregulation in a Model Estuarine Fish (*Menidia beryllina*)

*Sara J. Hutton*¹, *Samreen Siddiqui*¹, *Emily Pedersen*¹, *Amelie Segarra*², *Michelle L. Hladik*³, *Richard Connon*⁴ and *Susanne M Brander*, (she, her, hers)¹, (1)Oregon State University, United States, (2)University of California Davis, United States, (3)U.S. Geological Survey, United States, (4)University of California, Davis, United States

Climate change is causing changes in precipitation patterns and as well as increased sea levels. These alterations are linked with increased salinity in estuaries, making the potential differences in toxicity across a salinity gradient a topic of increasing interest in assessing risk to estuarine species. As ionic concentration increases the log K_{ow} and water solubility of a compound has been shown to increase and decrease respectively. Pyrethroid insecticides are commonly used in agricultural, industrial, and household settings and have been detected in watersheds globally. Several recent studies have shown that pyrethroid toxicity can change across a salinity gradient. Early life exposures in fish to pyrethroids has been found to cause toxicity at environmentally relevant concentrations and alter behavior, reproduction, and gene expression. Therefore, Inland Silversides (*Menidia beryllina*), a commonly used euryhaline, model fish species, were exposed from 5 days post fertilization (approximately 1-day pre-hatch) for 96 hours to six pyrethroids: bifenthrin, cyfluthrin, cyhalothrin, cypermethrin, esfenvalerate, and permethrin. Exposures were conducted at three salinities relevant to brackish, estuarine habitat (0.5, 2, and 6 PSU) and 3 concentrations, either 0.1, 1, 10, and/or 100 ng/L, determined from previous experiments to be sublethal and environmentally relevant. After exposure, Inland Silversides underwent behavioral assays and were subjected to a dark and light cycle to determine behavioral toxicity.

Additionally, Inland Silversides exposed to bifenthrin, cyfluthrin, and cyhalothrin at 6 and 10 psu and 1 ng/L, were placed in clean water and are being reared until reproductive age. F0 larvae, F0 adults, and F1 larvae will undergo behavioral analysis and gene expression analysis to inform on the potential multigenerational effect of pyrethroids. These results indicate that there may be different behavioral responses to pyrethroids depending on exposure salinity and concentration. There was developmental toxicity observed from cypermethrin exposure at 0.5 PSU, but not from other compounds. This suggests behavioral differences are related to neurological effects rather than developmental impacts. Results show different behavioral responses in each pyrethroid at different salinities. These data will provide knowledge to managers and environmental planners to help further protect threatened and endangered fishes in estuarine and bay regions.

2.06.T-05 Do Short-Chain Chlorinated Paraffins Have Endocrine Disrupting Potential? Molecular and Population-Based Investigation in the Rotifer *Brachionus calyciflorus*

*Jeremy Jaegers*¹, *Audrey Ducenne*², *Eric Gismond*³ and *Celia Joaquim-Justo*², (1)Department of Life Sciences, Université de Liège (ULiège), Liège, Belgium, (2)University of Liege, Belgium, (3)LEAE - University of Liege, Belgium

Rotifers, one of the most important zooplankton groups, play a vital role in nutrient cycles by feeding the upper levels of aquatic food chains. Their complex life cycle, alternating between periods of parthenogenetic and sexual reproduction which produces diapausing cysts, offers multiple endpoints with varying sensitivities to contaminants. This makes them attractive models for ecotoxicology, which is why the freshwater species *Brachionus calyciflorus* was chosen to study the impact of short-chain chlorinated paraffins (SCCP), persistent organic pollutants with known endocrine disrupting effects, on zooplankton. To this end, their demographic parameters and the mRNA levels of three endocrine receptors were measured after exposure to environmentally realistic SCCP concentrations (10-100-1000ng/L). A 4-day reproductive test on *B. calyciflorus* evaluated SCCP impact on the intrinsic population growth rate (r), mixis (M), fertilization (F), cyst production, and hatching rate. The mRNA levels of the endocrine genes retinoid X receptor (RXR), membrane-associated progesterone receptor (MAPR), and retinoid A receptor (RAR) were measured after 6-24-48-72-96 hours of exposure. Furthermore, both assays were carried out at two temperatures, 20°C and 25°C, to determine if the known effect of temperature on *B. calyciflorus* reproduction would influence SCCP effects. Results showed that multiple demographic values of *B. calyciflorus* are significantly impacted by SCCP exposure. Indeed, at both temperatures, M was significantly higher than control, while F was lower, indicating possible issues with sexual reproduction. However this did not affect cyst production and hatching rate. The only factor that differed between temperature treatments was r , which was significantly lower than controls at 100ng/L of SCCP only at 20°C. The three studied endocrine genes were all affected by SCCP exposure with significant increases in mRNA levels compared to controls taking place after 72h, which is the point where sexual reproduction happens in the reproduction assay. In conclusion, environmentally relevant SCCP exposure affects numerous reproductive factors in *B. calyciflorus*, as well as transcription levels of endocrine genes which are believed to influence reproduction. These effects did not affect cyst production and hatching. A 5°C difference between treatments seemed to mainly influence SCCP effects on two elements: parthenogenetic reproduction and the RXR gene.

2.06 Multi-stressor ecotoxicology in aquatic ecosystems in a rapidly changing climate (Part II)

2.06.T-06 Adaptation to Pesticides and Associated Fitness Costs Under Single and Multi-Stress Conditions

*Ayesha Siddique*¹, *Naeem Shahid*², *Jeremias Martin Becker*³ and *Matthias Liess Liess*⁴, (1)Ecotox, Helmholtz center for Environmental Research-UFZ, Leipzig, Leipzig, Germany, (2)System-Ecotoxicology, Helmholtz Center for Environmental Research - UFZ, Leipzig, Germany, (3)Helmholtz Centre for Environmental Research, Germany, (4)UFZ, Germany

Under global change scenarios, multi-stress conditions may occur regularly and requires adaptation. However, the adaptation to one stressor may reduce performance due to fitness costs and long-term effects of adaptation. Here we investigated the ecological consequences of adaptation under multiple stress and long-term consequences of pesticide exposure to ultra-low concentrations in the widespread crustacean *Gammarus pulex*. Under optimum temperature, *G. pulex* from agricultural streams were considerably more tolerant to pesticides as compared to the reference populations. Here we assume that the increased tolerance in agricultural populations is the combination of acclimation, epigenetic effect and genetic evolution. After experimental pre-exposure to very low concentration (LC₅₀/1000), reference populations showed increased pesticide tolerance. In contrast, pre-exposure did not further increase the tolerance of agricultural populations. Moreover, these populations were more sensitive to elevated temperature alone due to the hypothesized fitness cost of genetic adaptation to pesticides. However, both reference and agricultural populations showed a similar tolerance to the combined stress of pesticides and warming due to stronger synergistic effects in adapted populations. As a result pesticide adaptation loses its advantage. The combined effect was predicted well by the Stress Addition Model (SAM), developed for predicting the synergistic interaction of independent stressors. Long-term consequences of increased insecticide tolerance were characterized by significantly reduced survival, per capita growth and mating when organisms were cultured under pesticide-free conditions in the laboratory for three months. We conclude that under multi-stress conditions, adaptation to pesticides reduces the general stress capacity of individuals and trade-off processes increase the sensitivity to additional stressors. This causes strong synergistic effects of additional stressors on pesticide adapted individuals. The exposure and adaptation are also associated with impaired performance which potentially affects ecosystem functions such as leaf litter degradation. These long-term impairments need to be considered in deriving safe concentrations.

2.06.T-07 A Heat Spike Overrides Pesticide Tolerance: A CASE Study in *Daphnia magna*

*Mrs. Marlies Van de Maele*¹, *Lizanne Janssens*² and *Robby Stoks*³, (1)Biology, KU Leuven, Leuven, Belgium, (2)KU Leuven, Belgium, (3)University of Leuven, Belgium

Two important anthropogenic stressors that cause biodiversity loss in aquatic ecosystems are global warming and agricultural insecticides. Not only the mean temperature, but also temperature extremes are predicted to increase under global warming. Pesticide exposure can cause severe sublethal and lethal effects and therefore poses a strong selection pressure, leading to the evolution of pesticide tolerance. Despite making it possible for organisms to survive in a polluted environment, tolerance also comes with costs, most often due to energetic constraints. One such highly relevant, but rarely studied cost of tolerance is an increased sensitivity to heat. Building on an experimental evolution trial during which tolerance towards the pesticide chlorpyrifos evolved in *Daphnia magna*, we compared the heat sensitivity of chlorpyrifos-tolerant and non-tolerant clones, whereby both lethal and sublethal traits (reproduction) were investigated. All clones were exposed to one of the six combinations of four days exposure to chlorpyrifos (solvent control, 0.5 µg/L or 0.65 µg/L) followed by four days exposure to a heat treatment (20 °C vs 30 °C). Survival was defined as the percentage surviving individuals at maturity. To get an estimate of the reproductive outcome, both time to the release of first and second broods and the brood sizes were determined. We observed a strong cost of chlorpyrifos tolerance in terms of a lower heat tolerance, both for survival and traits related to reproduction. Most importantly, these heat-induced costs paid by the chlorpyrifos-tolerant clones did not disappear in the presence of the pesticide. Intriguingly, the opposite was true: when combined with exposure to chlorpyrifos, the heat spike caused the highest mortality (at the highest pesticide concentration), delayed reproduction and reduced the number of offspring the most. This suggests that heat spikes might offset pesticide tolerance. In the long term, this might mean that in a warming world where heat spikes will become more frequent, pesticide-tolerant clones might suffer more, possibly leading to shifts in the population composition and the population tolerance level.

2.06.T-08 Single and Combined Effects of the Herbicide Terbutylazine and Increased Temperature on Synthetic Periphyton Structure, Function and Microbial Composition

*Olga Lamprecht, Postdoctoral Researcher*¹, *Bettina Wagner*¹ and *Ahmed Tlili*¹, (1)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland,

Phototrophic biofilms, also known as periphyton, are microbial freshwater communities that drive crucial ecological processes in streams. Periphyton is influenced by a multitude of biotic and abiotic factors, which may alter its composition and the ecological functions it provides. Due to the complexity of natural periphyton, understanding species dynamics is challenging, yet fundamental to gain mechanistic insights into the impacts of multiple stressors such as chemical pollution under the conditions of climate change. To address this challenge, we used a fully defined but diverse, and highly reproducible synthetic periphyton, consisting of an assemblage of at least 22 phototrophic species (13 diatoms, at least 5 green algae, 4 cyanobacteria). We examined the single and combined effects of increased temperature (17°C vs 20°C) and four levels of the herbicide terbutylazine (0, 1, 10 and 100 µM) on the 3D-structure, function and microbial composition of the synthetic periphyton. Our results show that both temperature and 100 nM terbutylazine strongly impacted community composition and microbial succession. On the other hand, functional response of the entire community remained intact upon exposure to stressors, although the relative abundances of multiple species were strongly impacted. Importantly, we were able to examine precisely how each species within the community responded over time to the tested stressors, singly and in combination. Species-level resolution within the community provided an accurate understanding of how species interactions affect the community properties at the functional and structural levels when multiple stressors occur. Overall, our synthetic periphyton is a powerful tool to perform mechanistic studies on periphyton

structural and functional responses, as well as on species propagation, potentially to any biotic and abiotic stressor and their combinations. Indeed, our results provide strong evidence that such a synthetic periphyton, grown under controlled conditions, enables to overcome the complexity of its natural counterpart and to test for various mechanistic hypotheses via targeted manipulation.

2.06.T-09 Future Climate Change Effects of Reoccurring Heatwaves and Elevated Temperature Fluctuations Towards Chemically Stressed Freshwater Ecosystems

Markus Hermann¹, Edwin Peeters¹ and Paul van den Brink², (1) Wageningen University & Research, Netherlands, (2) Wageningen Environmental Research, Netherlands

Temperature alterations in consequence of future global climate change (GCC) will affect aquatic ecosystems, such as lentic freshwaters. Latest climate assessments predict higher mean temperatures and an increased severity and frequency of extreme weather events, such as heatwaves or warm spells in the future. The impacts of these natural pressures are, yet, unknown due to complex interactions with other anthropogenic stressors (i.e. chemicals), causing potential alterations in the environmental fate of these ubiquitous compounds. At present, the combined effects of nonchemical GCC-related stressors and chemicals on freshwater ecosystems continue to be understudied. While the majority of multiple stressor experiments observed responses of single species, only few experiments have been conducted at the more complex levels of population or community considering intra- and interspecific interactions at the same or adjoining trophic level. Besides that, studies which include daily temperature fluctuations and thus natural variability are very scarce. However, more severe effects on species under chemical stress were observed under changing thermal conditions when compared to constant, elevated temperature regimes. Therefore, we concluded that ecosystem complexity and the variability in temperature are crucial aspects when studying chemical effects under environmentally relevant climate change scenarios. Our goal was to study single and combined effects of GCC scenarios on zooplankton-dominated freshwater ecosystems under chemical stress. Temperature variability and extreme events were operated by the *Transportable temperature and heatwave control device (TENTACLE)*. All temperature scenarios were replicated five times in the presence or absence of the fungicide carbendazim in indoor freshwater microcosms. We studied ten endpoints over 48 days to comprehend changes in species dynamics, community structure, and ecosystem functioning. Results revealed a significant decline in the abundance of macro- and micro-zooplankton species after reoccurring heatwaves, elevated temperatures, and chemical stress ($F=0.6$, $p=0.002$). Zooplankton community analyses presented rotifers having highest tolerance compared to copepods, while cladocerans showed lowest tolerance towards combined stress. Additionally observed multiple stressor effects were bidirectional, depending on the trophic level and endpoint under investigation and thus highlighting the need for further research.

2.06.T-10 Too Cold and Too Hot Temperatures Increase Pesticide Toxicity

Julie Verheyen¹, Kiani Cuypers² and Robby Stoks³, (1) Biology, KU Leuven, Leuven, Belgium, (2) KU Leuven, Belgium, (3) University of Leuven, Belgium

The majority of studies on the combined impact of pesticides and temperature only considered a limited number of temperatures, typically including an intermediate 'room' temperature and a high temperature. This only captures some of the thermal range animals experience in natural populations. Although exposure to both colder and extreme high temperatures, and to daily temperature fluctuations (DTF), can be perceived as stressful, these are less considered in ecotoxicology. One powerful and conceptual tool to predict organismal responses and the fate of populations to climate change is the thermal performance curve (TPC). Despite their potential to also improve our insights in the fate of populations to warming in polluted world, studies that explicitly considered how TPCs are affected by pesticides are rare. We tested the effects of pesticide exposure and DTF on the latitude-specific thermal performance curves of the damselfly *Ischnura elegans*. While chlorpyrifos did not affect the life history traits at the intermediate temperatures (20, 24 °C), chlorpyrifos became toxic (caused lower survival and growth) at the warmer temperatures (? 28 °C), despite the higher chlorpyrifos degradation rates at these temperatures. At the extreme warm temperatures, AChE activity showed the strongest chlorpyrifos-induced inhibition, which contributed to the observed toxicity patterns at these temperatures. At the highest temperature the pesticide-induced toxicity was further magnified by DTF. Remarkably, chlorpyrifos also became toxic (reduced growth) at the colder temperatures (12, 16 °C). Overall, for all response variables, pesticide exposure resulted in more concave-shaped TPCs compared to the solvent control. By taking a thermal performance curve perspective, our study could identify different toxicity patterns at low, intermediate and high-to-extreme temperatures. This is important for pesticide risk assessment as in natural populations organisms may be exposed to pesticides not just at the advocated constant ecotox test temperature, but may regularly encounter a wide range of temperatures. Our results indicate that making predictions on the fate of populations under future warming based on TPCs, may be biased when ignoring pesticide exposure. This highlights the importance of studying pesticide toxicity across a range of temperatures to make more realistic predictions both about the impact of (i) pesticides in a warming world and (ii) warming in a polluted world.

2.06 Multi-stressor ecotoxicology in aquatic ecosystems in a rapidly changing climate (Virtual Only)

2.06.V-01 Application of Effect Based Methods in the Health Impact Assessment in Italy

Mario Carere¹, Ines Lacchetti², Walter Cristiano³, Kevin Di Domenico⁴ and Laura Mancini⁵, (1) Italian Institute of Health, Italy, (2) environmental and health, Italian Institute of Health (ISS), rome, Italy, (3) University of Torino, Italy, (4) Italian Institute of Health ISS, Italy, (5) Istituto Superiore di Sanità, Italy

The Health Impact Assessment (HIA) is a procedure aimed at protecting the health of the populations exposed to the impacts caused by large industrial enterprises. These enterprises (e.g. steel plants, petrochemical refineries) can potentially release and discharge several contaminants included in the industrial cycle. The legislations for the protection of air, soil and water quality

contain only short lists of chemicals and the potential effects of other contaminants and the mixtures are not taken into account. For this reason in Italy it has been decided to recommend to the enterprises to apply also effect based methods in the scoping (*ante operam*) and in the monitoring phase of an HIA. Effect Based Methods have been applied in different multistressors scenario (included climate changes) and can represent a valid support to the chemical analysis because they can give informations on the potential effects (e.g. mutagenicity, neurotoxicity, cardiotoxicity, embryotoxicity) caused by the chemical pollution included mixtures in the aquatic and terrestrial ecosystems. The effect based methods in the context of an HIA have been applied and proposed in different areas in Italy where the new building or an upgrading of industrial plants is foreseen. Ten industries have already applied the ecotoxicological assessment in the ante-operam phase submitting a complete monitoring plan. The EBM applied are mainly acute and chronic aquatic and terrestrial bioassays in vivo (e.g. test with earthworms, algae, crustaceans, fish embryos) and ecogenotoxicological assays such as the Ames test and the micronucleus tests. The ecotoxicological assessment may differ on the basis to specific local situations and on additional information acquired on the site and testing should be conducted according to the main national, international guidelines or validated protocols. We think that the application of EBM in an HIA with the role of early warning system and screening can guarantee a better level of protection for human health and ecosystems and at same time can address the industries to adopt the best available technologies to reduce or eliminate chemical emissions and releases.

2.06.V-02 Evaluation of the Phototoxic Effect of Microplastics and Avobenzone Using *Daphnia magna*

Haemi Kim, Dokyung Kim and Prof. Youn-Joo An, Konkuk University, Korea, South

Plastics are used in various fields and their production and consumption are steadily increasing. In disposal process, plastics discharge microplastics of various shapes and sizes. Microplastics can enter the aquatic environment by diverse pathway, and they can adsorb many pollutants. One of a pollutant in aquatic environment is UV filter. UV filters are contained in sunscreen and personal care products to prevent negative effects from the ultraviolet (UV). Particularly in summertime, UV filters can be emitted directly by increasing of water activities. Avobenzone is a commonly used UV filter, it can absorb UVA (320–400 nm) wavelength. When microplastics and avobenzone combined, it can be more toxic effects on aquatic organisms. So, this study aimed to observe combined and phototoxic effects of microplastics and avobenzone on aquatic organism *Daphnia magna*. Acute toxicity test was performed for 48 hours. After 48 hours, significant immobilization rate was observed both non-UV and UV irradiated exposure groups. And UV irradiated groups were not growth well. Combined and phototoxic seems induce more toxic effects on *D. magna*. This study is the first case to report the effect of microplastics and avobenzone on the aquatic organism *D. magna*. These results could be used to understand the effects of UV filter and microplastics in aquatic environment, and stricter regulations are needed. *Acknowledgement- This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT and future planning (2020R1A2B5B02001734)*

2.06.V-03 Legacy Contaminant in a Future Ocean: Effect of Mercury on Cuttlefish Behaviour Under Elevated pCO₂

Antoine Minet¹, Christelle Jozet-Alves², Marina Frenandez-Declerck³, Aude Andouche⁴, Sébastien Baratte⁴, Paco Bustamante⁵ and Thomas Lacoue-Labarthe⁶, (1)LIENSs, France, (2)Université de Caen Normandie, France, (3)LIENSs UMR7266 2 rue Olympe de Gouges 17000 La Rochelle, France, (4)MNHN, France, (5)Université de La Rochelle, France, (6)LIENSs CNRS & Université de la Rochelle UMR 7266, France

Among trace elements, mercury (Hg) is found in the marine environment under both inorganic and organic forms, mainly methylmercury (MeHg). This latter is well known for its efficient bioaccumulation in biota, biomagnification along food webs, and high neurotoxicity. Despite their central place in the trophic chain and their short life span, cephalopods can display Hg concentrations up to 1 µg.g⁻¹ dry weight in their tissue. Experimental evidence demonstrated that assimilated MeHg by the trophic route is the predominant pathway of total Hg bioaccumulation in the common cuttlefish *Sepia officinalis*. In addition, the cephalopod brains are target organs of Hg accumulation raising the question of its toxic effect on nervous system. Moreover, atmospheric emissions of carbon dioxide (CO₂) increases induce ocean acidification (OA) which affects the physiology and altered neurosensory capacities of marine organisms. However, information on Hg and OA toxicity in cephalopod are still scarce, even though these molluscs have a developed central nervous system, which could be affected by both of these stressors. In this context the main objective of this work is to assess the impact of these two neurotoxic (Hg and pCO₂) on behavioural and cognitive performance of cuttlefish. Juvenile were raised in control condition, high pCO₂ and/or dietary MeHg exposure and passed several behaviour assays (predation/anti-predation abilities and lateralisation acquisition) during the first month of life. Predatory activities were not impacted by Hg and/or pCO₂. However, the acquisition of visual lateralisation in juvenile exposed to high pCO₂, Hg or both combined was disturbed. While 60% vs. 10% of control cuttlefish use their left vs. right eyes, respectively, in a vigilant situation, this proportion changed to 35% vs. 35%, respectively, for cuttlefish exposed to stressors and thus demonstrated a reverse lateralisation. In addition, it was also observed that the cuttlefish exposed to single or combined stressors progressively lost their camouflage capacities during the 1st-month period. Scarce information on fish and mammals highlights Hg disruptions in cellular processes including synaptic function, excitability, ion regulation, and protein synthesis. Moreover, OA is known to altered GABA_A receptor function. Here, the GAD gene expression was quantified by *in situ* hybridization in brain of tested individuals and interpreted with respect to behavioural and cognitive performances.

2.06.V-04 Multi-Metallic Stress and Global Change at Contrasted Reproduction Cycle Stages: Combined Effects in a Sentinel Freshwater Mussel, *Dreissena polymorpha*

Fanny Louis¹, Laetitia Minguet², Vincent Felten¹, Sandrine Pain-Devin³, Simon Devin⁴ and Laure Giamberini⁵, (1)Université de Lorraine, France, (2)LIEC (CNRS UMR 7360, Université de Lorraine), France, (3)Université de Lorraine - UL, France, (4)LIEC

- Université de Lorraine - CNRS, France, (5)Université de Lorraine, CNRS UMR 7360, France

Global change issues constitute new challenges in ecotoxicology. Although no consensus was established between the occurrence of extreme events and global changes, the frequency and the magnitude of heat waves is still increasing. The basal metabolic activity of ectotherm organisms could be strongly affected by quick temperature variations, limiting thus their defence capacity facing to additional stresses. This study aimed to assess the combined effects of a multi-metallic stress and recurrent heat waves in a freshwater bivalve, *Dreissena polymorpha*, during contrasted reproduction cycle steps. Mussels were exposed to an environmental concentration of a nickel-chromium mix solution ($20 \mu\text{g.L}^{-1}$ and $5 \mu\text{g.L}^{-1}$, respectively) for 40 days. A gradual increase of the temperature ($+15^\circ\text{C}$) was weekly performed in exposed media for 24 hours. The same experimental design has been set up during the reproduction (May-June) and the rest (November-December) periods. Key metabolism functions were targeted along the biological organisation levels through a panel of markers involved in the energy metabolism, defence mechanisms and cellular damage. Different patterns of physiological responses were highlighted between both sexes and the two reproduction cycle stages. An effect of recurrent heat waves was observed in females' osmolality while males' one was only impacted by the multi-metallic stress. Mussels exposed to the combined stress showed a decrease of their global metabolic activity associated with an increase of defence mechanisms. This study pointed out the need to include global change issues and temporal variations for further ecotoxicological investigations.

2.06.V-05 The Use of Fatty Acids to Assess Nutritional Quality of Natural and Urban Gulls' Diets Relating to the Ingestion of Debris Materials

Catarina Lopes¹, María Casero², Ivo dos Santos³, Vitor Paiva³, Jaime Ramos³ and Ana M. M. Gonçalves⁴, (1)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Coimbra, Portugal, (2)Wildlife Rehabilitation and Investigation Centre (RIAS) – Associação ALDEIA, Portugal, (3)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Portugal, (4)University of Coimbra, MARE (Marine and Environmental Sciences Centre), Department of Life Sciences, Portugal

Urban habitats offer predictable anthropogenic food sources which attract opportunistic and generalist animals, such as gulls. These species are known to exploit urban areas and landfills taking advantage of accessible, abundant, and diverse food sources, allowing them to reduce foraging time and energy expenditure. Human-derived food, however, is characterized by a poorer nutritional quality when compared to the typical natural food resources; additionally, foraging in urban areas may increase birds' susceptibility of ingesting anthropogenic debris materials, both with unknown physiological consequences for urban and landfill dwellers. In this study, we compared fatty acids (FA) composition of two opportunistic gull species (yellow-legged *Larus michahellis* and lesser black-backed *Larus fuscus* gulls) from three different wildlife rescue centres that represent foraging and dwelling areas with different levels of urbanization, and from a feeding experiment of natural, urban and landfill diets. The two main goals were to 1) assess differences in gulls' diet nutritional quality among differently urbanized habitats and between different diets, through the analysis of gulls' FA composition, and to 2) investigate the possible sub-lethal impacts of ingesting debris materials, a toxicological stressor, on gulls' FA composition. Using GC-MS to identify FAs, significant differences in gulls' FA composition were detected among the three urbanization levels and between the three diets. Gulls from the most urbanized location, anthropogenically fed and landfill-caught gulls had lower percentages of physiologically important omega (ω)-3 FAs, consistent with a diet based on anthropogenic food resources. Landfill gulls had the highest ω -6: ω -3 FAs ratio, which may be associated with a diet-induced susceptibility to inflammation. We were unable to detect any effect of the ingestion of debris materials on gulls' FA composition, probably due to bias introduced in our study by using individuals from rescue centres, or due to the small amount of ingested debris materials detected, (i.e. below toxic levels), contrarily to what we expected. These data, however, constitute a valuable contribution to the limited FA literature in gulls. We encourage further studies to understand the long-term physiological impacts of a poorer nutritional quality diet for urban dwellers and to detect potential sub-lethal impacts caused by ingestion of debris materials.

2.06 Multi-stressor ecotoxicology in aquatic ecosystems in a rapidly changing climate (Poster)

2.06.P-Th037 Exposure to an Invasive Red Seaweed Exudate Under Short-Term Heatwave Events: Oxidative Stress Status and Genotoxic Effects in the Marine Mussel *Mytilus galloprovincialis*

Hugo Vieira¹, Sílvia Pires¹, Andreia Rodrigues², Rita Silva¹, Diogo Filipe Nunes Cardoso³, Amadeu Soares⁴, João Pestana³ and Maria Donas-Bôto Bordalo¹, (1)University of Aveiro, Portugal, (2)Italian National Research Council, Portugal, (3)CESAM & University of Aveiro, Portugal, (4)Universidade de Aveiro, Portugal

Climate change is leading to increased mean sea surface temperatures and extreme heat events. Temperature has a strategic influence on the physiology of poikilothermic organisms, affecting various biological processes. Thus, there is an urgent need to better understand how marine organisms respond to these rapid changes. Marine heatwaves have been attracted considerable scientific and public interest, but more knowledge is needed, especially in combination with co-occurring stressors that organisms commonly face in the marine environments. Also, invasive species are an important driver of biodiversity loss, causing declines and range shifts in other marine species. *Asparagopsis armata* is considered an invasive seaweed in the Atlantic and Mediterranean coasts. Exposure to *A. armata* exudate has been found to exert toxic effects at low concentrations to several macroinvertebrates, but knowledge on their impact under relevant scenarios including in combination with additional disturbances is still limited. Here, we focused on the responses of the mussel *Mytilus galloprovincialis* an ecologically and economically important species in coastal areas. Mussels were exposed to 0 and 2% exudate under different temperature scenarios: constant temperature (18°C) and two varying temperature conditions simulating heatwaves (increasing from 18°C to 22°C (low) and 26°C (high) for 7 days and decreasing again to 18°C). Effects of this stressor combination were assessed by evaluating DNA damage (comet assay) and biochemical alterations related to oxidative and neurophysiological stress as well as byssus production. Results

show that exposure to the exudate led to an increase in DNA damage in relation to control and a reduction in the byssus production. On the other hand, a potential reduction of neurotransmission processes in mussels' gills exposed to high heatwave scenario was observed. Mussel ability to produce byssus was impaired the most by the combined treatment of exudate and high heatwave, representing a decline of 38.6% relative to control. Furthermore, no significant oxidative stress damage caused by exposure to the *A. armata* exudate and/or by the temperature scenarios was observed in the gills, probably due to the involvement of antioxidant defences (e.g. catalase). This study brings new insights on effects of invasive species under heatwave scenarios, being such approaches crucial when determining the likely responses of marine species to environmental change.

2.06.P-Th038 Combined Effects of Boat Engine Effluent and a Simulated Heat Wave on Fertilization and Early Development of the Sand Dollar *Dendraster excentricus*

Sinja Rist¹, RODRIGO ALMEDA² and Craig Young³, (1)DTU (Technical University of Denmark), Denmark, (2)Danish Technical University, Spain, (3)University of Oregon, United States

Marine pollution and climate change concurrently affect marine environments, and both are predicted to intensify in the future. However, we lack a thorough understanding of how these events interact and may affect marine organisms in concert. A substantial fraction of coastal pollution comes from maritime activities. Recreational boat engines are known to release potentially toxic substances, such as heavy metals and polycyclic aromatic hydrocarbons (PAHs), into the water, but surprisingly little is known about the effects of boat engine effluent on marine zooplankton. Here, we tested the effects of effluent from a two-stroke gasoline outboard engine on fertilization success and early development of the sand dollar *Dendraster excentricus* at a range of dilutions. Exposure tests were conducted at ambient summer water temperature (13°C) as well as increased temperature (by 5°C), simulating a marine heat wave. Fertilization success was determined microscopically. Growth of embryos and larvae was measured for three days post fertilization and larval development was observed for signs of malformations. The engine effluent was analyzed for the composition and concentration of heavy metals and PAHs. Fertilization success varied between 77 and 92% and was affected neither by the effluent nor by increased temperature. At the end of the exposure, larvae in the heat wave treatments were consistently larger than larvae at ambient temperature. Exposure to engine effluent showed a small but significant concentration-dependent effect on body length and width at both temperature regimes (5-10% reduction compared to the control). Additionally, at ambient temperature the length of the anterolateral and post-oral arms significantly decreased with increasing effluent concentrations (by up to 27% and 16%, respectively). This was not observed in the heat wave treatment. We did not find any interaction between the two stressors. However, our observations could point towards higher temperatures mitigating some of the effluent effects on normal growth that were observed at ambient temperature, at least in the short term. Overall, our results show a potential for effluent of common boat engines to affect larval growth and development, and we will discuss the significance of these findings with respect to realistic current and future scenarios of marine pollution and climate change.

2.06.P-Th039 Potential Changes in Biofilm Functioning in Rivers Due to Vegetation Fires

Gabriel Sigmund¹, Lukas Thuile Bistarelli², Cristina Santin Nuno³, Marc Pignitter⁴, Thilo Hofmann⁴, Stefan Doerr⁵ and Gabriel Singer², (1)University of Vienna | AgroScope, Austria, (2)University of Innsbruck, Austria, (3)Swansea University, Austria, (4)University of Vienna, Austria, (5)Swansea University, UK

Globally, each year vegetation fires burn an area as large as the European Union (3-5 Mill. km²/year). Due to global change, ecosystems that to date had rarely experienced burning are becoming increasingly disturbed by fire. During burning, the incomplete combustion of biomass forms pyrogenic organic matter which can be transported into rivers via water-driven erosion. The effect of pyrogenic organic matter on river functioning to date remains poorly understood. In this in-situ flume study, a post-fire scenario was simulated under river-like conditions and compared to control in-situ flumes. We found that wildfire-derived pyrogenic organic matter can change biofilm functioning by modulating riverine organic matter composition and concentration, as well as pH. Furthermore, toxic substances generated and/or mobilized during the fire may also be introduced to the river and impact biofilms. These substances can include pyrogenic organic matter-bound persistent free radicals, which can generate reactive oxygen species. These in turn can cause oxidative stress to biofilms. We also observed the deposition of micron-sized charcoal particles on biofilms, which could additionally modulate their functioning. This study highlights the importance of pyrogenic organic matter for aquatic ecosystem functioning in fire-affected rivers. references:

<https://doi.org/10.1021/acsestwater.1c00185> <https://doi.org/10.1038/s43247-021-00138-2>

2.06.P-Th040 Wildfire Ashes As Risk Factor for Aquatic Invertebrates: MOLECULAR Response on *Chironomus riparius*

Ana-Belen Muniz-Gonzalez¹, Isabel Campos², Ana Re³, Fernando J. M. Gonçalves², Nelson Abrantes² and Jose-Luis Martinez-Guitarte⁴, (1)National Distance Education University (UNED), Spain, (2)CESAM & University of Aveiro, Portugal, (3)University of Aveiro, Portugal, (4)UNED, Spain

Climate change causes critical alterations on world dynamics with notable increment in temperature (T) deriving in heat waves (HWs). HWs with long-term drought, are the main contributors to wildfires even aggravating their severity and frequency, particularly in Southern Europe. Wildfires have become a relevant environmental problem even on and off-site, polluting nearby water bodies. The wildfire ashes are remarkable complex matrices including heterogeneous mixture of pollutants with considerable presence of metals and polycyclic aromatic hydrocarbons (PAHs) potentially toxic to aquatic life. Diverse alterations have been observed on different freshwater trophic levels, including growth inhibition on microalgae, aquatic plants and feeding inhibition on aquatic invertebrates. However, it remains unclear which mechanisms underlie the effects of wildfire ashes at sub-organismal level. In this study, we evaluated the impact of wildfire ashes from low (LS) and high (HS) severity origin, on the *Chironomus riparius* larvae at a transcriptional level. For that, organisms were exposed to a range of concentrations of aqueous extract of ashes (AEAs) at 12.5%, 25%, 50%, 75%, and 100% for each type for 72 hours. The transcriptional response was studied

using a specific array including 42 genes related to vital metabolic pathways' through Real Time PCR (RT-PCR). The metal composition from the extracts was analyzed by coupled plasma mass spectrometry (ICP-MS). The results showed a strong disruption on transcriptional response with all the systems altered (endocrine system, detoxification, stress, immune and DNA repair) in some way more after HS ashes exposure, mainly with upregulation, worrying due to their role in vital functions. In both, LS and HS ashes, higher concentrations were detected for Mn, Zn, or Pb being the main toxicity elements. In consequence, wildfire ashes were able to modify the development of *C. riparius* as evidenced by the strong disruption on genes related to essential hormones. Moreover, the activation of crucial systems (detoxification/ stress) could limit its future response to external aggression. Finally, the DNA repair modulation emphasizes the genotoxicity of these complex mixtures. The main advantage from this study is the early detection, preventing future damage to Chironomids populations. Overall, wildfire ashes showed to be a significant environmental risk to *C. riparius* even at this short exposure time and low concentrations (12.5%). This study supports the use of transcriptional markers for an early detection of potentially toxic effects of wildfires runoff on freshwater organisms.

2.06.P-Th041 A Transportable Temperature and Heatwave Control Device (TENTACLE) for Laboratory and Field Simulations of Different Climate Change Scenarios in Aquatic Micro- and Mesocosms

Markus Hermann¹, Richard Jansen², Johan van de Glind², Edwin Peeters¹ and Paul van den Brink³, (1)Wageningen University & Research, Netherlands, (2)Tupola Wageningen University & Research, Netherlands, (3)Wageningen Environmental Research, Netherlands

Future global climate change with higher mean temperatures and an increased severity and frequency of heatwaves as extreme weather events will affect various aquatic ecosystems to, yet, unpredictable severity and consequences. Although models suggest for series of climate change scenarios increased risk of species extinction up to the year 2050, the environmental complexity of ecosystems towards temperature changes and additional anthropogenic impacts, such as chemical release, may cause unconsidered multiple stressor interaction effects. Ongoing efforts to better comprehend such temperature-chemical interaction effects comprise almost exclusively experimental designs with a simplified approach of constant temperature regimes instead of environmentally realistic daily temperature variations. We describe here an Arduino-based temperature and heatwave control device (*TENTACLE*) that is transportable, inexpensive, multifunctional, and easily reproducible. *TENTACLE* offers water temperature monitoring and manipulation of up to 3 different climate change-related scenarios: i) current natural (ambient) sinusoidal fluctuations (suitable for indoor applications), ii) future elevated fluctuations, and iii) future heatwaves as extreme events offer significant improvements and new possibilities in experimental designs. The addition of replaceable heating element equipment and field-study suitable low-cost materials creates high flexibility for researchers who may conduct indoor or outdoor, small-scale or large-scale experiments, in fresh- or salt waters, and in different geographical locations.

2.06.P-Th042 Lumbriculus variegatus, How the Blackworm Tolerates Thermal and Toxic Stress

José Nereu Pinto¹, Diogo Filipe Nunes Cardoso², Amid Mostafaie³, Rita Silva⁴, Rui Morgado⁴, João Pestana² and Susana Loureiro⁵, (1)CESAM & Department of Biology, Department of Biology, University of Aveiro, Aveiro, Portugal, (2)CESAM & University of Aveiro, Portugal, (3)Universidade de Aveiro/CESAM, Portugal, (4)University of Aveiro, Portugal, (5)Universidade de Aveiro, Portugal

The California blackworm *Lumbriculus variegatus* (*Oligochaeta*, *Annelida*) is an endobenthic sediment-ingesting worm species that presents several advantages to be used in ecotoxicology, from its relevant role on leaf decomposition, improving sediment oxygenation, with a great ability of body regeneration, which allows asexual reproduction. Still, this species is not widely used in freshwater ecotoxicological assessments, namely regarding combined stressors such as different temperatures and chemical substances in a joint exposure. To overcome this data gap, mercury (Hg) was used as a model chemical, and the standardized OECD Test Guideline 203 96 hours acute test was followed, exposing blackworms to solely-water different Hg concentrations (14, 30, 60, 120, and 240 µg Hg/L) plus an ASTM (American Society for Testing and Materials medium) negative control. Concurrently, and to evaluate how and to what extent the toxicity of Hg can change at different temperature exposures, dose response tests ran at different temperatures scenarios (10, 15, 20, 25, 30°C). Different endpoints, from subcellular to individual endpoints, were assessed in the present work. At 96h, living organisms were then divided in two groups. The first group was used to assess the blackworms' Hg content by atomic absorption spectrophotometry with thermal decomposition using an Advanced Mercury Analyser (AMA) LECO 254. The other group was used to evaluate genotoxicity by utilizing the comet assay method. Mortality was reported with LC_{50s} derived for the different temperatures (10, 15, 20, 25, 30°C) of 104, 93.3, 166, 107, 177 µg Hg/L, for each respective temperature. Bioaccumulation and genotoxicity results are still ongoing, and data will be presented at the meeting. This study aims to contribute to a more profound knowledge of the combined effects of chemicals and temperature stressors in *L. variegatus*, additionally providing some hints on the blackworm's temperature tolerance.

2.06.P-Th043 Warming Lowers Critical Thresholds for Multiple Stressor-Induced Regime Shifts Between Aquatic Primary Producers

Bastian Polst¹, Vinita Vijayaraj², Nora Kipferler³, Joey Allen⁴, Gregorio Lopez⁵, Joséphine Leflaive⁶, Franz Hölker⁵, Sabine Hilt⁷, Herwig Stibor⁸, Elisabeth Maria Gross⁹ and Mechthild Schmitt-Jansen¹⁰, (1)UFZ - Helmholtz Centre for Environmental Research, Germany, (2)Université de Lorraine, France, (3)Ludwig Maximilians University of Munich, Germany, (4)CNRS - LIEC UMR7360, France, (5)Leibniz Institute of Freshwater Ecology and Inland Fisheries IGB, Germany, (6)University of Toulouse, France, (7)Institute of Freshwater Ecology and Inland Fisheries (IGB), Germany, (8)Ludwig-Maximilians-University Munich, Germany, (9)CNRS UMR 7360 / Université de Lorraine, France, (10)UFZ - Helmholtz Ctre Environm. Research, Germany

In shallow aquatic ecosystems, external stressors can induce regime shifts from macrophyte- to phytoplankton-dominated states

with severe consequences for ecosystem functioning and services. Shallow lakes are the most frequent freshwater type, worldwide, but effects from multiple stressors in the context of global warming are mainly undescribed. In agricultural landscapes they are exposed to mixtures of nutrients and pesticides, which can interact with other stressors as global warming in antagonistic, synergistic or reversed forms. However, to derive scientifically informed thresholds for regime shifts in the context of multiple stressors, interaction patterns need to be understood in a dose-dependent way. We tested the effects of global warming, nitrate, and a selection of pesticides typically found in agricultural run-off in a microcosm study. Effects on main autotrophic components of shallow lakes (macrophytes, periphyton, and phytoplankton) were assessed in a factorial dose-response experimental design applying stressors individually and in combination at 5 concentrations in two temperature settings. Individual stressors did not induce a regime shift, but in combination, pesticides and nitrate interacted synergistically, inducing a shift wherein phytoplankton biomass increased and macrophyte biomass decreased. Global warming amplified this effect and lowered critical thresholds for regime shifts. In conclusion, global warming increases the risk of shallow aquatic ecosystems for shifting to a turbid, phytoplankton-dominated state, and negatively impacting ecosystem service provisioning. Our study further confirmed the need of using a dose-dependent experimental design to conclude interaction patterns and critical thresholds for adverse ecological effects. Multiple stressor interactions must be considered when defining safe operating spaces for aquatic systems.

2.06.P-Th044 Can Seawater Acidification Influence the Effects of Three Antibiotics, Alone and As a Mixture, on the Early Life Stages of the Sea Urchin *Paracentrotus lividus*?

Davide Asnicar¹, Francesca Granziero² and Maria Gabriella Marin², (1)Department of Biology, Università degli Studi di Padova, Padova, Italy, (2)Università degli Studi di Padova, Italy

Amoxicillin, trimethoprim and ciprofloxacin are among the best-selling antibiotics worldwide and among the most relevant in aquatic ecosystems, having an average concentration of 50-100 ng/L. As a consequence of the increased use of antibiotics, their concentration in coastal systems is also expected to increase in the years to come. In the same time frame, the increase in CO₂ absorbed by the ocean is predicted to continuously lower the pH up to -0.4 units at the end of the present century, reaching an average value of 7.7. In the present work, embryos of the sea urchin *Paracentrotus lividus* were reared in the presence of the three contaminants mentioned above (individually and in mixture) at an environmentally relevant concentration (100 ng/L) in artificial seawater at natural pH (8.1). Moreover, embryos' performances were analyzed in a multiple stressor scenario using the same contaminants but in seawater at pH 7.7. Embryos were obtained pooling gametes of 3 females and 3 males. The experiment was replicated 4 times. Embryonic development was followed for 48 hours post-fertilization by assessing the effects of the experimental conditions on developmental rate, percentage of larval abnormalities, larval growth, oxygen consumption and activity of oxidative stress (superoxide-dismutase SOD, catalase CAT), xenobiotic metabolism (glutathione-S-transferase GST) and neurotoxicity (acetylcholinesterase AChE) related enzymes. Neither the contaminants nor the pH caused a delay in the development or modification in the oxygen consumption rate. On the other hand, in larvae morphological abnormalities and skeletal rod length were significantly influenced by the pH 7.7, but not by the contaminants. Although not significantly, enzymatic activity was influenced by both contaminants and reduced pH. Biochemical biomarkers, SOD and GST activity in particular, showed a generally pejorative trend effect in larvae exposed to the mixture. These results suggest that *P. lividus* larvae are able to cope with the presence of antibiotics and reduced pH, but might face a cost at the sub-cellular level where oxidative stress and xenobiotics can cause damages. Further analysis shall be carried out to fully understand if the combined exposure to antibiotics and reduced pH jeopardize the maintenance of sea urchin populations in the future.

2.06.P-Th045 The Effects of WATER Quality on Natterjack Toad Survival and Development

Sean MacLeod¹, Mhairi Alexander¹ and Frances Orton², (1)University of the West of Scotland, United Kingdom, (2)Health and Life Sciences, UWS, Glasgow, United Kingdom

The Anthropocene has seen the global decline of amphibians with 40 % of species threatened with extinction. In the UK, amphibians are also declining, particularly the natterjack toad (*Epidalea calamita*) which is threatened with extinction in Scotland. A widely documented threat to the survival of natterjack toads is habitat changes, characterised through the reduction of grazing regimes. However, even in areas where there is suitable habitat, natterjack toads are failing to recolonise, indicating that additional threats are also impacting their survival. Here, we investigated the impacts of water quality on survival, growth, and metamorphosis of natterjacks over two breeding seasons. The basic experimental design comprised rearing spawn collected from a site with a large natterjack toad population (Cumbria, England) with water collected from prospective natterjack toad breeding pools from five sites in Scotland. In year one, for three out of the five sites tested, 100 % mortality occurred at the hatching stage. This was likely due to the high salinity recorded in these sites, due to seawater inundation (a result of climate change). For the remaining two sites, natterjack toads reared in water from Mersehead – which is the only site in Scotland with a viable population – displayed higher growth compared to Southernness, which was deemed a historical site. In year 2, survival was > 90 % for both Mersehead and the other selected sites, which had previously supported natterjack toad populations (Caerlaverock, Newfield, Moss-side). However, metamorphs reared in water collected from the historical sites were smaller than those reared in water from Mersehead. Water quality differed at Mersehead compared to the three historic sites, which included higher pH, lower conductivity, and lower total dissolved solids observed at Mersehead. These differences found potentially explain why there is an absence of natterjack toads from previously viable sites. Further work will help elucidate the potential impacts of water quality on natterjack health and survival, with the ultimate aim to prevent extinction of the species in Scotland.

2.06.P-Th046 The Acute and Chronic Effects of Chemical Exposure and Climate Change on the Life History Traits and Gene Expression of Resurrected *Daphnia magna* Clones in a Multiple-Stressor World

Florian Gigl¹, Sarah Crawford¹, Jacob Ouellet², Luisa Orsini³, Matthias Hinderer⁴ and Henner Hollert⁵, (1)Goethe University

Frankfurt am Main, Germany, (2)Goethe University Frankfurt, Germany, (3)University of Birmingham, United Kingdom, (4)Technische Universität Darmstadt, Germany, (5)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany

The resilience of an organism is characterized by good adaptation and the resulting robustness to constantly changing environmental conditions. Due to increasing anthropogenic influences such as population growth, intensification of agriculture, advancing global industrialization and the climate change, conditions in different ecosystems are changing rapidly, making quick and targeted adaptation difficult for many organisms. However, ecotoxicology is generally concerned with the acute and chronic effects of contaminants on aquatic organisms and the environment over a short period of time, which would not consider genetic adaptations in exposed populations. Thus, long-term studies are critical to understanding ecological and evolutionary processes in nature and in assessing how species respond to and persist during environmental change. The emerging field of the evolutionary toxicology examines effects of pollutants on organisms both at the organismic and the molecular level. When combined with resurrection ecology approaches, evolutionary toxicology provides a novel opportunity to examine evolutionary adaptation at the genetic level to the deteriorating environment conditions over a long period of years to centuries without the traditional limitations of long-term or multi-generational studies. Resurrection ecology utilizes dormant eggs, for example of the keystone species *Daphnia*, retrieved from dated lake sediment cores that are hatched from over years to centuries ago. The aim of this research is to examine the effects of climate change and chemical exposure on the model keystone organism *Daphnia magna* using resurrection ecology approaches. The chemical test substance is the polycyclic aromatic hydrocarbon (PAH) phenanthrene. This is particularly suitable because it is a historical pollutant, which already occurs in the past due to incomplete combustion. Chronic (21-d reproduction test, OECD 211) and acute (Immobilisation test, OECD 202) effects on resurrected ancient and modern *D. magna* clones will be investigated using standardized bioassays to assess apical endpoints. Furthermore, qPCR is used as a molecular measurement tool to determine genetic adaptation via the measurement of gene expression of survivorship loci. The *Daphnia* clones for these studies were obtained from two lakes with different characteristics (Stadtsee, Germany & Lake Ring, Denmark). Historical data is available for both lakes. Preliminary results are already available for this study.

2.06.P-Th047 Multistressor Effects on Eukaryotic Phytoplankton. the CASE of Glyphosate and One Toxic Cyanobacterium on a Microalgal Experimental Community

Claudia Hernández-García¹ and Felipe Fernando Martínez-Jerónimo², (1)Instituto Politécnico Nacional. Escuela Nacional de Ciencias Biológicas, Mexico, (2)Escuela Nacional de Ciencias Biológicas, IPN, Mexico

Eutrophication is a current environmental problem related to the degradation process in limnetic ecosystems; this is caused by the discharge of limiting nutrients that could favor the development of harmful cyanobacterial blooms. Also, the discharge of toxic pollutants provokes adverse effects in the phytoplankton. Chemical pollutants in eutrophic environments can stimulate cyanobacteria to synthesize and release cyanotoxins. Toxic effects of herbicides such as glyphosate-based formulations, and the presence of cyanotoxins, can act jointly to increase the stress in microalgae, contributing to the modification in the algal community. This study assessed the alteration effects of an experimental microalgal community exposed to Faena® (glyphosate) combined with one toxigenic cyanobacterium. The effects of *Microcystis aeruginosa* on population growth of the green microalgae *Ankistrodesmus falcatus*, *Chlorella vulgaris*, *Pseudokirchneriella subcapitata*, and *Scenedesmus incrassatulus* was determined. In addition, the simultaneous effects of subinhibitory concentrations of Faena® (glyphosate) on the content of macromolecules, the enzymes SOD, CAT, and GPX, as well as in the concentration of T-BARS, were evaluated. In the assays without Faena®, the microalgae showed lower growth rates than *M. aeruginosa*. In the algal community + cyanobacteria, the herbicide reduced the growth rates of microalgae, but that of *M. aeruginosa* increased. The IC₅₀'s for Faena® varied from 1,022 to 2,702 mg L⁻¹ (as glyphosate) for the different microalgae. Exposure to Faena® stimulated the cyanotoxin synthesis. The simultaneous action of both stressors produced changes in growth rates and population dynamics and increased the macromolecule content in microalgae. The increase in CAT and GPX enzymes denoted oxidative stress in phytoplankters. The integrated biomarker response (IBR) indicated that the sensitivity to stressors depended on the algal species. In the experimental algal community, the presence of *M. aeruginosa* increased the chemical stress produced by the herbicide. These results warn about the possible consequences of chemical pollutants when combined with the flourish of toxigenic cyanobacteria on the structure and dynamics of the phytoplankton community in eutrophic environments.

2.06.P-Th048 Assessment of the Toxicity of Particles and Leachate From Polyethylene Terephthalate (PET) in Combination With Triasulfuron Using Lemna minor As Freshwater Model Organism

Patricia Caballero Carretero¹, Victor Carrasco Navarro², Jussi Kukkonen² and Jose-Luis Martinez-Guitarte³, (1)National Distance Education University (UNED), Spain, (2)University of Eastern Finland, Finland, (3)UNED, Spain

Caballero-Carretero P.¹, Carrasco-Navarro, V.², Kukkonen, J. V. K.², Martínez-Guitarte JL¹.¹ Group of Biology and Environmental Toxicology, Department Mathematical and Fluid Physics, Faculty of Sciences, National Distance Education University (UNED), Madrid, Spain. ² University of Eastern Finland, Department of Environmental and Biological Sciences, Yliopistoranta 1 E, Kuopio FI-70211, Finland. The discharge and accumulation of plastic waste in worldwide waters is a disturbing situation at present. In addition to the immense number of microplastic particles present virtually in every environmental compartment, chemical additives have been also a cause of concern. Polyethylene terephthalate (PET) is one of the most popular thermoplastics used in packaging foods and beverages and textile fibers. Currently, information on the joint toxicity of PET or its additives and other chemical stressors is scarce. In our study, the toxicity of PET microparticles and leachates at three different concentrations was evaluated separately and in combination with the herbicide triasulfuron (0.1, 0.24 and 0.4 µg L⁻¹), using the common duckweed *Lemna minor* as freshwater model organism. The monitored endpoints were number of fronds, their area and dry weight. These endpoints were used to obtain growth rates and inhibition in the growth rates for each test

treatment. The preliminary results corroborated the toxicity caused by triasulfuron, but discarded any toxicity caused by PET microplastics separately or in combination with triasulfuron. The experiments with the PET leachates will elucidate whether any combination of chemical additives leaching to water cause an enhanced toxicity when combined to triasulfuron. The results of this work will provide more information about the joint toxicity of plastics, their additives and organic pollutants to freshwater organisms, helping to establish guidelines for their use and disposal.

2.06.P-Th049 Molecular Analysis of Single and Mixture Exposure of Microplastics and Thallium in the Freshwater Snail *Physella acuta*

Patricia Caballero Carretero¹ and **Jose-Luis Martinez-Guitarte²**, (1)National Distance Education University (UNED), Spain, (2)UNED, Spain

Caballero-Carretero P., Martínez-Guitarte JL. Grupo de Biología y Toxicología Ambiental. Facultad de Ciencias. UNED, Madrid, Spain. Nowadays, microplastics (MPs) are an increasing challenge as an environmental pollutant. MPs are present in the aquatic environment affecting organisms that live in it. They can adsorb organic or inorganic compounds acting as carriers to enter the living organisms. One of such compounds might be thallium, a highly toxic metal. It is present in the environment because of its use in industries, burning of coal, metal mining, and smelting. Moreover, it is one waste from electronic trash. It has been shown that thallium is present in aquatic ecosystems. However, only a few studies are assessing the toxicity of thallium in freshwater ecosystems, and none of them examine the effect at the molecular level. This study assesses the effect of the exposure to MPs and thallium nitrate and their mixture to analyze a putative synergy or antagonism. For this purpose, to analyze changes in gene expression, an array covering different cellular processes has been designed for *Physella acuta*. It is a freshwater snail that lives in ponds and lakes. Two-month-adult snails were exposed to different concentrations of microparticles of polystyrene (8 µm), thallium nitrate, and their mixture to evaluate the transcriptional activity by Real-Time PCR. It has been used genes related to hormonal pathways, stress response, DNA repairing mechanisms, oxidative stress, and detoxification mechanisms. We also have examined the activity of the enzymes GST, phenoloxidase, and acetylcholinesterase. The results obtained in this work provide the first approach at the molecular and cellular levels to elucidate the impact of both pollutants and their mixture in gastropods.

2.06.P-Th050 Copper Sensitivity in Three Common Arctic Copepods

Jan Heuschele¹, **Khuong V. Dinh²**, **Torben Lode¹**, **Tjalling Jager³** and **Katrine Borga⁴**, (1)University of Oslo, Norway, (2)Department of Biosciences, Department of Biosciences, University of Oslo, Oslo, Norway, (3)DEBtox Research, Netherlands, (4)UiO, Norway

The current climate crisis increases temperature in polar regions faster and with greater magnitude than anywhere else on the planet. The decline of Arctic Sea ice extent and thickness during summer and winter opens up new passages. This development will lead to higher shipping, mining and other anthropogenic activities in Arctic regions. Intensifying anthropogenic activity will increase the risk of direct contaminant transport to the polar regions, adding to other transport pathways such as air and ocean currents from temperate regions. The shipping industry uses copper as an antifouling coating. Copper is also a trace element that is essential for many metabolic processes. However, copper becomes toxic at higher concentrations, especially for unicellular algae and invertebrates. Copepods are small but abundant crustaceans and a crucial link in the marine food web. Copper affects copepods by lowering reproductive output, prolonging developmental time, and causing mortality. The sensitivity, however, varies within and between species and also depends on the abiotic conditions. Data of copper sensitivity of polar copepods at low temperatures are rare. To fill the knowledge gap, we conducted survival experiments onboard the research vessel “Kronprins Håkon” with the three most common calanoid copepod species (*Calanus finmarchicus*, *C. glacialis*, *C. hyperboreus*) of the Arctic region. To analyse the data, we used a reduced GUTS analysis. We then placed our results in the context of published data on copper sensitivity of Antarctic and Arctic copepod species. The sensitivity of Cu exposure was comparable between the three *Calanus* species. Compared to published data from Antarctic species and tests done at low temperatures, the three *Calanus* species appeared to be less sensitive to copper. We discuss whether this is a general pattern or potentially caused by differences in life-history traits, energy reserves, body size, or other factors. Although it appears that the three Arctic species are less sensitive to copper, it has to be noted that the experimental temperature was close to the freezing point, reflecting the in-situ conditions. With rising temperatures caused by global warming, uptake and elimination kinetics are expected to become more rapid, which could well increase the copepod's sensitivity to copper, especially during short-term exposure.

2.06.P-Th051 Characterization of Three Potential Calcification Enzymes in the Mantle of Lab-Raised Pulmonate Snail (*Lymnaea stagnalis*)

Wenlong Zhang¹, **Martin Grosell²** and **Yadong Wang³**, (1)RSMAS, University of Miami, United States, (2)University of Miami, United States, (3)RSMAS University of Miami, United States

Calcifying organisms are constantly suffering from various negative impacts induced by climate change, such as CO₂-induced acidification, which may impair the formation of calcareous structures. Freshwater mollusks, likely suffer more from CO₂-induced acidification than marine calcifiers due to the lower buffering capacity of most freshwater systems. From a biochemical perspective, there are many important enzymes contributing to the biomineralization reaction. Examples include carbonic anhydrase (CA), the proton pump, and the plasma membrane calcium ATPase (PMCA). Specifically, carbonic anhydrase catalyzes the conversion from carbon dioxide to bicarbonate, as the major carbon source of the calcareous structure in calcifiers, while the proton pump acts to export the protons, generated from the calcification reaction, and thereby defend cellular pH. PMCA is proposed to import calcium from the surrounding freshwater environment, which is the major calcium source for the calcareous structure. In this study we characterized the α -CA isoform 2 (LsCA2), the proton pump subunit A (LsVHA-A), as well as partial PMCA (LsPMCA) from the freshwater snail *Lymnaea stagnalis*. We obtained the full encoding sequences, conducted

primary structure and gene expression analysis for all three enzymes, accompanied by enzyme activity measurements for carbonic anhydrase. LsCA2 is mainly expressed in the mantle tissue, which has long been proposed as the major site for biomineralization, and also expresses both LsVHA-A and LsPMCA. Further, expressions of all three enzymes are evident throughout embryonic development during which shell formation is occurring. Moreover, the primary protein structure analysis of LsCA2 and the LsCA2 enzymatic activity measurements both suggest that the LsCA2 might be embedded in the cell membrane, with the active site exposed to the extracellular environment. These findings form a strong basis for a more detailed physiological understanding of environmental effects of elevated CO₂ on calcification in freshwater mollusks.

2.07 Stress impact in food webs and across ecosystem boundaries

2.07.T-01 Ecosystem Metabolism in Streams Covering a Gradient in Agricultural Pesticide Exposure

Jes Rasmussen¹, Peter Wiberg-Larsen² and Nikolai Friberg³, (1)NIVA - Norwegian Institute for Water Research, Copenhagen S, Norway, (2)Aarhus Universitet, Denmark, (3)Norwegian Institute for Water Research (NIVA), Norway

Many factors related to land use influence stream ecosystem functions either positively or negatively depending on stressor type and intensity, but functional redundancy may mask some or all such influences. Very few studies have focused on pesticide effects on ecosystem functions at the ecosystem scale, and no studies have addressed potential effects of pesticides on ecosystem metabolism in streams. Our objective was to explore agricultural pesticides as a potential regulating force of ecosystem metabolism in streams. We conducted comprehensive field work in 19 Danish streams covering a gradient in agricultural intensity and measured pesticide exposure, diurnal oxygen fluctuations, and physical, chemical, and biological community information (surveys of higher plants and macroinvertebrate communities) to explore drivers of ecosystem metabolism. Based on quantified pesticide exposures, predicted pesticide toxicity towards algae (sumTUalgae) was more than one order of magnitudes higher than predicted pesticide toxicity towards arthropods (sumTUdaphnia), and pesticide concentrations and TU values generally increased with increasing agricultural intensity in a two-sided 100 m buffer zone extending 2,000 m upstream of the sampling sites. Ecosystem respiration was primarily correlated to standing biomass of aquatic plants, amount of dead organic material, and macronutrient concentrations. However, primary production was most strongly correlated to sumTUdaphnia and increased significantly with increasing sumTUdaphnia, whereas sumTUalgae did provide any significant correlations to any measure of ecosystem metabolism. We propose that our results reveal cascading effects of insecticidal toxicity probably reducing standing biomass of microalgal invertebrate grazers. This leads to higher contributions of microalgal primary production influencing the metabolic balance of streams at the ecosystem level. We conclude that indirect effect mechanisms may exert as strong influence as direct effect mechanisms at the ecosystem level, and that toxicity predictions based on direct effects alone cannot reliably predict effects on ecological functions at the ecosystem scale.

2.07.T-02 Standard vs. Natural: Stressor Responses of Three Methods to Investigate Organic Matter Decomposition in Streams

Verena Christina Schreiner¹, Mirco Bundschuh², Alexander Feckler³, Liana Liebmann⁴, Matthias Liess⁵, Moritz Link¹, Anke Schneeweiss⁶, Amélie Truchy⁷, Wolf von Tümpling⁴, Philipp Vormeier⁴, Oliver Weisner⁸ and Ralf Bernhard Schaefer⁹, (1)University of Koblenz-Landau, Germany, (2)Institute for Environmental Sciences University of Koblenz-Landau, Germany, (3)University Koblenz-Landau, Germany, (4)UFZ - Helmholtz Centre for Environmental Research, Germany, (5)UFZ, Germany, (6)Quantitative Landscape Ecology, University Koblenz-Landau, Landau in der Pfalz, Germany, (7)Swedish University of Agricultural Sciences (SLU), Sweden, (8)Helmholtz centre for environmental research - UFZ, Germany, (9)University Koblenz Landau, Germany

The decomposition of allochthonous organic matter is the base of the so-called brown food web, which dominates in headwater streams. Diverse agricultural stressors, such as pesticides or excessive nutrient input are known to alter decomposition by affecting aquatic hyphomycetes, the keystone fungal group for this ecosystem function. Organic matter decomposition is typically measured by deploying bags filled with leaves in streams and subsequently calculating the leaf mass loss. This, however, is labour intensive and can show high variability. Aiming to overcome this, standardised methods have been developed, but it remains unknown to which extent these respond to agricultural stressors such as pesticides. We compared two standardised methods, cotton strips and decotabs, to the traditional leaf bag method and assessed their association with extreme values of various agricultural variables in a nationwide monitoring (KgM) comprising 70 sites. Despite standardised methods being developed to decrease variability, in our study the inter-replicate variability per site of the two standardised methods was clearly higher than of the leaf bag method. Furthermore, the two standardised decomposition methods showed no or only a weak relationship to leaf decomposition, while they related stronger to each other. This lack of relationship between the leaf bag method and the two standardised methods is in accordance with previous studies. The decomposition determined with the three applied methods was explained by different variables. Leaf mass loss was explained by the ratio of agricultural land use and the maximum stream water concentrations of the trace metals arsenic and mercury. Cotton strips and decotabs decomposition were best explained by the maximum total phosphate concentration, however, exhibiting inverse relationships (Cotton strip negatively, decotabs positively related). In contrast to previous studies, none of the methods responded to the estimated pesticide toxicity towards fungi (i.e., of fungicides). The leaf bag and the standardised methods seem to capture different facets in the ecosystem function of decomposition and thus respond to different environmental drivers, which questions the use of standardised methods to estimate effects on the ecosystem function of leaf decomposition.

2.07.T-03 Aquatic-Terrestrial Linkages: Cascading Contaminant- or Emerging Insect-Mediated Effects on Riparian Spiders

Alexis Pieter Roodt¹, Nina Röder², Sebastian Pietz³, Sara Kolbenschlag⁴, Alessandro Manfrin⁵, Klaus Schwenk⁶, Mirco Bundschuh⁷ and Ralf Schulz², (1)University of Koblenz Landau, iES Landau, DFG Graduiertenkolleg Systemlink, Germany, (2)University of Koblenz-Landau, Germany, (3)Institute for Environmental Sciences, University of Koblenz-Landau, Germany, (4)University Koblenz Landau, Germany, (5)University of Koblenz-Landau, Germany, Germany, (6)University Koblenz-Landau, Germany, Germany, (7)Institute for Environmental Sciences University of Koblenz-Landau, Germany

Organic pesticides contaminating freshwater ecosystems, have the potential to change aquatic insect development and emergence. Additionally, emerging aquatic insects are known to transport a variety of anthropogenic micropollutants from aquatic to terrestrial ecosystems. Exposure of aquatic insect larvae to pesticides can therefore impact terrestrial food webs by direct dietary pesticide exposure or changes in the quantity or timing of emerging insect subsidies. Knowledge on the effects of pesticide- and organism-specific parameters, such as pesticide class and insect sex-specific life history, as well as concentrations of pesticides in exposed riparian spiders is lacking for many current-use pesticides in this context. We conducted laboratory microcosm scale experiments simulating two field relevant exposure scenarios, i.e. acute pulse exposure to single insecticides and chronic exposure to a mixture of fungicides and herbicides during the aquatic development stage of the midge, *Chironomus riparius*. We measured pesticide concentrations in the developing larvae, directly after emergence and at the end of the terrestrial life stage of the adults. Additionally, we measured effects on larval development time, emergence success and emergent biomass. Furthermore, field sampling of riparian spiders and adjacent aquatic ecosystems from river sites along a gradient of agricultural land use was conducted. These samples were analysed for a broad range of current-use pesticides and organic micropollutants. Exposure to pesticides during the larval development of midges resulted in potential negative effects for terrestrial consumers regardless of the exposure scenario, pesticide class or insect sex. Acute exposure to sublethal concentrations of insecticides affected development duration and emergence success. Chronic exposure to a mixture of fungicides and herbicides resulted in the majority of pesticides being retained in the adult insects after emergence. Furthermore, sex-specific effects were observed in larval development duration and pesticide concentrations in the emergent adults. Pesticides concentrations measured over the terrestrial life stage also exhibited sex-specific changes. A broad range of contaminants were measured in the field-collected riparian spiders. Pesticide concentrations in spiders were found to correlate with sampling site contamination and revealed potential biomagnification through the consumption of aquatic prey for some contaminants.

2.07.T-04 Carry-Over and Cumulative Effects of Opioid Exposure in European Common Frogs (*Rana temporaria*)

Tiffany Garcia¹, Evan Bredeweg² and Tomas Brodin³, (1)Fisheries, Wildlife, and Conservation Sciences, Oregon State University, Corvallis, OR, (2)Oregon State University, United States, (3)Swedish University of Agricultural Sciences (SLU), Sweden

Early-life exposure to environmental stressors can affect individuals later in ontogeny, particularly in species with multiple life history stages. Many species carry over stress or information gained in these early life history stages regarding predators, climate, and contaminants, which can influence adult behavior and development. Depending on the timing of these latent responses, carry-over effects can compound with direct stressors, both natural and anthropogenic, in additive or synergistic ways. We found that larval European Common frogs (*Rana temporaria*) exposed to tramadol, an opioid contaminant in freshwater systems, accumulated the drug in their tissues at ratios consistent with exposure concentrations. We found no treatment differences in larval development rates, larval behavior, metamorphic size or weight, or metamorphic timing. Carry-effects were only detected when individuals exposed to high levels of tramadol as larvae experienced highly competitive environments as a metamorph. Competition levels were consistent across treatments during the larval stages, with larvae held in groups of 5 individuals. These groups were maintained over ontogeny as metamorphosed individuals were transferred to terrariums. As such, metamorphic competition depended on the order of emergence within groups. Early emerging metamorphs experienced little competition in their terrariums while late emerging individuals faced a terrestrial environment with four conspecifics. This priority effect was found to compound with tramadol exposure rates in interesting ways. We assayed 2-wk old metamorphs for behavioral response to novel objects using a flight initiation test. We found late-emerging individuals exhibited significantly slower motor response to an approaching novel object. This delay in response, however, was only found in individuals exposed to high levels of tramadol during the larval life stage. Carry-over effects of tramadol in this multiple stressor framework highlights the need for ecology-based contaminant studies over an individual's lifetime and in naturally relevant scenarios.

2.07.T-05 Mosquito Control Agent *Bacillus Thuringiensis* Var. *israelensis* Alters Emergence Dynamics of Merolimnic Insects From Floodplain Mesocosms

Sara Kolbenschlag¹, Verena Gerstle², Nina Röder³, Julian Eberhardt³, Carsten Bruehl³ and Mirco Bundschuh⁴, (1)University Koblenz Landau, Germany, (2)DFG-Grk. SystemLink iES Landau, Institute for Environmental Sciences University of Koblenz-Landau, Germany, (3)University of Koblenz-Landau, Germany, (4)Institute for Environmental Sciences University of Koblenz-Landau, Germany

The bacterium *Bacillus thuringiensis* var. *israelensis* (Bti) is widely used as a mosquito control agent assuming a taxa-specific toxic mode of action against larvae. However, studies investigating (sub-)lethal effects on non-target organisms, especially on non-biting midges (Chironomidae), raised concerns about the selectivity of Bti. As Chironomidae are an important link between freshwater and adjacent riparian food webs, changes in the population development of this and other aquatic insect species point to adverse implications on subsidised food webs. To address this aspect experimentally, we investigated the emergence of insects in Bti-treated and control pond mesocosms (21 m x 5.80 m, n = 6). During April and May 2020, Bti, i.e. Vectobac WDG, was applied three times at the highest recommended field rate in Germany ($2.88 \cdot 10^9$ ITU/ha) aligned with an artificially generated flooding to mimic the common application scenario of Bti. The emergence of insects in each pond was collected by six floating traps (0.33 m²) which were emptied once or twice a week from mid-April until the end of July. Emerged insects were identified to

family level and their abundance and biomass were determined. More than 30 insect families were recorded with Chironomidae being the most abundant family covering 88% of the emerged individuals followed by Baetidae constituting 9%. Investigating family-specific emergence dynamics revealed a statistically significant effect of Bti over time on Chironomidae but not on Baetidae. The emergence peak of Chironomidae in Bti-treated ponds was earlier and reduced compared to the control ponds. It is assumed that Bti induced an accelerated development of current late-stage larvae as stress-response while early-stage larvae died from Bti resulting in a decreased emergence weeks after the last application. No statistically significant effect of Bti on the mean weight per individual emerged Chironomidae was found. Nevertheless, our results point to a negative impact of Bti on non-target Chironomidae in accordance with several other studies. Additionally, an earlier peak of the key emergence (i.e., Chironomidae) may have a strong impact on higher trophic levels in terrestrial systems such as birds or spiders depending on prey availability during their reproductive phase. Furthermore, the nutritional value of the available prey should not be ignored thus we aim to quantify the energetic budget of Chironomidae from treated and untreated ponds.

2.07 Stress impact in food webs and across ecosystem boundaries (Poster)

2.07.P-We038 Direct and Indirect Effects of the Fungicide Fluopyram on an Aquatic Decomposer-Detritivore System

Alexander Feckler¹, Michele Meyer², Marina Arias³ and Mirco Bundschuh⁴, (1)University Koblenz-Landau, Germany, (2)University of Koblenz-Landau, Germany, (3)Universidad Nacional de La Plata, Argentina, (4)Institute for Environmental Sciences University of Koblenz-Landau, Germany

Leaf litter breakdown is a key ecosystem process for energy provisioning in headwater streams and is primarily driven by microbial decomposers and detritivorous macroinvertebrates. Anthropogenic stressors like fungicides, however, can disrupt the functioning of decomposer-detritivore systems via direct (waterborne) and indirect (diet-related) pathways. Therefore, we performed a set of laboratory studies that assessed how the fungicide fluopyram affects the detritivore *Gammarus fossarum* and leaf litter-associated microbial decomposers. In the first experiment, *G. fossarum* was exposed to fluopyram (0 to 60 mg/L) over the water phase while feeding on microbially colonized leaf discs. *Gammarus*' feeding rate was assessed after seven days of exposure. Results showed that fluopyram induced 50% reduction in feeding at 1.49 ± 0.26 mg fluopyram/L. These results were used for a second experiment, during which *G. fossarum* was given the choice to feed on leaf discs for 24 hours that had either been microbially colonized in the presence (15 to 15,000 µg/L) or the absence (fungicide-free control) of fluopyram for 14 days (=diet-related pathway). The feeding preference of *G. fossarum* was estimated using its consumption on the two offered leaf discs as a proxy. In addition, the community composition, species richness, and number of released conidia of aquatic hyphomycetes (AH; a polyphyletic group of aquatic fungi) associated with the leaf discs were assessed. Fluopyram reduced the number of released conidia (~43-73%) and fungal species richness (~77-98%), while the AH community composition was concomitantly altered. These shifts at the structural level presumably affected the palatability and nutritional quality of leaf discs for *G. fossarum*, which was reflected in up to ~50% lower consumption of the fungicide-exposed leaf discs compared to the control leaf discs. This demonstrates that fluopyram likely does not pose a direct risk to *G. fossarum* over the water phase at environmentally relevant concentrations in the lower µg/L range. However, fluopyram effects on AH propagated to *G. fossarum* even at low concentrations by impacting their food choice behavior. The pronounced effect on AH pinpoints their vulnerability towards fungicides and calls for a more comprehensive understanding of each pathway's relevance to accurately predict effects on energy provisioning in heterotrophic stream food webs.

2.07.P-We039 Effects of Zinc Oxide Nanoparticles and Salinity on the Decomposition of Leaf Litter in Mangrove Ecosystems

Michael J Barry¹ and Suad Al Abri², (1)Sultan Qaboos University, Muscat, Oman, (2)Sultan Qaboos University, Oman

Mangroves exist at the boundary of terrestrial and marine ecosystems. As they are conduits for water flowing from the surrounding catchment they are particularly vulnerable to pollutants. The decomposition of leaf litter is a vital ecological process in mangrove ecosystems. The dominant mangrove species in Oman is *Avicennia marina*, which can thrive in a highly arid and saline environment. The decomposition of *A. marina* leaves drives the detrital ecosystem in mangroves. Any human activities that disrupt this process may have harmful impacts on the overall health of the mangrove system. Zinc oxide nanoparticles (nZn) are an emerging pollutant that are increasingly used in industrial applications and personal care products such as sunscreens. Toxicity is directly related to the size and physical form of the nanoparticles, which in turn depends on environmental conditions. Salinity can have a major impact on the structure and toxicity of nanoparticles but has rarely been investigated as an independent factor. The aim of this study was to investigate the effects of nZn and salinity on the decomposition of *A. marina* leaves. Leaves were collected from the Al Qurum nature reserve in Muscat, Oman. Experiments were conducted in 3L glass microcosms containing sediment from the collection site. Leaves were exposed to 1, 10, 50 mg/L nZn, or 10 mg/L ZnCl₂ in either 50 or 100% seawater for six weeks. Nanoparticle size was measured using TEM. At 2, 4, and 6 weeks leaf subsamples were collected and the decomposition rate calculated. We also measured dissolved ion zinc and fungal biomass. Effects of nZn on leaf morphology was assessed using SEM. In a second experiment we measured the effects of the nZn on decomposition in 25, 50, 75 or 100% seawater. Decomposition was inhibited by 10 and 50 mg/L nZn and was higher at 100% salinity, although there was no interaction between the factors. Fungal biomass was higher in the nanoparticle treatments compared with controls suggesting the effects were not mediated through fungal toxicity. In the second experiment decomposition rates increased with increasing salinity but were not affected by the nanoparticles. In conclusion, this study showed that salinity plays an important role in the decomposition of mangrove leaves but that higher concentrations of nanoparticles can inhibit decomposition. Future studies should examine the effects of nanoparticles on other components in the ecosystem and their interactions.

2.07.P-We040 Diuron Indirectly Affects the Feeding Activity and Physiology of the Grazer *Physella acuta* Through Shifts in the Periphyton Community Composition

Alexander Feckler¹, Marco Kanschak², Jochen Zubrod², Tomás Duque², Agnes Bouchez³, Alexandra Kroll⁴, Nina Röder², Patrick Baudy², Ralf Schulz² and Mirco Bundschuh⁵, (1)University Koblenz-Landau, Germany, (2)University of Koblenz-Landau, Germany, (3)INRAE Lyon, France, (4)Centre Ecotox, Switzerland, (5)Institute for Environmental Sciences University of Koblenz-Landau, Germany

Herbicide effects on freshwater periphyton communities are well documented. Considerably less knowledge, however, has been gained for subsequent diet-related effects on primary consumers through shifts in the periphyton community composition that potentially alter the food quality for higher trophic levels. We, therefore, offered periphyton grown for 15 days in absence or presence of 8 µg diuron/L as food to the gastropod grazer *Physella acuta* for 21 days to quantify changes in its feeding rate, growth rate and energy reserves (estimated as neutral lipid fatty acids; NLFAs). In order to support a mechanistic interpretation of the grazers' responses, we quantified periphyton biomass, cell viability, community structure of autotrophic microorganisms (phenotype-based algae community composition and the diatom community) and fatty acids (FA) as a proxy for the food quality. The focus on diatoms was driven by their high content in highly unsaturated fatty acids (HUFA). Although diuron did not alter periphyton biomass or the viability of algae, shifts in the periphyton community were indicated by significant changes in the composition of algal phenotypes as well as the diatom community composition that were characterized by a shift in the relative abundance of diatoms. This shift in the periphyton community was reflected in changes of the FA profile. Especially the higher share of HUFA mirrors the increase in the diatom abundance, which may lead to a higher food quality of periphyton for grazers. The increased quality of diuron-exposed food could explain the observed stimulated feeding activity of snails in the treatment compared to the control. Moreover, the enhanced feeding activity resulted in an increase in the snails' growth rate (55%) and energy reserves (increase of NLFAs by 65%). Furthermore, snails feeding on diuron-exposed periphyton showed shifts in their NLFAs profile that pointed towards a higher physiological fitness compared to the control at the end of the bioassay. Our results indicate that herbicides can indirectly alter the behavior and physiology of grazers. If merolimnic aquatic organisms are affected, which are considered a high-quality food source for terrestrial consumers in riparian ecosystems, knock-on effects in aquatic-terrestrial meta-ecosystems are conceivable. These concerns call for a deeper understanding of herbicide effects on periphyton-grazer systems that potentially trigger consequences at the ecosystem level.

2.07.P-We041 Specific Mosquito Control Agent? Effects of *Bacillus Thuringiensis* Var. *Israelensis* on Benthos Community Structure and Ecosystem Function in Semi-Field Mesocosms

Verena Gerstle¹, Alessandro Manfrin², Sara Kolbenschlag³, Maximilian Gerken², Mirco Bundschuh⁴ and Carsten Bruehl⁵, (1)DFG-Grk. SystemLink iES Landau, Institute for Environmental Sciences University of Koblenz-Landau, Germany, (2)University of Koblenz-Landau, Germany, (3)University Koblenz Landau, Germany, (4)Institute for Environmental Sciences University of Koblenz-Landau, Germany, (5)University of Landau, Institute for Environmental Sciences, Germany

Bacillus thuringiensis var. *israelensis* (Bti) is a widely used biocide to control mosquito populations in wetlands. Despite being considered to specifically act on larvae of target organisms, i.e. Culicidae, Bti was shown to reduce density of non-target Chironomidae in laboratory and field studies. Since Chironomidae larvae are a key food source in aquatic food webs, it is hypothesized that a possible reduction of Chironomidae larvae by Bti may also cascade on the aquatic food-web altering structure and composition of benthic communities, particularly in small lentic water bodies where many predators depend on high densities of Chironomidae larvae. Alterations in benthos community may also lead to impaired ecosystem functions such as leaf decomposition. In this experiment, we investigated changes in the benthos community structure and composition in twelve floodplain mesocosms (ponds; 21 x 5.8 x 0.3 m), from which six were treated with the maximum field rate of VectoBac WDG (i.e., three applications in six weeks), while the other six remained untreated and were used as a control. Sampling was conducted three weeks after the last Bti application in macrophytes and gravel substrate to investigate the influence of Bti on the benthos community structure, dependent on the habitat type. Organisms were identified to species (Ephemeroptera, Odonata) or family level (Diptera, Coleoptera, Mollusca). To investigate decomposition by benthic shredders, ten leaf bags were introduced to each pond after the last Bti application. Leaf decomposition was determined after 14 days and 28 days. Regardless of the treatment, habitat type 'macrophytes' showed a higher species diversity as well as a 73-fold increase in the total number of sampled individuals compared to habitat type 'gravel' ($p < 0.01$). In macrophytes, Chironomidae larvae were the most affected taxa with a significant ($p < 0.04$) reduction of ~45%. Furthermore, in ponds exposed to Bti, our results (although not significant) suggest a reduction of ~35% in the total number of dragonfly larvae (Odonata) collected in macrophytes with early instars of the family Libellulidae and suborder Zygoptera being most affected (reduction up to 45%). Such a reduction of Odonata larvae may be the consequence of a cascading effect along the food chain either due to the substantial reduction of Chironomidae abundance and/or possible cannibalism occurring in older larval stages of Odonata. We conclude that Bti can reduce the number of Chironomidae larvae and that the effects can cascade to higher trophic levels of the benthic community.

2.07.P-We042 Tropic Transfer of Pharmaceuticals in the Benthic Food Web - a Conceptual Approach

Sara Nicoline Grønlund¹, Henriette Selck² and Tomas Brodin³, (1)Roskilde University, Denmark, (2)Roskilde University, Roskilde, Denmark, (3)Swedish University of Agricultural Sciences (SLU), Sweden

Due to an increased and continuous human consumption and inefficient removal by wastewater treatment plants, pharmaceutical compounds are discharged continuously to the aquatic environment. Consequently, pharmaceuticals have been detected in both surface waters, biota such as fish and to some extent in sediments as it is more rarely included when doing environmental monitoring. However, to what degree most pharmaceuticals bioaccumulate through the benthic food web have to our knowledge yet to be investigated. As pharmaceutical compounds are a broad term describing diverse groups of compounds varying in chemical

properties (i.e., hydrophobicity and ionization potential) and mode of action, these compounds will distribute differently in the aquatic environment. Some of these pharmaceuticals (e.g. sertraline, citalopram, and fluoxetine) are likely to accumulate in the sediment compartment to concentrations that may exceed the concentrations of surrounding surface water. Sediment-associated pharmaceuticals may be taken up and potentially bioaccumulate in sediment-dwelling invertebrates and may further bioaccumulate in fish feeding on such prey. The aim of the study is to investigate to what degree selected pharmaceutical compounds transfer from surface water to sediment; from sediment to benthic invertebrates; and from invertebrates to fish by examining each transfer step in its own isolated system. The experiments will be conducted in the following matrices: distribution between water and sediment, bioaccumulation from sediment to benthic invertebrates (i.e., worms or sediment living amphipods) examining the whole body burden of the invertebrates and bioaccumulation from benthic invertebrates to fish by analysing target organs (i.e., liver, intestines and brain), each matrix based on the finding from the previous. The selection of pharmaceutical compounds will be based on environmental concentrations in water and sediment (if available) within the therapeutic groups of i.e., psychoactive pharmaceutical, anti-inflammatory drugs, cardiovascular drugs, antibiotics and antihistamines.

2.07.P-We043 Stable Isotope Analysis As a Promising Tool to Unveil Toxicant Effects in Food Webs

Eric Bollinger¹, Jochen Zubrod¹, Dominik Englert¹, Annika Pollitt¹, Bastian Fuß¹, Ralf Schulz¹ and Mirco Bundschuh²,

(1)University of Koblenz-Landau, Germany, (2)Institute for Environmental Sciences University of Koblenz-Landau, Germany

Despite having comparable effect sizes as direct effects, indirect effects that are conveyed via food webs have received far less attention mainly due to methodological limitations. Although stable isotope analysis (SIA) is used for decades to address ecological research questions, its use in a chemical stress context has been limited. The applicability of SIA to track indirect effects in food webs has recently been challenged by studies stating an effect of chemical stressors on an organism's isotope signature. To evaluate the application of SIA, this study investigates if trophic enrichment factors (TEFs, i.e., the difference of stable isotope signatures between consumer and prey) are affected by toxicants and if estimating dietary proportions with SIA fits the observations based on consumption data. To address the former, the amphipod *Gammarus fossarum* (Koch) was subjected to three levels (i.e., 0, 0.75, 5 $\mu\text{g L}^{-1}$) of the neonicotinoid thiacloprid and fed with either black alder leaves or *Baetis rhodani* larvae over six weeks. To address the latter, gammarids were subjected to two levels of thiacloprid (i.e., 0, 0.75 $\mu\text{g L}^{-1}$) and fed with either black alder leaves, *B. rhodani* larvae or both over two weeks. The first experiment showed that thiacloprid exposure induces changes in TEFs that are statistically significant but small compared to other factors (e.g., resource quality and physiological condition) and thus likely of minor importance. The second experiment showed that dietary proportions as suggested by SIA reasonably fit those derived from consumption data suggesting its applicability. However, the experimental assessment of TEFs and a sufficient separation of resources' stable isotope signatures are principal to generate accurate and precise predictions, respectively. Labelling resources with heavy isotopes addresses both issues in one sweep, potentially even enabling SIA to track indirect effects in more complex scenarios.

2.07.P-We044 Fatty Acid Profiles of *Chironomus riparius*: Effects of Developmental Stage and Heavy Metal Exposure

Sebastian Pietz¹, Martin Kainz² and Mirco Bundschuh³, (1)University Koblenz-Landau, Germany, (2)Inter-university Research Center WasserCluster Lunz – Biological Station, Austria, (3)Institute for Environmental Sciences University of Koblenz-Landau, Germany

Emerging merolimnic insects (i.e., insects with an aquatic larval and terrestrial adult life stage) are important vectors for dietary nutrients such as long-chain polyunsaturated fatty acids (LC-PUFA) for riparian consumers. This is because LC-PUFA are required to maintain vital physiological processes, but, at the same time, are lacking in terrestrial prey. Anthropogenic stressors can impair the development and emergence of merolimnic insects and thus the transport of these nutrients. In this context, heavy metals and water temperature increases might be of particular concern, since they can accumulate in sediments and have a direct effect on the FA composition of aquatic organisms, respectively. Therefore, we examined the interacting effects of sediments contaminated with non-essential (cadmium, Cd) or essential (copper, Cu) metals and short-term, recurrent water temperature increases on the FA profile of different developmental stages of *Chironomus riparius* (Diptera: Chironomidae). Preliminary results of both experiments suggest that the developmental stage (i.e., Larvae, Female or Male) had a statistically significant effect on the FA composition of *C. riparius*, explaining 22% (Cd experiment, PERMANOVA, $p = 0.0001$) and 43% (Cu experiment, PERMANOVA, $p = 0.0001$) of the total variance. Nonmetric multidimensional scaling revealed that PUFA and omega-6 FA were mainly associated with males and saturated FA and total FA contents mainly with females. In addition, we observed a trend towards a higher FA contents in adults compared to larvae in the Cu experiment. Furthermore, Cd had a statistically significant effect (PERMANOVA, $p = 0.0019$) on the FA composition of *C. riparius*, with increases in omega-6 FA, PUFA and omega-3 FA along the Cd gradient being the strongest contributors to differences in FA composition (according to SIMPER analyses). Recurrent temperature increases did not significantly affect FA composition, presumably due to the short (i.e., two to three days) periods. Given that more contaminants become ubiquitous in the environment and PUFA are required for many physiological processes and are mostly synthesized in the aquatic environment (particularly LC-PUFA), contaminant-induced effects on the emergence pattern and FA profile of merolimnic insects may cause alterations in the transport of FA that could cascade onto higher trophic levels.

2.07.P-We045 Emerging Aquatic Insects Transfer Environmental Stress Across Ecosystems

Iva Kokotović¹, Marina Veselić², Zrinka Kara?i?i³, Ivana Grgić³, Marko Rožman³ and Ana Previsić¹, (1)University of Zagreb, Faculty of Science, Department of Biology, Croatia, (2)University of Zagreb, Faculty of Science, Croatia, (3)Ru?er Bošković Institute, Croatia

Nowadays, freshwater ecosystems are contaminated with various pollutants, which can co-occur and interact in many ways, cross

ecosystem boundaries and propagate to adjacent terrestrial habitats. Moreover, these ecosystems are subjected to climate change which can impair their normal functions and balance, e.g. changing water temperature. Emerging aquatic insects play a crucial role in these environments, transferring resources and energy, as well as subsidies to higher trophic levels in both aquatic and terrestrial habitats. Accordingly, the aim of the current study was to investigate the single and combined effects of emerging contaminants (ECs); pharmaceuticals (PhACs) and endocrine disrupting compounds (EDCs) and elevated water temperature on aquatic insects at the aquatic-terrestrial habitat linkage. A laboratory microcosm experiment was conducted with a simplified freshwater food web containing nonvascular macrophytes and *Trichoptera* larvae feeding mainly as shredders. Sampling included initial and several consecutive collections including all life stages (larvae, pupae and adult stage). Analyses such as total protein content, total lipid content, metabolite profiling and fatty acids composition are being conducted in order to evaluate the response of non-model aquatic insects to selected stressors at molecular level. Increased water temperature had an impact on phenology causing earlier emergence of adults and a decrease in lipid mass. Furthermore, treatments with ECs mixture lowered the protein mass in larvae and pupae, irrespective of the water temperature. Multiple stressor effect was noticed in treatments with combined ECs and elevated water temperature as the highest decrease in total protein content in larvae and pupae and total lipid content in adults.

2.07.P-We046 Prescribed Burning As an Ecological Stressor and Its Effect on the Soil Ecosystem Services of a Fescue Prairie Grassland

Hamzat Fajana¹, Steven Siciliano¹, Kayode Jegede² and Eric Lamb³, (1)University of Saskatchewan, Canada, (2)Wageningen Environmental Research, Netherlands, (3)Saskatchewan University, Canada

Prescribed burning is a traditional management practice used across temperate grasslands to control natural fire regimes. In the Canadian Prairies, prescribed burning is a standard management technique to maintain the productivity of native plant species. Despite the benefits of this management practice, studies have shown its effect on soil ecological functions. However, most of these studies on the impact of prescribed burning in temperate grasslands focus on the dynamics in carbon storage for pre/post-burning regimes. Therefore, in this study, we decided to investigate the effect of prescribed burning on important soil ecosystem services after four years post-burning in a fescue prairie grassland of Saskatchewan, Canada. We measured and collected 2-years field data (2020/2021) for some soil ecosystem services proxies. Briefly, we measured greenhouse gases (GHGs) as the proxy for climate regulation, tea bag index (TBI) as the proxy for decomposition, vegetation cover/biomass as the proxy for food production/productivity, and soil invertebrate population as the proxy for soil biodiversity conservation. Interestingly, the results from this study showed that prescribed burning significantly affect soil invertebrate population, especially collembola after 4-5 years post-burning. There was also a reduction in the vegetation cover/biomass in the burned plots. In addition, the collembola population was driven by changes in litter cover for the burned and unburned fields. In conclusion, prescribed burning affects the soil's ecological functions by significantly affecting litter-dwelling soil invertebrates such as collembola. Therefore, soil invertebrates population should be monitored post-burning to maintain grassland's ecosystem integrity.

2.07.P-We047 Adverse Multigenerational Effects of a Nano-Façade Paint on *Daphnia magna*

Frank Seitz¹, Lea Gruenling², Rajdeep Roy³, Ricki Rosenfeldt⁴, Alexander Feckler⁵ and Mirco Bundschuh⁶, (1)Inst. for Environmental Sciences, Germany, (2)University of Koblenz-Landau, Germany, (3)Institute for Environmental Sciences; University of Koblenz-Landau, Germany, (4)nEcoTox GmbH, Germany, (5)University Koblenz-Landau, Germany, (6)Institute for Environmental Sciences University of Koblenz-Landau, Germany

Façade paints often contain organic biocides to protect wall surfaces from algal and fungal growth. Recent developments in related industry sectors focused on reducing the content of organic biocides, for instance by replacing them with inorganic nanomaterials (NM) that exhibit more natural biocidal properties. However, both organic biocides and inorganic NM can be washed off façades during rainfall and subsequently enter the aquatic environment. Once entered, adverse long term effects on respective ecosystems and their functions may be a consequence, with rather limited knowledge on NM effects. Thus, the present study aimed at investigating biological effects of silver NM (=AgNM) and a façade paint (=FP; containing AgNM) on the aquatic invertebrate *Daphnia magna* during a multigenerational test with three subsequent generations tested for 21d each, largely following OECD 211. Juveniles of the 3rd brood (of each treatment) from the 1st and 2nd generation served as a starting point for the following generation. The exposure of daphnids took place via algal food. In detail, 3 d before feeding, the food source was separately spiked with four different concentrations (< 72h EC₂₀ algae growth) of the two test items (AgNM [0.00, 0.08, 0.10, 0.12 mg/L], FP [0.00, 1.00, 3.00, 5.00 mg/L]). Afterwards, the spiked suspensions were used to feed daphnids (n=15). Daphnias' reproduction, growth and mortality were assessed over the entire exposure time. Results showed that even the lowest concentration affected the reproduction (~75% reduction compared to the control) of daphnids in all generations, independent of the substance tested. Similar patterns were observed for the growth of the adult daphnids. While respective effect sizes did not significantly differ over the three generations for both products (neglecting any transgenerational effects), mortality deviated significantly among generations when exposed to algae treated by FP. There, the survival of the test animals decreased significantly with increasing test item concentration and consecutive generation. For example the 3rd generation of daphnids exposed to FP showed only ~33% survival rates in the highest treatment versus ~ 100% in the 1st generation. Our findings suggest that the transport of nanomaterials along the aquatic food chain alone and as part of complex product mixtures such as façade paints may adversely affect such ecosystems, while the concentrations assessed are beyond field relevance.

2.07.P-We049 Simple Food Web Model for the Chronic Impact of Rare Earth Elements in an Aquatic Ecosystem

Chantal Kimberley Eline van Drimmelen¹, Jordi Vives i Batlle², Andrew Hursthouse³ and Susanne Heise⁴, (1)HAW Hamburg, Germany, (2)Belgian Nuclear Research Centre (SCK CEN), Belgium, (3)University of the West of Scotland, United Kingdom,

(4)Hamburg University of Applied Sciences, Hamburg, Germany

The rare earth elements (REE) are 17 chemical elements that possess unique properties. These make them crucial in modern technologies such as GPS, electrical cars and agriculture. REE are considered as emergent contaminants and there is a concern about their environmental safety. It is known that REE can cause disruptions in the biogeochemical cycles of aquatic ecosystems. Benthic organisms can be exposed to these contaminants, due to the strong adsorption of REE to sediment particles and fine organic particle matter. REE can also affect species in the overlying water body due to the coupling between the benthic habitat and the pelagic zone. We have developed a simple food web model for the chronic impact of two REEs lanthanum (La) and gadolinium (Gd) containing a sediment-water interface. For this purpose, five different organisms from various trophic levels (e.g. bacteria, microalgae, nematodes, daphnia, ostracods, and mussels) will be exposed in acute and chronic environmentally relevant REE concentrations in controlled micro- and mesocosm experiments. Our prototype food web model uses the Lotka-Volterra equations and first-order linear processes for the transfer of REE in the aquatic food web. Element uptake, toxicity data and a mechanism representing the repair of damage are integrated into a system of logistic mathematical equations, set and solved in the user-friendly ModelMaker software. This is an “open model” whereby partial parameter information can be readily incorporated as information is gradually gained from the micro- and mesocosm experiments, thus refining the model parameterisation. The model developed can be employed to optimise the experimental design of the micro- and mesocosms. The key challenge in this heuristic approach to modelling is that experiments are required to recalculate the relevant rate constants and the representation of the chemistry of the REE. We further elaborate on how we are dealing with the heuristic modelling challenge in this study and the first prototype of the theoretical model is presented. We will discuss the “lessons learned” regard to the potential of this approach and considering implications of REE-effects on biological communities.

2.08 Theoretical concepts to advance prediction in ecotoxicology and stress ecology (Poster Corner)

2.08.PC-Tu19 Three Perspectives on the Prediction of Chemical Effects in Ecosystems

Anke Schneeweiss¹, Noel Juvigny-Khenafou², Stephen Osakpolor², Andreas Scharmüller², Sebastian Scheu², Verena Christina Schreiner³, Roman Ashauer⁴, Beate Escher⁵, Florian Leese⁶ and Ralf Bernhard Schaefer⁷, (1)Quantitative Landscape Ecology, University Koblenz-Landau, Landau in der Pfalz, Germany, (2)University Koblenz-Landau, Germany, (3)University of Koblenz-Landau, Germany, (4)Syngenta Crop Protection AG, Switzerland, (5)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (6)University Duisburg-Essen, Germany, (7)University Koblenz Landau, Germany

A wide range of chemicals of urban, agricultural and industrial origin, including pesticides, metals, pharmaceuticals and industrial chemicals, can be detected in the environment, in particular in aquatic ecosystems, given that they often drain landscapes with diverse land use. The use and emissions of chemicals into the environment have increased at a higher rate than most other drivers of global change. Yet, the large number and increasing production volumes of synthetic chemicals, their interaction with other moderating factors and limited knowledge on exposure patterns and effects in organisms limit our ability to predict effects in real-world ecosystems. In our contribution, we identify three approaches for the prediction of chemical effects: 1) the mechanistic perspective, 2) the toxicokinetic-toxicodynamic perspective and 3) the eco-evolutionary perspective, which are currently largely separated. We describe these three perspectives, highlight methodical and conceptual advances as well as challenges and synthesise novel developments that can create links between the perspectives. Moreover, we provide guidance on how to approach the task of prediction using current tools and discuss future experiments and models that would foster our capacity to predict ecological responses in complex ecosystems. Overall, we provide a timely overview of the approaches and challenges to prediction of effects for an important global change driver that is characterised by a higher complexity than other drivers.

2.08.PC-Tu20 Comparing Recovery-Related Trait Profiles Between Sensitive and Tolerant Freshwater Macroinvertebrate Assemblages to Insecticides

Ruoyu Liang and Lorraine Maltby, The University of Sheffield, United Kingdom

The vulnerability of assemblages to stress is a function both of their ability to resist the stressor (i.e., sensitivity) and their ability to recover from any stressor-induced impacts once the stressors have been removed. The sensitivity of an assemblage is determined by the sensitivities of the individual populations making up the assemblage and will therefore depend on species compositions. As interspecific variation in chemical sensitivity is chemical dependent, assemblages that are sensitive to some toxicants may be relevantly tolerant to other toxicants. The recovery of assemblages is a function of internal recovery processes that depend on species-specific traits (e.g., generation time, number of offspring) and external recovery processes that are a function of both species-specific traits (e.g. dispersal, life-cycle) and landscape factors (e.g., source populations, connectivity). This study aimed to investigate: (1) whether sensitive and tolerant freshwater macroinvertebrate assemblages share similar recovery-related trait profiles; (2) if they are different, what recovery-related traits contribute to this variation. Freshwater invertebrate assemblages in England were used as a case study and seven insecticides were selected as study chemicals. As the sensitivity of most invertebrates in assemblages is unknown, the hierarchical species sensitivity distribution model was used to predict the toxicity of untested species. The concentration hazardous to 5% of species (i.e., HC5) was used as a measure of assemblage sensitivity. Chemical-specific HC5 values were calculated for all assemblages and for each insecticide, sensitive assemblages were defined as those in the lowest 5% of HC5 values whereas tolerant assemblages were defined as those in the highest 5% of HC5 values. The unique taxa from sensitive and tolerant groups were identified and their recovery-related traits were determined and compared. Sensitive and tolerant freshwater macroinvertebrate assemblages exhibited different recovery-related trait profiles. Locomotion and substrate relation and dispersal mode are the largest contributors to the difference in recovery profiles. Most taxa presented active aerial dispersal behaviors in tolerant assemblages, while taxa in sensitive

assemblages exhibited diverse dispersal modes. The difference in recovery profiles indicates that external recovery may be important for assessing the ecological risk of chemicals with intermittent exposure patterns.

2.08.PC-Tu21 Predicting Effects During Stressor Impact and Beyond: Understanding the Mechanisms Governing Community Response During Stressor Action and Release With the Asymmetric Response Concept

Helena Bayat¹, Matthijs Vos², Daniel Hering³, Bernd Sures⁴ and Ralf Bernhard Schaefer⁵, (1)Institute for Environmental Sciences University of Koblenz-Landau, Germany, (2)Faculty of Biology and Biotechnology, Ruhr University Bochum, Germany, (3)Centre for Water and Environmental Research (ZWU), University of Duisburg-Essen, Germany, (4)University of Duisburg Essen, Germany, (5)University of Koblenz-Landau, Germany

Predicting the effects of multiple stressors on communities is complicated by interacting ecological mechanisms that vary in importance during the time course of stressor action and release. The Asymmetric Response Concept (ARC) provides a conceptual framework to structure hypotheses and contextualize the importance of the three mechanisms, namely individual tolerance, dispersal, and biotic interactions of taxa, during the stressor impact and recovery period. According to the ARC, tolerance of individual taxa plays the most significant role as stressor impact increases. Individual tolerances of taxa, for which metrics are available for a range of stressors and organisms, are thus hypothesized to explain community response during stressor increase. Dispersal and biotic interactions become dominant after stressor release as the community recovers. Knowledge of each process can subsequently be used to predict effects at the relevant stage of stressor impact, with the goal of maximizing recovery of degraded ecosystems. A wide variety of data for single taxa tolerance to a range of environmental and chemical stressors is available in databases, for example EC/LCx values for chemicals or critical maximum values for temperature. Harnessing this information to extrapolate effects to higher levels of biological organization is of great interest to ecotoxicologists, ecologists, and risk assessors alike. Within the ARC framework, the success or failure of individual tolerance predictions on community response at different phases of stressor impact can be explained by the shifting relevance of the three mechanisms mentioned above. Illuminating which mechanism - tolerance, dispersal, or biotic interactions- governs the community response in which phase will ultimately improve our predictive capacities for effects of multiple stressors over time.

2.08.PC-Tu22 Caenorhabditis elegans Gut Microbes Decrease Arsenite and Perfluorosulfonate Toxic Effects on Nematode Reproduction and Fat Metabolism

Jagadish Chandra Kumar Mangu¹, Alba Cuecas², Abul Mandal³, Per-Erik Olsson⁴ and Jana Jass⁴, (1)Department of Science and Technology, Orebro University, Örebro, Sweden, (2)Orebro University, Sweden, (3)University of Skövde, Sweden, (4)School of Science and Technology, Orebro University, Örebro, Sweden

Environmental toxins such as arsenite (As^{III}) and Perfluorooctanesulfonic acid (PFOS) are associated with contamination of drinking water and food. Microbes that colonize the gut play an important role in host response to ingested environmental toxins. Exposure to arsenite or PFOS in animal models has shown to affect reproduction and fat metabolism, however, the effects of gut microbes on host physiological responses to environmental toxins is unclear. In toxicology, *Caenorhabditis elegans* is an invaluable model organism that shows good correlation of toxic responses with mammalian models. The aim of the study was to investigate the effect of 3-bacteria gut microbe combinations on *C. elegans* reproduction and fat metabolism in response to toxin exposure. *C. elegans* fed mixtures of 3-bacteria combinations or *Escherichia coli* OP50 (control) were exposed to As^{III} (150 µM) or PFOS (100 µM) and egg laying and the expression of genes associated with fat metabolism were analyzed. In comparison to the *E. coli* OP50 fed *C. elegans*, worms fed with the 3-bacteria models improved the nematode egg laying in the presence of either As^{III} or PFOS. Furthermore, worms fed with the above 3-bacteria combinations showed increased expression of fat metabolism genes (*elo-2*, *sams-1*), indicating gut microbes modulate the host fat metabolism and reproduction when exposed to toxins. Understanding the influence of gut microbes on host during toxin exposure provides insight into the possible mechanisms of host-microbe interactions and identifies novel biomarkers of toxicity for better prediction of the toxicological outcome.

Track 3: Environmental chemistry and exposure assessment: analysis, monitoring, fate and modeling

3.01 Advances in Bioaccumulation Science and Assessment (Part I)

3.01.T-01 Comprehensive Screening and Trophic Transfer Behaviour of Emerging Organic Contaminants in a Freshwater Food Web

Qiuguo Fu¹, Corina Meyer¹, Michael Patrick², Verena Kosfeld³, Heinz Ruedel⁴, Jan Koschorreck⁵ and Juliane Hollender¹, (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)UMTEC, Eastern Switzerland University of Applied Sciences (OST), Rapperswil-Jona, Switzerland, (3)Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Germany, (4)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (5)Umweltbundesamt, Umweltbundesamt, Berlin, Germany

Bioaccumulation and trophic transfer of persistent legacy contaminants have been intensively characterized, but little is known on the contaminants of emerging concern (CECs) in the freshwater food web. Herein, we comprehensively screened CECs with a focus on (semi) polar substances and further evaluated their trophic transfer behavior in one plankton, two mussel, and nine fish samples of a food chain in Lake Templin from Germany. With an effective multi-residue sample preparation method and high-resolution mass spectrometry-based target, suspect, and non-target screening, we characterized 477 targets and further screened unknown features in complex biota matrices. Of the 477 targets, 145 were detected and quantified in different species (0.02 - 3640 ng/g, dry weight). Additionally, the suspect and non-target analysis with experimental mass spectra libraries and *in silico* techniques (MetFrag and SIRIUS4/CSI:FingerID) enabled further identification of 27 unknown compounds with 19 confirmed by

reference standards. Overall, the detected compounds belong to a diverse group of chemicals, including 71 pharmaceuticals, 27 metabolites, 26 pesticides, 16 per- and polyfluoroalkyl substances (PFASs), 11 industrial chemicals, 4 plasticizers, 3 flame retardants, and 14 others. Moreover, we determined the trophic magnification factor (TMF) of 34 CECs with >80% detection frequency, among which 6 PFASs including perfluorooctanesulfonic acid (PFOS), perfluorodecanoic acid (PFDA), perfluorohexanesulfonic acid (PFHxS), perfluorotridecanoic acid (PFTrA), perfluorotetradecanoic acid (PFTeA), and perfluoroundecanoic acid (PFUnA), exhibited biomagnification potential (TMF = 1.8 - 4.2, $p < 0.05$), whereas 5 pharmaceuticals (phenazone, progesterone, venlafaxine, levamisole, and lidocaine) and 1 personal care product metabolite (galaxolidone) showed biodilution potential (TMF = 0.4 - 0.6, $p < 0.05$).

3.01.T-02 Lanthanide Distribution in *Daphnia magna* Via Nano-Sxrf Imaging

Marion Revel¹, Kadda Medjoubi², Andrew Hursthouse³ and Susanne Heise⁴, (1)Hamburg University of Applied Sciences (HAW Hamburg), Germany, (2)SOLEIL synchrotron, France, (3)University of the West of Scotland, United Kingdom, (4)Hamburg University of Applied Sciences, Hamburg, Germany

Rare earth elements (REE) are essential for many new technologies. Their increased application since the 1990s have led to elevated levels in aquatic system, and understanding their interaction with biological systems is an important area of research. Tests with daphnids (water fleas) let assume, that e.g. lanthanum toxicity could be similar to copper. Because of a number of chemical properties between Ln^{3+} and Ca^{3+} , Ln can block calcium channels and they interfere with signal recognition pathways and enzyme activity. All these toxic effects require uptake and potentially accumulation of REE into cells and tissues. But few data are available on the distribution of REE in organisms after exposure and on accumulated concentrations. In order to improve understanding of their bioavailability, the accumulation of two REE (La and Gd) in juvenile *Daphnia magna* has been measured at the NANOSCOPIUM hard X-ray scanning nanoprobe beamline of the synchrotron SOLEIL (Saint-Aubin, France). Neonates of less than 24h were exposed to 15 mg/L of La or Gd for 48 and 72h. At the end of the test, the survival organisms were dehydrated through an acetone-water series and dried in HDMS (1,1,1,3,3,3-hexamethyldisilazane) in order to be analysed by synchrotron nano-XRF (nano-SXRF). The measurement was performed with an incident monochromatic X-ray beam of 17.02 keV energy, producing nano-SXRF spectra for every pixel. The primary results showed a difference of distribution between La and Gd in the organism. Gd seemed to accumulate more than La and tended to be distributed in tissues. The accumulation increased over the exposure time and a stronger accumulation in the carapace was found at 72h compare to 48h. This may be due to the timing of the moulting. The first moult occurs in neonates before being exposed and the second after 48h. For 72h of exposure, La was found in the intestine tract and had a solid appearance in the hindgut. The ingestion of La was probably possible because of its precipitation either in the medium or in the animal's intestine itself. According to the speciation modelling by Geochemist Workbench, La tends to complex and precipitate more easily than Gd in solution conditions. Any solid matter generated might be ingested by the daphnids while the free ions may be taken up into the cells by e.g. Ca-channels. In conclusion, the accumulation of La and Gd in daphnid could depend on their speciation and free ion concentration.

3.01.T-03 Anionic and Cationic Organic Compounds Show Distinct Bioaccumulation in Rainbow Trout Cell Cultures

Fabian Gerhard Peter Balk¹, Bastian Huesser¹, Juliane Hollender¹ and Kristin Schirmer¹, (1)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland

The assessment of chemicals for their bioaccumulative potential requires *in vivo* testing with fish. These tests are resource intense, costly, time consuming and of ethical concern due to the sacrifice of animals. Therefore, alternative *in vitro* models are being sought to replace these tests. We have started to explore how well rainbow trout (*Oncorhynchus mykiss*) cell lines, in particular RTL-W1 (liver) and RTgill-W1 (gill), can predict the bioaccumulation and biotransformation potential of ionizable organic compounds (IOC) in fish. IOC comprise a large proportion of the chemicals in commerce and are ubiquitously detected in the environment and biota. Based on the availability of high quality *in vivo* data and the substances' charge state at physiological pH, four anionic and three cationic compounds were selected: Pentachlorophenol (PCP, CAS 87-86-5), Diclofenac (DCF, CAS 15307-79-6), Teclotalam (TT, CAS 76280-91-6) and Benzotriazol-t-butyl-hydroxyl-phenyl propanoic acid (BHPP, CAS 84268-36-0); and N,N,N-trimethyltetradecylamine (Q14, CAS 4574-04-3), N,N-dimethyldecylamine (T10, CAS 1120-24-7) and N-methyldodecylamine (S12, CAS 7311-30-0). First, non-toxic chemical concentrations for each compound were determined using the acute cell toxicity assay according to OECD TG249. Resulting exposure concentrations for bioaccumulation assessment ranged from 5 $\mu\text{g/L}$ to 200 $\mu\text{g/L}$, i.e. never higher than 1 μM . The kinetic experiments were performed over 48h and 72h for anions and cations, respectively, with a total of 6 sampling time points. Cell, medium and plastic fraction were sampled separately at each time point and measured using high resolution tandem mass spectrometry after online solid phase extraction (for anions) or with direct injection of extracts (for cations). The anionic compounds, given as a fraction of the total compound mass in the test system, accumulated in the following order in RTL-W1 cells: BHPP (6%) > TT (4%) > DCF and PCP (below limit of quantification, 0.07 to 0.45% respectively). In contrast, the thus far tested cations were associated with cells to a much larger extent, measured in RTgill-W1 as follows: 43% for T10 and 91% for S12. A comparison of the compounds' baseline bioconcentration factors and the *in vitro* derived steady-state bioconcentration factors gave a positive correlation ($R^2 = 0.79$), with deviations being within the 10-fold range of the line of unity.

3.01.T-04 Assessing Bioaccumulation of Silver Nanoparticles in Freshwater Benthic Invertebrates: From Single-Species to Mesocosm Approaches

Patricia Silva¹, Cornelis A.M. van Gestel² and Susana Loureiro¹, (1)Universidade de Aveiro, Portugal, (2)Vrije Universiteit Amsterdam, Netherlands

A sustainable nanotechnology development requires a robust environmental risk assessment. In line with this, studies on the

toxicokinetics and bioaccumulation of engineered nanomaterials (ENMs) have been highly requested by regulatory bodies. Aiming to contribute to this, the present study focused on understanding the toxicokinetics of different pristine silver nanoparticles (Ag NPs), silver sulfide nanoparticles (Ag₂S NPs, used as model of an environmentally aged Ag NP form) and AgNO₃ in the ecological relevant freshwater benthic species *Physa acuta* (pond snail), *Chironomus riparius* (non-biting midge) and *Girardia tigrina* (planarian). An integrated methodology was used, from lower (single-species bioaccumulation tests using different exposure routes) to higher tier (mesocosms, simulating a freshwater stream environment) approaches. Single-species tests with *P. acuta* revealed fast uptake and elimination of Ag from Ag₂S NPs in all experiments, and water exposure was the predominant Ag uptake route. *C. riparius* larvae consistently revealed higher Ag uptake upon exposure to Ag₂S NPs. In the individual chironomid exposures to water and sediment, Ag uptake was better explained by exposure to water than from the ingestion of sediment particles, while upon food exposure the larvae only revealed Ag uptake in the Ag₂S NP treatment. The Ag transfer from larvae to adult midges appeared to be limited. Planarians accumulated Ag from the food in Ag₂S NP and AgNO₃ treatments, uptake being higher for AgNO₃ exposures. The three species bioaccumulated Ag in Ag₂S NP and AgNO₃ exposures in the mesocosm test but showed higher internal Ag concentrations upon exposure to AgNO₃. The uptake observed in the Ag₂S NP treatment was likely in the particulate form, showing the bioavailability of this more environmentally persistent and relevant Ag nanoparticulate form in a more realistic exposure scenario. Single-species tests underestimated bioaccumulation when compared with mesocosms, albeit in some cases similar uptake patterns were observed. No apparent risk for biomagnification was observed in the food chain *P. acuta* to *G. tigrina* upon exposure to Ag₂S NPs in single-species and mesocosm tests. This work provides important data for modelling the potential exposure and bioaccumulation of relevant Ag forms in freshwater benthic environments and may be useful for predictive models for nanoregulation purposes, contributing to improving the environmental risk assessment of ENMs.

3.01 Advances in Bioaccumulation Science and Assessment (Part II)

3.01.T-06 Using In-Vitro Biotransformation Rates to Estimate the Bioaccumulation Potential of 6 Different Siloxane Compounds

Mark Cantu, Beatrice Chee and Frank Gobas, Simon Fraser University, Canada

Siloxanes are produced globally in high volumes and are considered substances of concern in the EU. Siloxanes pose a unique challenge to assess for their environmental and human health impacts due to their superhydrophobicity, high volatility, and their universal presence, including their use in analytical instrumentation. Using OECD Test Guideline 319B to conduct the in-vitro studies, we looked at the depletion rates of 6 different siloxanes in both Rainbow trout and mammalian sub-cellular fractions. Octamethyltrisiloxane (L3), decamethyltetrasiloxane (L4), dodecamethylpentasiloxane (L5), octamethylcyclotetrasiloxane (D4), Decamethylcyclopentasiloxane (D5), and dodecamethylcyclohexasiloxane (D6) biotransformation rates were determined in both aquatic and mammalian liver S9 fractions and incorporated into in-vitro to in-vivo extrapolation models (IVIVE) to predict the bioconcentration factors of the 6 siloxanes. Each siloxane was run separately in replicates of 3, and each reaction vessel contained both Phase I and Phase II biotransformation enzymes and co-factors to help catalyze the reactions. Pyrene was run as a positive control to ensure the enzymes were active and functional. A heat-inactivated negative control was run to ensure that any loss observed in the reaction vessel was due to biotransformation. In-vitro data are compared against measured dietary bioaccumulation data in trout with the hopes to further our understanding of the role hepatic biotransformation has on bioaccumulation and the uncertainties or error that come with running extrapolation models. Additionally, the study hopes to better understand the differences between various species and their ability to metabolize xenobiotic compounds.

3.01.T-07 An Empirical Regression Model Based on Trout Liver S9 In Vitro Intrinsic Clearance and Log Kow to Predict Bioconcentration Factors in Fish

Heike Laue, Lu Hostettler and Andreas Natsch, Givaudan Schweiz AG, Switzerland

Bioaccumulation in aquatic species is a critical endpoint in the regulatory assessment of chemicals which usually involves the determination of the bioconcentration factor (BCF) in fish. The *in vitro* assay to determine *in vitro* intrinsic clearance ($CL_{IN\ VITRO,INT}$) in liver S9 fractions (RT-S9) from rainbow trout (OECD TG 319B) has been validated to refine BCF predictions using *in vitro-in vivo* extrapolation (IVIVE) models. Although incorporation of measured *in vitro* clearance in IVIVE models does improve BCF predictions, a tendency for overprediction was shown for different chemicals. The goal of this study was to establish a regression model to predict BCFs based on empirical data. As training set, 40 chemicals, including 27 fragrance chemicals, with RT-S9 *in vitro* intrinsic clearance and *in vivo* BCFs determined in different fish species (OECD TG 305) were used. A simple regression model ($\log BCF = a \times \log K_{ow} + b \times \log CL_{IN\ VITRO,INT}$) was built by estimating the parameters *a* and *b* by statistical fit based on *in vivo* BCFs, measured $CL_{IN\ VITRO,INT}$ in RT-S9 and $\log K_{ow}$. The regression analysis was performed with multiple datasets including species-matched subsets to evaluate the robustness of the estimation of the parameters *a* and *b* and the prediction of BCFs. Both parameters have a high statistical weight confirming the strong positive contribution of $\log K_{ow}$ and the impact of the $CL_{IN\ VITRO,INT}$ to reduce the predicted BCF. A leave-one-out-analysis was performed on the training set. The predictions for the left-out chemicals using the respective 40 submodels are very similar to the predictions with the regression equation based on the complete training set indicating that the empirical regression model performs well. As an external test set for model validation, additional $CL_{IN\ VITRO,INT}$ were determined or taken from the literature for 20 chemicals with *in vivo* BCFs. Geometric mean mispredictions (i.e. predicted BCF / *in vivo* BCF) of predicted BCFs with the regression equation were in the same range or slightly lower compared to commonly applied IVIVE models. Species-matched regression models (n=18 for trout, n=21 for carp) did not result in significant improvements of BCF predictions. The empirical regression model could be used

complementary to current IVIVE models to predict BCFs based on *in vitro* intrinsic clearance for bioaccumulation assessment and can overcome ambiguities such as the choice of the correct k_1 estimation.

3.01.T-08 Investigating the Applicability of Laboratory Derived Toxicokinetics to the Field

Benedikt Lauper¹, Eva Anthamatten², Johannes Rath³, Maricor Jane Arlos⁴ and Juliane Hollender², (1)Environmental Chemistry, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (3)Uchem, Eawag, Zürich, Switzerland, (4)University of Alberta, Edmonton, AB, Canada

Knowledge on bioaccumulation and biotransformation of organic micropollutants are essential to link exposure to effect and to designate appropriate environmental quality standards. Bioaccumulation and biotransformation of organic micropollutants in aquatic organisms have been investigated in laboratory experiments extensively. For several micropollutants, especially pesticides, however, the measured internal concentrations in gammarids in field trials exceeded the predictions based on the laboratory data, sometimes by multiple orders of magnitude. In this work, we tested the applicability of laboratory derived toxicokinetic rate constants for caged gammarids deployed in a small Swiss stream known for high pesticide loads. Using an automated mobile LC-ESI-HRMS/MS system, the aqueous concentrations of 49 pesticides were measured at high temporal resolution throughout several rain events during the application season (every 20 min for 1 month). The water concentrations from this study were then employed to model the whole body concentration of gammarids using a one-compartment toxicokinetic model with toxicokinetic rate constants derived in an accompanying lab study. This data was then compared to the measured whole body concentration of the caged gammarids. Furthermore, the pesticide concentrations in the stream sediment, dietary source (leaves) as well as in suspended particles during rain events were measured and used to model their effect on the bioaccumulation of the pesticides. Our results show that the internal pesticide burden of gammarids is highly dynamic, with the aqueous exposure as the main influencing factor. While the laboratory derived toxicokinetic rate constants predicted the temporal trends in whole body concentrations reasonably well, the values were systematically underestimated over the whole time period. The highest underestimation occurred shortly after rain events with the model underestimating the pesticide concentrations by a factor of up to 31 ± 3.0 . Finally, we demonstrated that while uptake from sediment does not contribute significantly to the total body burden even under worst case uptake assumptions, the suspended solids had considerably higher pesticide concentrations than the sediment and could explain the observed underestimation after rain events partially. Further possible reasons such as decreased biotransformation under field conditions or concentration dependence of the toxicokinetics are currently explored.

3.01.T-09 Development and Testing of an In-Vitro S9 Rat Liver Bioassay for Assessing Biotransformation Rates of Neutral Hydrophobic Organic Chemicals in Air-Breathing Organisms of Terrestrial Food-Webs

Frank Gobas¹, Yung-Shan Lee², Talia Cole¹, Manpreet Jhutti¹, Beatrice Chee¹, Stephanie Stelmachuk¹ and Mark Cantu¹, (1)Simon Fraser University, Canada, (2)Simon Fraser University, Canada

In vitro biotransformation assays combined with in vitro-in vivo extrapolation (IVIVE) is a relatively novel approach to bioaccumulation assessments that can reduce cost, effort, time and animal testing and accelerate the assessment process. The Organization for Economic Co-operation and Development (OECD) has developed test guidelines 319B to determine in vitro biotransformation rates in fish using liver S9 of rainbow trout. However, similar protocols are not available for mammalian bioaccumulation assessments and in vitro liver S9 data for neutral hydrophobic substances with a high bioaccumulation potential in air-breathing organisms are largely unavailable. The objective of this study is to develop and test a refined protocol for in-vitro testing of biotransformation rates in rats using rat liver S9 that might be useful for bioaccumulation screening of neutral hydrophobic organic chemicals in air-breathing organisms. The framework has 4 components, including (a) S9 preparation and characterization, (b) preliminary experiments to optimize test conditions, (c) final experiments with multiple independent tests to determine in vitro biotransformation rates in a standardized way, and (d) analysis of assay results for bioaccumulation screening. The refined protocol was tested and evaluated using 14 test chemicals with a variety of chemical structures and biotransformation capacities. In vitro biotransformation rate constants (k_r) were measured and extrapolated to whole organism biotransformation rate constants (k_{met}) using 4 previously reported IVIVE models. Lipid-normalized biomagnification factors (BMF_L) were then calculated using a rat bioaccumulation model. The calculated total elimination rates were compared to available in vivo data. The results indicate that (a) measured in vitro depletion rates were highly reproducible in independent tests; (b) extrapolated whole organism biotransformation rates were similar among various IVIVE models; (c) calculated total elimination rate constants were in good agreement with reported in vivo data; and (d) application of the developed methodology shows that a substance is not expected to biomagnify in rats (i.e., $BMF_L < 1$) when in vitro $k_r > 0.3 \text{ h}^{-1}$ in rat liver S9. However, poorly metabolizable substances with an in vitro $k_r < 0.3 \text{ h}^{-1}$ in rat liver S9 are not expected to biomagnify if they have a low $\log K_{OA}$ (< 5), or a very low or very high $\log K_{OW}$ (< 1 or > 9), or exhibit a low dietary uptake efficiency ($< 5\%$).

3.01 Advances in Bioaccumulation Science and Assessment (Virtual Only)

3.01.V-01 Efficiency of Varied Xenobiotic Detoxification Biomarkers in Highlighting the Exposure of *Daphnia magna* to an Organophosphate Pesticide

Elodie Melo de Almeida, Floriane Tisserand and Nathalie Chevre, University of Lausanne, Switzerland

Freshwaters are among the most stressed ecosystems worldwide. Their increased overexploitation generates various anthropogenic stressors for living organisms. Among others, one stressor is the pollution by chemicals. Aquatic macroinvertebrates play an important role in aquatic food webs and are highly sensitive to chemicals. They can therefore be used as sentinel organisms for highlighting the deleterious effects of these compounds. The study of the biomarkers induced in these

organisms is of great interest for assessing the effects of low and chronic concentrations of compounds. In this study, we aim in finding out the most sensitive detoxification biomarker in *Daphnia magna* as a potential candidate for laboratory and *in situ* ecotoxic assessment. Cytochrome P450 system mostly operates in first step xenobiotic detoxification in aquatic invertebrates. The ability to measure this mixed function oxidase activity allows in understanding responses to chemical stressors. However, existing measurement of cytochrome P450 activities research for aquatic macroinvertebrates is limited with patchy and variable success. Our study is investigating several P450 biomarkers occurring during a process of detoxification on *D. magna*. Present work improves knowledge about P450 enzymatic biomarkers, specificity and accuracy to *D. magna* exposed to organophosphate chemicals and finally empowers determination level of aquatic macroinvertebrates' exposition to chemicals. Indeed, comparing and testing methodologies in laboratory is a crucial previous work for highlighting effects in the field. The main objective of the present work was therefore to test diverse cytochrome P450 enzymatic biomarkers (EROD, MROD, ECOD, APND and ERND) and to establish a suitable methodology for aquatic macroinvertebrates. Furthermore, our study investigated P450 biomarkers signal detection function of exposure time with the aim of understanding xenobiotic detoxification pattern through time. First, we tested these 5 biomarkers in *Daphnia magna* exposed for 5 days at 9 different concentrations of an organophosphate pesticide (diazinon). EROD, ECOD and APND showed a higher sensitivity. Secondly, we tested selected biomarkers, EROD, ECOD and APND in *D. magna* exposed for 1 to 5 days. Results are currently being analyzed.

3.01.V-02 Evaluating the Long-Term Toxicity and Bioaccumulation of Gold Nanobiomaterials in Fish

David Hernandez-Moreno¹, Rocío Fernández-Saavedra², Ana I. Cardona-García², Isabel Rucandio² and Maria Luisa Fernandez-Cruz³, (1)INIA, Spain, (2)CIEMAT, Spain, (3)Environment and Agronomy, INIA - National Institute for Agricultural and Food Research and Technology, Madrid, Spain

Nanobiomaterials (NBMs) are receiving much attention because of their application in biomedical devices. However, their production and use also imply the risk of delivery to the environment. The aim of the present study was to evaluate the potential effects of gold nanoparticles (Au NP) in *Oncorhynchus mykiss* after long-term exposure via water. Effects were evaluated at two levels, the growth effect in juveniles (OECD TG215) and the Au bioaccumulation in fish and fish tissues (OECD TG305). Au NP (5-20 nm) with citrate as capping agent and spherical shape was supplied by Colorobbia Consulting SRL (Italy) as a liquid stock suspension. Working solutions (growth: 0, 0.05, 0.15, 0.5, 1.5, and 5 mg/L; bioaccumulation: 0, 0.5 and 5 mg/L) were prepared by direct pipetting of the stock in aquarium water. Water was renewed every two days. The exposure period lasted for 28 days in both assays, followed by a depuration phase of 14 days (water without NBM). For the growth assay, 9 fish were weighted at the beginning of the experiment and introduced in each aquarium (6 in total). Fish were weighted and fed at a ration of 4% body weight/day. Animals were weighted again after 14 days and at the end of the exposure. Tissues were frozen at -80°C to study different markers of toxicity. For the bioaccumulation (minimized test) assay 3 aquaria were used with 16 fish each. Four fish were sampled at time 0, 14 and 28 days of exposure and time 7 and 14 of depuration. Carcass and tissues (liver, gills, intestine, stomach and muscle) were digested using aqua regia, Au was analysed by ICP-MS. The differences between the measured and the nominal concentrations of Au in water were lower than 20 %. There were no effects on the fish welfare, neither significant differences in growth among groups. The possible sublethal effects are still under study. Au levels could be measured in different tissues at the two exposure levels. There was a reduction in Au levels in the whole body after 7 days of depuration with a complete elimination after 14 days. Muscle was not a tissue target of Au, but gills, stomach and intestine showed to be the principal receptors and accumulated the biggest amount of metal, followed by liver. After 14 days of depuration, gills and liver still showed high levels of Au. In conclusion 14 days of depuration were not long enough to assure the complete elimination of Au from gills and liver at the two exposure levels. *Acknowledgement* – H2020 project BIORIMA 760928

3.01.V-03 The Effect of Sulfidation and Soil Type on the Uptake of Silver Nanoparticles in *Enchytraeus crypticus*

Zahra Khodaparast¹, Susana Loureiro², Rudo A. Verweij³ and Cornelis A.M. van Gestel³, (1)University of Aveiro, Portugal, (2)Universidade de Aveiro, Portugal, (3)Vrije Universiteit Amsterdam, Netherlands

AgNPs are used in a wide range of daily products leading to their emission to waste water treatment plants (WWTP). Due to the presence of a large proportion of sulfide and the reduced conditions during wastewater treatment, Ag₂S is expected to be formed from Ag ions or AgNPs. The application of sewage sludge on agricultural land triggers concerns about exposure of terrestrial organisms to pristine or sulfidized AgNPs. Therefore, hazard assessment must be accurately performed. This study determined the uptake and elimination kinetics in *Enchytraeus crypticus* of different Ag forms: paraffin-coated 3–8 nm, PVP-coated 50 nm, and 60 nm AgNPs, 20 nm Ag₂S NPs PVP-coated and AgNO₃. The Ag₂S NPs were synthesized to simulate aged AgNPs after passing through a WWTP, while the other NPs were tested as manufactured. To assess the effect of soil type on the bioavailability and uptake of the Ag₂S NPs as the most environmentally relevant Ag species, animals were exposed through three different soils, Dorset, Woburn, and Lufa 2.2 (the same was carried out for AgNO₃). In all tests, *E. crypticus* was exposed to soil spiked at 10 mg Ag kg⁻¹ dry soil for 14 days and then transferred to clean soil for a 14-day elimination phase. During both phases, animals were sampled from three replicate jars on days 1, 2, 4, 7, 9, 11, and 14, kept overnight to purge their gut and frozen (-20 °C), dried, digested and analysed for Ag by graphite furnace Atomic Absorption Spectrophotometry. A first-order one-compartment kinetics model was used to describe Ag accumulation in the animals. The uptake rate constants were similar for 3–8 nm and 60 nm AgNPs and AgNO₃, but significantly different between 3–8 nm and 50 nm AgNPs, so, Ag bioavailability was influenced by its form and characteristics. Uptake and elimination rate constants of Ag significantly differed between the test soils. For Ag₂S NPs the Ag uptake and elimination rate constants were significantly lower for Dorset than for Woburn and with no significant differences between the estimated kinetics for Lufa 2.2 compared to the other two soils. For AgNO₃, significantly higher uptake and elimination rate constants in enchytraeids were found in the sandy and acid Dorset soil compared to the other soils. Therefore, soil

properties affect the bioavailability of Ag directly and bioaccumulation indirectly by affecting the transformation and distribution of Ag in soil and pore water. The kinetics of Ag₂S NPs cannot be predicted by those of AgNO₃.

3.01 Advances in Bioaccumulation Science and Assessment (Poster)

3.01.P-Mo094 Sorption of Three Pesticides to the Seaweeds *Ulva Lactuca* and *Sargassum muticum*

Bas Buddendorf¹, Arrienne Matser², Wim Beltman² and Ivo Roessink², (1)Wageningen UR, Nederland, (2)Wageningen Environmental Research, Netherlands

Seaweed receives more and more global attention as a driver of a blue economy. It has the potential to deliver more food to an increasing world population and can provide basic ingredients for medicine, cosmetics, and even fuel. As a result, seaweed is being cultured in estuaries, open seas, or ponds. Seaweed grows best under nutrient-rich productive circumstances but here exposure to contaminants, such as pesticides, is likely. Depending on their hydrophobicity, an association of pesticides with seaweeds can occur. Although potentially problematic for some commercial uses, this also presents the possibility to use seaweed for remediation of effluent water from the pond- or tank-based aquaculture systems. To be able to predict associated (environmental) risks, we recommend extending existing models (e.g. the ERA-AQUA model) with a seaweed compartment. In order to assess seaweed-pesticide interactions, so-called sorption coefficients are required. Unfortunately, there is a general lack of sorption, uptake, bioaccumulation, and effects studies under laboratory conditions for seaweed species. In order to fill part of this data gap, a study on the sorption of three pesticides to the seaweeds *U. lactuca* and *S. muticum* was performed using a batch method according to OECD-106 at one concentration level. Three pesticides were selected to cover a representative range of expected sorption behavior, using sorption to the organic matter in soil K_{om} as a determinant. The K_{om} values of Thiamethoxam, Diazinon, and Chlorpyrifos are 33, 353, and 2072 L/kg, respectively. Results of the sorption experiments will be presented. In future work, the pesticide sorption coefficients determined for seaweeds can be used in risk assessment by extending existing models like ERA-AQUA with a seaweed compartment to calculate pesticide content of seaweed and pesticide concentrations in the pond or tank water and in effluent released from aquaculture systems.

3.01.P-Mo095 Trophic Magnification of Perfluoroalkyl Substances Within a Terrestrial Avian Food Web

Kate Fremlin¹, John E. Elliott², Robert J. Letcher³, Tom Harner⁴, Anita Eng⁴ and Frank Gobas⁵, (1)Simon Fraser University, Burnaby, BC, Canada, (2)Research Scientist, Environment and Climate Change Canada, Canada, (3)Science and Technology Branch, Environment and Climate Change Canada, Ottawa, ON, Canada, (4)Environment and Climate Change Canada, Canada, (5)Simon Fraser University, Canada

The primary endpoints and criteria currently used in North America to define a substance as bioaccumulative include log octanol-water partition coefficients (log KOW) >5 and/or bioconcentration or bioaccumulation factors (BCF or BAF) >5,000. However, these endpoints limit our ability to identify substances that may be bioaccumulative in air-breathing organisms or terrestrial ecosystems since they do not account for chemical exposure from air or in air-breathing organisms. In addition, these endpoints, particularly KOW, are not suitable for understanding the bioaccumulation potential of perfluoroalkyl substances (PFAS) within terrestrial systems because KOW cannot be reliably measured for ionic surfactants. To establish effective guidelines that protect terrestrial species, there is a need to further investigate the bioaccumulation process of PFAS in terrestrial organisms. Thus, we assessed biomagnification of a suite of PFAS [all perfluoroalkyl acids (PFAAs)] in an urban terrestrial food-web that included an avian apex predator, the Cooper's hawk (*Accipiter cooperii*). We analysed samples of Cooper's hawk eggs, songbirds, invertebrates, soil, and air samples for concentrations of PFAAs. Each organism sample was analysed for protein and phospholipid content to account for differences in sorbing matrices. Using stable isotope analysis of ¹³C and ¹⁵N signatures, we estimated the trophic position of each organism. Trophic Magnification Factors were determined using three approaches: 1) wet weight concentrations (TMFW); 2) concentrations normalized based on tissue composition in each organism (i.e., protein, lipid, and phospholipid; TMFN); and 3) concentrations expressed as thermodynamic activities (TMFA). TMFWs of PFAAs ranged from 0.75 to 6.8 and TMFNs ranged from 0.81 to 7.5, indicating that most PFAAs are biomagnifying in this urban terrestrial system.

3.01.P-Mo096 A Generic Model Based on the Properties of Nanoparticles and Cells for Predicting Cellular Uptake

Bingqing Lu¹, Prof. Jan A.J. Hendriks² and Tom Nolte³, (1)Department of environmental science, Radboud University, Nijmegen, Netherlands, (2)Radboud University Nijmegen, Nijmegen, Netherlands, (3)Radboud University Nijmegen, Netherlands

Nanoparticles (NPs) are widely used in industry and technology due to their small size and versatility, which makes them easy to enter organisms and pose threats to human and ecological health. Given the particularity and complex structure of NPs, statistical models alone cannot reliably predict uptake. Hence, we developed a generic model for predicting the cellular uptake of NPs with organic coatings, based on physicochemical interactions underlying uptake. The model utilized the concentration, experimental conditions and properties of NPs viz. size, surface coating and coverage. These parameters were converted to surface energy components and surface potentials, and combined with the components and potential for a cell membrane. For NPs uptake, we constructed energetic profiles and barriers for adsorption and permeation onto/through cell membranes. The relationships derived were compared to experimental uptake data. The model provided accurate and robust uptake estimates for neutrally charged NPs and six different cell types. Our model also has some applicability for charged NPs, which may indicate significance that physicochemical interactions is common in different cellular uptake pathways of various NPs. We envision that the model provides a reference for cellular accumulation of NPs and (ecological/human) risk assessment of NPs or microparticles.

3.01.P-Mo097 Influence of PFOs on the Bioaccumulation of Emerging Contaminants in Crops Cultivated Under Soil and Soilless Conditions

Eulalia María Beltrán¹, Maria Victoria Pablos², Carlos Fernández-Torija², Pilar Garcia Hortigüela², Miguel Porcel³ and Miguel Gonzalez-Doncel⁴, (1)Environment and Agronomy, INIA - National Institute for Agricultural and Food Research and Technology, Madrid, Spain, (2)Spanish National Institute for Agricultural and Food Research and Technology (INIA-CSIC), Spain, (3)INIA National Institute for Agricultural and Food Research and Technology, Spain, (4)Environment and Agronomy, National Institute for Agricultural and Food Research and Technology (INIA-CSIC), Madrid, Spain

The Mediterranean is a region of substantial agriculture production that faces concurrent environmental stresses and freshwater pollution given the occurrence of Pharmaceuticals and Personal Care Products (PPCPs). Among these pollutants, the surface-active substances have been suggested to enhance the bioavailability of other PPCPs. This research evaluates a comparative uptake and translocation assessment of irrigation exposure to atenolol (ATN), carbamazepine (CBZ) and triclosan (TCS) alone vs. combined with perfluorooctanesulfonic acid (PFOS) under semi-field (i.e. soil experimental set) vs. hydroponics (i.e., soilless experimental set) growing conditions with lettuce, radish and tomato plants. Both experimental sets revealed efficient root uptake and translocation for the three PPCPs regardless of their co-existence with PFOS. The overall results of the uptake and translocation of the PPCPs in the lettuce and tomato plants suggested a simultaneous treatment-plant organ interaction, which was not affected by PFOS being present in both experimental sets. These observations support the hypothesis of factors other than PFOS being responsible for the differential bioaccumulation and translocation potentials seen in both experimental sets. However, the radish plants co-irrigated with PFOS brought about increased movement of PPCPs from roots to aerial parts. These results support the notion that factors inherent to the physiological characteristics of this root vegetable contributed to PPCPs' increased tendency to move from roots to aerial parts. This work has been supported by Spanish Government Grants (CTM-2013-44986-R and CTM-2014-52388-R) funded by MCIN/AEI/ 10.13039/501100011033 and the ERDF.

3.01.P-Mo098 How Can Passive Sampling Be Used to Help Understand POP Bioaccumulation in Fish?

Ian John Allan¹, Branislav Vrana² and Anders Ruus³, (1)Norwegian Institute for Water Research, Norway, (2)Masaryk University, Faculty of Science, RECETOX, Czech Republic, (3)NIVA, Norway

Hexachlorobenzene is ubiquitously distributed in the environment and is assumed to mildly biomagnify in aquatic foodwebs. The use of trophic magnification factors (TMF) in the procedure to compare contaminant levels in biota with Water Framework Directive (WFD) Environmental Quality Standards has been proposed. An understanding of biomagnification and reliable selection of TMF is therefore crucial in this framework. Passive sampling for nonpolar non-ionised chemicals has been the subject of much progress over the last two decades. Latest advances include the ability through the use of lipid-polymer partition coefficients to estimate equivalent contaminant concentrations in lipids at equilibrium with the water (sampled by the passive sampler). This can in turn help with understanding bioaccumulation processes through comparisons with actual biota data. Here we compare datasets of penta- and hexachlorobenzene (PeCB and HCB) concentration ratios (i) from passive sampling in water and (ii) in freshwater and marine fish acquired through routine monitoring programmes in Norway in the last 5-10 years. In our procedure, PeCB is used for benchmarking bioconcentration in fish and observed HCB/PeCB ratios in fish are compared with ratios expected in the case of (a) HCB bioconcentration only or (b) biomagnification using published TMFs. Our results show that we cannot conclude that HCB biomagnifies in fish species that would be used for WFD monitoring in Norway. Finally, fish-water chemical activity ratios for HCB and PeCB as well as for polychlorinated biphenyls (PCBs) calculated for coastal sampling locations where biota and passive sampling were conducted alongside rarely exceed unity for cod. Implications are discussed.

3.01.P-Mo099 Contaminants of Emerging Concern in Glass-Eel (*Anguilla anguilla*): Occurrence, Bioconcentration and Biotransformation

Iker Alvarez¹, Nestor Etxebarria¹, Mathilde Monperrus², Valérie Bollier³ and Lyen Castro⁴, (1)University of the Basque Country, Spain, (2)IPREM CNRS UMR 5254 LCABIE, France, (3)UMR ECOBIOP INRA - Université de Pau, France, (4)University of the Basque Country, Philippines

Undoubtedly, the presence of contaminants of emerging concern in the aquatic environment has a direct impact on water-living organisms and can alter their living functions. These compounds are often metabolized and excreted but they can also be accumulated and spread through the food chain. The metabolized contaminants can also lead to the formation of new compounds with equal or higher toxicity and bioaccumulation potential as the parent compound. In this work we have studied the occurrence, bioconcentration and biotransformation of CECs in glass-eels (*Anguilla anguilla*) using UHPLC-Q-Exactive Orbitrap. We first carried out an environmental risk assessment of the WWTP effluent that releases directly into the estuary of Adour (Bayonne, Basque Country, France). The risk quotients of every detected contaminant were calculated and three ecotoxicologically relevant contaminants were chosen to perform the exposure experiment: propranolol, diazepam and irbesartan. An experiment of 14 days consisting of 7 days of exposure and 7 days of depuration was carried out to measure the bioconcentration of the chosen compounds. The quantitative results of the concentrations in glass eel showed that diazepam and irbesartan reach BCF ? 10 at day 7, but both compounds are completely eliminated after 7 days of depuration. On the other hand, propranolol's concentration remains constant all along the experiment, and its presence can be detected even in the non-exposed control group. Two additional suspect screening strategies were used to identify both the metabolization products of the target compounds, and other xenobiotics already present in wild glass eels. Several metabolites were annotated for propranolol and diazepam, whereas none was detected for irbesartan. The xenobiotic screening confirmed the presence of more xenobiotics in wild glass eels, prominent among them, the pharmaceuticals exemestane, primidone, iloprost and norethandrolone, the industrial products caprolactam and diethylenetriamine or THC among the recreational drugs.

3.01.P-Mo100 Uptake of Pharmaceuticals and Personal Care Products by Crops Irrigated With Reclaimed WATER in a Mediterranean Scenario

Eulalia María Beltrán¹, Maria Victoria Pablos², Carlos Fernández-Torija², Miguel Porcel³, Pilar Garcia Hortigüela² and Miguel Gonzalez-Doncel⁴, (1)Environment and Agronomy, INIA - National Institute for Agricultural and Food Research and Technology, Madrid, Spain, (2)Spanish National Institute for Agricultural and Food Research and Technology (INIA-CSIC), Spain, (3)INIA National Institute for Agricultural and Food Research and Technology, Spain, (4)Environment and Agronomy, National Institute for Agricultural and Food Research and Technology (INIA-CSIC), Madrid, Spain

Water scarcity is a natural condition in the Mediterranean rim countries. In this region, reuse of reclaimed water (RW) from wastewater treatment plants (WWTPs) is becoming a potential source for highly water-demanding activities such as agriculture. Considering a Mediterranean scenario, we investigated the plant uptake and translocation of three representative pharmaceuticals and personal care products (PPCPs) (atenolol -ATN-, carbamazepine -CBZ- and triclosan -TCS-) typically present in RW samples from a WWTP located in an urban area in Spain. We then assessed the potential risk to humans from plant consumption. To consider two worst-case scenarios the contaminants were spiked at two levels in the RW samples. Three plant models (lettuce, maize and radish) were grown outdoors and irrigated with four treatments: tap water; RW samples, and the two spiked RW samples. Results revealed an efficient root uptake for the three PPCPs regardless of plant species and fortification level. Different bioaccumulation and translocation potentials of the three PPCPs were seen in the aerial plants organs. We hypothesized that several factors, including physical-chemical properties of the PPCPs and physiological plant variables, could be responsible for the differential accumulation and translocation potentials observed. These variables could be critical for crops irrigated with RW in regions with extended dry seasons, high solar incidence and low annual rainfall including those in the Mediterranean rim. The results suggested a negligible risk to humans from consumption of edible plants irrigated with RW samples with presence of PPCPs. This work has been supported by Spanish Government Grants (CTM-2013-44986-R and CTM-2014-52388-R) funded by MCIN/AEI/ 10.13039/501100011033 and the ERDF.

3.01.P-Mo101 Investigations on the Uptake and Accumulation of Wastewater-Borne Nanomaterials and Released Metals by the Benthic Amphipod *Hyalella azteca* Under Environmentally Relevant Conditions

Sebastian Kuehr¹, Johannes Rath², Brian Sinnet³, Marco Kipf³, Mark Rehkemper⁴, Karl Andreas Jensen⁵, Andy Booth⁶, Anastasia Georgantzopoulou¹ and Ralf Kaegi⁷, (1)NIVA - Norwegian Institute for Water Research, Norway, (2)Uchem, Eawag, Zürich, Switzerland, (3)Eawag Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (4)Imperial College London, UK, (5)Norwegian University of Life Sciences, Norway, (6)Climate and Environment, SINTEF Ocean, Trondheim, Norway, (7)Swiss Federal Institute of Aquatic Science and Technology (EAWAG), Switzerland

With an increasing range of applications, the diversity, production levels and use of engineered nanomaterials (ENMs) is growing at a global level. When ENMs are incorporated into consumer products, such as cosmetics, textiles and nanomedicine, a proportion can be released into wastewaters during use or end of life. After entering the wastewater stream, ENMs become primarily attached to the sludge flocs and are thus removed relatively efficiently by wastewater treatment plants (WWTPs). Nevertheless, small amounts of ENMs entering WWTPs can reach the environment directly via the effluent, attached to sludge flocs or even as free particles. Furthermore, the biosolids from WWTPs are often used as agricultural fertilizer and from there ENMs may enter aquatic systems via surface runoff. Relatively few data are available regarding the fate and transformation of ENMs released from WWTP and their potential bioavailability to organisms in different aquatic systems. Most studies on bioavailability or accumulation of ENMs have been performed using pristine ENMs, where important physicochemical transformation processes are rarely taken into account. A few studies have been conducted with artificial wastewater to simulate the transformation processes in WWTP, but mostly using high ENM concentrations. In this study, we used a pilot WWTP operating with real wastewater and spiked with low concentrations of Au, Ag or ZnO ENMs, to achieve sludge concentrations comparable to levels observed in the field. Concentrations of 1 (Au), 10 (Ag) and 100 (Zn) mg/kg dry mass of the digested sludge were produced. To allow the detection of the spiked ENMs at low concentrations in complex matrices, as well as to differentiate against the background, we used isotopically enriched ENMs (Ag and ZnO -NP). Methods for ENM extraction were developed and measurement of total metal and particle concentrations was carried out by Inductively Coupled Plasma - Mass Spectrometry (ICP-MS) and single particle-ICP-MS, respectively. The benthic amphipod *H. azteca* was used as model organism, as the uptake and detoxification mechanisms for metals in this species are well known and described. After exposures with effluent or biosolids from the pilot WWTP, we examined the uptake, accumulation and bioavailability of the wastewater borne ENMs and the respective metals. The obtained results were compared with further data from exposures conducted with pristine ENMs, the dissolved metals and different exposure conditions.

3.01.P-Mo102 Acute Aquatic Toxicity in Zebrafish and Bioaccumulation in Mussels of Antimony Tin Oxide Nanoparticles

Begoña Espina¹, Ivone Pinheiro², Antonio Moreda-Piñeiro³, Monica Quarato⁴, Virginie Serin⁵, David Neumeyer⁵, Nicolas Ratel-Ramond⁵, Sebastien Joulie⁵, Alain Claverie⁵, Pilar Bermejo-Barrera³ and Laura Rodríguez-Lorenzo⁴, (1)International Iberian Nanotechnology Laboratory, Braga, Portugal, (2)International Iberian Nanotechnology Laboratory, Portugal, (3)Universidade de Santiago de Compostela, Spain, (4)INL International Iberian Nanotechnology Laboratory, Portugal, (5)CEMES/CNRS, France

Antimony Tin Oxide (Sb₂O₅/SnO₂) is effective in the absorption of infrared radiation for applications such as skylights. This nanoparticle (NP) can be incorporated into film or sheet applications and provides infrared radiation attenuation while allowing for a transparent final product. Despite of being integrated in many products, including plastics, very scarce information is available regarding their ecotoxicity and bioaccumulation. In this work, after extensive characterization of the nanomaterials (DLS, Z-potential, TEM, SEM, XRD), we studied the acute toxicity exerted by commercial Sb₂O₅/SnO₂ in adults and embryos of

zebrafish (*Danio rerio*). Our results suggests that these NPs do not induce an acute toxicity on zebrafish, nor the adults, either the embryos. However, some sub-lethal parameters were altered; eye volume, heart rate and spontaneous movements. Finally, we studied the possible bioaccumulation of these NPs in aquacultured marine mussel *Mytilus* sp. as a potential bioconcentrator prior human intake. We performed a quantitative analysis by sp-ICP-MS and biodistribution analysis by TEM of the mussel's tissues. The results indicated that despite being scarce ($2.31E+06 \pm 9.05E+05$ particles/g), there is some accumulation of the Sb_2O_5/SnO_2 NPs in the mussel. No NPs could be observed in the tissues due to the relatively low concentration and no significant alterations were observed in the ultrastructure of the tissue or cells. In conclusion, commercial Sb_2O_5/SnO_2 NPs seem to be quite innocuous to aquatic organisms, however, the fact that some of the developmental parameters in zebrafish embryos are altered should be considered for further investigation. More in deep analysis of these NPs transformations in the digestive tract of humans, their bioaccessibility and bioavailability are needed to understand if their accumulation in mussels pose an effective risk to humans.

3.01.P-Mo103 Differences in Chemical Contaminants Bioaccumulation in Presence or Not of Microplastics in Mussels (*Mytilus galloprovincialis*)

Julian Campo¹, Rodrigo Alvarez-Ruiz², Dyana Vitale², Yolanda Pico² and Vasiliki Soursou³, (1)CIDE-CSIC, Spain, (2)University of Valencia, Spain, (3)University of Valencia, MONCADA, Spain

Persistent Organic Pollutants (POPs) are one of the most important indicators of the anthropic influence on the environment, specially on the biota as they are bioaccumulable and have recently shown to interact with microplastics (MPs) [1]. Mussels are suitable for in-lab aquarium experiments, such as bioaccumulation studies, which provide insight about the occurrence and fate of pollutants in the organisms. In the present study, bioaccumulation in *Mytilus galloprovincialis* of 20 POPs including pharmaceuticals and personal care products (PPCPs), pesticides, and perfluoroalkyl substances (PFASs) was assessed with or without the influence of MPs. Mussels (*M. galloprovincialis*) were distributed randomly in three groups: (B): control; (C): exposed to POPs; and (C+M): exposed to POPs+MPs (polyethylene). The experiment was carried out in two stages: exposure (0-28 days) and depuration (29-58 days). Visceral mass and haemolymph of the mussels were extracted separately, using QuEChERS and solid phase extraction. Extracts were analysed via UHPLC-MS/MS. Results showed that 3 PPCPs, 4 pesticides and 3 PFASs accumulated in visceral mass with bio-concentration factors (BCFs) ranging 6.7–15000 L/kg. In haemolymph, 2 PPCPs, 2 pesticides and PFPeA were detected with BCFs ranging 0.9–3.3 L/kg. Comparing C and C+M, MPs worked as a vector for the accumulation of the PFASs with higher BCFs in the presence of MPs. Furthermore, the elimination of PFDA and PFOS was slower in the mussels exposed to MPs. On the other hand, the pesticides terbuthylazine and chlorpyrifos showed lower BCFs and more rapid elimination in the mussels exposed to MPs. **Acknowledgements** This work has been supported by Grant RTI2018-097158-B-C31 funded by MCIN/AEI/ 10.13039/501100011033 and “ERDF A way of making Europe”. 3.01.P-Mo104 Size- and Shape-Dependent Bioaccumulation Dynamics of Microplastic and Microrubber Particles in the Eastern Oyster, *Crassostrea virginica*

John E. Weinstein and Bonnie Ertel, The Citadel, United States

Microplastics (MP) are ubiquitous in coastal waters and have been documented in filter-feeding organisms such as oysters. Along the South Carolina coast (U.S.) where the ecologically and economically important eastern oyster (*Crassostrea virginica*) forms large intertidal reefs, recent surface water surveys found that fibers, fragments, and microscopic tire particles represented 43.6%, 30.9%, and 17.7% of the total MP, respectively. The aim of the current study was to characterize the bioaccumulation dynamics of these three particle types in the eastern oyster. In the laboratory, oysters were exposed to either purple polyethylene fibers, green nylon fragments, or micronized crumb rubber at a concentration of 5000 MP/L. Oysters (n=8 to 10) were sacrificed after 0, 24, 48, and 96 hours of exposure to characterize MP uptake. Following 96 hours of exposure, remaining oysters were transferred to MP-free seawater and sacrificed at 24, 48, and 96 hours (n=8 to 10) to characterize MP depuration. Oysters accumulated significantly longer fibers, smaller fragments, and smaller crumb rubber particles relative to the average sizes to which they were initially exposed. For fibers and fragments, MP levels increased during the uptake phase in a hyperbolic fashion with apparent steady states being achieved at 96 h at 1.61 ± 0.56 particles/g w.w. (mean \pm SE) and 0.46 ± 0.08 particles/g w.w., respectively. For fibers, K_u was estimated to be 0.0057 ± 0.0016 mL/g*h (mean \pm SE), and K_d was estimated to be 0.0151 ± 0.0059 /h. For fragments, K_u was estimated to be 0.0016 ± 0.0003 mL/g*h (mean \pm SE), and K_d was estimated to be 0.0168 ± 0.0047 /h. For crumb rubber, levels increased during the uptake phase following a linear relationship with levels after 96-h at 3.62 ± 0.84 particles/g w.w. The K_u and K_d were estimated to be 0.0071 mL/g*h and 0.0067 ± 0.0033 /h, respectively. MP levels in oysters decreased during the 96-h depuration phase by 78.6% for fibers, 80.8% for fragments, and 64.2% for crumb rubber. The present study demonstrates accumulation of MP and microrubber in eastern oysters is size- and shape-dependent and depuration is an effective method to reduce MP levels. Although it has been asserted that bivalves make poor general bioindicators of MP pollution because of their particle selectivity, we suggest that the eastern oyster has the potential to be specific bioindicators for smaller, low aspect-ratio fragments and tire particles, and larger, higher aspect-ratio fibers.

3.01.P-Mo105 Environmental Occurrence of Organophosphate Esters and Micro-Plastics in Sediments and Benthic Organisms From the Loire Estuary (France)

Javier Castro-Jimenez¹, Yann Amino², Charles Pollono², Babatounde Idjaton², Lucie Bizzozero², Olivier Pierre-Duplessix², Johnny Gasperi³ and Ngoc-Nam PHUONG³, (1)Chemical Contamination of Marine Ecosystems, IFREMER, Nantes, France, (2)IFREMER, France, (3)Gustave Eiffel University, France

Organophosphate ester (OPE) flame retardants and plasticizers are organic plastic additives commonly incorporated in many industrial products in order to minimise fire risks and/or to improve some properties of manufactured products [1]. These

chemicals present multiple sources in the environment and are widely distributed in seas and oceans of the planet [2]. Another emerging threat to the marine environment is micro-plastics (MPs) due to substantial loading from rivers, coastal cities, and through maritime traffic and fishing activities [3,4]. Marine sediments are thought to be a sink for both OPEs and MPs. In addition, leaching from MPs could constitute in-situ sources of OPEs [2]. Therefore, determining their environmental occurrence in sediments becomes crucial to better understand their current stocks, the exposure of benthic organisms, and possible impacts on the global functioning of marine ecosystems. The Loire is the longest river in France representing an important freshwater discharge to the North-East Atlantic Ocean. Its estuary is considered as an ecosystem of high ecological value as well as an ocean/land interface for sea trade and associated industrial activities. Three sampling campaigns conducted in 2021-2022 allowed the collection of surface sediments and the deposit feeder clam *Scrobicularia plana* (*SP*) in four study areas subjected to different anthropogenic pressures. A large set of OPEs were quantified by isotopic dilution LC-MS/MS after thorough clean-up and MP abundance was determined after matrix digestion and polymer isolation and the fragments were characterized by μ -FTIR. Our results confirm the overall presence of most abundant chlorinated and non-chlorinated OPEs in sediments from the study area. Six out of the 11 monitored OPEs in biota were also detected in *SP*, at concentrations as high as 7 ng/g d.w for tris(chloro-2-propyl) phosphate (TCIPP). The OPE concentrations in sediment and geographical distributions are discussed with regards to MP abundances. A first estimation of the field-derived biota-sediment accumulation factors (BSAFs) of OPEs is also presented. These results emphasize the need to further explore the sources and fate of this class of compounds ubiquitous in the marine environment. **References:** [1] van der Veen, I., de Boer, J. Chemospher 2012, 88, 1119–1153; [2] Xie et al., Nat. Rev. Earth Environ, in press; [3] Lebreton et al. Nat. Commun. 2017, 8, ncomms15611; [3] Schmidt, et al. Environ. Sci. Technol. 2017, 51, 12,246–12,253.

3.01.P-Mo106 New Insights on In Vitro Biotransformation of Anticoagulant Rodenticides in Fish

Julia Regnery¹, **Carolin Riegraf¹**, **Stefanie Jacob²** and **Anton Friesen³**, (1)Federal Institute of Hydrology, Germany, (2)German Environment Agency (UBA), Germany, (3)German Environment Agency UBA, Germany

The assessment of the bioaccumulation potential of chemicals is an essential and mandatory part of their regulatory environmental risk and hazard assessment. Within the EU active substance approval under the Biocidal Products Regulation, the bioaccumulation potential of most anticoagulant rodenticides (ARs) was assessed from quantitative structure activity relationship (QSAR) derived bioconcentration factors (BCFs). *In silico* approaches are based on the experience that the BCF value of a substance is usually related to its lipophilicity and susceptibility to biotransformation. However, BCF estimations relying on the *n*-octanol/water partition coefficient neglect other driving forces concerning ARs. The majority of ARs is presumed to be ionizable under environmentally relevant conditions. Additional complicating factors are their stereochemistry and tissue specific protein binding to the target enzyme vitamin K epoxide reductase with the liver being the main organ of accumulation and storage. Moreover, QSARs often do not account for the contribution of fish metabolism on intrinsic clearance. So far, *in vitro* data on fish metabolism is rarely available for biocidal active substances such as ARs. In this study we present *in vitro* biotransformation rates of eight biocidal and one pharmaceutical anticoagulants in rainbow trout (*Oncorhynchus mykiss*) liver subcellular S9 fraction (RT-S9) determined following the OECD test guideline 319B method at two different incubation temperatures (i.e., 12 ± 1 °C and 23 ± 2 °C). Furthermore, we address challenges associated with the usability and interpretation of *in vitro* data to support the decision making within the regulatory bioaccumulation assessment in bridging the gap between *in silico* methods and *in vivo* studies. Overall, four of the tested substances (i.e., chlorophacinone, coumatetralyl, bromadiolone, and difenacoum) exhibited significant intrinsic clearance ($p < .001$) in the RT-S9 assay. The observed metabolism was (very) slow and clearance rates were temperature-dependent. For substances with otherwise scarce experimental data availability, the known presence or absence of *in vitro* intrinsic clearance in fish using the RT-S9 assay is expected to improve the decision base for regulators to request or avoid further *in vivo*/animal testing during environmental risk and hazard assessments.

3.01.P-Mo107 Tiered Approach to Assess Bioaccumulation in Air-Breathing Organisms

Caren Rauert¹, **Aaron Redman²**, **Alberto Martin-Aparicio³**, **Doris Hirmann⁴**, **Eric Verbruggen⁵**, **Frank Gobas⁶**, **Frank Wania⁷**, **Jon Arno⁸**, **Kai-Uwe Goss⁹**, **Maike Habekost¹⁰**, **Michel Laurentie¹¹**, **Paul Whalley¹²**, **Sophia Krause¹³**, **Sylvia Jacobi¹⁴**, **Tim Hofer¹⁵** and **Gabriele Treu¹⁶**, (1)Umweltbundesamt, Germany, (2)Exxon Mobil Biomedical Sciences, Inc., United States, (3)CONCAWE, Belgium, (4)European Chemicals Agency, Finland, (5)RIVM Expertise Centre for Substance, Netherlands, (6)Simon Fraser University, Canada, (7)University of Toronto Scarborough, Toronto, ON, Canada, (8)ARC Arnot Research & Consulting Inc., Canada, (9)Analytical Environmental Chemistry, Helmholtz Centre for Environmental Research - UFZ, Leipzig, Germany, (10)BASF SE, Germany, (11)ANSES, France, (12)Syngenta, United Kingdom, (13)Helmholtz centre for environmental research - UFZ, Germany, (14)Albemarle Europe, Belgium, (15)Norwegian Institute of Public Health, Norway, (16)German Environment Agency (Umweltbundesamt), Germany

Bioaccumulation assessment has focused mainly on aquatic species in the past, with the fish bioconcentration factor (BCF) as a widely accepted endpoint. The BCF is used as criterion in PBT and POP assessment. Although for many substances this is sufficient, some substances like endosulfan, many perfluorinated alkyl substances or highly lipophilic compounds, accumulate substantially in air-breathing organisms and may not be recognised as bioaccumulative if based on aquatic testing only. An ECHA working group including members from academia, industry and government (from Europe and Canada) are developing an approach to use toxicokinetic data for the prioritisation and assessment of substances, potentially bioaccumulating in air-breathing organisms. The working group proposes a tiered approach, where the first tiers can be used for (de)prioritisation and higher tiers include testing strategies that allow a definitive conclusion. The relevant assessment endpoint is the biomagnification factor (BMF), with a value greater than 1 indicating concern regarding bioaccumulation potential in the food chain. Other endpoints, such as elimination rates and biotransformation rates can be related to this BMF reference value. Tier 1 assessment compares a

chemical's properties (volatility, hydrophilicity, and susceptibility to biotransformation) with threshold values to separate chemicals that are potentially bioaccumulative from those that clearly will not be able to bioaccumulate. The subsequent tiers use data of increasing complexity, ranging from biotransformation rates estimated with quantitative structure activity relationships (QSARs), to in vitro test results combined with in vitro in vivo extrapolation (IVIVE), to biotransformation rates derived from in vivo studies for air-breathing organisms. A standard protocol for in vitro tests, similar to that currently available for fish in OECD TG 319 A and B, could also be developed for e.g. rat. The assessment in the highest tier involves in vivo testing with air-breathing vertebrates and therefore should only be applied as last resort. Existing guidelines which are being explored regarding their utility for bioaccumulation assessment (either as such or with modifications) include OECD TG 417 (toxicokinetic) and OECD TG 422 (combined repeated dose toxicity study). The use of food chain data can be very useful information to be considered in this tier while guidance on the use is needed.

3.01.P-Mo108 Bioaccumulation Assessment Methods for Hydrocarbons and Related Substances in Terrestrial Organisms

Frank Gobas¹, Aaron Redman², Alberto Martin-Aparicio³ and Louise Camenzuli⁴, (1)Simon Fraser University, Canada, (2)Exxon Mobil Biomedical Sciences, Inc., United States, (3)CONCAWE, Belgium, (4)ExxonMobil, Belgium

Currently, there is an increased interest in the development of regulatory metrics for assessing the bioaccumulation of hydrocarbons and related substances in terrestrial organisms. This is due to a lack of regulatory methods and criteria for evaluating the bioaccumulation of substances in air-breathing organisms of terrestrial systems; the recognition that “low Kow-high Koa” substances exert a bioaccumulation behaviour in terrestrial organisms that cannot be adequately determined from bioaccumulation tests in fish; the finding that certain polyfluorinated organic chemicals bioaccumulate to a high degree without being lipid soluble; as well as the phase-out of animal studies for testing and the urgent need for an enhanced capacity for bioaccumulation testing at lower costs and within a shorter time frame. Fortunately, over the last few years, several new developments in bioaccumulation science have emerged that can contribute to the development of effective regulatory tools for the management of hydrocarbons and related substances in terrestrial wildlife. They include in-vitro biotransformation testing; the developments of in-vivo protocols for dietary bioaccumulation tests; the development of quantitative structure activity relationships (QSARs) for biotransformation and bioaccumulation; and the growing capacity to measure trophic magnification of substances in real-world food-webs. have provided a number of options for better assessment and management of hydrocarbons and other chemicals. It is the objective of this study to review these developments and evaluate their potential to generate bioaccumulation metrics and data for air-breathing organisms that have a strong scientific foundation and are informative and useful for regulations. The study explores in-vitro depletion tests and in-vitro-to-in-vivo extrapolation techniques to assess biomagnification factors in air-breathing organisms of terrestrial food-webs; in-vivo biomagnification factors for lipid soluble and non-lipid soluble substances; QSARs for biotransformation and biomagnification; and field derived trophic magnification factors (TMF). Merits and limitations of the various approaches to terrestrial bioaccumulation assessment are discussed and the potential for a weight-of-evidence approach drawing on available information from several sources is highlighted.

3.01.P-Mo109 High-Resolution Mass Spectrometry for the Metabolomic Profiling of Endometriosis Patients and Pregnant Subjects

Alfonso Narvaez¹, Roberto Gonzalez-Martin², Andrea Palomar², Mercedes Taroncher¹, Francisco Dominguez², Maria-Jose Ruiz³ and Yelko Rodriguez-Carrasco¹, (1)Faculty of Pharmacy, University of Valencia, Spain, (2)IVI Foundation-RMA Global, Spain, (3)Laboratory of Toxicology, Faculty of Pharmacy, University of Valencia, Burjassot, Spain

Metabolomic tools represent a step forward in clinical studies that help to clarify the underlying processes triggered by specific health-related conditions. These studies are mainly based on the comparison of the different metabolic fingerprints from biological samples obtained through advanced analytical techniques. In this line, liquid chromatography (LC) coupled to high resolution mass spectrometry (HRMS) have emerged as a promising tool in metabolomic studies due to its ability to identify untargeted compounds contained in complex samples with a high degree of precision. The most common biological matrix for metabolomics studies is urine, due to its easy and non-invasive collection. Thus, the goal of the present study was to assess the suitability of a simple salt-assisted liquid-liquid microextraction (SALLE) followed by a HRMS strategy for determining the metabolic profile of urine samples from endometriosis patients, pregnant and control subjects ($n = 10$). The SALLE procedure was applied in parallel with acetonitrile and ethyl acetate aiming to extract compounds with different polar character. HRMS data were compared with records from the spectral library METLIN and a threshold identity score of 80 was selected for further identification. Results showed the tentative presence of up to 167 compounds belonging to different classes. Differential compounds across conditions were mainly molecules involved within the endocrine system, such as pregnanolone sulfate or dibutyl phthalate, an endocrine disruptor, exclusively found in samples from endometriosis patients, whereas 11-deoxy-11-methylene-prostaglandin D2 or prostaglandin D2 were only present in samples from pregnant subjects. Results showed that the use of a simple sample preparation procedure followed by HRMS analysis evidenced the hormonal imbalance among the assessed conditions and point to specific molecules as responsible for these differences. Therefore, these results provide more evidence about the key role of HRMS in clinical biomonitoring studies and support its applicability for further studies. **Acknowledgments:** This research was supported by the Spanish Ministry of Science and Innovation PID2020-115871RB-I00

3.01.P-Mo110 A New Integrated Screening-Level Bioaccumulation Modelling Framework for Organic Chemicals

Alessandro Sangion¹, James M Armitage², Liisa Toose, M.Sc.³, Trevor Brown⁴ and Jon Arnot³, (1)ARC Arnot Research and Consulting Inc. and University of Toronto Scarborough, Canada, (2)AES Armitage Environmental Sciences, Inc, Canada, (3)ARC Arnot Research & Consulting Inc., Canada, (4)TNB Research, Canada

Bioaccumulation (B) assessments can use various methods, data, and metrics. Measured B data for aquatic organisms are only

available for about 5% of the organic chemicals that require B assessment necessitating the use for models and new approach methods (NAMs) to address data gaps. There is now increasing recognition that B assessments should consider air-breathing organisms. Mechanistic mass-balance models have been developed for simulating the bioaccumulation of organic chemicals in aquatic and terrestrial organisms. While the partitioning of legacy neutral organic pollutants is often well characterized using octanol as a surrogate for lipids and other organic phases, this simplifying assumption is not appropriate for certain types of chemicals such as ionizable organic chemicals (IOCs). In particular, the charged form of IOCs shows relatively high affinity for phospholipids and in some case serum albumin. Approximately 45% of the organic chemicals that require regulatory evaluations are IOCs, therefore there is a need for evaluated B models for IOCs. Mass-balance models require biological and system properties as well as chemical-specific input parameters. Data gaps for physical-chemical properties can be addressed using quantitative structure-activity relationships (QSARs) and polyparameter linear free energy relationships (PP-LFERs). Data gaps for biotransformation rates can be addressed using in vitro methods and QSARs for estimating biotransformation rates. In this work we describe and evaluate a new screening-level bioaccumulation modelling framework for neutral and ionizable organic chemicals for a diverse range of representative aquatic and terrestrial organisms. The “B-Screen” model is developed in a tiered approach for input parameters allowing the user to use inputs at different level of complexity. The new model is integrated in the on-line Exposure And Safety Estimation (EAS-E) Suite platform (www.eas-e-suite.com) which can autoparameterize the model for >50K chemicals and facilitates its operation in the regulatory community. The B Screen model is consistent with the models built into the Bioaccumulation Assessment Tool (BAT Ver.2.0), such that higher tiered evaluations requiring multiple lines of evidence in a weight of evidence approach can evolve, if necessary, from the screening calculations provided by the B-Screening model. Details of the models, input parameters and case applications are presented.

3.01.P-Mo111 QSAR Models for the Prediction of Bioaccumulation in Aquatic and Terrestrial Organisms

Ester Papa, Linda Bertato and Nicola Chirico, University of Insubria, Italy

Experimental data related to metrics which describe the potential bioaccumulative behaviour of chemicals in different organisms and environments is important to support risk assessment procedures. Bioaccumulation (B) is a process by which the concentration of a chemical in an organism exceeds the concentration in its natural environment. B can be described by different metrics such as Kow, Koa, Bioaccumulation Factor (BAF), Bioconcentration Factor (BCF), Biomagnification Factor (BMF), Biota-Sediment Accumulation Factor (BSAF), Trophic Magnification Factor (TMF). Since experimental determination of these quantities can be time consuming and expensive, in terms of money, resources and animal lives, the maximization of the existing information and the use of alternatives strategies, such as QSAR models, are useful to fill data gaps and to estimate the properties of interest from the molecular structure of new and existing chemicals. In this work, some of the B metrics reported above, have been modelled by QSAR starting from data collected and curated from the literature or from online databases. The molecular structures represented by SMILES were standardized and used to calculate molecular descriptors, which are the independent variables necessary to develop multiple linear regression (MLR) QSAR models. Two heterogeneous sets of about 1400 and 300 chemicals respectively, were collected and curated in order to develop QSARs for the prediction of BCF and BMF in fish. These QSARs are characterized by good statistical performances (R^2 and Q^2 between 0.60 and 0.85). Additional QSARs were created for the BSAF measured in three organisms, belonging to either soil (*Lumbriculus variegatus*) or to sediment (*Monoporeia affinis* and *Lytechinus pictus*). R^2 and Q^2 values of these BSAF QSARs are in the range 0.70-0.91 and 0.62-0.87, respectively. The development of models for B in plants is ongoing and preliminary results are promising. All the models were developed considering the OECD requirements for model's transparency, statistical validity, and defined domains of applicability. The here proposed QSARs can be used to support the evaluation of the risk that chemicals may pose to different organisms in the environment, using multiple bioaccumulation metrics.

3.01.P-Mo112 The Bioaccumulation Assessment Tool (BAT, Ver.2.0): A Weight-Of-Evidence Framework for Bioaccumulation Assessment

Liisa Toose, M.Sc.¹, James M Armitage², Alessandro Sangion³, Michelle Embry⁴, Lauren Hughes¹ and Jon Arnot¹, (1)ARC Arnot Research & Consulting Inc., Canada, (2)AES Armitage Environmental Sciences, Inc, Canada, (3)ARC Arnot Research and Consulting Inc. and University of Toronto Scarborough, Canada, (4)Health and Environmental Sciences Institute (HESI), United States

Bioaccumulation (B) assessments using various methods, data, metrics, and classification criteria are routinely conducted as a part of chemical regulatory programs. For some chemicals B assessments can be challenging because of the myriad of metrics and threshold values combined with the uncertainty and variability in measured data. The Bioaccumulation Assessment Tool (BAT) guides a user through the process of collecting and generating various lines of evidence (LOE) required for assessing the bioaccumulation of neutral and ionizable organic chemicals in aquatic organisms and homeotherms (mammals). The BAT Ver.2.0 provides a formal Weight of Evidence (WOE) framework for B assessment considering both aquatic and terrestrial data sources (lab, field, in silico) consistent with OECD WOE principles. The BAT allows the user to enter various B metrics (i.e., LOE) for aquatic organisms (fish and invertebrates) such as in vivo laboratory BCFs and BMFs, field BAFs and field TMFs. B metrics relevant to air-breathing animals (e.g., field BMFs/TMFs, terminal elimination half-lives) can also be considered. For each LOE, the BAT includes Data Evaluation Templates (DETs) developed from standardized testing guidance to evaluate the reliability of the LOE used in the assessment. In vivo, in vitro and in silico biotransformation rate data can be entered to predict various B metrics using built in mechanistic mass balance bioaccumulation models for representative vertebrate species. These in silico B metrics can then be compared to the empirical data entered by the user or if empirical data are not available, the built-in BAT models can be used to obtain various B metrics in aquatic and terrestrial organisms. As illustrative examples, the BAT 2.0 was applied to assess the bioaccumulation potential of hexachlorobenzene (HCB) and ?-hexachlorocyclohexane (?-HCH) and

successfully captures key similarities and differences in the behaviour of these two chemicals in the environment. The BAT 2.0 is freely available and can readily be used by interested stakeholders from academia, industry, and the regulatory community.

3.01.P-Mo113 Assessing Bioaccumulation of Linear Volatile Methylsiloxanes in Aquatic Species Using the Bioaccumulation Assessment Tool

Jaeshin Kim¹, Sami Belkhiria² and Kathleen Plotzke³, (1)The Dow Chemical Company, United States, (2)Dow Silicones Belgium srl, Belgium, (3)Dow Chemical Company, United States

Bioaccumulation of a chemical is predicted or assessed using different metrics such as bioconcentration factor (BCF), bioaccumulation factor (BAF), biomagnification factor (BMF), and trophic magnification factor (TMF). The metrics have different criteria for bioaccumulation according to the design of the endpoint. It is not uncommon to obtain conflicting results using the different metrics. To evaluate bioaccumulation of linear volatile methylsiloxanes (VMS), we have employed the Bioaccumulation Assessment Tool (BAT, ver2.02) that facilitates the evaluation of multiple kinds of bioaccumulation data in a quantitative weight-of-evidence (QWoE) approach. The model assesses bioaccumulation potential with consideration of the relevance and reliability of each available data point. Four selected low molecular weight linear VMS were hexamethyldisiloxane (L2), octamethyltrisiloxane (L3), decamethyltetrasiloxane (L4), and dodecamethylpentasiloxane (L5). Although they are used as chemical intermediates and can be found as ingredients in consumer products, their environmental concentrations are very low or under detection limits in different media including biota, surface water, air, and sediment. Thus, there is only laboratory-based data available. According to the existing bioaccumulation studies for linear VMS, only BCF and BMF values were available for the inputs of the BAT. This is in contrast with data-rich cyclic VMS that have both laboratory and field-based data. However, the BAT can evaluate bioaccumulation potential using QSAR predicted biotransformation rates and BCFs from the EAS-E Suite (QSARINS, IFS, and OPERA) and the EPA CompTox Chemicals Dashboard. These predictions filled the knowledge gaps due to limited field measurements. According to the measured BCFs, L2 would not be considered bioaccumulative whereas L3-L5 would be considered bioaccumulative or very bioaccumulative depending on water concentrations. However, the measured laboratory BMFs of L3 and L4 supported non-bioaccumulative behavior (BMFs of L2 and L5 have not been measured yet). The use of predicted biotransformation rates and BCFs was advantageous for assessing bioaccumulation potential of the linear VMS in the BAT. The overall evaluation will be presented with all the measured and predicted bioaccumulation metrics.

3.01.P-Mo114 Bioaccumulation Assessment of Ionisable Chemicals - When Are Experimental BCF Values Necessary?

Michiel Claessens, Chemours, Belgium

When investigating a substance's bioaccumulation potential within a REACH PBT/vPvB assessment, the octanol-water partition coefficient (Kow) can be used in a first screening step in the absence of an experimental bioconcentration factor (BCF) in fish. In case a substance's log Kow value is greater than 4.5, it should be considered potentially B/vB and additional data are then required to assess its bioaccumulation potential. In case of substances that are expected to ionise completely or partially within an environmentally relevant pH-range (e.g., 5 to 9), a bioaccumulation screening based solely on log Kow is not always accepted as such substances can bioaccumulate through mechanisms other than partitioning to lipids. This has led to regulatory requests to perform experimental BCF studies, even in cases where the log Kow of the neutral form is several orders of magnitude below 4.5. Nonetheless, even for ionisable substances, lipid-based partitioning is still a dominant bioaccumulation mechanism. In this poster, we present an analysis of existing experimental fish BCF data of ionisable substances in relation to the Kow values of their neutral form. The findings are discussed in view of the known bioaccumulation mechanisms of ionisable substances (e.g., binding to blood proteins) as well as existing QSAR models that estimate the aquatic bioaccumulation of ionisable substances. The added value of performing experimental BCF studies for such substances, is critically examined for different scenarios.

3.01.P-Mo115 A New BCF In Silico Model Based on the Critical Body Burden (CBB) Principle

Paul Thomas and Pascal Bichere, KREATiS, France

This fish BCF model provides a quantitative prediction of bioconcentration factor (BCF) of a test substance in fish divided by the concentration of the chemical in the surrounding medium at steady state. The model is based on an *a priori* calculation method following Critical Body Burden (CBB) principles and hydrophobicity. The model uses different Simple Linear Regressions or fixed values, selected on the basis of an initial classification regarding the chemical class. The Subcooled Liquid Water Solubility (SLWS) of the compound of interest is used as the descriptor rather than the log K_{OW} which is used in most other BCF models. The method is based on a critical body burden (CBB) concept which states that: $BCF (L/Kg) = CBB (Mol/Kg) / EC_{10} (Mol/L)$ (McCarty *et al.*, 1992) The calculation of BCF was developed from the knowledge acquired in modelling the chronic toxicity to fish for MechoA 1.1 compounds following Bauer *et al.* (2018). This endpoint has been modeled in the high-accuracy QSAR iSafeRat® using fish EC₁₀ data with an R²/Q² at circa 0.9. This model is based on experimental data obtained using 32-day exposure data to fish embryos/larvae. In the iSafeRat® fishEC₁₀ model, the relationship between the toxicity and the subcooled liquid water solubility can be mathematically described using a linear simple regression up to the point where the solubility of the compounds is so low than no chronic toxic effects are found. This model can be separated into three phases, a linear regression phase, using sub-cooled liquid water solubility as the descriptor; a plateau phase where equilibrium is not fully reached during the toxicity study and finally a phase where toxicity is greater than the solubility limit (Thomas *et al.*, 2019). These data are transposed to BCF values using the equation above as a "mirror image" of the toxicity data. Issues such as the positioning of the regressions and impact of metabolism on BCF are discussed.

3.01.P-Mo116 Sensitivity Analysis for the Input Parameters for the In Vitro In-Vivo BCF Approach

Sophia Krause¹ and Kai-Uwe Goss², (1)Helmholtz centre for environmental research - UFZ, Germany, (2)Analytical

The idea to predict *in vivo* biotransformation from *in vitro* data originated decades ago in the pharmaceutical field. Later on, the methods were adapted for fish in the environmental field and have continued to evolve over the years. A lack of agreement of *in vivo* and extrapolated *in vitro* results triggered a search for possible sources of error. Here we present results of this analysis: 1) The often used mathematical extrapolation scheme needs some correction but from a quantitative perspective this brings about little change. 2) Also there is only a marginal difference between models of different complexity (well stirred liver model versus parallel tube liver model; one-box versus multiple-compartment fish model. 3) The specific consideration of desorption and permeation kinetics in blood did also not lead to noticeably different results. 4) Uncertainties in the estimated fraction unbound (f_u) term can be relevant. Here we conclude that mechanistic composition-based algorithms are to be preferred for the prediction of f_u . In the light of this analysis we have conducted a sensitivity analysis for the *in vivo* *in vitro* extrapolation scheme with all remaining relevant input parameters. The results of this sensitivity analysis are presented in this poster. We also note an immanent problem in the IVIVE approach: the induction of enzymes for the degradation of the investigated chemical that may occur during the course of a typical BCF test (OECD 305) is not accounted for by the IVIVE approach. **Acknowledgments** This research was financially supported by CEFIC LRI (ECO 47 project) and the German Environment Agency under FKZ 3718 65 406 0.

3.01.P-Mo117 Fragrances Not Only Scent: Pre-Experimental Toxicity Testing for the Freshwater Amphipod *Hyaella azteca* Bioconcentration Test (HYBIT) With Difficult to Test Chemicals

Sabine Groß¹, Ricarda Schumacher², Carolin Moertl² and Christian Schlechtriem³, (1)RWTH Aachen University, Afghanistan, (2)Fraunhofer IME / Bioaccumulation and Animal Metabolism, Germany, (3)Fraunhofer IME, Schmallenberg, Germany
Bioconcentration factors (BCF) for regulatory purposes are conventionally determined experimentally by aqueous exposure bioconcentration fish tests according to OECD test guideline (TG) 305. The *Hyaella azteca* Bioconcentration Test (HYBIT) provides a non-vertebrate alternative. An OECD TG covering this new approach is in preparation. As for the fish test, the selection of suitable concentration(s) of the test substance is required to avoid toxic effects during the uptake phase. However, information on the test substance toxicity to *Hyaella* (e.g. acute 96-h LC50 or a NOAEC & LOAEC from a chronic study) are usually missing. Therefore, a toxicity test design was developed which can help in the setting of suitable experimental conditions. The protocol involving a semi-static exposure scenario was evaluated as part of the multi-laboratory ring trial supporting the development of the new OECD TG. The present study explores the suitability of the acute toxicity test for volatile chemicals in form of fragrances. The results show that the toxicity of such difficult to test chemicals can be also tested as part of a pre-experimental approach for bioconcentration tests with *Hyaella azteca*.

3.01.P-Mo118 Life Cycle Exposure to Dietary 2,2', 4,4'-Tetrabromodiphenyl Ether (BDE-47) on Medaka Fish (*Oryzias latipes*)

Eulalia María Beltrán¹, Miguel Gonzalez-Doncel², José Enrique García-Mauriño³, Pilar Garcia Hortigüela⁴ and Maria Victoria Pablos⁴, (1)Environment and Agronomy, INIA - National Institute for Agricultural and Food Research and Technology, Madrid, Spain, (2)Environment and Agronomy, National Institute for Agricultural and Food Research and Technology (INIA-CSIC), Madrid, Spain, (3)School of Medicine, Complutense University, Spain, (4)Spanish National Institute for Agricultural and Food Research and Technology (INIA-CSIC), Spain

Previous studies in our laboratory, resorted to 40-day oral exposures to BDE-47 in specific developmental windows of medaka (*Oryzias latipes*) did not evidence effects on the growing or breeding period. In this new study, full life cycle (i.e. 140-day) dietary exposure to 1000 ng of BDE-47/g was performed with medaka to evaluate effects on growth and reproduction (i.e. fecundity, fertility and hatchability), and to analyze the bioaccumulated BDE-47 and transferred to offspring. The biometric analysis during the growth and maturation periods did not reveal significant effects and no biased sex ratios were found. Reproductive capacity was not affected by the presence of BDE-47 in diet. There was no evidence of effects during embryo and eleutheroembryo development from parental exposure. The analytical results revealed steady BDE-47 bioaccumulation during the growing period, which remained in males in the reproductive phase, and a decreasing tendency was noted in females. The lowering BDE-47 levels in females coincided with the detected BDE-47 levels offloaded in embryos. In the 10-day-old post-hatch larvae, the BDE-47 concentrations dropped to comparatively lower values than those detected in parents suggesting an efficient metabolic process in the eleutheroembryonic and post-eleutheroembryonic phases. This 140-day dietary approach found no BDE-47 effects on medaka growth and reproduction, or in early progeny stages despite effective bioaccumulation and maternal transfer. This work was made possible by Spanish Government Grant RTI2018-096046-B-C21 funded by the MCIN/AEI/ 10.13039/501100011033 and the ERDF.

3.01.P-Mo119 Qsar-Me Profiler a New Software for QSAR Predictions and Structural Similarity Analysis

Nicola Chirico¹, Linda Bertato² and Ester Papa², (1)Università degli Studi dell'Insubria, Italy, (2)University of Insubria, Italy
In the last 20 years, our research group has developed many validated QSARs for the prediction of different endpoints, useful to support the assessment of the potential hazard and risk of heterogeneous organic chemicals. Recently our research has been focussed on the development of QSARs specific for the prediction of biotransformation and bioaccumulation related endpoints. This raised the need for a user-friendly software able to collect and simplify the application of these QSARs, for both a detailed visualization of the underlying models and to generate streamlined multiple QSARs predictions. To this end, the new software "QSAR multiple endpoints profiler" (QSAR-ME Profiler) was developed using the Java™ language, thus allowing for its execution on different platforms like, for example, Windows™, Mac OS™ and Linux. This software is user-friendly, and displays the available QSARs and the related output both in tabular and graphical forms. Furthermore, the software automatically detects chemicals similar to those entered by the user, which can be used for comparison across predictions. In particular, chemicals used

to train the models, as well as chemicals entered by the user, and those most similar detected by the software, are automatically depicted allowing for an easier comparison across similar structures. The software also automatically selects the suitable QSARs and runs, if needed, the external supporting software (e.g. PaDEL-Descriptor or Toxtree), also allowing the application of multiple models in batch, which output is displayed in user-friendly tables including both single and combined predictions. QSAR-ME Profiler further expands the concepts of the other two software recently developed by our research group, i.e. QSARINS-Chem ECO.44 and IVBP-Suite, by pooling their functions in a single package. We want to highlight that the new fundamental, additional feature, i.e. the automatic depiction and detection of chemicals, is important for better profiling chemicals of interest as well as the specific endpoints. The structural depiction function allows to display the user-entered chemicals, and to compare them by means of distance measures, with the automatically detected similar chemicals included in the QSARs training sets. QSAR-ME Profiler simplifies and streamlines the application of QSARs, which are provided in bundle, and is particularly aimed for regulatory purposes. It will be available soon at <http://dunant.dista.uninsubria.it/qsar/>.

3.01.P-Mo120 A New Data Source for PBTK Models: Physiological Measures Combined With Biomolecular Organ Composition From Different Fish Species to Improve In-Silico Assessment of Bioaccumulation and Ecotoxicity

Heidrun Windisch¹, Matthias Teigeler², Christian Schlechtriem³, Daniel Faber⁴, Yvonne Wolf⁴ and Thomas Preuss⁴, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Germany, (2)Fraunhofer IME, Germany, (3)Fraunhofer IME, Schmallingenberg, Germany, (4)Bayer Crop Science, Germany

PBTK (physiologically based toxicokinetic) modelling is an important tool with increasing relevance for the assessment of the bioaccumulation and toxicity potential of chemicals in the aquatic environment. The significance of in-silico generated results do highly depend on the exact parameterization of physiological processes, as well as the characterisation of the matrix composition and allometric measures of the organism. Typically, bioaccumulation and toxicity studies are performed as in-life studies using fish following the respective OECD Test Guidelines (OECD 305, 203 & 210). Different fish species are suggested for testing, assuming comparable results from testing chemicals at the animals' ambient conditions. However, the list of species comprises cold and warm water fish, which implies differences in metabolism and thus in the uptake and depuration kinetics of the tested compounds. For the refinement of PBTK models, we provide a holistic data set for the warm-water species *Danio rerio* and *Pimephales promelas* (both *Cyprinidae*), *Oryzias latipes* (*Adrianichthyidae*) and *Lepomis macrochirus* (*Centrarchidae*), as well as for *Oncorhynchus mykiss* (*Salmonidae*) as a representative of cold-water fish species. The dataset comprises information on allometry (age, size, sex), physiological measurements (respiratory rates), as well as composition of the different organ matrices with respect to lipid and protein content. More specifically, for three selected species (*P. promelas*, *L. macrochirus* and *O. mykiss*) we also provide information on the contents of polar and unpolar lipids to reveal the proportion of storage and membrane lipids, as the lipid content is a strong driver for bioaccumulation of uncharged chemicals, dependent on their Log K_{ow} . In addition, the contents of the main matrix proteins collagen and albumin were quantified to yield an important data basis for the assessment of ionic chemicals, which preferably bind to these molecules and drive bioaccumulation. In general, organ-specific compositions of the assessed biomolecules were observed, which were comparable across species. Nevertheless, species-specific allometries of organs differed, which implies variations for binding and release of chemicals from matrix-biomolecules. Thus, the featured dataset will provide a sound basis for PBTK modelling and significantly improve PBTK-models for in-silico assessment.

3.02 Advances in detection, remediation, transport, fate and bioaccumulation of legacy and emerging per- and polyfluoroalkyl substances (Part I)

3.02.T-01 The Direct Total Oxidizable Precursor (dTOP) Assay As a Tool to Detect Unknown PFAS in German Rivers

Bernd Göckener¹, Annette Fliedner², Heinz Ruedel³, Mark Buecking³, Alexander Badry⁴ and Jan Koschorreck⁵, (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallingenberg, Germany, (2)Fraunhofer IME Institute for Molecular Biology and Applied Ecology, Germany, (3)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (4)German Environment Agency (Umweltbundesamt), Germany, (5)Umweltbundesamt, Umweltbundesamt, Berlin, Germany

The outstanding properties of per- and polyfluoroalkyl substances (PFAS) enable them to be used in a variety of industrial processes and consumer products. The group comprises several thousand compounds, which poses a major challenge for chemical analysis. Sum parameters such as the total oxidizable precursor assay (TOP assay) are of increasing importance to cover the complexity of PFAS. To gain a more comprehensive overview on the total PFAS burden, the TOP assay was further modified to the direct TOP (dTOP) assay by directly digesting a small amount of solid sample with high amounts of oxidation agents. This has the benefit of covering also non-extractable PFAS that might be overlooked in the conventional TOP assay. In the present study, a time series of suspended particulate matter (SPM) samples taken from German Rivers for the German Environmental Specimen Bank were analyzed for known (target analysis) and unknown (dTOP assay) PFAS. The results revealed the ubiquitous distribution of PFAS in the major German Rivers. In almost all samples, the dTOP assay yielded substantially higher amounts of PFAS than the conventional target analysis, thus indicating the presence of considerable amounts of unknown precursors. Temporal trends from 2005 – 2019 demonstrated a significant decline in the levels of both, known and unknown, PFAS. The decline, however, was observed to be more extensive for the known PFAS than for the unknown PFAS, thus demonstrating that the target analysis of known PFAS overestimates the temporal decline of the total PFAS burden. Accordingly, the proportion of unknown PFAS increased over time. Furthermore, additional time trend analysis separating long chain and short chain PFCAs indicated a shift to precursors of shorter-chain PFCAs over time. The results highlight the relevance of sum parameters such as the dTOP assay for a comprehensive analysis and assessment of the total environmental burden with PFAS.

3.02.T-03 Occurrence of Legacy and Novel Fluorochemicals in Aquatic and Terrestrial Chains Around a Fluoropolymer Manufacturing Plant

Sara Valsecchi¹, Michelangelo Morganti¹, Marco Parolini², Diego Rubolini² and Stefano Polesello³, (1)Water Research Institute - Italian National Research Council IRSA-CNR, Italy, (2)University of Milan, Italy, (3)Water Research Institute- CNR, Italy

It is well known that the fluorochemical plants, where poly- and perfluoroalkyl substances (PFAS) are synthesized or used, are relevant sources of PFAS for the surrounding environment. The whole characterisation of the environmental release is hindered because information on the unknown PFAS that have been using for many years or that have recently replaced the banned PFAS (and so potentially released into the environment) is often covered by patents and industrial confidentiality. Besides, to comprehensively evaluate the environmental risks posed by an industrial activity, it is crucial to track the possible transfer of the emitted pollutants through terrestrial and aquatic trophic chains of the ecosystems neighboring the production sites. In this communication, a comprehensive study to assess the environmental PFAS contamination due to legacy and novel PFAS deriving from a fluorochemical industrial site that has been releasing large amounts of PFAS in the Po River valley (Northern Italy) over the past decades, have been carried out, analysing both abiotic (wastewater, river water and soil) and biotic (vegetable, invertebrates, fish, and wild bird eggs) matrices. Abiotic and biotic samples were collected within 5 km from the fluorochemical plant. The same matrices were collected 20 km far from the industrial site, within the plume of air emissions. Additionally, wild bird eggs from clutches laid in a rural site (RS) far from any known point source of PFAS were also collected. The occurrence of nine perfluorocarboxylic acids (from C6 to C14), four perfluorosulfonic acids (C4, C6, C8 and C10), two fluorotelomer sulfonates (6:2 and 8:2 FTS), the perfluorooctane sulfonamide (FOSA) and, some novel fluorochemicals was investigated. Quantification with analytical standard was carried out for two novel perfluoro ether carboxylic acids: C6O4 (C6HF9O6; 2,2-difluoro-2-((2,2,4,5-tetrafluoro-5-(trifluoromethoxy)-1,3-dioxolan-4-yl)oxy)-acetic acid; CAS No. 1190931-41-9), and the mixture of Cl-PFPECA also known as ADV (C3F6ClO-[CF(CF3)O]_e-[CF2CF(CF3)O]_p-CF2COOH, e=0-4, p=0-4, CAS No. 329238-24-6). Other novel PFAS were only revealed, since no analytical standards were available. The analysis of the collected samples revealed high contamination of the fluorochemical plant surrounding area, raising environmental concern. The contamination is not confined to few kilometers far the industrial site but atmospheric transport of emitted PFAS probably occurs.

3.02.T-04 Perfluorinated Substances in WATER, Macrophytes and Fish From the Amazon River

Belen Gonzalez-Gaya¹, Ainhua Huarte², Anne San Roman², Zuriñe García², Irene de Prado², Ailette Prieto², Nestor Etxebarria², Rhaul de Oliveira³, Gabriel Silva de Souza Nunes⁴, Andrea Waichman⁵ and Andreu Rico⁶, (1)ESTACIÓN MARINA DE PLENTZIA. UPV/EHU, Spain, (2)University of the Basque Country, Spain, (3)State University of Campinas, Brazil, (4)Federal University of Pernambuco, Brazil, (5)Federal University of the Amazon, Brazil, (6)IMDEA Water Institute/University of Valencia, Spain

Perfluorinated alkyl substances (PFASs) are receiving an increasing worldwide attention due to their persistence, toxicity and widespread occurrence. This study provides the first wide-spread assessment of the occurrence and distribution of these contaminants in the Amazon River, the largest drainage basin in the world, including three different abiotic and biotic matrices: water, macrophytes and fish. A monitoring campaign covering more than 1500 km of the Brazilian Amazon River was carried out in November-December 2019. Thirty-nine water surface samples were taken in urban streams (Manaus, Santarem, Macapá, Belém), the dilution areas of such streams and along the Amazon river (including three of its major tributaries). In the same or close areas, 17 samples belonging to three aquatic macrophyte species (*Eichhornia crassipes*, *Eichhornia azurea* and *Pontederia rotundifolia*) were gathered and analysed separately in aerial (leaves) and submerged (stems and roots) parts. Likewise, 53 fish samples were acquired at local markets in the sampled areas. Those belonged to 14 different species including carnivorous, omnivorous, herbivorous and detritivorous feeding habits. Identification of 27 individual PFAS including carboxylates, sulfonates, phosphonic, propanoic and ethanoic acids, fluorotelomers and phosphates, and also Gen X was performed by HPLC-QqQ. In the water, 12 compounds were identified for the first time in Amazon river, being PFPeA, PFOS and PFHxS the most abundant ones, and being all short chained. *P. rotundifolia* significantly bioaccumulated more PFAS than the other two species. Specifically, short-chain PFCAs were significantly more bioaccumulated on aerial parts of this species. Significant differences were also found for different PFASs families and chain lengths between plant parts. In the fish samples, PFOS and PFOA concentrations were lower than fish reported previous studies in other basins from Europe and Asia, although concentrations of compounds such as PFHxA, PFBA, PFHPA, FPNA y PFHxS were higher than expected. Gen-X was detected and further analysis will assess the presence of non-previously detected PFAS in the Amazon River. ACKNOWLEDGEMENTS: This study has partly been funded by the National Geographic Society (EC-59809C-19), www.silentamazon.com and by the Agencia Estatal de Investigación of Spain and the European Regional Development Fund through project CTM2017-84763-C3-1-R.

3.02.T-05 PFOS Bioaccumulation and Bio-Concentration Factors in Multi-Generational Zebrafish Exposures

Kurt A. Gust¹, Ashley Kimble², David W. Moore³, Natalia Reyero⁴, Mitchell Wilbanks⁵, J. Erik Mylroie⁵, Catherine Cox⁶, Kathleen Jensen⁷, Russell Erickson⁷, Gerald Ankley⁷, Jason Conder⁸ and Jennifer Arblaster⁸, (1)U.S. Army Engineer Research and Development Center, United States, (2)US Army Engineer Research & Development Center, United States, (3)U.S. Army Corps of Engineers, United States, (4)USACE Engineer Research and Development Center, United States, (5)US Army Engineer Research and Development Center, United States, (6)ORISE Fellow at USACE ERDC, Wallis and Futuna Islands, (7)U.S. Environmental Protection Agency, United States, (8)Geosyntec Consultants, Inc., United States

Bioaccumulation and bio-concentration of per- and polyfluoroalkyl substances (PFAS) strongly influence PFAS toxicity thresholds in zebrafish (*Danio rerio*) where perfluorooctane sulfonic acid (PFOS) is among the most strongly bio-accumulative and potent PFAS chemical structures. As part of a multi-generational PFOS toxicity investigation in zebrafish, PFOS bioaccumulation and bio-concentration factor (BCF) measurements were taken over extended life-time water exposures (180d) in

parental generation (P1) and first familial generation (F1) fish from a continuous exposure to environmentally-relevant PFOS concentrations (0, 0.1, 0.6, 3.2, 20, 100 µg/L PFOS) including 5 replicates per exposure and 50 fish per replicate. At 14 and 29 days post-fertilization (dpf), P1 fish were collected from each of the 5 replicate tanks and flash frozen for tissue analysis. Both male and female fish were individually collected from 5 replicate tanks for each the P1 and F1 generation fish at 180 dpf and flash frozen. PFOS was extracted from whole-body tissues for all experimental replicates, measured by LC MS/MS, and tissue concentrations calculated based on wet weights. PFOS bioaccumulation tended to follow a power law relationship with measured PFOS exposure concentration in water where apparent steady state was reached by 14 dpf where whole-body tissue concentrations remained largely constant through 180 dpf in the P1 generation. Statistically significant increases in PFOS bioaccumulation were observed in male fish relative to females across all PFOS exposure concentrations in 180 dpf fish from both the P1 and F1 generations. PFOS was strongly bio-accumulative in zebrafish tissues with mean wet weight values ranging from 255 to 2,136 L/kg. Comparative tests of measured BCFs among PFOS exposure concentrations revealed multiple instances of significant reduction in the 20 and 100 µg/L PFOS exposures relative to the sub-ppb exposures, 0.1 and 0.6 µg/L. Similar to the observation of increased PFOS bioaccumulation in males, BCF values were significantly increased relative to females for all PFOS exposure concentrations in both the P1 and F1 generations. Overall, PFOS bio-concentrates rapidly in zebrafish tissues where apparent steady state concentrations remain stable through constant life-time exposure durations, where males ultimately have greater bio-accumulative potential. Note: Abstract contents neither constitute nor necessarily reflect DOD or US EPA policy.

3.02 Advances in detection, remediation, transport, fate and bioaccumulation of legacy and emerging per- and polyfluoroalkyl substances (Part II)

3.02.T-06 Analysis of PFAS in Environmental Samples and Materials: Different Approaches Via Fluorine K-Edge XANES Spectroscopy and Combustion Ion Chromatography

Philipp Roesch¹, Christian Vogel², Philipp Wittwer¹, Ute Kalbe³ and Franz Simon¹, (1)Bundesanstalt für Materialforschung und -prüfung (BAM), Germany, (2)Division 4.3, Bundesanstalt für Materialforschung und -prüfung (BAM), Germany, (3)BAM Federal Institute for Materials Research and Testing, Germany

Per- and polyfluoroalkyl substances (PFAS) have emerged over the course of the last twenty years as a global pollution issue. Altogether, there are currently more than 4700 known but only partly characterized fluorinated compounds identified by the Organization for Economic Cooperation and Development (OECD). The ongoing production of new, yet unrestricted PFAS alternatives has become a major challenge for environmental routine analytics, since the state-of-the-art method LC-MS/MS relies on structural information and availability of isotope standards of the targeted compound. Fluorine sum parameters like adsorbable organic fluorine (AOF), extractable organic fluorine (EOF) and total fluorine (TF) can be applied to survey and detect the presence of large amounts of unidentified organofluorine compounds in environmental matrices. Today fluorine sum parameters have been established as a useful supplement to classic target-analytical approaches of PFAS and were implemented for the first time as a sum value “PFAS-total” in the recently revised Drinking Water Directive (2020/2184) by the European Commission. In contrast, X-ray absorption near-edge structure (XANES) spectroscopy has been widely applied to identify low concentration of element-specific contamination without pre-treatment in environmental samples in the past. The XANES approach enables a penetration depth of approx. 1 µm (at fluorine K-edge energy; depending on the matrix) which is significantly deeper than for X-ray photoelectron spectroscopy (XPS; penetration depth approx. 10 nm). Furthermore, the method is fast, non-destructive and only simple preparation of the samples is required. In our work, we combined both F K-edge XANES spectroscopy and combustion ion chromatography (CIC) in order to present a new analytical perspective on the investigation of PFAS in environmental media and material samples.

3.02.T-07 Set up and Validation of an Hplc-Ms/Ms Targeted Method for the Biomonitoring of 30 PFASs, Including Emerging GenX, DONA, and cC6O4, in Human Plasma Samples

Gianfranco Frigerio¹, Simone Cafagna², Elisa Polledri³, Rosa Mercadante³ and Silvia Fustinoni³, (1)Luxembourg Centre for Systems Biomedicine, University of Luxembourg, Belvaux, Luxembourg, (2)Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Italy, (3)University of Milan, Italy

Per- and polyfluoroalkyl substances (PFASs) are a group of artificial compounds characterised by a high resistance to degradation. Some of the most persistent PFASs were gradually phased out and alternatives such as HFPO-DA (or GenX), DONA (or ADONA) and cC6O4 were introduced. The aim of this work was to develop and validate an isotopic dilution LC-MS/MS method to quantify 30 PFASs in human plasma samples. The sample preparation consisted in adding the internal standards diluted in methanol to plasma to crush the proteins; the solution was then vortexed and centrifuged. A linear gradient was set up to separate the analytes and the spectrometer operated in scheduled multiple reaction monitoring. A pooled plasma was prepared by mixing several human plasma samples previously screened for low PFASs concentrations and used as blank matrix. The analytes were spiked to the blank matrix at different levels in order to obtain the solutions for the calibration curve and the quality controls. Mean R² from 0.989 to 0.999 showed a good linearity for the considered concentration ranges. The selectivity of the method was suitable for most analytes and no carry-over effect was detected. The precision of the method, calculated as mean %RSD, was good both for within-run (ranged from 2.7% to 15.7%), and between-run (from 3.0% to 17.6%). The accuracy was also verified as mean within-run accuracy (ranged from 87.9% to 113.1%) and between-run accuracy (ranged from 93.6% to 107.2%). The lower limit of quantitation (LLOQ) ranged from 0.009 to 0.078 µg/L for all compounds with the exception of PFOA, PFOS, and PFHxS (from 0.116 to 0.245 µg/L). The results of the short-term stability (1 week at autosampler temperature) ranged from 87.4% to 113.5%, while the results of the long-term stability (1 month at -20°C) ranged from 84.9% to 114.5%. The analytes were also spiked to seven different plasma samples to verify the matrix effects. Accuracy of the assay was also tested in the interlaboratory

comparisons and external quality assurance schemes (ICI-EQUAS) and in the German External Quality Assessment Scheme (G-EQUAS); the results confirmed the suitability of the method, although only for a subgroup of analytes. Finally, the method was applied to 38 plasma samples collected from the Italian general population. The analytical method developed in this work was fully validated and demonstrated to be robust and suitable for the biomonitoring of both legacy and emerging PFASs.

3.02.T-08 Thyroid Hormone Disrupting ACTivity of Polyfluorinated Alkylated Substances (PFAS) Analyzed by PFAS CALUX in WATER, Animal Feed As Well As in Farmed and Wildlife Animals

Peter Behnisch, Harrie Besselink and Abraham Brouwer, BioDetection Systems, Netherlands

PFAS are a complex mixture of thousands of known and mostly unknown chemicals found in water, soil and animals. Our newly developed high-throughput screening PFAS CALUX aims to capture the total thyroid hormone disrupting activity from this persistent bioaccumulating compound class. We call for an urgent change in the testing paradigm from the currently regulated few PFAS congeners to the total effects of this complex mixture of thousands of PFAS by using potency factors (REPs) and PFOA-equivalents (EQ) for both the chemical and effect-based PFAS CALUX testing results. We present a visionary study in applying these REP/PFOA-EQ concept in water, soil, feed as well as from farmed and wildlife animals with our in vitro PFAS CALUX bioassay based on thyroid-transferrin disruption (TTR-TR). The aim of this study was to establish potency factors for several PFAS and apply them on complex mixtures of PFAS in water, soil, compost, grass, spiked animal tissue as well as wildlife animals from contaminated sites used in an international interlaboratory study. All here tested 14 PFAS congeners did show full dose-response curves on the PFAS-CALUX with REP values ranging from 0,0018 (PFBA) to 2,0 (PFOS) compared to PFOA (1,0). One spiked water sample, one spiked and unspiked calf liver sample, one wild pig and one fish muscle sample (from a contaminated area), one potato, grass and feed sample were tested by PFAS CALUX for PFOA-EQ and compared to the by LC/MS/MS obtained PFOA-EQs. In case of the wild pig, calf liver spiked and potato samples both chemical and bioassay-related PFOA-EQs were in the same range of magnitude (between 130 to 1600 ng PFOA-EQ/g), while in the contaminated fish muscle and calf liver (up to 11000 ng PFOA-EQ/g) samples only a small percentage of the PFOA-EQ could be explained through the by LC/MS/MS measured 6 PFAS. This indicates a strong impact from the other expected hundreds to thousands of unknown PFAS and indicates the urgent need to implement bioassays covering the whole class of such per- and polyhalogenated compounds, such as PFAS-CALUX in the testing strategy for monitoring especially contaminated sites. The PFAS bioassay results, which represent a total effect measurement on one of the most sensitive toxic effects, namely thyroid hormone disruption, can provide an important bridge between chemical PFAS analysis, measuring only a limited number of congeners as demanded from the regulators with the expected toxic effect-based activities.

3.02.T-09 Optimizing Soil Washing for PFAS Contaminated Soil

Michel Hubert¹, Mona Hansen², Sarah Hale², Gabriela Varela³, Alexandros Asimakopoulos⁴, Thomas Henriksen⁵ and Hans Peter Arp², (1)Environmental Chemistry, Norges Geotekniske Institutt, Oslo, Norway, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)Norwegian University for Science and Technology, Norway, (4)Norwegian University of Science and Technology (NTNU), Norway, (5)AF Gruppen, Norway

The number of potentially highly contaminated PFAS sites in Europe is estimated to approach 100,000. Soil washing can be used both as in-situ and ex-situ technology to remove contaminants from soil. Previously this method has been shown to be effective on various soil contaminants like PCBs, petroleum residues, heavy metals, etc. To date, there are few soil-washing facilities worldwide processing PFAS contaminated soils. To support the use of soil washing as a remediation technique, this research focuses on the optimization and development of guidelines for soil-washing of PFAS contaminated soil and the reuse of the resulting processed material. Deriving K_d values (soil-water partition coefficients) for different soil size fractions representative of the materials produced at different stages in a typical washing process is one objective of this work. The findings of this research will help to develop a 1D-box-model to evaluate and model soil washing processes for different PFAS contaminated materials. Batch tests using different soil fractions (silt to gravel) from historical contaminated soil from the use of AFFF were carried out. Clean soil spiked with 26 different PFAS was also used. K_d values were calculated. Results indicate that to minimize residual PFAS concentrations in processed soil, the separation of coarse-grained fractions and fine-grained fractions like silt and clays including Organic matter (OM) must be prioritised in the soil washing process. Back diffusion of PFAS must be considered when reintroducing the soil into the environment in order to achieve low regulatory criteria set by environmental agencies.

3.02.T-10 Foam Fractionation Coupled to Electrochemical Degradation for Treatment of Per- and Polyfluoroalkyl Substances in Contaminated Water - a Pilot Scale Study

Sanne Smith¹, Karin Wiberg², Philip McCleaff³, Patrik Hollman⁴ and Lutz Ahrens², (1)SLU, Sweden, (2)Swedish University of Agricultural Sciences, Sweden, (3)Uppsala Vatten och Avfall AB, Sweden, (4)Nova Diamant AB, Sweden

Per- and polyfluoroalkyl substances (PFAS) have become increasingly infamous over the past decades for their persistent, bioaccumulative and toxic properties. They are ubiquitous in the aqueous environment and exceptionally difficult to remove or degrade. Foam fractionation is a relatively easy and cheap novel water treatment method that can achieve competitive PFAS removal. It works by bubbling air through the contaminated water and separating a foam fraction from the liquid phase. The foam fraction is enriched in PFAS, whereas the effluent water is relatively PFAS-free. Further treatment of the foam in an electrochemical degradation system provides a compact, robust and effective treatment train for on-site remediation of PFAS-contaminated water. In the current study, a pilot-scale electrochemical reactor with boron-doped diamond anodes was used in batch mode to degrade PFAS in landfill leachate and groundwater. Additionally, an optimized continuous process for PFAS removal from leachate water was developed using a pilot-scale foam fractionation system. This optimized process was then used

to treat both groundwater and leachate and produce PFAS-depleted effluent and PFAS-enriched foam. The foam was subsequently treated electrochemically as well, to assess the performance of the proposed treatment scheme as compared to using either of the techniques separately. The presented work was the first to explore these two technologies as a treatment train. Moreover, to the best of our knowledge, no pilot-scale investigations using real water have been conducted prior to this research. The highest PFAS degradations reached in leachate and groundwater were 78 % and 82 %, respectively. Production of short-chain PFAS was observed during the degradation process, which indicates that the degradation follows a step-wise mechanism. In the foam fractionation process, PFAS removal reached approximately 60 %, but the removal of individual long-chain compounds exceeded 90 %. For the electrochemical degradation of the produced foam, modifications to the electrochemical reactor were required to prevent overflow of foam. These experiments are currently ongoing, and similar or higher degradation efficiencies as found for the untreated leachate and groundwater are expected. The findings will be of interest to a wide range of stakeholders who are trying to decrease their aqueous PFAS contamination to acceptable levels.

3.02 Advances in detection, remediation, transport, fate and bioaccumulation of legacy and emerging per- and polyfluoroalkyl substances (Virtual Only)

3.02.V-01 Investigating the Fate of Polyfluorinated Phosphate Diesters (diPAPs) in a Lysimeter System

René Lämmer¹, Janine Kowalczyk², Hildegard Just², Jörn Breuer³, Bernd Göckener¹, Matthias Gaßmann⁴, Eva Weidemann⁵, Thorsten Stahl⁶ and Mark Buecking⁷, (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallingenberg, Germany, (2)German Federal Institute for Risk Assessment BfR, Germany, (3)Agricultural Technology Centre Augustenberg, Germany, (4)University of Kassel, Germany, (5)Hydrology and Substance Balance, University of Kassel, Kassel, Germany, (6)Chemisches und Veterinäruntersuchungsamt Münsterland-Emscher-Lippe (CVUA-MEL), Germany, (7)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany

Per- and polyfluoroalkyl substances (PFAS) are a group of environmental persistent, bioaccumulative and often toxic substances. While perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) are intensively studied and regulated, the environmental behaviour of other PFAS such as polyfluoroalkyl phosphate diesters (diPAPs) is not yet fully understood. As a PFAS-contaminated site in southwestern Germany shows high concentrations of diPAPs in field soil, investigating their environmental fate is necessary to assess potential risks. In this study, the behaviour of 6:2 diPAP and 8:2 diPAP was investigated in an outdoor soil system (lysimeter) under near-natural conditions. In addition, the manner in which their degradation products leach through the soil horizons carried by natural precipitation was observed. To study the fate of 6:2 diPAP and 8:2 diPAP, lysimeters were filled with PFAS-free subsoil and a top layer of soil separately spiked with both diPAPs. Leachate was collected at least monthly as available. After two years, the soil in each lysimeter was sampled in five depths. The analysis of all samples was performed by UHPLC-HRMS. In the leachate of the 6:2 diPAP-spiked soil, PFCAs of different chain lengths (C₄ to C₆) were detected with perfluoropentanoic acid (PFPeA) and perfluorohexanoic acid (PFHxA) representing the most prevalent components. At the end of the experiment the upper soil layers still contained 6:2 diPAP. In the leachate of the 8:2 diPAP-spiked soil, PFCAs with chain lengths from C₄ to C₈ were detected with PFOA as the major component. The soil samples of the 8:2 diPAP variant contained high concentrations of 8:2 diPAP and low concentrations of different PFCAs. The detection of PFCAs with chain lengths C₆ (6:2 diPAP application) and chain lengths C₈ (8:2 diPAP application) in the leachate shows the degradation of diPAPs into persistent PFCAs in the environment and a subsequent PFCA-transport into deeper soil horizons. These results provide important insights into the environmental fate of diPAPs as PFAS precursors and the behaviour of the formed PFCAs as their main degradation products. The transport of PFCAs into deeper soil horizons may also serve as a pathway for human exposure to PFAS, as groundwater is an important source of drinking water.

3.02.V-02 Long-Range Environmental Transport and Atmospheric Deposition of Legacy and Emerging Per- and Polyfluoroalkyl Substances in the Arctic

Zhiyong Xie, Helmholtz-Zentrum Hereon, Germany

The pristine Arctic have been impacted by numerous natural and anthropogenic factors. Increasing human activities and changing climate are subjects to the major pressure of the Arctic environment. Input of man-made pollutants from local emission and remote continental sources led the Arctic acting as ultimate sink, which can cause unexpected disturbance and risk to the Arctic ecosystems. Among the chemical contaminants, per- and polyfluoroalkyl substances (PFASs) have attracted significant attention of the scientific society because they become 'forever contaminants' in the global environment. In this work, both neutral and ionic PFASs have been investigated in different environmental matrices in the Arctic. Snow, seawater and the ship-borne air samples are collected on the research vessel R/V Polarstern during the cruises PS85 and PS114 from Bremerhaven to the East Greenland Sea in summer 2014 and 2018. Air samples were collected using a high-volume air sampler operating at a flow rate of 15 m³/h for 24- 48 hours on the upper deck of R/V Polarstern. Seawater samples are collected using both Keel in-situ Pump (KISP) and 1 liter sea water for solid-phase extraction. Neutral PFASs from PUF/XAD-2, XAD-2 columns and GF filters are extracted with dichloromethane. The Oasis Wax cartridges (6 mL) are eluted using 10mL methanol with 0.1 % ammonium hydroxide for ionic PFASs. Neutral PFCs are quantified by an Agilent 6890 gas chromatography coupled to 5973 mass spectrometer using positive chemical ionization mode (GC-MS-PCI). Ionic PFCs are analysed using liquid chromatography coupled with tandem mass spectrometers (LC-MS-MS). This study confirmed that the neutral PFAS, especially FTOHs could be efficiently transported via atmosphere to the remote areas and distribute in Arctic environment. While, oceanic current transport is the important pathway for ionic PFASs. The air to sea deposition fluxes of FTOHs, suggesting degradation and transformation of the precursors is an important source of the ionic PFASs in the remote ocean. Moreover, this work showed that ice and snow melting in summer could release the PFASs accumulated in winter to the high Arctic.

3.02 Advances in detection, remediation, transport, fate and bioaccumulation of legacy and emerging per- and polyfluoroalkyl substances (Poster)

3.02.P-We050 In Vitro and In Vivo Apical Effects of Exposure to the Emerging Per-Fluoroalkyl Substance, Perfluoro-4-Ethylcyclohexane Sulphonate

Hannah Mahoney¹, Yuwei Xie², Garry Codling³, Jonathan Challis⁴, Natacha Hogan⁵, Markus Brinkmann⁴ and John Giesy⁴, (1)Student, Canada, (2)Toxicology Center, University of Saskatchewan, Saskatoon, SK, Canada, (3)University of Saskatchewan, Czech Republic, (4)University of Saskatchewan, Canada, (5)University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Widespread application of poly- and per-fluoroalkyl substances (PFAS) has resulted in some isomers being ubiquitous in environmental matrices. This along with their resistance to degradation has allowed them to accumulate in wildlife and humans with the potential for toxic effects. While certain isomers of concern have been phased-out or banned, other PFAS that are emerging as alternative substances are still produced and are released into the environment. One such substance of concern is perfluoro-4-ethylcyclohexanesulphonate (PFECHS). PFECHS, which is an analogue of perfluorooctanesulphonic acid (PFOS), has recently been detected in various environmental media. However, there is little information on toxic potencies or mechanisms of action of PFECHS or other cyclic-PFAS. Research reported here elucidated the effects of PFECHS in a two-tiered approach. Tier 1 focused on *in vitro* experiments and has quantified cytotoxicity and generation of reactive oxygen species (ROS) in rainbow trout cell lines, while Tier 2 focused on *in vivo* experiments and has quantified apical effects related to the development of zebrafish embryos. Results pertaining to *in vitro* cytotoxicity and ROS generation have suggested PFECHS is not as acutely toxic as PFOS. While significantly increased mortalities and abnormalities were observed at concentrations of 150ug/L and greater *in vivo*, no significant effects were observed at environmentally relevant concentrations. Determining toxicities associated with exposure to PFECHS will not only characterize a new and emerging chemical of concern but also further elucidate molecular mechanisms associated with cyclic PFAS.

3.02.P-We051 Occurrence and Bioaccumulation of Novel PFAS in the Delaware River Estuary, USA

Anna Robuck¹, James McCord², Mark Strynar³, Mark Cantwell³, Douglas Walker¹, Michaela Cashman³ and Rainer Lohmann⁴, (1)Icahn School of Medicine at Mount Sinai, United States, (2)U.S. Environmental Protection Agency, (3)U.S. Environmental Protection Agency, United States, (4)University of Rhode Island, Narragansett, RI

With the phase-out of some legacy per- and polyfluoroalkyl substances (PFAS), new PFAS have been introduced in consumer and industrial applications. Little is known about the occurrence, biological accumulation, or potential impacts of novel PFAS. Here, we used high resolution mass spectrometry to evaluate legacy and novel PFAS in surface water, passive samplers, fish muscle, and fish liver from the Delaware River, USA. This region is home to historical and current PFAS producers and users. Samples were collected within the mainstem River and tributaries at sites located between Bristol, PA downstream to Elsinboro, NJ, spanning over 50 river miles. Targeted, suspect, and non-targeted analysis were conducted, and features identified using suspect lists and non-targeted analysis were semi-quantified using surrogate normalization, or presented as raw abundances. We identified a series of ether-based novel PFAS in surface water and fish tissue from across the sampled area, with the highest abundances adjacent to and downstream from a suspected point source in southwest New Jersey. Some of the chlorinated and hydrogenated species within this series were previously identified in soil, groundwater, and local surface water; here, we present the first information establishing the presence of these and additional chlorinated, hydrogenated, and fluorinated congeners in the wider ambient aquatic ecosystem. Some novel compounds were orders of magnitude more abundant than legacy PFAS in each sampled matrix. In white perch liver, the novel Cl-PFPECA_s were an order of magnitude more bioaccumulative compared to PFOS based on bioaccumulation factor calculations using surface water and fish liver tissue from the same location. We also describe previously unidentified PFAS associated with recent changes in fluoropolymer production process; spectral evidence suggests these unique structures possess variable degree of fluorination, incorporation of ethers, and multiple acid moieties. Legacy PFAS including PFNA, PFOS, and PFOA were also identified in surface water and fish tissue, with some fish muscle concentrations exceeding human consumption advisories issued by the state of NJ. This work highlights the continuing evolution of PFAS occurrence in the environment, and underscores the importance of non-targeted methods to screen for PFAS beyond limited targeted lists.

3.02.P-We052 Assessment of the Occurrence and Distribution of Per- and Polyfluoroalkyl Substances in the River Liffey, Ireland

Belinda Huerta¹ and Fiona Regan², (1)Dublin City University, Ireland, (2)DCU Water Institute, Dublin City University, Ireland

Per- and polyfluoroalkyl substances (PFAS) are a large family of widely used legacy and emerging contaminants that are pervasive in aquatic habitats globally. These molecules are chemically very stable and are highly resistant to biological degradation; therefore, they belong to a class of compounds that tend to persist in the environment and potentially may present a risk to the health of humans and wildlife. In Ireland, data on the occurrence of these chemicals in freshwater ecosystems is scarce. In order to assess the threat PFAS pose for the environment and public health, this study had the objective of evaluating the occurrence, levels and distribution of fifteen PFAS, both legacy and emerging, in the Liffey river in the city of Dublin. The Liffey flows through agricultural land and into a large urban area, and the sampling points selected contained multiple diffuse and point sources. Analytes were extracted by solid phase extraction (SPE) and determined by liquid chromatography triple quadrupole mass spectrometer (LC-QqQ-MS). Target compounds included 8 perfluorocarboxylates (PFCAs) C₅-C₁₂, 7 perfluorosulfonates (PFSS) C₄-C₁₀ and 1 perfluorosulfonamide (FOSA), C₈. The quality parameters for the fifteen selected compounds presented good limits of detection (LOD) ranging, in general, from 0.56–12.6 ng/L. The method was applied to assess the occurrence of PFAS in 80 river water samples over four sampling campaigns, accounting for seasonal variation. Ten out of fifteen compounds were

consistently detected in the majority of the samples, at levels that range from 1 to 400 ng/L. The study offers an overview of the correlation between use land and PFAS occurrence in a major city.

3.02.P-We053 An Investigation Into PFAS in Artificial Turf Around Stockholm

Melanie Lauria¹, Ayman Naim², Jenny Fäldt³, Roxana Suehring⁴ and Jonathan Benskin², (1)Department of Environmental Science, Stockholm University, Stockholm, Sweden, (2)Stockholm University, Sweden, (3)Stockholms Stad, Sweden, (4)Ryerson University, Canada

The objective of this work was to investigate the occurrence of per- and polyfluoroalkyl substances (PFAS) in artificial turfs around Stockholm. A list of 103 football fields located in Stockholm containing artificial turf was provided by the City of Stockholm and a stratified design was used to randomly select a limited number of locations for sampling. Following collection, samples were analysed for total fluorine (TF), extractable organic fluorine (EOF) and target PFAS. Detectable levels of total fluorine were observed in all samples, with concentrations ranging from 13-310 µg/g in backing, 8-305 µg/g in filling materials, and 20-652 µg/g in blade samples. EOF analyses revealed fluorine in 6 samples of backing (?145 ng F/g), 6 filling materials (?179 ng F/g), and 9 blade samples (?192 ng F/g), while target PFAS were only detected in 3 filling and 12 backing samples at very low concentrations (?0.782 ng F/g). Overall these findings suggest that PFAS occurring in artificial turf components are polymeric and therefore unlikely to be readily bioavailable. Nevertheless, their identities and fate require further investigation, in particular with regards to disposal.

3.02.P-We054 Source Attribution of Perfluoroalkyl Substances in Wastewater Treatment Plant Influent

Jessica Clouthier¹, Venita Sitahal¹, Amila De Silva², Shirley Anne Smyth², Sarah Gewurtz³, Christine Spencer² and Cora Young¹, (1)York University, Canada, (2)Environment and Climate Change Canada, Canada, (3)Environment Canada, Canada

Perfluoroalkyl substances (PFAS) are widely used in many consumer and industrial products including stain repellents, non-stick food paper or pans, and firefighting foams. Perfluoroalkyl acids (PFAAs) are resistant to degradation and have adverse effects to the environment and human health. This study analyzed twenty PFAAs in fourteen wastewater treatment plants (WWTP) across Canada. Due to the ubiquitous nature of PFAAs and their resistance to degradation they can be found in both WWTP influent and effluent. Previous studies have shown that in most WWTPs, regardless of treatment type, PFAA in the effluent is higher than in the influent suggesting a production of PFAS and/or a low removal efficiency. For PFAAs this is due to the limited affinity for solids sorption and transformation of precursors. Most current studies focus on the effluent in WWTP to assess removal efficiency and the pollution and hazards of contaminants reentering the environment. However, wastewater influent could give insight to help determine sources of PFAAs. This study focused on comparing and correlating the WWTP influent and possible sources (e.g. drinking water, rainwater). There were not any observable correlations with population size and PFAAs concentrations across all WWTPs influent. The total range of PFAS was 11-440 ng L⁻¹ in the influent and 20-240 ng L⁻¹ in the effluent. A breakdown of the PFAS composition shows short chain perfluoroalkyl carboxylic acids (PFCAs) dominate WWTP influent, with perfluorobutanoic acid and perfluoropentanoic acid the dominant PFAA homologues in 78% of the influent samples.

3.02.P-We055 Diffusive Gradients in Thin-Films (DGT) Technique As Screening Tool for Per- and Polyfluoroalkyl Substances (PFAS) Contamination in Wastewater-Based Fertilizers

Christian Vogel¹, Philipp Roesch², Philipp Wittwer², Ute Kalbe³ and Franz Simon², (1)Division 4.3, Bundesanstalt für Materialforschung und -prüfung (BAM), Germany, (2)Bundesanstalt für Materialforschung und -prüfung (BAM), Germany, (3)BAM Federal Institute for Materials Research and Testing, Germany

Per- and polyfluoroalkyl substances (PFAS) are a large group of organofluorine surfactants used in the formulations of thousands of consumer goods, including aqueous film-forming foams (AFFF) used to suppress aviation fires in training scenarios, non-stick cookware, fast-food wrappers, water-repellent fabrics, medical equipment, and plastic and leather products. As a result of the perpetual use of PFAS containing products, effluents and sewage sludge from wastewater treatment plants (WWTPs) have been observed to be an important pathway for PFAS into the environment. In Germany, phosphorus and other nutrients from sewage sludge and wastewater should be recycled in WWTPs of cities with a large population. However, it is not clear if PFAS contamination from wastewater and sewage sludge end up in novel wastewater-based fertilizers. Normally, PFAS are analyzed using PFAS protocols typically with time-consuming extraction steps and LC-MS-MS quantification. However, for screening of PFAS contaminations in sewage sludge or wastewater-based fertilizers also passive samplers based on the Diffusive Gradients in Thin-films (DGT) technique can be used for the PFAS extraction. Afterward, combustion ion chromatography (CIC) can be applied to analyze the “total” amount of PFAS on the passive sampler. Here, we show results from the DGT method in comparison to those of the extractable organic fluorine (EOF) method for a variety of wastewater-based fertilizers. Additionally, we analyzed the adsorption of PFAS on the weak anion exchanger (WAX) based DGT passive sampler binding layer by infrared and fluorine K-edge X-ray absorption near-edge structure (XANES) spectroscopy.

3.02.P-We056 Development of a Comprehensive PFAS Monitoring Strategy for the Dutch WATER SECTOR

Frederic Magnus Been¹, Dennis Vughs², Elvio D Amato³, Sanne Brekelmans², Francesca Cappelli⁴, Nienke Meeke², Stefan Kools², Milou Dingemans² and Thomas L ter Laak⁵, (1)KWR Watercycle Research Institute, Netherlands, (2)KWR Water Research Institute, Netherlands, (3)University of Antwerp, Netherlands, (4)CNR-IRSA, Italy, (5)KWR, Netherlands

Short abstract Title: Development of a comprehensive PFAS monitoring strategy for the Dutch water sector Per- and polyfluoroalkyl substances (PFAS) represent a particularly complex challenge for water authorities due to their widespread use, difficult removal, the large number of compounds that fall in this category, and the limited information about their toxicity. In addition to efforts to phase out their usage and, consequently minimize their emissions to the environment, implementing

comprehensive monitoring strategies allowing to determine their occurrence and identify less known congeners and emerging PFAS is of crucial importance for water authorities. Besides sophisticated analytical techniques, which allow covering as many PFAS as possible, comprehensive monitoring strategies need to include adequate sampling strategies to cover the broad range of potential PFAS sources which can impact water bodies. The goal of this study consisted in developing and implementing a comprehensive and tailored monitoring strategy that can be used to assess the quality of water sources across The Netherlands. For this purpose, a broad range of (aqueous) samples was collected, namely surface-, groundwater, influent and effluent of wastewater treatment plants (WWTPs) as well as passive samplers for contaminated groundwater.[FB1] Both targeted and suspect and non-target screening (NTS) analysis of ultra-short (< C4) to long-chain (up to C14) PFAS were used for the analysis of the collected samples. For NTS, various workflows to detect and, where possible, (tentatively) identify PFAS were implemented. These involve among others the use of Kendrick Mass Defect to detect the presence of homologous series of PFAS and precursors, as well as *in-silico* fragmentation for tentative structure annotation. Total oxidizable precursor assay (TOPA) was also implemented to determine the influence of precursors on the overall PFAS mass balance in collected samples. Results of this study provided a unique and comprehensive picture of PFAS contamination in water sources across the Netherlands. The obtained information can be used by water authorities to tailor, per location, their routine monitoring strategies and focus only on those compounds which are most relevant, while comprehensive monitoring can be performed occasionally or upon specific request to assess whether changes have occurred.

3.02.P-We057 Reference Materials for Per- and Polyfluoroalkyl Substances (PFAS)

Jessica Reiner¹, Alix E. Rodowa², Jennifer Lynch¹ and Benjamin Place¹, (1)National Institute of Standards and Technology, United States, (2)National Institute of Standards and Technology, Gaithersburg, MD

Standard Reference Materials (SRMs) are homogeneous, well-characterized materials that are used to validate measurements and improve the quality of analytical data (www.nist.gov/srm). The National Institute of Standards and Technology (NIST) has a wide range of SRMs that have values assigned for legacy organic pollutants. These SRMs can serve as target materials for method development and quality assurance and quality control (QA/QC) of chemical measurements. As a unique class of organic contaminants, per and polyfluoroalkyl substances (PFAS) present measurement challenges to the environmental analytical community that can affect the accuracy and precision of quantitative measurements. Currently, NIST has eleven different reference materials with values of PFAS measured in them; however, there are relevant gaps in the NIST library of reference materials. A major gap is a reference material of technical mixtures, specifically an aqueous film-forming foam (AFFF) material. This presentation will discuss the existing reference materials, along with the past and current efforts at NIST to produce new reference materials for PFAS.

3.02.P-We058 Distribution of Per- and Polyfluoroalkyl Substances (PFAS) in Home-Produced Food Across Flanders

Robin Lasters¹, Marcel Eens², Thimo Groffen² and Lieven Bervoets², (1)ECOSPHERE, Belgium, (2)University of Antwerp, Belgium

Per- and polyfluoroalkyl substances (PFAS) can enter the human food chain due to their persistence, widespread use and global distribution. Generally, food is considered as the major exposure source of PFAS to humans. While plenty of data are available on commercial food products, little information exists on the contribution of self-cultivated food to the total dietary PFAS intake. Therefore, the main goal of this study was to examine the distribution of PFAS, including both legacy and emerging compounds, in home-produced food. Secondly, potential health-risks were assessed through the consumption of home-produced food to local residents. To this end, 65 volunteers were recruited across Flanders (Belgium) from industrial, urban as well as rural residential areas. Various food items (eggs from free-ranging laying hens, fruits and vegetables) were collected from the corresponding private gardens during the summer of 2021 and were analyzed for 29 target PFAS. In total, 16 PFAS could be detected in the food matrices and large differences were observed, in terms PFAS profile and concentrations, among and within food matrices. In eggs, long-chain compounds were dominant with PFOS contributing the most to the egg PFAS profile, as concentrations were detected up to 215 ng/g wet weight of whole egg content. Egg PFOS and PFBA concentrations decreased with increasing distance from fluorochemical industry, whereas this pattern was less evident or absent for other compounds and fruits/vegetables. On the other hand, fruits and vegetables contained much lower total PFAS concentrations, compared to eggs and consisted mostly of short-chain PFCAs (PFBA and PFPeA) and long-chain PFCAs, with the latter being increasingly detected as the chain length increased (?C8). Notably, several emerging PFAS were frequently detected in fruits and vegetables, whereas this was not the case in eggs. Clearly, home-produced eggs contributed to a large extent to the total PFAS exposure compared to other home-produced food matrices. In all residential areas, currently available human health guidelines with respect to PFAS were often exceeded. This study demonstrates that the consumption of home-produced food, especially eggs, can be an important dietary exposure pathway of PFAS to humans.

3.02.P-We059 ZeroPM - Alternatives Assessment

Ian Cousins¹, Romain Figuière², Luc Miaz¹, Eleni Savvidou³, Gregory Peters⁴, Ellise Suffill⁵, Mathew White⁵, Sabine Pahl⁵, Hans Peter Arp⁶ and Sarah Hale⁷, (1)Stockholm University, Sweden, (2)Department of Environmental science, Stockholm University, Stockholm, Sweden, (3)Department of Environmental Science, Stockholm University ACES, Stockholm, Sweden, (4)Chalmers University of Technology, Sweden, (5)University of Vienna, Austria, (6)NGI, Norway, (7)Norwegian Geotechnical Institute (NGI), Norway

This work package focuses on the development and application of alternatives assessment methods both for uses of persistent and mobile (PM) substances and their treatment technologies. Per- and polyfluoroalkyl substances (PFAS) are given special attention as certain PFAS are PM substances and because PFAS are under the spotlight within the European Commission's Chemicals

Strategy for Sustainability (CSS). The essential use concept, also integral to the CSS, is further developed and applied to facilitate the rapid phaseout of some PM substances, considering technical functional and social/behavioural science approaches.

3.03 Advances in exposure modelling

3.03.T-01 PERK: An Interactive Tool to Predict Concentration of Pharmaceutical Ingredients in Different Environmental Matrices

Kishore Kumar Jagadeesan and Barbara Kasprzyk-Hordern, University of Bath, United Kingdom

Predicting an active pharmaceuticals ingredient (API) concentration in the environment using different modelling approaches is an important aspect in the assessment of their environmental risk, especially for the APIs with no or limited analytical detection methods. However, handling, validating, and incorporating different datasets including prescription or consumption data of API, API metabolism data, wastewater flow data, removal efficiency during wastewater treatment, dilution factor for the modelling is often laborious and time-consuming. The aim of this presentation is to evaluate our in-house developed R based open-source software tool, PERK, to facilitate automated modelling and reporting predicted concentration (PC) and risk quotient (RQ) of a comprehensive set of APIs derived from a wide range of therapeutic classes in different environmental matrices. Prediction accuracy (PA) i.e., ratio between the PC and MC to validate the calculated PC, can be generated with the tool. The tool provides a consistent interactive and user friendly interface in a familiar dashboard layout, enabling users to visualise predicted values and compare with their measured values. Users can download data and graphs generated using the tool in .csv or publication ready images. We have used PrAna, our in-house developed R package to get API prescription data for the PC calculations in wastewater influent, effluent, and river and compared with measured concentrations (MC) for five different catchments located in Southwest England. Our initial investigation revealed that using the API metabolism including the faecal excretion rate, provided better PA. Furthermore, this approach provides better spatial resolution as PCs are calculated using postcode level prescription data. This presentation will focus on the concept and methodology used, and the software functionalities will be demonstrated with attention to its PC, PA and RQ features.

3.03.T-02 The Full Multi: An Open Source Framework for Modelling the Transport and Fate of Nano- and Microplastics in Aquatic Systems

Maria del Prado Domercq¹, Antonia Praetorius² and Matthew MacLeod³, (1)Environmental Science, Stockholm University, ACES, Stockholm, Sweden, (2)University of Amsterdam/IBED Institute, Netherlands, (3)Stockholm University, Sweden

In the context of the increased attention placed on plastic pollution, data on microplastics (MPs) fate and hazard potential has multiplied in recent years. However, such data is still poorly understood within a risk assessment context and needs integration so that relevant exposure indicators can be derived and sources of uncertainty and knowledge gaps identified. Mathematical models, such as multimedia mass-balance environmental fate models, can be designed to integrate the most recent findings on MPs transport and fate mechanisms, becoming extremely useful tools that can improve our understanding on the processes and parameters that govern MPs fate. Furthermore such models can provide much-needed estimates of environmental exposure concentrations, and help derive relevant exposure indicators for risk assessment. Here we present an open source flexible fate and transport modelling framework for microplastics in freshwater systems that integrates all up to date MPs fate and transport process descriptors and that can easily be parameterized for a variety of spatial and temporal scales. With this model we are able to investigate on the open questions about MPs speciation and distribution in natural systems that will provide bounding information for microplastic risk assessment.

3.03.T-03 Validating Great-Er Simulations for WWTP Born Micropollutants in a River Network With Passive Sampler Campaigns. a Case-Study From Luxembourg

Tom Galle¹, Christian Koehler², Michael Bayerle³, Denis Pittois³, Viola Huck³, Volker Lämmchen⁴ and Joerg Klasmeier⁵, (1)ERIN, Luxembourg Institute of Science and Technology, Esch sur Alzette, Luxembourg, (2)SIDERO Luxembourg, Luxembourg, (3)Luxembourg Institute of Science and Technology LIST, Luxembourg, (4)Universität Osnabrück, Germany, (5)University of Osnabrueck, Germany

The ecotoxicological impact of WWTP born micropollutants on surface waters has entailed several European countries to implement advanced treatment on biological treatment plants. Distributed modelling of whole river networks is a good alternative to costly measurement campaigns but it also demands locally specific input data and a thorough validation. Here we show how the GREAT-ER model was implemented in Luxembourg using passive sampler results for feeding the model and validating the simulation results. The passive sampler campaigns showed that best performance is achieved when WWTP emission load data are regional and of the same season. While well-known compounds like carbamazepine, diclofenac, antibiotics or β -blockers can be reasonably predicted within a factor 2, the anti-inflammatory ibuprofen showed poor predictability which was probably related to variable nitrification in the treatment plants. In-stream concentration were often underestimated and ibuprofen proved to have a comparable impact to diclofenac on surface waters.

3.03.T-04 Modelling Organic Contaminants in Northern Ecosystems Across Time, Space and Species Using the Integrated NEM Model

Ingjerd Sunde Krogseth¹, Knut Breivik², Sylvia Frantzen³, Bente Nilssen³, Sabine Eckhardt⁴, Therese Nøst⁵ and Frank Wania⁶, (1)Norwegian Institute for Air Research, Tromsø, Norway, (2)Norwegian Inst. for Air Research, Kjeller, Norway, (3)Institute of Marine Research, Norway, (4)NILU - Norwegian Institute for Air Research, Norway, (5)UiT - The Arctic University of Norway, Norway, (6)University of Toronto Scarborough, Toronto, ON, Canada

There is concern over possible effects on ecosystems and humans from exposure to persistent organic pollutants (POPs) and chemicals with similar properties. A solid understanding of the link between global emissions and resulting exposure to ecosystems is vital to enable scientifically sound mitigation strategies. Here, we introduce the integration of a modified version of the ACC-Human model into the Nested Exposure Model (NEM). The NEM model is designed to comprehensively and dynamically link global emissions with biotic exposure. We evaluate NEM's ability to predict measured PCB-153 concentrations across time, space and species in northern ecosystems. Detailed environmental data, global emissions and physicochemical properties were used to predict PCB-153 concentrations in the physical environment and biota for 1930 – 2020 (resolution 5°×5° lat/long). Predicted concentrations in biota were compared to (i) measured concentrations across time and space in Norwegian spring-spawning herring (*Clupea harengus*) and Atlantic cod (*Gadus morhua*) from large baseline studies and monitoring in Norwegian marine areas, and (ii) measured concentrations in multiple species of a marine food web in the Svalbard area. The NEM reproduced well spatial and temporal trends of PCB-153 in NSS herring and cod. Individual predictions for herring and cod were slightly too high and low, respectively, when compared to measurements. Better overall model performance for herring than for cod probably reflects that herring is more homogenous than cod in terms of diet and habitat. Detailed results, including exploration of past, present and future emission scenarios, will be presented. Predicted PCB-153 concentrations were also in good agreement with measured concentrations in an Arctic marine food web on Svalbard including zooplankton, fish and marine mammals. Considering all the uncertainties inherent in input parameters, model assumptions, and measurement data, model performance is judged good. This suggests that the NEM model succeeds in quantitatively and mechanistically linking global historical emission of PCB-153 with northern ecosystem exposure, including trends across time, space and species. NEM has potential to be expanded to other contaminants, species, and ecosystems of interest, making it a useful tool for both scientific and regulatory communities interested in understanding and protecting ecosystem and human health from legacy and emerging organic contaminants.

3.03.T-05 Uncertainty Analysis at the Catchment Scale for Higher-Tier BPR and REACH Risk Assessments

Fabienne Ericher, CEA, United Kingdom

Characterising and communicating uncertainty is an important step in the evaluation of chemicals. Due to the difficulty in validating models against field data, catchment-based scenarios are often used as benchmarks to test and compare products, using worst-case assumptions. This leads to a disconnect between the risk assessment's exposure estimates and the likely real-life exposure from actual product use, which makes it difficult to progress into higher tiers, measure uncertainty and review potential benefits from mitigation measures and alternative practices. There is a common saying, that all models are wrong but some are useful (George E. P. Box). Current regulatory catchment models are useful in providing a standard for substance and product evaluation. However, they are not useful in simulating actual product use and environmental exposure. A computer model was designed to expand from standard regulatory catchment models to a more complex framework that enables the investigation of alternative behaviours. One example of the use of the model would be to visualise potential daily variation in product use across a catchment. Some variability can be simulated in behaviours within individual buildings, the use of a Box-Muller transform for parameter values which are derived from a range of experimental results, and/or the consideration of alternative treatment options. Graphical outputs from such models can be a powerful communication tool: by allowing easy visualisation of likely variations, they help risk assessors and risk managers to develop an understanding of the potential uncertainty attached to a range of scenarios and products. This, in turn, would facilitate moving away from benchmark regulatory scenarios and towards more realistic risk assessments that better simulate the link between product use and environmental exposure.

3.03 Advances in exposure modelling (Virtual Only)

3.03.V-01 Environmental Fate Modelling of Shaped Nano- and Micromaterials

Johannes Meesters¹, Joris T.K. Quik² and Martine Bakker³, (1)National Institute for Public Health and the Environment (RIVM), Netherlands, (2)RIVM, Nederland, (3)RIVM, Netherlands

Several fate models have recently been developed for use with nanomaterials. For instance, the SimpleBox model, prescribed under REACH to simulate environmental fate and exposure of chemicals. SimpleBox has been extended to include substances that occur in a nano- or micromaterial form: SimpleBox4nano. However, the SimpleBox4nano model, as well as others, are only able to predict the environmental fate and exposure of materials that are spherically shaped, while nano- or micromaterials can have various shapes, such as fibers, plates, films, rods or irregular shapes. Now a module was developed for SimpleBox4nano to include the transport and fate of non-spherical shaped nano- or micromaterials. The new shape module consists of a selection of routines for non-spherical materials that can replace the ones in SimpleBox4nano for spherical materials. The routines included refer to the settling behavior of nano- an micromaterials in air or water accounting for the additional drag that non-spherical shaped materials are subjected to. The shape module consists of input fields referring to the longest, intermediate, and shortest side of the material and to its density. The module then classifies the material: (i) by size as 'nanoparticle', 'nanomaterial', 'microparticle', 'micromaterial' or 'coarse' based on the inserted sizes (ii) by shape as isometric, rod, plate/disc, film/sheet rod or disc, based on the proportions of the length, height and width of the particles' of material (iii) by buoyancy, as settling or rising based on the difference in density of the solid material and its surrounding medium and (iv) by the extent to which the material is subject to drag based on the calculated Reynolds Number. Subsequently, the shape module selects the appropriate routine to calculate the terminal velocity including the corrections for drag for the specific non-spherical material. The ambition is to extend the shape module with routines to simulate more environmental fate processes that need corrections for the shape of the material, such as atmospheric scavenging and deposition, attachment with natural particles and filtration in soil or sediment. SimpleBox4nano is available at rivm.nl/SimpleBox4nano and <https://github.com/rivm-syso/SimpleBox>.

3.03.V-02 Using Hydrodynamic Modeling in Combination With Passive Sampler Measurements to Evaluate PCB Mass Balance and Sources in an Estuary

Ishita Shrivastava¹, Peter H Israelsson², Daniel Prendergast³, Jennifer Apell³, Eric Adams³ and Philip Gschwend³, (1)Gradient, United States, (2)Synthesis Environmental LLC, United States, (3)Massachusetts Institute of Technology, United States

Polychlorinated biphenyls (PCBs) are a class of legacy pollutants that drive health risk at many contaminated sediment sites. Remedial actions typically seek to remove or sequester sediments with concentrations exceeding risk-based thresholds. Successful remedy design depends on identifying the sources controlling water column and sediment concentrations, which may not be effectively captured by sediment sampling in the event of ongoing external inputs (e.g., upstream inflows, point sources like combined sewer overflows, groundwater discharges) or unidentified sediment flux hotspots. To aid such efforts and help inform decision making, we investigated a coordinated use of modeling and passive sampler measurements to help characterize dissolved PCB sources at an urban estuary, the Lower Duwamish Waterway in Seattle, USA. PCB transport in the estuary was modeled using conservative tracer simulations made with a three-dimensional hydrodynamic model, i.e., assuming tidal flushing to be the sole sink of PCBs. The model simulations were used in two modes – forward and inverse. In the forward mode, sediment-water fluxes of dissolved and colloid-bound PCBs (estimated using chemical gradients measured by passive samplers co-located across the sediment-water interface) were used as an input to the hydrodynamic model. Freely dissolved PCB concentrations in the water column calculated as a result of these fluxes were compared with water-column passive sampler measurements to assess the mass balance of PCBs within the estuary. This comparison indicated that these sediment-water fluxes were too small to explain the measured water column concentrations, suggesting that either other sediment-to-water transfer mechanisms or other inputs must be predominant. This mass balance assessment was augmented with inverse modeling to infer the source locations that would be consistent with the water column PCB measurements. The hydrodynamic model was used to simulate concentrations generated by unit tracer input at potential source locations and the source strengths that yielded the best match to the measured concentrations were calculated. The sensitivity of inferred source locations and strengths to measurement precision, density of potential sources, mixing parameters, and loss processes was assessed. Results were also propagated to a food web model to evaluate contaminant uptake by various trophic levels and evaluate hypothetical source removals.

3.03 Advances in exposure modelling (Poster)

3.03.P-Mo121 Alternative Metrics for Long-Range Atmospheric Transport Potential (LRATP)

Knut Breivik¹, Michael McLachlan² and Frank Wania³, (1)Norwegian Inst. for Air Research, Kjeller, Norway, (2)Department of Environmental Science, Stockholm University, Stockholm, Sweden, (3)University of Toronto Scarborough, Toronto, ON, Canada

Several metrics have been developed to characterize the potential of chemicals to undergo long-range environmental transport (LRTP). It is common to distinguish between transport- and target-oriented metrics. An example of the former metric is the characteristic travel distance (CTD in km), which describes the potential for transport in the mobile media air and/or water with simultaneous exchange with the surface media. An example of the latter metric is the transfer efficiency (TE in %), which represents an estimate of the mass flux into a selected compartment in a target region, divided by the emission mass flux in a source region. Both metrics are calculated by the non-spatially resolved, steady-state model in The OECD Tool and were motivated by regulatory needs (Wegmann et al. 2009). The objective of this study was to develop and explore the potential utility of alternative LRATP metrics which could offer a coherent description of the overall link between emissions into air and surface media exposure in a remote region. Specifically, we propose three metrics describing the potential for atmospheric dispersal (DP), transfer to surface media (TP) and contamination of surface media (CP) that complement each other by describing different and distinct aspects of long-range atmospheric transport. We define the dispersion potential (DP) as the ratio of the tropospheric residence time of a chemical of interest, divided by the tropospheric residence time of a highly volatile inert constituent. The transfer potential (TP) quantifies the fraction of the dispersed chemical which undergoes net atmospheric deposition to surface media, whereas the contamination potential (CP) quantifies the fraction of transferred chemical that accumulates in surface media. The Stockholm Convention targets chemicals that are “likely, as a result of their long-range environmental transport, to lead to significant adverse human health and/or environmental effects, such that global action is warranted”. Because most atmospherically dispersed chemicals will need to be able to accumulate in surface media to exert such effects, the CP is designed explicitly to aid in evaluations of LRTP in this regulatory context. In contrast to earlier such metrics, such as the Arctic Contamination Potential, it can be calculated with a non-spatially resolved, steady-state model such as the OECD Tool and does not require the delineation of a specific geographic target region.

3.03.P-Mo122 ChemicalDrift: Development and Application of a Lagrangian Chemical Fate Model for the Exposure Assessment of Pollutants From Shipping Activity in the Northern Adriatic Sea

Manuel Aghito¹, Loris Calgaro², Elisa Giubilato², Mattia Boscherini³, Lars Hole¹ and Antonio Marcomini⁴, (1)Norwegian Meteorological Institute, Norway, (2)University Ca Foscari of Venice, Italy, (3)University Ca' Foscari of Venice, Italy, (4)University of Venice, Italy

One of the main challenges in the assessment of impact of anthropogenic stressors on marine and coastal ecosystems is to estimate the exposure to these contaminants while also keeping track of their origin, especially in the case of multiple sources of chemical pollution. In particular, Lagrangian modelling can serve as a platform to assess the main drivers of contaminant fate and predict exposure concentrations in different scenarios without losing information on their origin, thus giving fundamental data on the contribution each source has on the overall exposure of the target ecosystem. Pollutants emissions from shipping due to the use of atmospheric emission abatement technologies such as exhaust gas cleaning system (scrubbers) may significantly contribute to the exposure of organic and inorganic pollutants, especially for areas that are already subjected to multiple contamination sources of

anthropogenic origin. In this work, carried out within the European project EMERGE, we developed ChemicalDrift, a new model capable to dynamically simulate the transport of chemical substances in the marine environment while accounting for the chemical's degradation, volatilization, and partitioning between phases (e.g. between dissolved and adsorbed to colloidal and suspended particles). In detail, ChemicalDrift is built as a module of OpenDrift, the open-source Lagrangian framework developed by MET Norway for modelling the trajectories and fate of objects or substances drifting in the ocean. OpenDrift is highly flexible and can be interfaced to different formats of metocean forcing data. The model has been applied to carry out an exposure assessment for Northern Adriatic Sea of selected pollutants considering both land-based sources and discharges from shipping activities. In detail, emissions from shipping have been estimated from Automatic Identification System data and emission factors from scrubber water analysis by applying the STEAM model, while ChemicalDrift forcing data for the case study area, including ocean currents, temperature, salinity, mixed layer depth, and winds have been obtained from Copernicus Marine Services.

3.03.P-Mo123 A Global Environmental Exposure Modeling Framework for Risk Assessment of Chemicals Disposed Down-The-Drain

Raghu Vamshi¹, Kathleen McDonough², Susan Csiszar³, Brenna Kent¹, Ryan E. Heisler⁴ and Kathleen Stanton⁵, (1)Waterborne Environmental, Inc., United States, (2)P&G, United States, (3)Procter & Gamble Company, United States, (4)1401 H St NW, 1401 H St NW, Washington, DC, (5)American Cleaning Institute

Despite advancements in exposure modeling and the growth of global and local data resources, environmental exposure assessment of chemicals disposed down-the-drain (DtD), including consumer product ingredients at the global scale within a consistent framework, has been a challenge over the years. Most assessments have been applied to specific geographies, using simplistic approaches to building a spatially resolved global assessment infrastructure. Challenges such as inconsistent or scarce data, particularly for countries with high assessment needs, have further complicated the evolution of spatially resolved global exposure assessment tools. However, through strategic integration of existing global data resources and established modeling tools, a standardized framework and methodology for spatial exposure modeling can be developed for the global scale. Here we present a spatially resolved global environmental exposure modeling framework that incorporates the best-available data and modeling tools. The global hydrology network from HydroSHEDS and HydroBASINS, global river flow, detailed population estimates, and the best-available country-specific water use and wastewater treatment information were integrated with the iSTREEM® framework (<https://www.istreem.org/>) to provide a means of estimating the distribution of concentrations of a chemical disposed DtD across a river network. The framework was first developed for China and further extended to include Japan, Canada, and Mexico. Country-level case studies were generated based on chemical production volume, consumer use estimates, and chemical-specific removals at wastewater treatment. Modeling results (probabilistic and spatial) from the case studies were compared with available monitoring data from literature; results showed good agreement between modeled and measured data. The framework developed is highly adaptable to parametrize the model for countries with an abundance of data (e.g., North America) or those scarce with data (e.g., developing countries). This work highlights the practical application of the model as a ready-to-use tool for exposure assessments. The iSTREEM® model's evolution reflects recent scientific advances in DtD exposure modeling to address global challenges and needs such as assessment over broad geographies, the incorporation of probabilistic variability, spatially explicit distributions, and accessibility of this enhanced utility for end-users.

3.03.P-Mo124 Regulatory Risk Assessment of Down-The-Drain Products: Giving Catchments a Story

Fabienne Ericher, CEA, United Kingdom

Risk assessments of down-the-drain products, under REACH and the BPR, are largely reliant on the specifications of the simulated catchment, from the number and type of buildings to the collective inhabitants' product usage behaviour. This poster looks at Biocides Product Type 18 (insecticides) ERA as a case study. The current emission document (OECD series on emission scenario documents – Nb 18 – emission scenario document for insecticides, acaricides and products to control other arthropods for household and professional uses) proposes default scenarios for the assessment of potential environmental emission for the use of biocides in the residential environment. The typical pathway for biocidal substances that are applied indoor are generally down-the-drain, following a wet-cleaning event indoors. The $F_{\text{simultaneity}}$ parameter, which defines the likelihood/extent of product usage across the catchment, simplify usage to a single conservative value representing daily likelihood, which is shared across all buildings. This poster aims to compare results obtained using this standard approach, to a model that more closely reflects individual consumer behaviour, where each building would have its own story. Can a more complex representation of product use provide insights into uncertainty and on the potential impact of mitigation measures which can influence user behaviour?

3.03.P-Mo125 Exposure and Risk Assessment of Contaminants in Fertilisers - Comparison of Exposure Tools and Establishment of a Strategy for Meaningful 'Screening' Assessment

Nele Deleebeeck and Laura Lefevre, Arcadis Belgium, Belgium

In this project for the European Commission, Directorate General Environment, the exposure and risk of contaminants/impurities of potential concern in fertilisers needed to be assessed, to identify contaminants/impurities or fertilisers for which additional regulatory measures may be required. Exposure and risk assessment was required for the different environmental compartments, as well as for secondary poisoning and humans exposed via the environment. In principle, these could all be assessed using EUSES, however, EUSES currently has too many limitations to assess the use under consideration (direct application to agricultural soil) in terms of (1) potential scenarios, (2) relevant environmental fate processes modelled, and (3) applicability for both organics and inorganics/metals. Therefore, a thorough comparison of different available tools (e.g., EUSES, FEE tool, ECPA-LET, FOCUS models, ...) was performed to select the most suitable tool for modelling this type of use. Further, for

secondary poisoning and humans exposed via the environment, the possibility to perform manual calculations or – for metals – a combination of calculations and the use of monitoring data was considered to obtain more realistic estimates of exposure where crucial input parameters are not readily available. Finally, the issue of background concentrations and source contribution analysis was carefully considered to get a clearer idea on the magnitude of the contribution of fertiliser use to the total input/presence of the assessed contaminants/impurities in the environment. The general approach followed during the project was described in this poster, whereas one of the cases is discussed in further detail in the platform presentation “PFAS in recycled fertilisers: potential issues, identified uncertainties, and need for monitoring” submitted under the session “Poly- and perfluoroalkyl substances (PFAS): Addressing Urgent Questions in the 21st Century”. It should be noted that the views expressed in the poster are those of the contractor with the context of the service contract 070201/2019/817112/SER/ENV.B2 and according to the terms of reference associated with that contract.

3.03.P-Mo126 A Tiered Approach for Ecological Exposure Estimation Using Eas-E Suite

Alessandro Sangion¹, James M Armitage², Liisa Toose, M.Sc.³, Li Li⁴, Todd Gouin⁵ and Jon Arnot³, (1)ARC Arnot Research and Consulting Inc. and University of Toronto Scarborough, Canada, (2)AES Armitage Environmental Sciences, Inc, Canada, (3)ARC Arnot Research & Consulting Inc., Canada, (4)University of Nevada, Reno, United States, (5)TG Environmental Research, Sharnbrook, United Kingdom

Thousands of chemicals require hazard, exposure and risk assessment for ecological and human health. Measured data to inform exposure characterization are quite limited in comparison to the number of chemicals requiring evaluation. Fate and exposure models are required to address data gaps. The Risk Assessment IDentification And Ranking (RAIDAR) model combines chemical fate and transport at a regional scale with bioaccumulation in aquatic, terrestrial and agricultural food webs using toxicokinetic models. RAIDAR includes representative aquatic and terrestrial ecological receptors (e.g., plants, invertebrates, fish, herbivores, carnivores) and far-field exposure to humans. The latest version of RAIDAR includes methods to better simulate the fate, bioaccumulation and exposure for ionogenic organic chemicals (IOCs). The evaluative RAIDAR model provides the opportunity for holistic exposure- and risk-based high-throughput (priority setting) and screening-level assessments. A key obstacle to parameterize environmental fate models is an absence of reliable chemical use and emission rate data. The Chemicals in Products - Comprehensive Anthropospheric Fate Estimation (CiP-CAFE) is a life cycle chemical emissions estimation model. The RAIDAR and CiP-CAFE models are integrated in the free on-line Exposure And Safety Estimation (EAS-E) Suite platform (www.eas-e-suite.com) which can autoperparameterize the models for > 50,000 chemicals and facilitates its operation in the regulatory community. Here we conduct a tiered ecological exposure assessment for selected cyclic volatile methyl siloxanes (cVMS) as a case study using different tiers of model input parameters. The model is initially parameterized with production volumes as a surrogate for emissions data and default chemical partitioning data. The model is then parameterized using the CiP-CAFE model and other higher tiered data sources for estimating chemical partitioning. The model predictions for environmental concentrations are compared with monitoring data demonstrating how the higher tiered model input data improve the RAIDAR model performance.

3.03.P-Mo127 Applying the Multimedia Fate Model SimpleBox With Temporally Resolved Emission Data -Opportunities to Support Risk Management Decisions and Design

Joris T.K. Quik¹, Carlos Blanco, M.Sc.², Matthias Hof³, Johannes Meesters⁴ and Silke Gabbert⁴, (1)RIVM, Nederland, (2)Institute of Environmental Sciences, Leiden University, Netherlands, (3)National Institute for Public Health and the Environment (RIVM), Nederland, (4)National Institute for Public Health and the Environment (RIVM), Netherlands

SimpleBox is a screening level multimedia fate model which can be applied for deriving PECs as part of Environmental Risk Assessment, deriving a chemical footprint as well as fate factors for life cycle impact assessment. The basic implementation in these applications has mostly been using the steady state (level III) calculations. SimpleBox can also perform dynamic non steady state (level IV) calculations for defined time periods and this has recently become relevant for examining environmental dynamics of substances and materials with extremes in mobility and persistence, such as PFAS and microplastics. We present the latest approach to applying SimpleBox dynamically using R (<https://github.com/rivm-syso/SimpleBox>). This is illustrated by means of two case studies: The first applies Simplebox for assessing the cumulative stock mass in environmental compartments, which feeds into cost-effectiveness analyses of risk management measures as part of Socio Economic Analysis under REACH. The second is the probabilistic and temporal prediction of local, regional and continental PECs of substances leaching from emerging PV panel designs throughout their life cycles. We show that dynamic assessments with SimpleBox provides a better understanding of the environmental fate and distribution of chemicals in time. This can contribute to evaluating the performance of policy measures in a regulatory context, and guide technological research and development towards safer and more sustainable designs.

3.03.P-Mo128 Spatiotemporal Multimedia Modelling of Nanomaterials: A Framework for Advanced Chemical Exposure Modelling

Sam Harrison¹, Virginie Keller², Michael Hutchins², Richard Williams², Jasmine Pullen², Joris T.K. Quik³, Egon Dumont⁴ and Stephen Loftis², (1)UK Centre for Ecology & Hydrology, Lancaster, United Kingdom, (2)UK Centre for Ecology & Hydrology, United Kingdom, (3)RIVM, Nederland, (4)Waterschap Noorderzijlvest, United Kingdom

The emergence of new and novel chemical classes in recent decades has led to concern about the potential risks they pose to the environment. One such example is that of nanomaterials (NMs), whose ability to form thermodynamically unstable suspensions means conventional equilibrium-based exposure models cannot be used to accurately predict their exposure. To address such concerns, NM exposure science has seen significant attention, resulting in the development of tools and models that arguably place NM exposure modelling ahead of that for “conventional” chemicals. One example is a focus on the development of spatial,

dynamic, and multimedia models, with the goal of facilitating the most realistic predictions of NM exposure possible with the data available. Herein, we present the state-of-the-art in NM exposure modelling, the NanoFASE model (Nanomaterial Fate And Speciation in the Environment), a spatiotemporal multimedia model of NM fate, speciation and exposure. We demonstrate its application to nano-TiO₂ and nano-Ag in the Ebro (Spain) and Thames (UK) catchments. We discuss how its flexible spatiotemporal transport framework makes it useful for broader chemical classes than just NMs. For example, in its current form it is particularly suited to modelling other particulate matter, such as micro- and nanoplastics. It is designed to be as easy as possible to transfer to different geographical regions, utilising Europe-wide or global datasets, having comprehensive automated data processing (e.g. reprojection of spatial data), and requiring a minimal amount of calibration. It has been developed in a modular fashion, which enables extensions to be written to extend its chemical domain to contaminants with a broad range of chemistries. Importantly, it is open source and aims to adhere to FAIR principles (Findable, Accessible, Interoperable and Reproducible). These combined make the model a useful asset not just in NM exposure assessment, but as a general framework for advanced exposure assessment.

3.03.P-Mo129 Application of Multimedia Fate and Transport Models to Volatile Methylsiloxanes: A Critical Review

Jaeshin Kim¹ and Michael Whelan², (1)The Dow Chemical Company, United States, (2)University of Leicester, United Kingdom

We critically review generic aspects and applications of multimedia fate and transport models (MFTMs) to better understand the behavior of volatile methylsiloxanes (VMS) in the environment. MFTMs have long been employed to predict chemical behavior and exposure in the environment, along with associated ecotoxicological risk assessment, and to estimate persistence, long-range transport, and bioaccumulation potential. These models require a set of inputs such as the inherent properties of the chemicals under investigation and the characteristics of the receiving environmental systems. It is critical to make accurate estimations of these parameters to ensure that model predictions are reliable. The physico-chemical properties of VMS compounds differ markedly from those of most carbon-based organic compounds, which can have a major effect on their behavior. It is, therefore, particularly important to ensure that these properties are accurately described by MFTMs. Good agreements between modeled and measured concentrations in air, sediment, and biota indicate that our general understanding of the environmental fate of VMS is reasonable: VMS compounds are “fliers” that principally partition to the atmosphere but have low redeposition potential. They are degraded in air by reacting with OH radicals with half-lives of 3–10 days, which means that they have high characteristic travel distances but low overall persistence and low target-oriented long-range transport potential. Since they are released to water and soil via the wastewater and biosolids-to-land pathways, VMS have been detected in these compartments, where exposure can be limited by hydrolysis, volatilization, and partitioning to sediments. In soil, concentrations are reduced by volatilization and clay-catalyzed hydrolysis. In aquatic food webs, metabolism in biota tends to drive trophic dilution resulting in trophic magnification factors which are often (but not always) < 1. Three key areas where model uncertainties still need to be addressed include: (i) the strength and direction of the temperature dependence for K_{OC} which will improve confidence in model predictions of partitioning, particularly in cooler regions; (ii) the fate of atmospheric reaction products including silanols which can be deposited to surface compartments and (iii) global variations in the magnitude of emissions to wastewater which will vary with socioeconomic status and regulatory restrictions on chemical use.

3.03.P-Mo130 How Confidently Can Current Computational Models Evaluate Ecological and Human Exposure to the Myriad of Chemicals in Commerce?

Zhizhen Zhang¹, Alessandro Sangion², Shenghong Wang³ and Li Li¹, (1)University of Nevada, Reno, United States, (2)ARC Arnot Research and Consulting Inc. and University of Toronto Scarborough, Canada, (3)University of Nevada Reno, United States

More than 350,000 chemicals and mixtures registered in national and regional chemical inventories are awaiting exposure and risk assessments. Generic mechanistic exposure models are cost-effective and user-friendly tools for this goal. Excellent examples of these models, e.g., EUSES, PROTEX, USEtox, RAIDAR(ICE), have been used to track ecological and human exposure to thousands of chemicals through multiple routes from multiple sources. In general, the applicability of these models is constrained by (i) the applicability domain of tools used for parameterization of fundamental properties, e.g., quantitative structure-activity relationships (QSARs), (ii) built-in empirical relationships generalized from experimental measurements for parameterization of the rest parameters, and (iii) assumptions adopted by model algorithms, e.g., well-mixing homogenous environmental compartments, steady state, and equilibrium partition between sub-compartments. In this presentation, we evaluate the extent to which existing generic mechanistic exposure models apply to 112,000+ chemicals registered in five comprehensive chemical inventories. In brief, using the state-of-the-art QSAR tools, we parameterize the selected models with partitioning and reaction properties to predict exposures of ecological receptors and humans to this myriad of chemicals. We systematically analyze the applicability domains of QSARs, built-in empirical relationships, and model assumptions for these chemicals, whereby we determine the chemicals in these inventories for which these models can make predictions with the highest confidence.

Preliminary results indicate that we can be confident in evaluations of exposure for only a small fraction of commercial chemicals using the current computational models. Specifically, violating the assumption of well-mixing in outdoor compartments (notably large water bodies) limits the application of generic, mechanistic exposure models to most chemicals. The applicability domain of empirical relationships limits the application of generic, mechanistic exposure models to more than half of chemicals. The combination of multiple QSAR models greatly expands the applicability domain. Reliably predicting the biodegradation half-life is the current bottleneck of QSAR applications. This presentation, for the first time, systematically informs academia and regulatory agencies on the applicability and uncertainty of the generic, mechanistic exposure models.

3.03.P-Mo131 Development and Evaluation of a Heavy Metals Speciation and Transport Model in the Multimedia Environment

Ja Eun Jung¹, Hee Kim², Jihyun Park³ and Dong Soo Lee³, (1)Seoul National University, Seoul, Korea, Republic of (South), (2)Seokyeong University, Korea, Korea, South, (3)Seoul National University, Korea, South

A heavy metal (HM) can exist in multiple forms (species) in the environment. For more accurate and reasonable risk assessments, it is necessary to predict the concentrations of individual species of the HM as the fate and toxicity depend on the forms. For environmental modeling purposes, HMs may be divided into three groups, i.e., Group I at a single oxidation state (Al, Co, Ni, Cu, Zn, and Pb), Group II with redox process (Cr, Mn, Fe, and Cu), and Group III involving many complex speciation processes (As, Se, and Hg). In this study, we developed a multimedia model for HMs in the Groups I and II. In the model, HMs speciation is accounted for by equilibrium and kinetic approaches. With the equilibrium approach, partitioning is calculated using a partition coefficient estimated as a function of pH, soil organic matter and/or the total HM concentration. Three forms (free ion, DOM-metal, and inorganics-metal complexes) are proposed in the dissolved phase and their distribution is estimated by V.MINTEQ. With the kinetic approach, redox processes are modeled based on the relationship between oxidation and reduction rates. The model can estimate concentrations of particulate and the three dissolved phase species (for both the oxidized and reduced HMs in Group II). The predicted concentrations in water were compared against measurements obtained in South Korea. The ratios ($C_{\text{predicted}}/C_{\text{measured}}$) based on the average total concentration in water are 0.24 (Al), 0.11 (Cd), 0.28 (Co), 0.29 (Ni), 2.67 (Pb), and 0.32 (Zn) in Group I, and 0.48 (Cr), 0.41 (Cu), 0.28 (Fe), and 0.21 (Mn) in Group II, indicating generally underestimation by the model. However, most of the predictions (99.9% (Al), 99.9% (Ni), 97.6% (Pb), and 100% (Zn) in Group I, and 97% (Cr), 99.2% (Cu), 98.4% (Fe), and 96.2% (Mn) in Group II) fell within the range of the measured concentrations. The predicted concentration fractions of the dissolved and the particulate Zn were 0.56 (± 0.27) and 0.44 (± 0.26), respectively while those of the measurements were 0.74 (± 0.24) and 0.25 (± 0.24), respectively. The estimated concentration fractions of the dissolved Cr^{III} and Cr^{VI} , and the particulate Cr were 0.29 (± 0.04), 0.13 (± 0.12), and 0.58 (± 0.08), respectively, as compared to the measured values of 0.24 (± 0.28) for dissolved Cr^{VI} . While further evaluation is needed, these demonstrate the feasibility of the model to be used for risk assessments accounting for HMs speciation. **keywords** Heavy Metals, Multimedia Model, Speciation

3.03.P-Mo132 Incorporating Channel Geometry and Sediment Characteristics Into Predictions of In-Stream Biodegradation

Robert Newbould¹, Michael Whelan², Mark Powell², Nejumal Khalid³, Charuvila Aravindakumar³, Juliet Hodges⁴ and Alessia Giorgis⁵, (1)School of Geography, Geology and the Environment, University of Leicester, Leicester, United Kingdom, (2)University of Leicester, United Kingdom, (3)Mahatma Gandhi University, India, (4)Unilever, United Kingdom, (5)Unilever R&D Colworth, United Kingdom

Some chemical pollutants emitted via wastewater to rivers may pose a risk for aquatic organisms. In order to quantify exposure we need to understand how quickly these pollutants dissipate from receiving environments under different conditions. In rivers, removal processes include sorption to suspended solids and sediment, photodegradation and importantly biodegradation. Each of these processes will depend on chemical-specific (intrinsic) and system-specific (extrinsic) factors. Although biodegradation can be mediated by suspended organisms, fixed biofilms are believed to be much more important. As a result, the bulk biodegradation rate constant (k) should vary with the size and shape of a river's channel and the size and sorting of its bed material because these factors affect biofilm development and how much of a chemical in solution comes into contact with the bed and banks. These geomorphic controls on biodegradation, however, have not received much attention in the literature and most in-stream exposure models do not account for them. We hypothesize k is proportional to the ratio of wetted perimeter to cross-sectional area (i.e. inversely proportional to the hydraulic radius). This means biodegradation will be faster in wide, shallow channels compared to narrow, deep channels. We also hypothesize that biodegradation will be more rapid in fine and poorly-sorted sediments compared to coarse and well-sorted sediments because the sediment surface area available for biofilm colonisation is higher, although this may be confounded by the differences in the depth of the active sediment layer in rivers with different sediment characteristics. This poster outlines a research project designed to test these hypotheses using a combination of manipulative laboratory experiments, field monitoring and numerical modelling. The lab experiments employ a low-cost annular flume, where a biofilm is cultivated and water is spiked with organic pollutants, to determine their degradation rate under different channel geometries, bed material sizes and grain size distributions. Field experiments will use dye tracing to measure in-stream degradation downstream of wastewater emission points under different channel geometries and bed materials. These observations will be used to develop empirical relationships between degradation rate constants in rivers and channel geometry and sediment characteristics in order to model in-stream biodegradation.

3.03.P-Mo133 Mechanistic Explanation of Biphasic Dissipation Kinetics by FOCUS TOXSWA

Alexander Dorn¹, Klaus Hammel², Philipp Dalkmann³, Daniel Faber², Christina Kaiser², Eric Bruns², Erika Seidel² and Henner Hollert⁴, (1)RWTH Aachen University, Germany, (2)Bayer Crop Science, Germany, (3)Environmental Safety, Bayer Crop Science, Germany, (4)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany

Dissipation half-lives are determined by kinetic fitting of measured overlying water concentrations as part of sediment risk assessment. Although the resulting kinetics are commonly accepted, there is no mechanistic explanation, exemplarily for biphasic dissipation kinetics such as Double First Order in Parallel. To obtain a mechanistic understanding, the parameterized FOCUS TOXSWA model was employed creating predicted dissipation half-lives and corresponding dissipation curves. Goal of this work was to evaluate, whether models based on diffusion (Fick's laws) can deliver a mechanistic explanation for biphasic kinetics. Water-sediment studies with spiked water (OECD 219&308) were conducted with fluopyram (KfOM: 162 ml/g) and bixafen (KfOM: 2244 ml/g), in which artificial and two natural sediments were employed, respectively. To measure the dissipation, overlying waters were sampled on six sampling days within 28 days. The Toxic Substances in Surface Waters (TOXSWA) model

was used to model the behavior of the compounds in the test systems. While a 75 mm depth water body and 25 mm sediment layer were assumed in the OECD 308 studies, a 60 mm depth water body and 15 mm sediment layer were set for the OECD 219 studies. Relevant sediment parameters were derived from the experimental design. In OECD 219 water-sediment systems, predicted and fitted dissipation half-lives of bixafen yielded 1.0 and 1.3 days, respectively. Those of fluopyram equaled 3.0 and 4.2 days. Bixafen has a strong adsorption affinity promoting faster dissipation into the sediment, as compared to fluopyram with a moderate adsorption affinity. Besides the adsorption affinities, the sediment's content of organic matter as well as the height of the water layer influenced the dissipation period. Spiking the overlying water results in large concentration gradients established at the interface between overlying water and sediment. In the early phase of the studies, high mass fluxes driven by a large initial gradient promoted the dissipation. In the later phase of the studies, a certain amount of fluopyram and bixafen were adsorbed on the sediment and the gradient declined slower leading to the biphasic dissipation pattern. Biphasic dissipation can be predicted by the mechanistic TOXSWA model, which considers diffusion as relevant transport process. The extent of the water layer as well as the compounds' adsorption affinity and the contents' of organic matter determine the dissipation.

3.03.P-Mo134 Estimating the Temperature Dependence of the Octanol-Air Partition Ratio: A New ppLFER Model for ?"UOA"

Sivani Baskaran¹, Akshay Podagatlapalli², Alessandro Sangion³ and Frank Wania⁴, (1)University of Toronto - Department of Chemistry, Canada, (2)University of Toronto Scarborough, Canada, (3)ARC Arnot Research and Consulting Inc. and University of Toronto Scarborough, Canada, (4)University of Toronto Scarborough, Toronto, ON, Canada

The octanol-air partition ratio (K_{OA}) describes the partitioning of a chemical between air and octanol and is often used as a surrogate to describe other partitioning phenomena in environmental and atmospheric chemistry (e.g. blood-air, atmospheric particulate matter-air, polyurethane foam-air). Because the K_{OA} is regularly applied to describe partitioning processes occurring at temperatures other than 25 °C, reliable methods for obtaining quantitative information on the temperature dependence of the K_{OA} are required. While poly-parameter linear free energy relationships (ppLFERs) have previously been shown to reliably predict the K_{OA} of organic chemicals at different temperature, the current ppLFERs for calculating the enthalpy of the phase change between octanol and the gas phase ($?H_{OA}$) were developed using a relatively small dataset and could possibly be improved. In this work we build on a recently assembled, comprehensive and curated database of measured K_{OA} values to develop a new ppLFER for the internal energy of phase change between octanol and the gas phase ($?U_{OA}$). Relying on over 200 empirical $?U_{OA}$ values and the QSAR development platform QSARINS, we explored the use of Abraham solute descriptors, PaDEL molecular descriptors and the log K_{OA} at 25 °C itself as an independent variable in multiple multilinear regression equations for $?U_{OA}$. The $?U_{OA}$ of neutral organic chemicals can be reliably predicted using only a solute's hydrogen bond acidity (A) and logarithmic hexadecane-air partition ratio (L). The latter could also be substituted with the log K_{OA} .

3.03.P-Mo135 Indoor Concentrations of Flame-Retardants in Spanish Environments: A Multimedia Modelling Approach

Joaquim Rovira¹, Roser Esplugas², Vikas Kumar², Montse Mari³, Jose Domingo² and Marta Schuhmacher⁴, (1)University Rovira i Virgili, Spain, (2)Universitat Rovira i Virgili, Spain, (3)Rovira i Virgili University, Spain, (4)Rovira i Virgili University, Spain

Flame-retardants (FRs) are present in several consumer products (i.e.: furniture foam, electronic devices and plastics) to comply with flammability standards for household and industrial items. Therefore, FRs can migrate from the consumer products meaning a potential impact on human health. In fact, these chemicals are found in indoor environments such as air, particulate matter and dust. It has been reported that some FRs are endocrine disrupting chemicals, which can affect thyroid hormone homeostasis, neurodevelopment, behavior and reproduction. Thus, there is a need in understanding the emission, transport, sorption, and distribution of FRs. Nowadays, models constitute useful tools for elucidating and predicting the emissions, behavior and fate of semi-volatile organic compounds (SVOCs) in indoor environments. i-SVOC is a software application that implements a framework for dynamic modeling of these chemicals by covering six types of indoor compartments: air (gas phase), air (particle phase), sources, sinks (i.e., sorption by interior surfaces), contaminant barriers, and settled dust. In the present study, we determined the concentrations of two FRs, tris(chloroisopropyl)-phosphate (TCIPP) and triphenyl phosphate (TPhP), in Spanish indoor environments (schools, office and homes). A model was constructed and validated using i-SVOC software considering previously measured indoor air and dust samples for both FRs, building parameters (i.e.: room volume and ventilation) and FR sources (i.e., electronic devices). To get an overview about the presence of TCIPP and TPhP in indoor environments, four scenarios were run, considering high and low ventilation, as well as high and medium emissions factors. Modelled results have shown a good adjustment with measured FR indoor air and dust levels. Consequently, the current model may be useful in the prediction of indoor levels of these two FRs (TCIPP and TPhP) as well as their exposure in large cohort studies where measurements in indoor environment are not possible.

3.03.P-Mo136 Exposure to Chemicals From Food Contact Materials: FCCmigex, a New Resource Based on Empirical Evidence

Birgit Geueke¹, Justin Boucher¹, Yu-Ting Chiang², Ksenia J Groh³, Frank Gwosdz⁴, Phoenix Jieh¹, Chris Kassotis², Paulina Lanska⁵, Maricel Maffini⁶, Olwenn Martin⁵, Alex Odermatt⁷, Lindsey Parkinson¹, Verena Schreier⁸, Vanessa Srebny⁹, Lisa Zimmermann¹ and Jane Muncke¹, (1)Food Packaging Forum Foundation, Switzerland, (2)Wayne State University, United States, (3)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (4)entrepre.nerds, Germany, (5)Brunel University London, United Kingdom, (6)Independent Consultant, United States, (7)University of Basel, Switzerland, (8)University of Basel (UNIBAS), Switzerland, (9)Empa Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Food contact materials and articles (FCMs), like food packaging, are a relevant source of human exposure to xenobiotics: foodstuff comes into contact with many different FCMs during transport, processing, storage, preparation, and consumption, and

chemicals in FCMs can migrate into food. Chemicals in FCMs may also leach into the environment when food packaging is littered or landfilled. We have previously compiled an inventory of 12,285 chemicals that are associated with the manufacture of FCMs, but it is not clear if these chemicals are also relevant for human and environmental exposure. Until now, exposure assessments for food contact chemicals (FCCs) have mostly focused on a few dozen chemicals of concern, such as members of the bisphenols, the phthalates, per- and polyfluoroalkyl substances (PFAS), and heavy metals. No systematic overview of which FCCs have been shown to migrate or to be extractable from FCMs has been available. Therefore, we systematically mapped evidence of migrating and extractable FCCs by analyzing over 1200 publicly available studies meeting our study's criteria and published globally up to May 2021. The systematic analysis of the studies was carried out by trained experts applying a custom-built software tool developed by the Food Packaging Forum and partners. As a result, a freely available database (FCCmigex) provides details about approximately 3000 different FCCs with evidence for migration and/or extraction from FCMs. These data can serve as a basis for modeling exposure to chemicals from food contact materials and articles. It can support shifting the focus from a few well-known and widely tested FCCs to the entirety of FCCs with evidence for presence in food and thus relevance for human exposure. Furthermore, FCCmigex facilitates recognition of trends in chemicals use over time, which is important for exposure assessment, enables identification of key knowledge gaps as well as further systematic reviews, and provides a basis for the prioritization of migration measurements and toxicological studies. In this presentation, we will describe the methodology and process for deriving the systematic evidence map and show how these results can be used for human exposure modeling and for informing environmental exposure assessments.

3.03.P-Mo137 Probabilistic Cancer Risk Assessment to Polycyclic Aromatic Hydrocarbons (PAHs) in Human Breast Milk From Colombia

Boris Johnson-Restrepo, *Adriana Torres-Moreno and Laura Puente-Delacruz, University of Cartagena, Colombia*

Most polycyclic aromatic hydrocarbons (PAHs) and their derivatives are generated through anthropogenic activities. The diet is the main route that polycyclic PAHs enter the body and measuring breast milk is one of the best ways to understand the maternal body burden and can be passed on to infants. In this study, it was measured the concentrations of 23 PAHs in milk samples from 3 Colombian cities (Bogota, Cartagena and Medellin) and assessed the potential cancer risk to human. PAH exposure and risk assessment via breast milk in infants was estimated under different scenarios. Outlining Daily intake dose (DID), hazard quotient (HQ) and incremental lifetime cancer risk (ILCR) as simple point estimations are not accurate because they are obtained from measured factors containing uncertainties of a variety of sources. Therefore, we performed an uncertainty analysis associated relative errors of the factors through the Monte Carlo simulation (MCS). Consequently, the general purpose of the MCS technique was to determine the level of uncertainty of the risk model. MCS uses randomly sampling from probability distribution functions (PDF) of the random variables involved to approach the solution of a mathematical model. Monte Carlo simulations were used to estimate the hazard quotient (HQ) and incremental lifetime cancer risk (ILCR) for infant dietary exposure to PAHs. HQs were below the safe thresholds ($HQ < 1$) while ILCRs were greater than the reference value equal to 10^{-6} ($\text{mg kg}^{-1}\text{day}^{-1}$). Dietary source assessment indicated that fish is a significant source of PAHs, with mothers that consumed fish at least once per week having ~2.5 times greater PAH milk concentrations than other groups. While disparity was also observed between consumers of exclusively marine (?PAHs 198.5 ng mL⁻¹ lipid base) or freshwater fish (?PAHs 85.7 ng mL⁻¹ lipid base). However, geographical considerations can be significant in this finding.

3.03.P-Mo138 First Characterization of Blue Mussel Gene-Based Sensor in Mediterranean Ports (Corsica, France)

Marion Pillet¹, *K. Garrett Evensen², Michel Marengo³, Pierre Lejeune³, Helen Poynton² and Helene Thomas⁴, (1)STation de REcherches Sous-marines et Océanographiques, France, (2)University of Massachusetts, Boston, United States, (3)STation de REcherche Sous-marines et Océanographiques (STARESO), France, (4)LIENSs UMR7266, France*

Coastal port areas are subjected to a myriad of pollution sources. Contaminants in such systems include legacy pollutants (metals and hydrocarbons) and emerging contaminants (e.g. pharmaceuticals) with largely unknown effects. Monitoring for such complex chemical mixtures in marine ecosystems is difficult. Transcriptomics is a promising approach applied to toxicity monitoring in the 21st century but its development is challenging for non-model organisms and emerging contaminants. The Coastal Biosensor for Endocrine Disruption (C-BED), has been developed in Boston harbour (USA) to detect emerging contaminants and their effects on *Mytilus edulis*. The assay measures biological responses and produces a signature identifying which contaminants the mussels have been exposed to. The present study was designed to verify the use of the C-BED assay on another mussel specie, *Mytilus galloprovincialis*, in a Mediterranean ecosystem. Mussel were caged on one port area in North Corsica (St-Florent) and on one reference station (Punta Revellata). After three months of exposure, mussels were collected and dissected immediately. Gene expression analyses targeting the nongenomic oestrogen signalling pathway and steroidogenesis pathway were performed on digestive gland tissue. In parallel to these analyses, the stress response (*via* superoxide dismutase [SOD], catalase [CAT] and glutathione peroxidase [GPx] activity) of mussel and the bioaccumulation of trace element in their tissue were measured. The first results demonstrated that the trace elements contamination is higher in St-Florent compared to the reference station. This is reflected in the stress response of mussel, as CAT and GPx activities were also higher on contaminated site. The results from the C-BED assay indicate that mussels at St-Florent may be experiencing endocrine disruption. The C-BED assay provides an innovative method to monitor for chemicals and expands our ability to detect emerging contaminants before they cause ecological damage or public health concerns. It will help the local authorities to the progress of port clean-ups and evaluate water quality, aiming to promote and integrated management of these port zones.

3.04 Advances in the detection, monitoring and fate of emerging contaminants in the environment (Part I)

3.04.T-01 Three Reasons Why the Water Framework Directive (WFD) Fails to Identify Pesticide Risks

Oliver Weisner¹, Jens Arle², Liana Liebmann³, Moritz Link⁴, Ralf Bernhard Schaefer⁴, Anke Schneeweiss⁵, Verena Christina Schreiner⁴, Philipp Vormeier¹ and Matthias Liess Liess⁶, (1)Helmholtz centre for environmental research - UFZ, Germany, (2)German Federal Environment Agency (UBA), Germany, (3)Helmholtz Centre for Environmental Research – UFZ, Germany, (4)University of Koblenz-Landau, Germany, (5)Quantitative Landscape Ecology, University Koblenz-Landau, Landau in der Pfalz, Germany, (6)UFZ, Germany

The Water Framework Directive (WFD) demands that good status is to be achieved for all European water bodies. While governmental monitoring under the WFD mostly concludes a good status with respect to pesticide pollution, numerous scientific studies have demonstrated widespread negative ecological impacts of pesticide exposure in surface waters. To identify reasons for this discrepancy, we analysed pesticide concentrations measured in a monitoring campaign of 91 agricultural streams in 2018 and 2019 using methods that go beyond the requirements of the WFD. This included a sampling strategy that takes into account the periodic occurrence of pesticides and a different analyte spectrum designed to reflect current pesticide use. We found that regulatory acceptable concentrations (RACs) were exceeded for 39 different pesticides at 81% of monitoring sites. In comparison, WFD-compliant monitoring of the same sites would have detected only eleven pesticides as exceeding the WFD-based environmental quality standards (EQS) at 35% of monitoring sites. We suggest three reasons for this underestimation of pesticide risk under the WFD-compliant monitoring: (1) The sampling approach - the timing and site selection are unable to adequately capture the periodic occurrence of pesticides and investigate surface waters particularly susceptible to pesticide risks; (2) the measuring method - a too narrow analyte spectrum (6% of pesticides currently approved in Germany) and insufficient analytical capacities result in risk drivers being overlooked; (3) the assessment method for measured concentrations - the protectivity and availability of regulatory thresholds are not sufficient to ensure a good ecological status. We therefore propose practical and legal refinements to improve the WFD's monitoring and assessment strategy in order to gain a more realistic picture of pesticide surface water pollution. This will enable more rapid identification of risk drivers and suitable risk management measures to ultimately improve the status of European surface waters.

3.04.T-02 Large-Scale Chemical Monitoring of the Aquatic Environment: Perspectives From the Largest Global Study

John Wilkinson¹ and Alistair Boxall², (1)Environment and Geography, The University of York, York, United Kingdom, (2)University of York, United Kingdom

Significant knowledge gaps exist regarding the occurrence of Active Pharmaceutical Ingredients (APIs) in the environment, particularly regarding the socioeconomic indices potentially driving contamination. Available data focuses on a heavily studied set of relatively few APIs and studies often overlook potential toxicity/risk when presenting monitoring data. Here, we present new findings from the largest global study of APIs in the aquatic environment. Novel sample collection methodologies were used to characterise API contamination in >250 rivers of 104 countries of all continents, thus representing the pharmaceutical fingerprint of 471.4 million people. Of these countries, 36 had never been monitored previously for APIs. Duplicate grab samples were obtained from 1052 locations via 137 sampling campaigns using identical water collection/storage methodologies. All samples were sent frozen to the University of York and analysed for 61 APIs using a single validated analytical method. Globally, 53 of the 61 APIs were quantified. Highest concentrations were observed at locations associated with (a) inputs from pharmaceutical manufacturing, (b) untreated sewage, (c) arid climates and (d) sewage exhauster truck and municipal waste dumping. Available predicted no effect concentrations and critical environmental concentrations for the studied APIs indicate concentrations are typically lower than those that may elicit ecological effects. The exceptions were amitriptyline, citalopram, fexofenadine, ketotifen, loratadine, propranolol, sulfamethoxazole and verapamil. River concentrations exceeded safe effect levels for at least one API at 270 of 1052 study sites. Distance-based linear modelling indicates API concentrations were positively associated with population, median age, unemployment, and poverty rates (AICc=325.26, p=0.025, cumulative r²=0.241). Furthermore, multicollinearity analysis indicates the colinear indicators of the most significant socioeconomic factor associated with API contamination (population) included disability-adjusted life years attributable to the environment (r=0.95), real gross domestic product (r=0.74) and the amount of produced, collected and untreated municipal wastewater (r=0.66-0.69). As data availability and analytical techniques improve, novel monitoring approaches for emerging contaminants in the environment should include reference to both toxicity and socioeconomics to better understand where/how future monitoring may be most beneficial.

3.04.T-03 Pharmaceuticals in Sewage Sludge: Degradation Studies

EGGE Haiba¹, Lembit Nei² and Jane Raamets³, (1)Tartu College, Tallinn University of Technology, School of Engineering, Tartu, Estonia, (2)Tallinn University of Technology Tartu College, Tartu, Estonia, (3)Tallinn University of Technology, Estonia

Pharmaceutical residues are always present in sewage sludge and this is among major global problems. In recent years studies have been conducted with the aim of optimizing sewage sludge composting technologies directed to the efficient degradation of pharmaceutical residues present in this matter. Without reliable treatment, sewage sludge and its compost pose a threat to human health due to the presence of a large number of different persistent organic pollutants in these matters. Peat is widely used as a bulking agent in sewage sludge compost by wastewater treatment companies in Estonia. It is preferred due to peat's ability to provide better aeration in compost piles. Due to this phenomenon, the current work was devoted to finding ways of speeding up the sewage sludge composting process in the sewage sludge mixtures with peat. The degradation rate of the studied pharmaceuticals in these mixtures – diclofenac, triclosan, and carbamazepine – turned out to be poor or even negligible. This phenomenon was essential as the C/N ratio of the sewage sludge and peat mixture was only 10 at the beginning of the experiment, and during a 3-months period remained unchanged. It is known from previous studies that triclosan and especially carbamazepine are persistent during different sewage sludge treatments, but diclofenac does not suffer from this drawback. Peat affects the

microbial population by its antimicrobial properties. Based on the experiments performed, it can be concluded that the residues of pharmaceuticals did not affect the microbial population, but other factors like pH, macronutrient content, and C/N ratio were limiting the microbial communities' activity and biomass. Sawdust turned out to be the best bulking agent in the sewage sludge compost mixture, assuring a reasonable duration of the maturation period of compost and sufficient degradation level of several widely used pharmaceuticals. Still, some of the studied residues of pharmaceuticals, as for example carbamazepine, and also triclosan, did not show full degradation or even any degradation during different composting periods. It is of utmost importance to find ways of eliminating persistent organic pollutants from sewage sludge compost. The work should be continued in developing more efficient composting technologies. Both novel compost mixtures should be developed, and the fate of different pollutants should be studied.

3.04.T-04 Increasing Trends of Legacy and Emerging Organic Contaminants in a Dated Sediment Core From East-Africa

Maja Nipen¹, Rolf Vogt², Pernilla Bohlin-Nizzetto³, Katrine Borga⁴, Eliezer Mwakalapa⁵, Anders Borgen³, Martin Schlabach³, Guttorm Christensen⁶, Aviti Mmochi⁷ and Knut Breivik⁸, (1)MILK, NILU - Norwegian Institute for Air Research, Kjeller, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)NILU - Norwegian Institute for Air Research, Norway, (4)UiO, Norway, (5)Mbeya University of Science and Technology, Tanzania, (6)Akvaplan-niva, Norway, (7)Institute of Marine Sciences, Tanzania, (8)Norwegian Inst. for Air Research, Kjeller, Norway

Temporal trends in levels of industrial organic contaminants can reflect how environmental burdens respond to changes in production, regulation, and other anthropogenic and environmental factors. There are numerous studies documenting such trends from the Northern Hemisphere, while there is very limited data in the literature from sub-Saharan Africa, where growth in population and consumption has been high, and there is low capacity for environmentally sound waste and e-waste handling. We hypothesized that the temporal trends of legacy and contemporary industrial contaminants in sub-Saharan Africa differ greatly from the Northern regions in which many of these chemicals were initially produced and more extensively used. To investigate this, a dated sediment core covering six decades from a floodplain system in urban Dar es Salaam, Tanzania, was analysed. Layers of the sediment core were analysed for the persistent organic pollutants (POPs) polychlorinated biphenyls (PCBs) and polybrominated biphenyl ethers (PBDEs), and the chemicals of emerging concern (CECs) alternative brominated flame retardants (aBFRs), chlorinated paraffins (CPs), and dechloranes using gas chromatography-high resolution mass spectrometry. All groups of chemicals showed a steep increase in concentrations towards the uppermost sediment layers reflecting the more recent years. This trend was particularly notable for CPs and the aBFR decabromodiphenyl ethane (DBDPE). Concentrations of the individual compound groups in surface sediment were found in the order CPs >> aBFRs ~ PBDEs > dechloranes ~ PCBs. Time trends for the individual compounds and compound groups differed, with PCBs being present in sediments since at least the early 1960s, while DBDPE first occurred in sediments corresponding to the last decade. The POPs time trends corresponded to trends from other developing regions but diverged from Northern industrialized regions. For CECs, trends were generally consistent with both developing and industrialized regions. Investigations into potential drivers for the observed trends showed that socioeconomic factors related to growth in the Dar es Salaam population, economy, and waste generation have contributed to the increasing concentrations of PBDEs, aBFRs, CPs, and Dechlorane Plus. Given the notable increase in POPs and CECs, further monitoring of temporal trends of these industrial organic contaminants in urban areas in the Global South is recommended.

3.04.T-05 Human Impacts on the Contamination of Canadian Lakes

Lisa Lahens¹, Hubert Cabana², Yannick Huot² and Pedro Segura², (1)Chemistry, Universite de Sherbrooke, Sherbrooke, QC, Canada, (2)Université de Sherbrooke, Canada

Trace organic contaminants (TrOCs) are mostly studied in drinking waters, rivers, and wastewater, but data is lacking regarding their presence in lakes. For that reason, a multi-residue method was developed to quantify 51 TrOCs in lake water. This method was applied to evaluate the contamination of 295 lakes sampled across Canada in a stratified random design with ecozones, size, and human activities in their watersheds as strata. This includes many remote lakes with limited access. The purpose of this work was to fill the gap of knowledge on lakes' contamination in Canada and to highlight the factors influencing the spatial distribution of the various contaminants. The TrOCs analyzed in this study include regulated organic pollutants, such as pesticides, as well as contaminants of emerging concern, such as pharmaceuticals, personal care products and consumer products additives. The compounds were extracted by solid phase extraction (SPE) and analyzed using ultra performance liquid chromatography coupled to triple quadrupole mass spectrometry (UPLC-QqQMS). Detected concentrations spanned from 0.4 ng L⁻¹ to 18 µg L⁻¹ and 7 TrOCs from various sources had concentrations over 1 µg L⁻¹. The most frequently encountered compound was diethyltoluamide (DEET), and at least one contaminant was detected in 84% of the analysed lakes, with 41% having a total contaminant concentration over 100 ng L⁻¹. Preliminary study of the explanatory factors of occurrence of contaminants shows that some contaminants found in the samples were linked to the type of human activity on the watersheds. For example, pesticide detection, more specifically for 2,4-dichlorophenoxyacetic acid (2,4-D), was linked to agricultural land use, while pharmaceuticals and additives, such as carbamazepine and the anticorrosive 5-methyl-1H-benzotriazole, were observed mostly in urbanized watersheds. The concentration of contaminants was also linked to the extent of land use on the lakes' watersheds. For example, pesticide concentrations increased with the amount of agriculture around a lake. The results of this work represent the first reference point to monitor the evolution of the contamination of Canadian lakes by TrOCs and demonstrate that a high proportion of the sampled lakes show a significant anthropogenic chemical footprint. More specific factors are being examined to explain the occurrence of each contaminant class in lake water.

3.04 Advances in the detection, monitoring and fate of emerging contaminants in the environment (Part II)

3.04.T-06 Field-Based Distribution and Bioaccumulation Factors for Perfluoro-4-Ethylcyclohexanesulfonate (PFECHS) in a Sedentary Waterbird Population

Drew Szabo¹, Damien Moodie², Raoul Mulder³, Mark Green³ and Bradley Clarke³, (1)University of Melbourne, Melbourne, Victoria, Australia, Australia, (2)RMIT Uni., Melbourne, Australia, (3)University of Melbourne, Australia

The field-based distribution and bioaccumulation factor (BAF) for per- and polyfluoroalkyl substances (PFASs), including the novel cyclic perfluoro-4-ethylcyclohexanesulfonate (PFECHS, 67584-42-3; C₈HF₁₅SO₃), were determined in residential Black Swans (*Cygnus atratus*) from an urban lake (Melbourne, Australia). The concentrations of 46 PFASs were determined by HPLC-MS/MS in serum and excrement from swans, and water, sediment, aquatic macrophytes, soil and grass samples in and around the lake. Average concentrations of Σ_{46} PFASs were 120 ng mL⁻¹ in serum and 110 ng g⁻¹ dw in swan excrement, with environmental concentrations consistent with a highly impacted ecosystem. Elevated PFECHS concentrations were detected in water (27 ng L⁻¹) and serum (16 ng mL⁻¹). In the absence of credible putative alternative sources of PFECHS input to the lake, we propose that the use of high-performance vehicles are the most likely source of contamination to this ecosystem. The BAF of PFECHS was estimated as 593 L kg⁻¹, while the BAF of PFOS was 1100 L kg⁻¹. The BAF of perfluorocarboxylic acids increased with CF₂ moiety from PFOA (15.7 L kg⁻¹) to PFDoDA (2770 L kg⁻¹), indicating that further research is warranted for long-chain PFASs, especially in underrepresented lower trophic avian species. Residential species with limited ranges in urban environments, with greater levels of PFAS contamination, can serve as useful sites for the development of robust models for the transport and bioaccumulation pathways of PFASs and other novel compounds. This allows the generation of fundamental field-based BAF for novel compounds which is necessary for assessing risks posed to wildlife and is an approach that can be adopted throughout the world.

3.04.T-07 Quantification of Toxic Tire Degradant 6ppd-Quinone in Surface Waters

Tarun Anumol¹, Ralph Hindle² and Kathy Hunt², (1)Agilent Technologies, Inc., United States, (2)Vogon Labs, Canada

For decades, coho salmon in the North West of the US suffered from acute mortality when returning to spawn from the Pacific Ocean into Urban Surface Waters. The phenomena was unidentified and known as urban runoff mortality syndrome due to its association with surface runoffs. Recently, researchers from the University of Washington, identified the cause that is associated with chemicals leached from tires that gets into surface waters. Widely used tire-rubber stabilizer 6PPD (N-1,3-dimethylbutyl-N'-phenyl-p-phenylenediamine) degrades to form 6PPD-quinone, which is toxic to juvenile coho salmon and potentially toxic to other aquatic species when present even at low ug/L levels in water. Once this compound was identified with an LC-Q/TOF, there was an urgent need to quantify its presence in surface waters globally. This work describes a fast, direct-inject analytical method for the quantitation of 6PPD-quinone in surface water using liquid chromatography/triple quadrupole mass spectrometry (LC/TQ), including sample preparation, recovery, precision, stability, and reporting limit. Chromatographic resolution was found to be an important step to achieve sufficient retention and separation from possible interferences in some real-world samples. Further, Results from real-world samples collected in Canada and the United States obtained in this study indicate that samples in most urban areas have levels of 6PPD-Quinone close to the median lethal concentration for salmon calculated sub-ug/L level.

3.04.T-08 Environmental Monitoring of Selected Tire-Derived Organic Contaminants

Cassandra Johannessen¹ and Chris D. Metcalfe², (1)Chemistry, Trent University, Peterborough, ON, Canada, (2)School of the Environment, Trent University, Peterborough, ON, Canada

Runoff from highways is a vector for the transport of potentially toxic chemicals into surface waters. In this study, selected tire-derived chemicals were monitored in surface waters of rivers adjacent to two high traffic highways in the Greater Toronto Area in Ontario, Canada. Composite samples were collected from the Don River and Highland Creek in the GTA during 5 hydrological events that occurred in the period between early October 2019 and late March 2020, as well as an event in August 2020. Grab samples were collected from these rivers during a period of low flow in August 2020, as well as during a storm event in July of 2020. Analysis was performed using ultra-high pressure liquid chromatography with high resolution mass spectrometric detection (UHPLC-HRMS) using the Thermo Scientific Orbitrap Mass Spectrometer. Hexamethoxymethylmelamine (HMMM), a cross-linker of tire material, was detected at elevated concentrations (> 1 µg/L) during rain events and 15 of HMMM's transformation products were detected at a maximum summed concentration of 18 µg/L. Environmental samples were also analyzed for the tire additive, 6PPD, and its toxic oxidation by-product, 6PPD-quinone, as well as 1,3-diphenylguanidine (DPG). In many samples collected from the Don River and Highland Creek during storm events, the estimated concentrations of 6PPD-quinone exceeded the reported LC50 of 0.8 µg/L for Coho salmon exposed to this compound. Flush dynamics and temporal trends were established for each compound. Overall, this study contributes to the growing literature indicating that potentially toxic tire-wear compounds are transported via road runoff into urban surface waters.

3.04.T-09 A Rapid Screening Method for the detection of Additives in Electronics and Plastic Consumer Products

Maurice de Jonker¹, Pim Leonards², Marja Lamoree³ and Sicco Brandsma⁴, (1)Vrije Universiteit Amsterdam, Nederland, (2)Vrije Universiteit Amsterdam, Nederland, (3)VU University, Department Environment & Health, Netherlands, (4)E&H, VU University Amsterdam, Amsterdam, Netherlands

Plastics have become an intrinsic part of our society. Since the mass production of plastics has started, the annual world production increased to 314 million tonnes in 2014. Plastics are complex mixtures of polymers and unreactive toxic intermediates, monomers, and additives, such as pigments, dyes, fillers, antioxidants, flame retardants, UV stabilizers, surfactants, and plasticizers, all to improve or modify the performance of the product. Some additives leach during use, resulting in potential human and environmental hazards. Elevated levels of various toxic additives have been detected in house dust. Still, more research is needed to identify sources in order to understand indoor exposures and fate of these substances. In addition, recycling

may introduce these toxic additives into recycled products. These findings call for fast and improved analytical techniques to identify toxic additives in consumer products and recycled plastics to better understand indoor exposure and fate. Due to the complexity of plastics multiple extractions and cleanup steps are needed before analysis can be performed, which is laborious, costly, time-consuming, and unsuitable for high throughput. To address these limitations, we developed a fast screening method by coupling an atmospheric pressure matrix-assisted laser desorption/ionization (AP-MALDI) to high-resolution time-of-flight mass spectrometry (HR-TOF-MS). The AP-MALDI-TOF-MS method was applied to screen for additives in various electronics and plastic consumer products. Multiple additives including antioxidants, flame retardants, plasticizers, and UV filters have been identified. Identification of certain plastic additives in plastic children's toys may indicate that they are recycled from waste electronic and electronic equipment (WEEE).

3.04 Advances in the detection, monitoring and fate of emerging contaminants in the environment (Part III)

3.04.T-11 Suspect and Non-Target Screening of Organic Contaminants in Indoor Dust From Danish Kindergartens Using Gc-Orbitrap

Linyan Zhu¹, Patrik Fauser¹, Lone Mikkelsen², Hans Sanderson¹ and Katrin Vorkamp³, (1)Aarhus Universitet, Denmark, (2)Green Transition Denmark, Denmark, (3)Aarhus University, Denmark

Indoor dust can contain complex mixtures of hundreds of chemicals in varying concentrations. Some chemicals, such as bisphenols, phthalates, biocides, flame retardants, parabens, and poly- and perfluoroalkyl substances, have been shown to be potentially harmful. As most people spend more than 90% of their time in indoor environments, indoor dust is an important pathway for human exposure to contaminants, in particular for toddlers and infants. This study aimed to screen indoor dust from Danish kindergarten for multiple groups of contaminants, which are known to be potentially toxic, using target and suspect analysis. Furthermore, non-target analysis based on online libraries can identify further compounds not pre-selected as suspected contaminants. Dust samples were extracted using accelerated solvent extraction with a mixture of hexane and dichloromethane and cleaned on Florisil. The extracts were analyzed on gas chromatography (GC)-Orbitrap to obtain a full scan mass spectrum. The high-resolution mass spectra (HRMS) were first deconvoluted. The peaks from HRMS were picked up based on several criteria: mass error < 5 ppm, signal-noise ratio (S/N) > 10, TIC intensity > 1000, ion overlap window > 95% and sample/blank ratio > 10. An in-house suspect library for suspect screening was built up with a total of 53 chemicals. Non-target screening was performed to identify unknown compounds in the samples by matching the NIST library and MassBank libraries. Afterward, certain filters on the HRMS data were applied to identify phthalates, polycyclic aromatic hydrocarbons (PAHs), chlorinated or brominated compounds, and aromatic nitro compounds. Twenty-six known and suspected emerging contaminants were identified in 12 dust samples from Danish kindergartens using target and suspect analysis, including ten phthalate and non-phthalate plasticizers, four flame retardants, two bisphenols, three UV filters, four plastic additives, and three parabens. Notably, many banned or restricted emerging contaminants, such as Decabromodiphenyl ether (DecaBDE, BDE-209), ethyl hexyl phthalate (DEHP), Bisphenol (BPA), and parabens, were still frequently detected. Sixteen chemicals were tentatively identified using non-target screening, including four phthalate plasticizers, two organophosphate flame retardants, four polychlorinated biphenyls (PCBs), two fragrances. In addition, three contaminants with limited information were also detected, which will need further investigation.

3.04.T-12 Emerging Contaminants in Household Chicken Eggs and Soil Around Waste Disposal Sites in Tanzania

Ane Haarr¹, Eliezer Mwakalapa², Maja Nipen³, Aviti Mmochi⁴ and Katrine Borga⁵, (1)Department of Biosciences, University of Oslo, Oslo, Norway, (2)Mbeya University of Science and Technology, Tanzania, (3)MILK, NILU - Norwegian Institute for Air Research, Kjeller, Norway, (4)Institute of Marine Sciences, Tanzania, (5)UiO, Norway

Tanzania is experiencing rapid economic and population growth, expanding industry, and increasing import of consumer goods and potentially also waste. Limited capacity to safely manage an increasing stream of waste represents a challenge as a potential source to environmental contamination. In addition to industrial-use legacy contaminants such as PCBs and PBDEs, chlorinated paraffins and dechloranes are also associated with various consumer products and electronic waste (e-waste) and are expected to increase in developing regions. A recent study from Tanzania shows elevated levels of chlorinated paraffins (CPs) and dechloranes in air and soil samples collected in the vicinity of landfills and e-waste handling sites, as well as increasing temporal trends of both legacy and emerging contaminants. Not much is known regarding the occurrence of these high-production, emerging contaminants in African biota, their fate in the environment, and food-web dynamics. Diet is the main uptake route for contaminants in humans, especially intake of fatty foods such as animal meat and eggs. Household chickens can represent sentinel species for local contamination as they ingest a considerable amount of soil in addition to feed and household leftovers. In the present study, sampling of soil and eggs was conducted around historical and active landfills on mainland Tanzania and Zanzibar to investigate contamination from waste in general and e-waste in particular. We assess spatial variation in occurrence of chlorinated paraffins and dechloranes and the relationship between occurrence in soil and egg. Contaminant concentrations in eggs ranged from 0.3 to 8.2 ng/g lipid wt for dechloranes, < LOD – 1730 ng/g lw for SCCPs, and < LOD – 9700 ng/g lw for MCCP. Eggs from the reference location were not significantly lower compared to eggs from the landfill locations. However, concentrations of CPs and dechloranes were highest at the sampling sites in Dar es Salaam, suggesting different sources comparing Zanzibar and the Tanzanian mainland. Limited data exist for comparison of results, but high levels of chlorinated paraffins were found in eggs collected at a former e-waste recycling site in China, exceeding levels found in the present study with up to two orders of magnitude. This was as expected as China is a major producer and consumer of these contaminants. CP concentrations and congener patterns in egg and soil did not match, suggesting specific accumulation mechanisms.

3.04.T-13 Comprehensive Two-Dimensional Gas Chromatography-Time-Of-Flight Mass Spectrometry in Conjunction With Derivatisation for the Targeted and Non-Targeted Analysis of Contaminants of Emerging Concern in Wastewater

Jason Devers Mr¹, David Pattison², Asger Hansen² and Jan Christensen³, (1)Analytical Chemistry Group, PLEN, Univeristy of Copenhagen, Copenhagen, Denmark, (2)Univeristy of Copenhagen, Denmark, (3)University of Copenhagen, Denmark

Within the field of environmental analysis and wastewater analysis, contaminants of emerging concern, “chemicals that are currently not regulated, but may be under scrutiny for future regulation”¹, have experienced a recent surge in interest. Amongst these compounds, fractionated analysis of wastewater extracts has shown that polar compounds are the main carriers of the toxic effects of wastewater^{2,3}. While liquid chromatography remains the most common analytical platform for the analysis of more-polar compounds, gas chromatography (GC) fills the niche of non-polar to mid-polar compounds⁴. Supplementarily, derivatisation in the context of GC, allows for the conversion of more-polar analytes to non-polar derivatives, improving their amenability to GC analysis. In addition to benefits of higher separation efficiency, lower cost of operation, large availability of reference retention indices and mass spectra for compound identification⁴, the development of two-dimensional GC (GC×GC) has greatly extended the platform’s peak capacity separational capability for more-polar compounds, using both a non-polar and polar column in tandem⁵. Within this presentation, we will first discuss the development of an analytical method using GC×GC and sample derivatisation, illustrating the benefit over analysis without derivatisation and conventional one-dimensional gas chromatography. Following this, the application of the method to a large sample set of both effluent and influent wastewater samples will be discussed, characterizing both polar and non-polar contaminants, and temporal and spatial variation between samples. 1. 3.04.T-14 Identification of Precipitation-Related Pollution Patterns in a Large River by Non-Target Screening and Cluster Analysis

Liza-Marie Beckers¹ and Arne Wick², (1)Federal Institute of Hydrology - BfG, Koblenz, Germany, (2)German Federal Institute of Hydrology, Germany

Heavy rain events potentially lead to short-term, but extraordinary changes in the composition of mixtures of organic micropollutants (OMPs). While pollution dynamics during rain events have been studied at point sources and small rivers, less is known about the impact on OMPs mixtures in large rivers. By means of high-time resolved monitoring in combination with nontarget screening and multivariate methods, this study aimed at unravelling precipitation-related pollution patterns in large rivers and at identifying relevant sources and entry pathways relevant for rain-related pollution. Daily composite samples were collected by automatic samplers at three stations located along the German part of the Moselle River since April 2021. Based on precipitation and water level data, daily composite samples were selected for chemical analysis. Chemical analysis was performed by liquid chromatography coupled to a hybrid quadrupole time-of-flight mass spectrometer. Peak picking, alignment, blank correction and annotation of known OMPs was performed in an R based workflow including an extensive in-house spectral library. Cluster analysis on the resulting peak lists was performed using the R package ‘kmL’. Since April 2021 until November 2021, 35 rain events were selected for chemical analysis. In the daily composite samples following the extreme rain events on July 14th 2021 with a maximum amount of precipitation of 145.7 l/m³*d, the pollutant composition changed dramatically. This was reflected by three pollution patterns. By means of annotated OMPs and water level data, the individual patterns represented a) wastewater-related compounds diluted with increasing water level, b) features introduced via increased groundwater discharge and c) features likely related to direct surface runoff. While for the later, the maximum feature intensity correlated with the maximum discharge, the pattern related to groundwater input was characterized by a delay in maximum feature intensity relative to the maximum water level (i.e., kinematic wave effect). The study confirmed that rain events can also have an effect on the composition of OMPs mixtures in large rivers. To gain a deeper understanding on the dynamics and sources behind the occurrence of these patterns in large rivers, monitoring is continued and the patterns are currently further characterized, i.e., by identification of functional groups and halogenated compounds, to prioritize unknown features for identification.

3.04.T-15 Impact of a Megacity on a Tropical Estuary Assessed With a Combination of Chemical Analysis and In Vitro bioAssays

Romane Luce Caracciolo¹, Beate Escher², Foon Yin Lai³, Truong An Nguyen⁴, Thi Minh Tam Le⁵, Rita Schlichting⁶, Maria Koenig⁶, Rikard Tröger³, Julien Némery⁴, Karin Wiberg⁷, Phuoc Dan Nguyen⁵ and Christine Baduel⁸, (1)Université Grenoble Alpes, France, (2)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (3)Swedish University of Agricultural Sciences (SLU), Sweden, (4)Institute of Engineering and Management Univ. Grenoble Alpes (Grenoble-INP), France, (5)Asian center for water research (CARE), Ho Chi Minh City University of Technology, Vietnam, (6)Helmholtz Centre for Environmental Research – UFZ, Germany, (7)Swedish University of Agricultural Sciences, Sweden, (8)CNRS IGE UMR 5001, Univ. Grenoble, France

Contaminants of Emerging Concern (CECs) are a broad range of non-regulated chemicals including pharmaceuticals and personal care products (PPCPs), plasticizers, flame retardants, etc. Even though they are considered at risk for human and environmental health, there is still an important data gap on their occurrence and fate in tropical environments and under high anthropic pressure. This study aims to assess the occurrence and spatial distribution of CECs in surface water along a tropical estuary impacted by a megacity. 26 grab samples (500 mL) were collected in duplicates on a total length of 140 km - integrating the full continuum of

the Saigon River from upstream the megacity of Ho Chi Minh (9.2 million inhabitants) to the estuary mouth in the East Sea - during the dry season of March 2020. Four additional duplicate samples were collected in the main urban canals. Quantitative chemical analysis was performed using isotope dilution high performance liquid chromatography - tandem mass spectrometry (LC-MS/MS) and targeting 259 CECs (PPCPs, pesticides, flame retardants, plasticizers - among others). In addition, six *in vitro* bioassays (Er², PR, GR and PPAR α GeneBLAzer, AhR CALUX and AREc32 gene reporter assay) were conducted to capture the effects of all the active chemicals present in the samples. Finally, iceberg modelling was carried out to link the biological equivalent concentrations (BEQs) measured in both chemical and toxicity analyses. The highest quantification frequencies and total concentrations were measured in the city center and the urban canals, reaching a maximum of 2.5 $\mu\text{g/L}$ in the river and up to 100 $\mu\text{g/L}$ in an urban canal (*Bên Nghé* canal). An attenuation was observed towards the estuary: 50 chemicals were quantified in the river mouth accounting for a total of 100 ng/L. Diverse spatial trends were underscored along the continuum for the different chemical groups (PPCPs, industrial products, pesticides) highlighting the different and complex chemical mixtures that can occur in such system. Furthermore, the activation of specific effects of the reporter gene bioassays was partly masked by the cytotoxicity burst phenomenon. No general spatial tendency was observed along the river except for the urban canals which displayed high estrogenic activity, with BEQs exceeding the effect-based trigger (EBT), and high cytotoxicity.

3.04 Advances in the detection, monitoring and fate of emerging contaminants in the environment (Part IV)

3.04.T-16 In Vitro Bioassay Monitoring in Receiving Aquatic Environments Prior to Potential Discharge of Treated Oil Sands Process-Affected WATER

Kia Barrow¹, **Maricor Jane Arlos**² and **Keegan Hicks**³, (1)Civil & Environmental Engineering, University of Alberta, Edmonton, AB, Canada, (2)University of Alberta, Edmonton, AB, Canada, (3)Alberta Environment and Parks, Canada

As a part of the Alberta oil sands operations, there is a zero-discharge policy for oil sands process-affected water (OSPW which means that OSPW is currently stored in tailing ponds. However, with recent developments to discharge treated OSPW into regional waterbodies, several treatment technologies are underway to sufficiently remove OSPW-derived contaminants, including *naphthenic acids*, metals, polycyclic aromatic compounds, and petroleum hydrocarbons. Hence, there is a need to assess the *potential ecotoxicological impacts* of treated OSPW in the receiving aquatic environment. For a comprehensive assessment of the cell toxicity pathways of a mixture, *in vitro* bioassays are bioanalytical effect-based monitoring tools, which complement chemical analysis in water quality assessment. In this study, the chosen toxicity pathways for OSPW-derived contaminants are (1) non-specific toxicity: *cytotoxicity*; (2) specific toxicity: *activation of xenobiotic metabolism endpoints (peroxisome proliferator-activated receptor-gamma and aryl hydrocarbon receptor) and activation of endocrine estrogen receptor*; and (3) reactive modes of action: *genotoxicity and mutagenicity*. The main goal of this study will employ *in vitro* bioassays to develop a *baseline of the biological activity in the Lower Athabasca River* (Alberta, Canada) where the treated OSPW will be discharged. Additionally, this study will compare the relevant toxicity pathways associated with OSPW and municipal wastewater treatment plants whose effluents are discharged into the same river. These results will open opportunities for future evaluations of the biological conditions in the Athabasca River to compare the conditions before and after potential discharges, and to detect the long-term exposure effects.

3.04.T-17 WATERSCAN: WATER Pollution Warning System Combining bioAssays on Passive Sampling Extracts and Real Time Mixture Toxicity detection

Roberta Carafa¹, **Jordi Sierra**², **Nora Exposito Lorenzo**³, **Teresa Lettieri**⁴, **Montserrat Real**¹, **Mechthild Schmitt-Jansen**⁵ and **Marta Schuhmacher**⁶, (1)AECOM, Spain, (2)Universitat Rovira i Virgili, Spain, (3)University Rovira i Virgili, Spain, (4)European Commission - Joint Research Centre, Italy, (5)UFZ - Helmholtz Ctre Environm. Research, Germany, (6)Rovira i Virgili University, Spain

There is no doubt that human activity depends on water quality and availability. Despite the efforts made in the last decades for the implementation of the Water Framework Directive, water pollution is still a main cause of water quality deterioration. The traditional monitoring, based on grab samples, is not economically affordable and interest is rising in effect-based methods. Bioassays and biosensors can determine biological responses caused by complex mixtures by measuring their combined effects. The aim of WATERSCAN project is: 1. To bring to the market an already patented biofilm-based sensor that provides detection of mixture toxicity in water, real time measures and good sensitivity. 2. To test a panel of standard bioassays exposed to environmental toxic mixtures. Calibration of the PAM sensor was performed with biofilm exposed (acute and chronic exposure) to a mixture of selected heavy metals, pesticide and pharmaceuticals based on most detected and impacting compounds in European WWTP: the bio-sensor was very sensitive as YII depression was measured at environmental concentrations; biofilm growth is affected only at very high exposure rates. The prototype, protected by a granted patent, has been tested in field, first results indicate that the device can work with minimal maintenance maintaining a high level of sensitivity and a constant water flow during several days. More field tests are needed to confirm its efficiency in detecting contamination events and to better calibrate the device.

3.04.T-18 Investigating Atmospheric Sources of Organic Contaminants to the Habitats of the Saint Lawrence Beluga Whales and Southern Resident Killer Whales in Canada

Faqiang Zhan¹, **Yuening Li**¹, **Chubashini Shunthirasingham**², **Ying Duan Lei**³, **Zhe Lu**⁴, **Abigaëlle Dalpé**⁴, **Nick Alexandrou**², **Chunwen Weng**⁵, **Kelsey Lee**⁶, **Frank Gobas**⁶, **Hayley Hung**⁷ and **Frank Wania**⁸, (1)Department of Physical and Environmental Sciences, University of Toronto, Scarborough, Toronto, ON, Canada, (2)Environment and Climate Change Canada, Canada, (3)University of Toronto, Canada, (4)Université du Québec À Rimouski, Canada, (5)University of Toronto, Scarborough,

Canada, (6)Simon Fraser University, Canada, (7)Air Quality Processes Research Section, Environment and Climate Change Canada, Toronto, ON, Canada, (8)University of Toronto Scarborough, Toronto, ON, Canada

Contaminants have been identified as one of the main threats to many marine mammals, including two of the most endangered cetacean populations in Canada, the St. Lawrence Estuary beluga whales (*Delphinapterus leucas*) and Southern Resident killer whales (*Orcinus orca*). This study seeks to identify atmospheric sources of organic contaminants to their critical habitats in the St. Lawrence estuary (Quebec, QC) and Southern Salish Sea region (British Columbia, BC). A network of passive air samplers (PASs) was established to investigate the magnitude and spatial variability in the concentrations of numerous organic contaminants in the regional atmosphere and to identify potential sources. PASs were deployed at ~50 sites in each of the two regions for a period of 5 to 9 months during 2020. Extracts were analyzed for polychlorinated biphenyls (PCBs), halogenated flame retardants (HFRs), neutral poly- and per-fluoroalkyl substances, other halogenated compounds including organochlorine pesticides and natural halogenated substances, polycyclic aromatic hydrocarbons (PAHs) and alkylated PAHs, and organophosphate esters (OPEs). Multivariate statistics were applied to a data set of sequestered amounts in units of ng sampler⁻¹ day⁻¹ to explore differences and similarities between sampling sites and between compounds. The analysis identified groups of sites with similar organic contaminant signatures. For example, the concentrations of OPEs, HFRs and PCBs were elevated at most sites along the Montreal-Quebec City corridor and in the Vancouver area, consistent with a relatively high population density and industrial history of these areas. Distinct from this “urban” signature, elevated levels of PAHs and alkyl-PAHs were found at sites near oil refineries and fuel storage depots, e.g. in Levis and Trois-Rivières in QC, and Burnaby and Port Moody in BC, but also at some remote sites in BC, for which natural sources such as forest fires might be expected. A “marine” signature, with generally low levels but elevated concentrations of γ -hexachlorocyclohexane and some natural halogenated compounds (e.g. tribromoanisole) was noted at Saturna Island, BC and at sites along the outer St. Lawrence estuary, especially on the south shore. This pattern is consistent with seawater as a source of contaminants to the atmosphere. Urban, petrochemical and marine contaminant signatures appear to be quite universal across Canada and possibly beyond.

3.04.T-19 Developing a Rapid High Throughput Test to Detect Biodegradation of Environmentally Relevant Chemicals

Katie Endersby¹, Lijiang Song², Hendrik Schaefer², Jason Snape³ and Gary Bending², (1)School of Life Sciences, University of Warwick, Coventry, United Kingdom, (2)University of Warwick, United Kingdom, (3)AstraZeneca, United Kingdom

Pharmaceuticals are present in the aquatic environment as a consequence of their use by society, and their effects on the biota present are of growing concern. Determination of the persistence of these pharmaceutical chemicals in aquatic systems is crucial, with standardised OECD tests, including OECD tests 301 and 309 in place to assess this. However, these tests are low throughput, do not characterise the microbial inocula, and their stringent standardisation does not always accurately reflect real, variable environmental conditions, such as temperature. We developed a high-throughput, replicable method of measuring chemical biodegradation, using inocula concentrated by tangential flow filtration and microcentrifugation, to overcome the biodegradation lottery seen in degradation studies using environmental samples with low microbial biomass. This methodology was utilised in a year-long assay, which assessed the microbial cell number, microbial cell viability, time to 50% degradation (DT₅₀) of *p*-Nitrophenol and Q10, at five timepoints. Results show that the degradation rate of *p*-Nitrophenol showed less variability, a smaller DT₅₀ (P < 0.0001), and lower Q10 (P = 0.0368) with concentrated samples, compared to un-concentrated samples. This demonstrates that microbial cell number and incubation temperature exert significant impacts on the outcomes of biodegradation and persistence tests, with the methodologies established allowing for subsequent testing on multiple environmentally relevant pharmaceutical chemicals.

3.04 Advances in the detection, monitoring and fate of emerging contaminants in the environment (Virtual Only)

3.04.V-01 A Multiresidue GC-MS Method for the Enantiomeric Determination of Psychoactive Substances in Effluents and Surface Waters

Ivan Langa¹, Maria Tiritan², Diana Silva³ and Cláudia Ribeiro⁴, (1)CESPU/IUCS/TOXRUN, Portugal, (2)TOXRUN – IUCS, CESPU; CHIMAR; LQOF - FFUP, Portugal, (3)FFUP, Portugal, (4)Pharmaceutical Sciences, CESPU/IUCS/TOXRUN, Paredes, Portugal

The consumption of psychoactive substances (PAS) has increased worldwide, and current wastewater treatment processes are not able to eliminate them [1,2]. Consequently, these substances have emerged as a new class of environmental pollutants. Many PAS are chiral and available either as racemate or pure enantiomers. Determination of their enantiomeric fraction (EF) and/or metabolites in surface waters is crucial for environmental risk assessment and allow discrimination between consumption, direct disposal, and synthesis pathways [3]. Therefore, the aim of this study was to develop an indirect method by gas chromatography coupled to mass spectrometry based on derivatization using (*R*)-(?)-?-methoxy-?(trifluoromethyl) phenylacetyl chloride as chiral derivatization reagent, for enantiomeric quantification of eight PAS including amphetamine (AMP), methamphetamine (MAMP), 3,4-methylenedioxymethamphetamine (MDMA), norketamine (NK), buphedrone (BPD), butylone (BTL), 3,4-dimethylmethcathinone (3,4-DMMC), 3-methylmethcathinone (3-MMC), and quantification of two piperazines: 1-benzylpiperazine (1-BP) and 1-(4-methoxyphenyl)-piperazine (1,4-MPP) [4]. The method was used to evaluate the occurrence, spatial distribution, and the EF of the target PAS in Portuguese surface waters in the Great Porto region and in effluents from 2 wastewater treatment plants. Regarding surface waters, both enantiomers of AMP, and only one enantiomer of MAMP, MDMA and BPD were found although below the limit of quantification (LOQ). Effluents samples showed only one enantiomer of AMP, BPD, 3,4-DMMC and both enantiomers of MDMA though at concentrations < LOQ. MAMP was also detected in both WWTPs in range of < LOQ - 57.30 ng L⁻¹ with enantiomeric fraction (EF) ?1. This is the first multiresidue analytical method by CG-MS enrolling cathinones, amphetamines, and piperazines. The presence of illicit synthetic cathinones in Douro River estuary was

reported for the first time, along with other amphetamine derivatives showing the potential of the method to monitor the target PAS [4]. Acknowledgments: This work was supported by National Funds through the Portuguese Science Foundation, FCT, I.P., project PTDC/CTA-AMB/6686/2020.

3.04.V-02 Concentrations of Organic Contaminants in Bio-Based Fertilizer Treated Soil

Supta Das¹, Rick Helmus², Yan Dong³, Steven Beijer⁴, Chris Slootweg⁴, Antonia Praetorius⁵, John Parsons⁶ and Boris Jansen², (1)University of Amsterdam/IBED Institute, Amsterdam, Netherlands, (2)University of Amsterdam/Institute for Biodiversity and Ecosystem Dynamics (IBED), Netherlands, (3)University of Amsterdam/Institute for Biodiversity & Ecosystem Dynamics (IBED), Netherlands, (4)University of Amsterdam, Netherlands, (5)University of Amsterdam/IBED Institute, Netherlands, (6)IBED, University of Amsterdam, Amsterdam, Netherlands

The use of bio-based fertilizer (BBF) for agricultural soil treatment can reduce the dependency on chemical fertilizer and improve sustainability by recycling nutrient-rich side-streams. However, the presence of organic contaminants in BBFs may lead to the occurrence of residues in the treated soil. Thus, the objectives of this study are to measure organic contaminants concentration and evaluate the ecological risk of BBFs application in agricultural soil. Measuring a wide range of organic contaminants using a single workflow is difficult due to the complex nature of the pollutants and the complexity of the environmental matrices. In this work, first, we optimized a simple QuEChERS-based extraction and liquid chromatography quadrupole time of flight mass spectrometry (LC-qToF) method for the simultaneous quantitative analysis of a wide range of organic contaminants, including pesticides, pharmaceuticals and per- and polyfluoroalkyl substances (PFAS) in agricultural soil. The optimized workflow was then applied to screen organic contaminants in two agricultural soils treated with BBFs. The QuEChERS technique, optimized for the determination of a wide range of organic contaminants, showed satisfactory recovery for most targeted compounds. Several contaminants were detected in soil samples treated with BBFs. In all soil samples, a further suspect screening will be performed for pollutants, such as pharmaceuticals and PFAS and the risk of different BBFs treatment will be evaluated.

3.04.V-03 Occurrence and Temperature Dependence of Atmospheric Gas-Phase Semi-Volatile Organic Pollutants in Remote High-Mountains (Pyrenees)

Raimon Prats¹, Barend Leendert van Drooge Sr², Pilar Fernández³ and Prof. Joan Grimalt⁴, (1)Environmental Chemistry, Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Barcelona, Spain, (2)Environmental Chemistry, IDAEA-CSIC, Barcelona, Spain, (3)Institute of Environmental Assessment and Water Research IDAEA CSIC, Spain, (4)IDAEA-CSIC, Spain

Effects of global diffuse pollution caused by Persistent Organic Pollutants (POPs) have been observed in fish from remote high-mountain lakes through mRNA measurements that showed feminization effects and oxidative stress. Here, polyurethane foam passive air samplers (PUF-PAS) were used for the study of the occurrence and distribution of organophosphate esters (OPE), organochlorine compounds, and polycyclic aromatic hydrocarbons (PAH) in six high-mountain sites along an altitudinal gradient in the Catalan Pyrenees (1,619–2,453 m) between 2017 and 2020. The PUF-PAS were extracted by Soxhlet using hexane, cleaned up and fractionated by high-performance liquid chromatography (HPLC), and analysed by gas chromatography coupled to mass spectrometry (GC-MS) and tandem mass spectrometry (GC-MS/MS). Experimental and estimated expanded theoretical sampling rate uncertainties were generally below 15%, indicating an adequate precision of the PRC calibration of the PUF-PASs. Extreme wind speeds (up to 130 km h⁻¹) and particle infiltration efficiency (16–23%) had limited impact for the sampler configuration used, and PAS-derived concentrations agreed with AAS samples. Atmospheric gas-phase PAH concentrations ranged between 409 ± 208 and 764 ± 201 pg m⁻³, dominated by phenanthrene (49%) and fluorene (41%). PCBs were between 10 ± 3 and 18 ± 3 pg m⁻³, and relative congener compositions were 12–20% except for PCB180 (3%). OPEs were between 16 ± 9 and 53 ± 32 pg m⁻³, dominated by tris(1-chloro-2-propyl) phosphate (TCIPP, 46%). Mean hexachlorobenzene and pentachlorobenzene concentrations ranged from 17 to 90 pg m⁻³, and from 5.3 to 69 pg m⁻³, respectively. Statistically significant increases in gas-phase concentrations with temperature were observed for more than half of the studied compounds. Phase-change enthalpies (ΔH_{AS}, KJ mol⁻¹) estimated from temperature regressions were not significantly different from laboratory-estimated values for all OPEs, benz[a]anthracene, and PCB180. This indicates a dominance secondary sources and evaporation from surfaces that reflects the less volatile nature of OPEs and high molecular mass pollutants. Snowmelt was suggested as a possible main factor driving the increase of OPE gas-phase concentrations in warmer periods. Contrarily, most lighter PAHs and PCBs showed significantly lower ΔH_{AS} that point at a larger influence of advection of air masses, with differences that increased with their volatility.

3.04.V-04 Seasonal Trends of Emerging Contaminant in Water and Sediments From WWTPs in Saskatchewan

Ana Cardenas Perez, University of Saskatchewan, Saskatoon, SK, Canada

Emerging contaminants such as pharmaceutical drugs have been detected in waters across the globe. Most pharmaceuticals are found at trace concentrations, but the continuous use and potential accumulation of some of these compounds can lead to potential effects in aquatic organisms due to their continuous-release, high biological efficacy, and possible accumulation in aquatic organisms. Wastewater treatment plants (WWTPs) are not designed to remove pharmaceuticals, so these compounds are virtually unattained before the treated water is discharged. Consequently, management of WWTPs plays a key role in the removal and monitoring of pharmaceutical products with challenges related to the polar nature of these chemicals that facilitate their presence in different environmental compartments. Pharmaceutical concentrations can be affected by temporal variations, the flow velocity of water receptors, the sorption capacity of sediments, and other abiotic dynamics in aquatic ecosystems. Currently, most experimental approaches have not considered these dynamics to evaluate the chemical activity, bioavailability, and toxicity of pharmaceuticals. The principal aim of this research is to enhance our understanding of the environmental risks associated with pharmaceuticals as one group of emerging contaminants. To this end, the presence of a suite of representative pharmaceuticals

was measured upstream and downstream of two WWTPs located in the South Saskatchewan River basin and Wascana Creek, Saskatchewan, Canada, during three sampling campaigns (spring, summer, and fall of 2021), through both conventional and passive water sampling. According to the chemical analysis conducted, Amitriptyline with a concentration of 3.35 µg/L was the most abundant compound in comparison to the other pharmaceuticals evaluated in the water and sediment samples at the four sampling sites and across the three seasons. Generally, concentrations of analytes were higher downstream of WWTPs compared to upstream sites. The data collected from this monitoring campaign indicates widespread contamination with psychoactive pharmaceuticals, which can have marked impacts on exposed organisms.

3.04.V-06 The Effect of Sample Degradation During Long Batch Acquisitions With Non-Target Analysis

Bastian Schulze¹, Amy Heffernan², Saer Samanipour³, Kevin Thomas⁴ and Sarit Kaserzon⁵, (1)QAEHS - The University of Queensland, Australia, (2)Eurofins Environment Testing Australia & New Zealand, Australia, (3)University of Amsterdam, Nederland, (4)The University of Queensland, Australia, (5)University of Queensland, Australia

Non-target analysis (NTA) is gaining popularity as a comprehensive tool for analysis of chemicals of concern in various matrices. One possible way to use NTA in environmental monitoring is by comparing several samples, looking for differences in their compound composition (i.e. their fingerprint), due to spatial or temporal trends. These observed differences can then inform more specific analysis, like target and suspect analysis. However, depending on the matrix and compounds of interest, degradation and transformation may take place, changing the composition of the sample. Historically, this has been researched in the context of target analysis for specific compounds. However, the full effect on NTA is not known. Degradation and / or transformation may start the moment a sample is taken and can only be slowed down by appropriate storing conditions. Usually this includes temperatures of -20 or -80 °C, however samples cannot always be immediately stored or kept at these temperatures during shipping and normal lab activities. Additionally, often not considered is the waiting time of samples in the autosampler, before injection into the instrument for chromatography. Depending on the number of samples and runtime of the chromatographic method, the time between the first and last sample injection can be up to several days. If these samples are then to be compared, wrong conclusions might be made based on degradation/transformation instead of the actual differences between the samples at the time of sampling. Our aim for this study was thus to investigate how much the composition of a wastewater sample changes within normal lab timeframes. For this we obtained a fresh wastewater sample and started data acquisition with liquid chromatography – high resolution mass spectrometry (LC-HRMS) within an hour after sampling. The sample was then rerun for 24 hours, collecting 48 datapoints. Additionally, parts of the sample were left at room temperature, in the fridge and the freezer and measured daily over the following week. Results show the decrease of the intensity of some compounds over time, while others increase in intensity or have been formed as part of the degradation process. These findings will have implications for the use of NTA when conducting temporal / spatial assessments and recommendations to acknowledge or minimise these effects are discussed.

3.04.V-07 The Effect of Toxic Elements on Antioxidants Glutathione S Transferase and Diphosphotriphosphodiaphorase of Freshwater Snail *Helisoma Duryi*: A CASE Study on a Coal Mining Area

Joanna Change¹, Andrew Siwela² and Norah Basopo³, (1)Applied Biology and biochemistry, National University of Science and Technology, Bulawayo, Zimbabwe, (2)National University of Science and Technology, Zimbabwe, (3)Applied Biology and Biochemistry, National University of Science & Technology, Bulawayo, Zimbabwe

Coal mining is destructive by nature and produces large volumes of waste. The excavation processes bring many minerals to the surface exposing them to the weather elements such as wind, humidity and precipitation. The combination of the exposed minerals and the large quantities of water used during mining results in contamination of water bodies. The contaminants accumulate in the environment and end up in the food chain and this ultimately affects human health. The aim of the present study was to assess the impact of toxic elements emanating from coal mining activities in aquatic bodies in the vicinity of a coal mine. Water samples were collected during the wet season from 6 different sites in a coal mining area in Zimbabwe. Water samples were prepared and analysed to determine the concentration of copper, lead, zinc and cadmium. Snails were exposed to sampled water over a duration of 28 days with snails collected at 7 day intervals to determine the time dependent effects of effluent from mining activities on selected biomarkers of *Helisoma duryi*. Post mitochondrial fractions were prepared from exposed snails and used to determine glutathione s-transferase (GST) and diphosphotriphosphodiaphorase (DTD) enzyme activities. Water samples had high Zinc values of 525 ± 2.63 mg/l and 540 ± 4.86 mg/l for two sites. Inhibitions of GST and DTD enzyme activities were observed in the study for the majority of the sites. Overall, this study showed that there is a need for constant monitoring of water bodies in coal mining areas to safeguard the health of aquatic life from adverse effects of effluent from coal mining activities.

3.04 Advances in the detection, monitoring and fate of emerging contaminants in the environment (Poster)

3.04.P-Tu076 Automated Methods for Monitoring the Chemical Surface Water Quality of the River Rhine

Julia Kirchner¹, Julia Arndt², Alexander Zavarsky², Ingrid Nett², Michael Schluesener², Anna-Lena Gerloff², Kevin Jewell², Lars Duester² and Arne Wick², (1)German Federal Institute of Hydrology, Koblenz, Germany, (2)German Federal Institute of Hydrology, Germany

A good chemical status of surface water bodies is fundamental for protecting aquatic communities and drinking water resources. This is expected to become even more important owing to progressing climate change and thus more frequent times of water shortage and the need for water re-use. However, the chemical status cannot be described adequately using those monitoring routines that are currently applied. Sampling campaigns are usually performed with large time intervals and the subsequent analysis and data evaluation are completed with delay. As a consequence, it is likely that event-related or occasional pollution

inputs are not recorded and protective measures cannot be initiated. We address this issue and are constructing an experimental monitoring station in Koblenz (Germany) at the river Rhine. Via automatization it provides high-resolution data in near real-time. Different analytical instruments are already installed ranging from relatively simple sensor-based technologies to more complex mass spectrometry systems. To enable a continuous operation, water is pumped from the Rhine into the station and distributed to the different instruments with or without prior filtration. Several basic water parameters, nutrients and anions can be successfully analyzed via sensors or by ion exchange chromatography. Nutrient analyses via colorimetric methods currently run in test mode. Main and trace elements will be measured via inductively coupled plasma mass spectrometry and a liquid chromatography time-of-flight mass spectrometer is available for non-target screening of organic substances. Both mass spectrometry systems are currently being modified to allow continuous measurements. Non-target analysis is not limited to specific target substances but enables the analysis of all compounds that can be effectively separated and detected by the applied chromatographic method and mass spectrometer, respectively. Especially the evaluation of non-target data is challenging and will be performed by coupling and automation of already existing, in-house-developed routines for data processing, annotation of substances and prioritization of unknown signals. We present the current status of the monitoring station and identify optimal sampling intervals for several parameters, where concentration peaks in the time-series are captured but the number of samples to be analyzed is minimized.

3.04.P-Tu077 Oceanic Transport of Pharmaceuticals From Northern Europe to the High Arctic

Ida Beathe Overjordet¹, Konstantinos Kotzakoulakis¹, Ingrid Ellingsen¹, Sławomir Kwaśniewski², Dominika Walecka³, Filip Spiralski⁴, Magda Caban⁴, Antonio Sarno¹, Roland Kallenborn⁵, Mari Creese¹, Trond Nordtug⁶, Lisbet Sørensen¹, Katarzyna Smolarz⁴ and Adam Sokółowski⁴, (1)SINTEF Ocean, Norway, (2)IO PAS, Poland, (3)University of Gdansk, Norway, (4)University of Gdansk, Poland, (5)Norwegian University of Life Sciences, Norway, (6)SINTEF Materials & Chemistry, Norway

Pharmaceuticals are used in large numbers across Europe which has raised concern about their impacts in marine ecosystems. Although many pharmaceuticals undergo degradation and removal in sewage treatment systems, some compounds are released to the environment where they may persist over time. Information about the concentrations of pharmaceuticals in major rivers ending in the North Sea and the Baltic Sea has been gathered and used to estimate the annual release to the marine environment of northern Europe. The potential for oceanic transport of pharmaceuticals northwards to the European Arctic has been simulated using oceanographic models. Based on these data a transect of ten sampling stations were selected starting in the North Sea and ending in at the west coast of Spitsbergen. Sampling of large volumes of water and zooplankton was performed in water masses representing the coastal systems and open sea system of the north Atlantic currents along the transect. Pharmaceuticals were directly extracted from seawater using custom made solid phase extraction columns onboard the research vessel "Oceania". The water was sampled either from sea surface (approx. 2 m, 800 L) on sections during steaming using the ship's online sampling system or from two depths (surface and 50 m, 400 L each) at stations using Niskin water bottle. Zooplankton was collected using WP-2 180 µm mesh plankton net, collecting two types of samples, mass sample for pharmaceuticals and faunistic samples for zooplankton composition and vertical distribution in the epipelagial. Oceanographic data was recorded at each sampling station. We will present the initial simulations of pharmaceutical releases and oceanic transport as well as the pharmaceutical concentrations found in seawater and zooplankton in the marine system studied.

3.04.P-Tu078 Degradation of Micropollutants by Gamma Irradiation: Insight of By-Product Formation Explored by Suspect and Non-Target Screening Using Lc-Hrms

Heewon Jang¹ and Junho Jeon², (1)University, Korea, South, (2)Changwon National University, Korea, South

Incomplete removal of micropollutants remains a challenge for wastewater treatment processes. As an alternative, a decomposition process using gamma irradiation has been proposed. The aim of the study was to get insight into the degradation of micropollutants in water using gamma irradiation, the by-product formations identified by suspect/non-target screening based on LC-HRMS and the environmental risks of the by-products by the QSAR estimations for bioaccumulation, biodegradability and toxicity. Carbamazepine (CBZ), cetirizine (CTZ) and tramadol (TRM), showing the highest exposure levels and detection frequency in Korean rivers, were selected as the test compounds. The gamma irradiation was conducted with a total of 7 steps (0.1, 0.2, 0.3, 0.4, 0.5, 1, 5) kGy of absorbed dose. As a result, all three compounds showed about 50% removal rate at absorbed dose of 1 kGy or less, but 100 % removal rate at absorbed dose of 5 kGy. In total, 23 by-products were identified from parent compounds via suspect/non-target screening. Among them, CBZ-BP271A, CBZ-EP and CBZ-OX were confirmed with reference standard. Other substances were tentatively identified through comparison of MS/MS fragment with library (eg., mzCloud, massBank) or interpretation of MS/MS spectra. By-products were mainly formed through hydroxylation, dehydration, and dealkylation reactions. Based on the identifications the degradation pathway of the by-products was proposed. Through the estimation for the properties, it is expected that most by-products have lower risk in the environment than their parent compound. It indicates that the gamma irradiation can be an alternative tool to eliminate hardly degradable pollutants in conventional WWTP.

3.04.P-Tu079 The Pollution of Yesterday: Historic Landfills As Potential Sources of Aquatic Contaminants Across Scotland

John Wilkinson¹ and Alistair Boxall², (1)Environment and Geography, The University of York, York, United Kingdom, (2)University of York, United Kingdom

Until recently, landfilling was the major disposal route for anthropogenic waste in the UK. While emissions from newer landfill sites are controlled, legacy landfills may be an important source of contaminants, including Active Pharmaceutical Ingredients (APIs) and other Emerging Contaminants (ECs), in the environment. However, few monitoring data are available on emissions from these sites and the potential effects on ecosystems. In Scotland, the potential impact of such facilities on the surrounding environment may be most significant in areas where historic landfills are located (e.g., un-lined/capped facilities created before

the Pollution Control Act of 1974). Using Scottish Environmental Protection Agency waste site and capacity data, contaminated land registries and the knowledge of local community groups, a source mapping exercise took place for two regions of Scotland. A total of 81 potential historic and 8 current landfills were identified within 3 km of the coastline or a river in the greater Forth of Forth catchment and within Aberdeenshire and Moray. Water sampling locations (n=46) were selected along rivers potentially affected by the landfill locations as well as other potential sources of APIs/ECs. Duplicate grab water samples were obtained monthly for 1 year across the Forth catchment and for 6 months in Aberdeenshire/Moray (n=912 total samples). Targeted analysis occurred for 70 APIs and ECs using high performance liquid chromatography tandem mass spectrometry generating 63,840 contaminant determinations. Data analysis is ongoing but results to date show that compounds occurring at highest concentrations include the APIs paracetamol (max of 5890ng/L), carbamazepine (2300ng/L), gabapentin (1840ng/L) and metformin (1060ng/L), the lifestyle chemical caffeine (513ng/L) and ECs tris-2-chloroethyl phosphate (389ng/L) and bisphenol-S (107ng/L). Concentrations were highest in the most heavily populated region of the Forth catchment from Dalkeith, through Edinburgh to Falkirk. The most contaminated site was consistently a location on the River Carron (Grangemouth) 7 km downstream from a historic landfill which erodes into the river during high-flow conditions. Here, cumulative concentrations of the studied contaminants (mean= 9380ng/L) were typically 2-3-fold higher than the next most contaminated location. Contaminants with >90% detection frequency included caffeine, carbamazepine, cotinine and gabapentin. This work offers novel insights into historical landfills as API/EC sources.

3.04.P-Tu080 Strategies for Conducting Environmental Fate Studies on UVCB Substances

Avril Crowe¹ and Emma Danby², (1)Labcorp Research Limited, United Kingdom, (2)Covance, United Kingdom

The European Chemicals Agency (ECHA) requires chemical substances to be registered, evaluated, authorised and restricted under REACH. The evaluation process may require environmental fate investigations to be undertaken. This may take the form of simulation studies in soil (OECD 307), aquatic sediment (OECD 308) and surface water (OECD 309). In the course of conducting these studies it is a requirement that certain data will be obtained. The required data may include mass balance, the amounts of extracted and non-extracted material, a rate and route of transformation, the extent of mineralisation and identification of transformation products. The use of a radiolabeled substance will facilitate achieving these objectives. Radiolabeling of chemical substances can be challenging. It is relatively straightforward when the chemical substance comprises a single constituent. However, when the chemical is a substance of unknown or variable composition, complex reaction products or biological materials (UVCB) radiolabeling becomes highly challenging. In addition, the conduct of the studies and analysis of samples may also raise many challenges. The poster will explore strategies for overcoming these challenges.

3.04.P-Tu081 Improving Data Quality and Reproducibility in High-Resolution Mass Spectrometry for Identification and Quantification of Micropollutants in Water

Malte Posselt¹, Anton Ribbenstedt², Run Tian³ and Michael McLachlan⁴, (1)Stockholm University, Rosersberg, Sweden, (2)Biology and Biological Engineering, Chalmers University of Technology, Gothenburg, Sweden, (3)Stockholm University ACES, Stockholm, Sweden, (4)Department of Environmental Science, Stockholm University, Stockholm, Sweden

Knowledge about the fate of organic micropollutants in aquatic environments is sparse and the lack of analytical methods is a major research gap. Previous studies mostly focused on the behavior of selected target compounds in individual systems, and the acquired information often cannot be generalized. Given the complex manner in which chemical structure influences micropollutant fate, especially biotransformation, we need to consider a wide range of compounds in order to gain an understanding sufficient for exposure assessment or predictive modeling. In recent years high-resolution (HR) mass spectrometry (MS) techniques such as non-target data acquisition and suspect screening coupled to tandem MS/MS have emerged allowing us to examine thousands of chemicals simultaneously. These techniques are relatively new and important limitations have not been resolved including: i) a lack of reproducibility between HR measurements and instruments ii) a lack of comprehensive spectral libraries hampering high level identification iii) the limited usability of semi-quantitative data produced in screening without appropriate signal correction and reference standards. We optimized an existing method and aimed to advance in all three areas by: i) employing an algorithm-based signal correction method for data processing – supplementing the classical isotope labelled internal standard (IS) method which loses power with increasing numbers of captured compounds and correspondingly increasingly deviant ionization behavior. ii) collecting spectral and retention time (RT) information for over 400 targets in in-house libraries and uploading new data to NORMAN MassBank. iii) confirming the linearity of the corrected instrument response for a large number of known and suspected chemicals. Water samples were analyzed using UHPLC coupled to an Orbitrap HRMS/MS with electrospray ionization. Level 1 and 2a identification was achieved by matching exact mass, spectra and RTs with an in-house mzVault library, standard mixtures and the online databases mzCloud and MassBank. Trials with this new method and river water, municipal wastewater and WWTP effluent regularly delivered >1000 high quality compound hits. Algorithm based signal correction yielded similar or better results than use of ISs in all matrices. The new method substantially improved the linearity of the instrument response and might aid in moving towards full quantification in non-targeted suspect screening analyses.

3.04.P-Tu082 Determination of Multi-Class Emerging Organic Contaminants in Sediments and Soils: Development of a Modified QuEChERS Method Coupled to LC-MS/MS

Thi Ngoc Tuyet Nguyen¹ and Christine Baduel², (1)IRD, Institut des Géosciences de l'Environnement (IGE), France, (2)CNRS IGE UMR 5001, Univ. Grenoble, France

CECs and their transformation products are widely distributed in the environment and have been qualified as a risk to human health and environmental ecosystems that urgently need to be addressed. Sorption by soils and sediments plays an important role

in the transport, bioavailability, and ultimately, the fate of these contaminants in the environment. Data concerning the presence and concentration of these chemicals in these matrices have to be evaluated thus, adequate analytical methods for trace level determination have to be developed. The analytical methods for the determination of CECs in soil and sediment are scarce and target only one specific chemical group of contaminants, such as pesticides or pharmaceuticals. Therefore, the development of a multi-residue method that allows the simultaneous extraction and analysis of several classes of contaminants presenting different physicochemical properties is necessary. In this context, we present the optimization of an analytical strategy that combines efficient and reliable extraction, purification, and analysis of a broad range of CECs. Therefore, a new multi-residue and inter-family extraction method for analyzing around 80 emerging pollutants (including pharmaceuticals and personal care products, pesticides, plasticizers, and flame retardants) in sediments and soils based on the QuEChERS method and LC-MS/MS analysis is reported. This procedure involves the extraction of a sample with solvents followed by a liquid-liquid partitioning step. After centrifugation, the extracts are decanted into a tube containing sorbent which constituted a clean-up step called dispersive solid-phase extraction. Different steps were optimized such as the choice of the buffer, the amount of water to add, the choice of the clean-up. The method was fully validated for soil and sediment through the evaluation of recoveries, matrix effects, the limit of quantification, linearity, and precision. Mean recoveries (n=5) were between 70% and 120% with relative standard deviations less than 20% in most of the cases. Using this protocol, a few sediments and agricultural soil samples were extracted and analyzed. The developed method was simple and fast, and good results were obtained in terms of sensitivity, recoveries, and precision. In addition, this strategy could be suitable for non-target screening to provide a more comprehensive overview of the contaminants and their degradation products present in the samples.

3.04.P-Tu083 Analysing ~150 Plant Protection Products in Soil: You Can't Be Everybody's Darling

Andrea Rösch¹, Felix Wettstein², Vanessa Reininger³, Daniel Waechter⁴ and Thomas Bucheli², (1)Environmental Analytics, Agroscope, Switzerland, (2)Agroscope, Switzerland, (3)Swiss Soil Monitoring Network (NABO), Switzerland, (4)NABO Swiss Soil Monitoring Network, Switzerland

Plant protection products (PPP) are applied on agricultural fields to fight crop pests in order to increase crop yields. PPP are designed to be biologically active and to act on target organisms; however, as soon as PPP enter the environment, non-target organisms are exposed as well and may suffer from acute and chronic effects. Whereas knowledge on chemical pollution in surface water bodies located in agriculturally influenced areas is constantly improving, information on soil contamination with agrochemicals is relatively scarce. Therefore, within the *Swiss Action Plan for Risk Minimization and Sustainable Use of PPP* one measure focuses on developing an analytical method to quantify PPP residues in soil. Relevant PPP residues have been selected based on their application rates, environmental behaviour (half-lives, mobility) and toxicity (acute and chronic effects, bioaccumulation potential). The aim of this project was to develop a multi-residue method to be able to quantify ~150 relevant PPP residues in soil with liquid chromatography coupled to mass spectrometry (triple quadrupole) using electrospray ionisation. The main challenge during method validation is the lack of a certified aged reference soil which contains the majority of the target analytes. Only aged soils can reflect extraction efficiencies comparable to those of field soils. Therefore, a “partly-aged” soil was prepared (*RefSoil*) at which the ~150 spiked target analytes had time to interact with the soil matrix for seven days while suspending and mixing. Additionally, five Swiss agricultural soils (*field soils*) were included into the method development which contain native PPP residues. Accelerated solvent extraction and the standardized AOAC QuEChERS method were compared with regard to their extraction efficiencies using the *RefSoil* and the *field soils*. Overall, the extraction comparison led to similar results for the *RefSoil* and the *field soils* in terms of number and identity of the detected substances, the detected concentration ranges and precisions. However, multi-residue methods always rely on a compromise and an appropriate extraction method has to be chosen based on the results of the majority of all target analytes. QuEChERS meets the necessary criteria to be a suitable extraction method for soil monitoring, both from an analytical point of view as well as from a holistic point of view so that soon this method can be applied in routine monitoring to evaluate soil quality.

3.04.P-Tu084 Monitoring of Pesticide Residues in a Potato Field

Simon Mangold, Nora Bartolome, Isabel Hilber and Thomas Bucheli, Agroscope, Switzerland

Plant protection products (PPP) commonly used for potato crops were monitored in soil of a field under real world conditions. The plot was treated with commercial formulations of 13 fungicides (F), five herbicides (H), one insecticide (I), and one molluscicide. Atrazine (H) was last applied in 2009 and also measured. Of the 21 active ingredients (ai) 19, including eight metabolites (M), were measured. Soil was sampled 14 times between March 2020 and January 2021 with 14 days sampling cycles during the potato growing between April and August. Sampling depths were top- (0-5 cm) and subsoil (5-20 cm). Prior to analysis the soils were dried at 40 °C, crushed and sieved over 2 mm, extracted by accelerated solvent extraction and determined by large-volume injection liquid chromatography coupled to tandem mass spectrometry with electrospray ionization (LVI-LC-ESI-MS/MS). Median concentrations of topsoils ranged from 0.2 ng/g_{soil} (fluzifop-p-butyl, (H)) to 190 ng/g_{soil} (dimethomorph, (F)) and those of subsoils from 0.3 ng/g_{soil} (trifloxystrobin CGA (M)) to 17.0 ng/g_{soil} (dimethomorph). Atrazine, a legacy pesticide, had a median of 1.5 ng/g_{soil} in the top- and 1.6 ng/g_{soil} in the subsoil and atrazine-2-hydroxy, a degradation product of atrazine, 14 ng/g_{soil} at each soil layer. Atrazine and its metabolite were detected in all 14 samples in both soil layers. The same (14/14) holds for prosulfocarb, (H), clomazon (H), metribuzin (H), metribuzin desamino (M), and difenoconazol (F). Hence, of seven analytes found, five were ai and four of them belong to herbicides, of which three were applied four days before the first sampling. Difenoconazol was already detected in April although its application was in May possibly because its residues survived from the previous crop. Observed compound's dissipation rates over time were compared with highest and lowest half-life predictions based on pseudo first order kinetics (DT₅₀) from literature¹. All topsoil concentrations were within concentrations ranges predicted by DT₅₀, only those from fluzinam and fluzifop-p-butyl were lower than predicted. Subsoil concentrations were less in comparison to topsoils because

they depend on the mobility of the compounds in soil, which in turn depends on the soil organic carbon to water partition coefficient. The subsoil concentrations did not fit into the predicted concentration range because residues did not mirror peak concentrations from pesticide applications as the topsoils did. Ref: ¹EFSA (European Food Safety Authority), EFSA Journal 2017; 15(10):4989, 29 pp. <https://doi.org/10.2903/j.efsa.2017.4989>

3.04.P-Tu085 Different Chromatographic Approaches to Determine and Compare Residues of Modern Pesticides in Agricultural Soils in Cuba

Arturo Escobar¹, Isabel Hilber², Dayana Sosa³, Brizeidi Peña⁴, Nilda Perez⁵ and Thomas Bucheli², (1)CENSA, San José de las Lajas, Cuba, (2)Agroscope, Switzerland, (3)Centro Nacional de Sanidad Agropecuaria (CENSA), San José de las Lajas, Cuba, (4)National Center for Animal and Plant Health, Cuba, (5)Univerdidad Agraria de La Habana, Cuba

In Cuba, there is little to no information about residues of modern pesticides in agricultural soils despite the fact that pesticides are currently heavily applied. For countries with economic limitations such as Cuba, a proper pesticide management avoiding pesticide residues in the food and environment is all the more important. The main objective of this work is to assess pesticide residues in soils of potato production by gas (GC) and liquid chromatography (LC) coupled with mass spectroscopy and to compare the residues with the pesticide records of 12 different agricultural cooperatives in Mayabeque, Cuba. From 2017-2019 farmers in Mayabeque applied different commercial pesticides in 35 soils and of them, 52 active ingredients (ai) were investigated by LC. Eighteen percent of the ai were detected in the soil by LC (true positive). Around a third of the ai measured by LC were false positives meaning the pesticides were detected but not applied. These are for example clothianidin, dichlorbenzamid (2,6), atrazin-2-hydroxy, carbendazim, linuron, and napropamid. This indicated that residues of pesticides from applications of previous years and for other crops in the same field remained in the soil and/or that the records were not complete. For instance clothianidin is persistent according to the Pesticide Property Data Base¹ and atrazine-2-hydroxy is a degradation product of the persistent atrazine, a triazine herbicide applied in large amounts in the past and now forbidden.² More than half of the ai applied were not detected because they might simply have dissipated by degradation or other processes and therefore fell below the detection limit. Also, this relatively large fraction of no detects is due to the fact that the LC method was tailored for Swiss agriculture and the ai typically applied there. The GC method contained ai that are mostly used in agriculture in the tropics and consisted of 27 ai of which six were detected. In total 16 ai employed were identified and quantified. Eleven of them were detected by both types of chromatographs. This preliminary assessment provides a basic idea about pesticide residues in Cuban soils and contributes to transfer these measurement methods from Switzerland to the lab in Cuba. This allows us to establish for the first time a Cuban measurement technique for the next potato campaign 2020–2022 and to study more ai applied in that period. ¹PPDB, Pesticide Properties DataBase, Version September 2016, accessed Nov 23, 2019, © Copyright University of Hertfordshire <https://sitem.herts.ac.uk/aeru/ppdb/en/> ²Chiaia-Hernandez, A. Sci. Technol.* 2017, 51, (18), 10642-10651.

3.04.P-Tu086 Detection and Occurrence of Diazepam and Clonazepam in Wastewater Samples

Silumko Nzube¹ and Vernon S Somerset², (1)Cape Peninsula University of Technology, South Africa, (2)CPUT, South Africa

Pharmaceutical pollutants entering the aquatic environment have become a growing environmental concern. These pharmaceuticals are unique pollutants because of their special characteristics and behaviour that cannot be simulated with other organic pollutants. The untreated wastewater effluent that contains pharmaceuticals poses considerable threat to the aquatic ecosystem because of the negative effects of non-target organisms in the water. Recent years have seen a growing concern about the benzodiazepines, as emerging pollutants, and their effects on the aquatic environment. These compounds are nowadays widely detected in sewage wastewater. It is important to increase the emphasis on the characteristics of the benzodiazepines in order to differentiate them from industrial chemical compounds. In this study various solid phase extraction techniques have been employed focusing on isolation of benzodiazepines in wastewater matrices. Employing this methodology has shown improved detection and analysis of diazepam and clonazepam as benzodiazepines. Preliminary results have shown the diazepam concentrations to range between 1 to 9 ppm in seasonal wastewater samples analysed, with higher concentrations during the winter season. In the case of clonazepam, concentrations ranged between 0.4 to 2 ppm. Seasonal characteristics of the benzodiazepines are discussed along the trends observed for the water quality characteristics of the final treated wastewater.

3.04.P-Tu087 Occurrence and Fate of Contaminants of Emerging Concern (CECs) and Their Transformation Products After Uptake by Pak Choi Vegetable

Adria Sunyer Caldu¹, Malin Hultberg², Rubén Gil Solsona¹, Pablo Gago Ferrero³, Silvia Diaz-Cruz⁴, Lutz Ahrens⁵ and Oksana Golovko⁶, (1)IDAEA, CID-CSIC, Spain, (2)Swedish University of Agricultural Sciences (SLU), Sweden, (3)IDAEA-CSIC, Spain, (4)QA, IDAEA-CSIC, Barcelona, Spain, (5)Swedish University of Agricultural Sciences, Sweden, (6)University of South Bohemia in CB, Sweden

Nowadays, big quantities of food are lost or wasted, so new ways are being explored to recover and reuse the nutrients, in support to a circular economy. Anaerobic digestion is an ecofriendly solution to recover organic matter and other useful nutritional components from foodstuffs, producing digestate. It can be used in soil and hydroponic agriculture. However, all materials present in the digestate are also preconcentrated. Thus, metals, food pathogens and contaminants of emerging concern (CECs) can reach high concentrations that, afterwards, are recirculated in the food chain when soils are fertilized to grow new crops. These compounds are likely to be uptaken by the crops and, once inside, they can be degraded or transformed, originating transformation products (TPs). Both the uptaken CECs and the formed TPs may pose a risk to the environment and ultimately, to human health. In this study, CECs occurrence in several food waste facilities in Sweden was evaluated and, based on this, twenty of the most

frequently detected compounds were selected (four pharmaceuticals and thirteen per- and polyfluoroalkyl substances (PFAS)). The aim of the work was to evaluate the potential uptake of the selected compounds by Pak Choi vegetable (one of the most consumed in Sweden), but also the identification of their TPs. The crops were cultivated under hydroponic conditions using both mineral and biosolid-based substrates which were irrigated with water spiked with the 20 selected compounds. After harvesting, the samples were extracted with a solid-liquid procedure and bead beating Tyssuelyser. The extracts were analyzed by UHPLC-(QqQ)-MS/MS for the target screening and by UHPLC-Q-Exactive MS for the suspect screening. In the target analysis, different behaviours were observed among compounds (some were less uptaken or transformed), among substrates (biosolid substrate seemed to favour the uptake) and among families (PFAS' uptake was more stable than pharmaceutical's one). In the suspect screening, different transformations processes were confirmed, as hydroxylations, dihydroxylations, methylations or desmethylations, and some phase II transformations as glucuronations, glucosidations, or acetylations. Thus, both target and suspect screenings demonstrated a real uptake and transformation of the adsorbed compounds in Pak Choi.

3.04.P-Tu088 Multi-Residue Pesticide Analysis In Soils of Mayabeque, Cuba: Method Validation and First Applications

Brizeidi Peña¹, Isabel Hilber², Dayana Sosa³, Nilda Perez⁴, Arturo Escobar⁵ and Thomas Bucheli², (1)Centro Nacional de Sanidad Agropecuaria (CENSA), Cuba, (2)Agroscope, Switzerland, (3)Centro Nacional de Sanidad Agropecuaria (CENSA), San José de las Lajas, Cuba, (4)Universidad Agraria de La Habana, Cuba, (5)CENSA, San José de las Lajas, Cuba

Potato is a prioritized crop in Cuba and irrespective of climate, tropical or temperate, pesticide intensive. Mayabeque is one of the provinces in Cuba with a high intensity of potato plots and was therefore chosen for a pesticide monitoring. Here, the study objectives were (i) to establish an analytical method to determine and quantify modern pesticides, (ii) to evaluate matrix effects (ME) of different soils from tropical but also from temperate climate. The extraction method was QuEChERS and 31 active ingredients (ai) and five metabolites were validated by gas chromatography coupled with a triple quadrupole mass selective detection (GC-TQ). Ten isotope labelled internal standards (IS), spiked prior to extraction, compensated for losses and indicated absolute recoveries. The calibration curves contained seven concentration levels (0, 5, 10, 25, 50, 75, 100 ng/ml) per analyte and were done in acetonitrile with 2.5% formic acid (ACN) or in soil matrix (matrix matched (MM) calibration). Although only red ferralitic soil was sampled, ME was evaluated for four other Cuban soils i.e. skeletal, red ferralitic, grey-brown and yellow ferralitic, and one brown soil from Switzerland. About half of the analytes showed an ME lower than $\pm 20\%$, an average of 35% of the analytes had a medium ME (± 20 to $\pm 50\%$) and only six out of 36 analytes showed a strong ME ($> \pm 50\%$). A skeletal forest soil (SS) without pesticide residues was used for method validation. The Linearity shows linear regression coefficients for all analytes ($R^2 > 0.99$). Absolute recoveries ranged from 44 to 122% (average: 94%, RSD $\approx 26\%$). Limit of detection (LoD) and quantification (LoQ) showed range from 0.0002-1.17 $\mu\text{g}/\text{kg}$ and 0.0008-3.89 $\mu\text{g}/\text{kg}$, respectively. First analyses of soil samples from 12 sites taken before planting potatoes (t₀) revealed pesticide residues of 22 ai and two metabolites and the sum of concentrations per sample ranged from 4.37 and 78.4 $\mu\text{g}/\text{kg}$. T₀ indicates that pesticides are residues from applications to former crops and are therefore considered persistent. However, the pesticide properties data base (PPDB)¹ indicates some of the ai found (trifloxystrobin, metribuzin) as not persistent in the field. Hence, this work does not only shed light on the influence of different (tropical) soils on the ME but also provides evidence for an updating for tropical soils in the PPDB and serves as a basis to establish a pesticide assessment method in the Cuban lab. ¹Pesticide properties data base (PPDB), <https://sitem.herts.ac.uk/aeru/ppdb/>, accessed 26.11.2021

3.04.P-Tu089 Multitarget and Suspect Analysis for the Identification of Emerging Contaminants in Aqueous Samples: Application to Real Cases

Narora Lopez¹, Mireia Irazola-Duñabeitia¹, Iker Alvarez¹, GORKA ORIVE², UNAX LERTXUNDI³, Nestor Etxebarria¹, Olatz Zuloaga¹, Maitane Olivares¹ and Ailette Prieto¹, (1)University of the Basque Country, Spain, (2)NanoBioCel Group, Laboratory of Pharmaceutics, School of Pharmacy, University of the Basque Country UPV/EHU, Spain, (3)Araba Psychiat Hosp, Araba Mental Hlth Network, Osakidetza Basque Hlth Serv, Bioaraba Hlth Res Inst, Pharm Serv, C Alava, Spain

A combination of multitarget quantitative analysis and suspect screening was developed and applied to influent and effluent samples of two wastewater treatment plants (WWTPs) located in the Basque Country: Galindo and Crispijana, responsible for the wastewater treatment of the metropolitan area of Bilbao (approximately 1 million inhabitants) and Vitoria-Gasteiz (approximately 480.000 inhabitants). The detection of contaminants of emerging concern (CECs) was performed by means of an ultra high liquid chromatograph coupled to an Orbitrap high resolution mass spectrometer (UHPLC-q-Orbitrap). Among the compounds detected antibiotics, antiinflammatories and antihypertensives prevail over pesticides and industrial products, being higher concentrations found in Galindo. In addition, the detection of pharmaceutical compounds used during the pandemic's first months in the COVID-19 treatment including the antibiotic azithromycin, the antimalarial hydroxychloroquine and the antiretrovirals lopinavir and ritonavir may indicate an increase in their use during this period. The complementary suspect analysis enlarged the list of detected compounds with 93 and 16 additional xenobiotic compounds annotated at levels 2a and 3, respectively. Although some compounds showed higher or similar concentrations in secondary and tertiary effluent samples (i.e. azithromycin, clozapine, primidone), in general, a reduction on their concentrations was observed, suggesting some efficiency in their removal. The analytical methodology used in this study demonstrated to be a suitable approach when characterizing the presence of different CECs in WWTP samples, highlighting the need for monitoring studies in aquatic environments as well as the implementation of new advanced technologies in WWTPs for further elimination of CECs.

3.04.P-Tu090 Chemicals of Emerging Concern in Food Waste and Oyster Mushrooms

Oksana Golovko¹, Michal Kaczmarek², Jenny Schelin³, Mattias Söregårda², Håkan Asp², Karl-Johan Bergstrand², Lutz Ahrens⁴, Karin Wiberg⁴ and Malin Hultberg², (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural

Sciences, Uppsala, Sweden, (2)Swedish University of Agricultural Sciences (SLU), Sweden, (3)Lund University, Sweden, (4)Swedish University of Agricultural Sciences, Sweden

In recent years, there has been increasing interest in food production using resource-optimising systems, such as hydroponics and mushroom production, particularly in densely populated areas with low availability of arable soil. The anaerobic digestate from food waste deriving from biogas production plants (BPs) has the potential for use as the plant nutrient source in hydroponic systems as well as for mushroom production. This proposed use of anaerobically digested organic waste as biofertilizer in urban farming creates an urgent need to define occurrence and levels of water-soluble (hydrophilic), (semi-) persistent chemicals of emerging concern (CECs), especially residues from currently used chemicals, drugs, and pesticides. Thus, in-depth knowledge of the chemical of the anaerobic digestate derived from organic waste is a necessity for safe urban food production. CECs pose potential threats to environmental ecosystems and human health. This study examined the characteristics of anaerobic digestate based on food waste in terms of CECs, such as currently used drugs and pesticides ($n=133$). The same substrate was used to test uptake of per-fluoroalkyl substances (PFASs), pharmaceuticals, and parabens by edible oyster mushrooms (*Pleurotus ostreatus*), cultivated on spiked growth substrate. The different biofertilizers from three different BPs had similar CEC profiles. If this profile is found to be spatially and temporally consistent, it can help regulatory agencies to establish priority lists of CECs of highest concern. There are currently limited data available on CECs in food waste and biofertilizers, and more studies are urgently needed. This study provides insights into the uptake of CECs by oyster mushrooms from spiked substrate and potential risks for human consumption. The concentrations of CECs over time depended on the physico-chemical properties of the CECs. It was shown that oyster mushrooms are capable of uptake of some CECs, with higher uptake of PFASs than of parabens or pharmaceuticals. This study showed that oyster mushrooms have the potential to degrade pharmaceuticals and parabens. Thus, more studies are needed on use of oyster mushrooms for remediation purposes through uptake and degradation of CECs.

3.04.P-Tu091 Assessment of Modern Pesticides in Soils of Potato Production in Mayabeque Province, Cuba

Dayana Sosa¹, Brizeidi Peña², Isabel Hilber³, Nilda Perez⁴, Arturo Escobar⁵ and Thomas Bucheli³, (1)Centro Nacional de Sanidad Agropecuaria (CENSA), San José de las Lajas, Cuba, (2)Centro Nacional de Sanidad Agropecuaria (CENSA), Cuba, (3)Agroscope, Switzerland, (4)Universidad Agraria de La Habana, Cuba, (5)CENSA, San José de las Lajas, Cuba

Pesticides application is prioritized for potato cultivation in Cuba. Potato soils receive a mix of 17 - 41 kg_{ai}/(ha*y), with a total of 40 to 45 treatments on average per year. Mayabeque province is a major contributor to potato production¹ and the objective of this study is to assess pesticide residues in potato soils of three different pesticide application levels: intensive, semi-intensive, and agro-ecological (no pesticide application, serves as control) and in three time points: before and after sowing, and at harvest in Mayabeque, Cuba. This is the first study until now that quantifies pesticide residues in Cuban soils taken at 12 sites [intensive ($n=6$), semi-intensive ($n=5$), agro-ecological ($n=1$)] and at three time points. All sites were red ferralitic soils selected following the criteria of potato production (kg/ha) and record pesticides applications. Forty-six pesticides and/or metabolites were analyzed in the soils at the Agrocope laboratory. The extraction was done by Accelerated Solvent Extraction with an organic solvent mix. The identification and quantification of pesticide were made by high performance liquid chromatograph-triple quadrupole mass spectroscopy (HPLC-MS/MS). A minimum of five and a maximum of 24 pesticides were detected in all samples. Clothianidin, atrazin-2-hydroxy, imidacloprid, tebuconazole, S-metolachlor, propiconazole, and azoxystrobin were present in more than half of the samples. These compounds are persistent in soil^{2,3}, which corresponds with the high prevalence. The sum ($\mu\text{g}/\text{kg}$) of pesticide concentrations and the range (min-max) before planting were in intensive systems 174 (63-234), semi-intensive 86 (48-129), agro-ecological 12; at sowing in intensive systems 257 (45-545), semi-intensive 180 (38-477), agro-ecological 11; at harvest in intensive systems 202 (56-429), semi-intensive 253 (159-329), agro-ecological 14. Pesticide concentrations were lowest before sowing and highest after sowing or at harvest. The agro-ecological site had the lowest pesticide concentrations and remained stable at all time points. The concentrations in intensive and semi-intensive managed fields were higher than the control and not quite distinguishable after sowing and at harvest. Pesticide management categories will therefore be revised. This preliminary study serves as a basis to establish a method in Cuba in order to be able, in the long run, to quantify pesticides residues in soil, potato and other crops independently. 3.04.P-Tu092 Anthropogenic Footprint in Canadian Lake Sediments: The CASE of Trace Organic Contaminants

François-Xavier Teysseire¹, Yannick Huot², Hubert Cabana² and Pedro Segura², (1)Université de Sherbrooke, Canada, (2)Université de Sherbrooke, Canada

Anthropogenic activities introduce continuously large number of trace organic contaminants (TrOCs) into lakes and their tributaries. Sediments are a sink for many TrOCs and their transformation products. Due to the process of sorption / desorption in the water-sediment system, the sediments can expose benthic and aquatic organisms to potentially toxic compounds. The presence of TrOCs in Canadian Great Lakes sediments has been described, but there is no systematic study of their presence in lake sediments across Canada. The goal of the present study was to assess the occurrence (concentrations and detection frequencies) of 47 TrOCs in 230 Canadian lake sediments, and how they vary by province and land cover. Sediments of lakes impacted by different levels of anthropogenic activities were sampled and a methodology based on pressurized-liquid extraction, solid-phase extraction and liquid chromatography-triple quadrupole mass spectrometry was developed to determine the occurrence of 43 TrOCs and 4 transformation products representative of urbanization and agricultural activities. Preliminary results on 28 lakes in the eastern Canada provinces (Ontario, Quebec, New Brunswick, and Nova Scotia) show that at least 1 contaminant was found in each sample, and up to 12 contaminants were found in some lakes. In total, 25 analytes out of 47 were detected in at least 1 lake,

with detection frequencies ranging from 0 to 100% and concentrations from 476 pg/g to 9540 ng/g, respectively. TrOCs concentrations varied greatly from lake to lake, with the highest concentrations found in lakes within watersheds impacted by agricultural activities. The spatial distribution of TrOCs concentrations shows hot spots close to the major cities (Toronto and Montreal) and the heavily agricultural areas of southern Ontario. Significant relationships ($p < 0.05$) between land use and TrOCs concentrations show positive correlations ($r > 0.4$) between atrazine, metolachlor and dimethenamid with agricultural fraction of land use in the watershed, and 5-H-methyl-benzotriazole with urbanization. Our analyses reveal that recreational activities could be a major source of DEET and oxybenzone in more natural lakes. This is the first study to assess the occurrence of TrOC in small (< 100 km²) lakes in Canada.

3.04.P-Tu093 Plants As Bioindicators of Pollution in Riyadh and Abha Urban Areas, Saudi Arabia

Yolanda Pico¹, Julian Campo², Ahmed Alfarhan³, Mohamed El-Sheikh⁴ and Damia Barcelo⁵, (1)University of Valencia, Spain, (2)CIDE-CSIC, Spain, (3)King Saud University, Saudi Arabia, (4)King Saud University, United States, (5)ICRA- G17920851, Spain

Anthropogenic pollution can assume different forms and impact on all environmental compartments. Tracking pollution through pollutants present in living organisms such as plants, so-called bio-indicators, can be a useful approach to environmental monitoring. The purpose of this study was to investigate and compare plants growing in several industrial or traffic heavily affected areas of Riyadh (large industrial city, >10 million inhabitants, intense traffic) and in Abha (small city, < 760000 inhabitants, near a natural park), as bioindicators and biomarkers of anthropic pollution. Pharmaceuticals and personal care products (PPCPs), perfluoroalkyl substances (PFASs), organophosphorus flame retardants (OFRs) and polycyclic aromatic hydrocarbons (PAHs) were measured in several plant species (e.g. *Digitaria ciliaris*, *Ocimum bacilicum*, *Salsola imbricata*, *Conocarpus erectus*, *Tamarix aphylla*) by liquid-chromatography tandem mass spectrometry (LC-MS/MS) or gas chromatography-mass spectrometry (GC-MS). There were significantly higher levels of contaminants in the plants growing in industrial and traffic heavily areas compared to those growing in more rural environments ($P < 0.05$). Our study shows that pollution has effects on total PPCPs, PFASs, OFRs and PAHs, not only providing evidence of the impact of contamination on ecosystem health, but also pointing the way for the use of plants not only as bio-indicators but also for bio-remediation. Acknowledgment The financial support from the project number (RSP-2021/11) King Saud University, Riyadh, Saudi Arabia.

3.04.P-Tu094 Evaluation of the Relevance of Disinfection By-Products (DBPs) for the Environmental Risk Assessment of Biocides

Michael Huben¹, Miriam Diehle², Muhammad Usman³, Volker Linnemann⁴, Michael Klein⁵ and Stefan Hahn⁶, (1)Fraunhofer IME, Schmallenberg, Germany, (2)Umweltbundesamt, Germany, (3)Institute of Environmental Engineering, Germany, (4)RWTH Aachen University, Germany, (5)Fraunhofer IME, Germany, (6)Fraunhofer ITEM, Hannover, Germany

Disinfectants are widely used biocidal products which are regulated by the EU Biocides Regulation 528/2012. Their scopes of applications are quite broad and include different fields such as (drinking) water, health care, food processing or construction industry. Among the active ingredients used, highly reactive substances like chlorine, peroxides or ozone are common. During their application, numerous disinfection by-products (DBPs) are formed, especially if organic matter is present. The specific uses and the reaction conditions have great influence on the formation of DBPs. The intended use also determines possible releases of the formed DBPs into the environment. This complex situation is not adequately considered in the guidance within the European Biocides Regulation at the moment. The authorisation of biocidal products is regulated by the EU Biocides Regulation 528/2012 which also requires the assessment of possible DBPs. The existing "Guidance on Disinfection By-Products" is limited to halogen-containing biocidal active substances and selected product types and includes only general scientific strategies for the risk assessment of DBPs. On this basis a harmonized environmental risk assessment (ERA) of biocidal products and their DBPs within the EU is questionable. In order to fill this regulatory gap and develop a feasible regulatory toolkit, the German Environment Agency (Umweltbundesamt, UBA) launched a research project for the consideration of DBPs within the environmental risk assessment of biocidal products (FKZ 3718 65 403 0). In a systematic literature based search potential active substances which are competent to form DBPs have been assigned to already known DBPs also considering the conditions of use in their respective experiments. The obtained results were complemented by an experimental validation. Simulated product applications considering uses in aqueous matrix as well as on hard surfaces under different experimental conditions were analysed for a selection of approx. 60 DBPs. The laboratory simulations were accompanied by analysis of samples from professional applications. The experimental setup and the analytical results of the validation experiments will be presented. 3.04.P-Tu096 Proposal of Watch List for Emerging Pollutants Occurring in the Nakdong River, Korea

Lee Sangyoon, Changwon National University, Korea, South

Nakdong River, one of the four major rivers in Korea, has been polluted as receiving numerous pollutants from heavily industrialized and populated areas while being used as a drinking water source. Recently, a number of researches have reported occurrences of emerging pollutants (EPs) in the river and requested efficient monitoring and management plans such as EU watch list. The aim of this study is to suggest a watch list through preliminary monitorings of the river and risk assessment based prioritization approach. Initially, 633 candidates were selected as EPs from literature and database searches (e.g., research articles, national chemical database, reports from domestic monitoring program, international regulations and mechanisms for monitoring of EPs). Through the review for applicability of LC-HRMS, 175 substances were subjected to target screening method whereas 458 were qualitatively identified via suspect screening. A risk assessment-based prioritization was applied to substances quantified through target screening, and a scoring system-based prioritization was applied to substances tentatively identified through suspect screening. Sampling campaigns (n=12) were conducted from October 2020 to September 2021, at 8 sampling

sites along the river. As a result targets, 131 substances were quantified above the LOQ. Tris(2-butoxyethyl) phosphate, used as a OPFR, showed the highest mean concentration, followed by alachlor/acetochlor ESA, tris(2-chloroethyl) phosphate and dimethyl phthalate, all with mean concentrations above 100 ng/L. Among the 21 substances whose priority score was assigned through risk-based prioritization, 8 substances (azithromycin, candesartan., clotrimazole, imidacloprid, iprobenfos, irgarol, telmisartan and tris(2-butoxyethyl) phosphate) were identified as high environmental risk. As result of the scoring system for 39 tentatively identified substances, 6 substances (crotamiton, caprolactam, heptaethylene glycol, octaethylene glycol, simetryn and tridemorph) showed a potential environmental risk. In total, 14 EPs was hereby suggested for inclusion in the watch list to extensively monitor and manage the quality of Nakdong river threatened by newly recognized pollutants.

3.04.P-Tu097 Mapping Policy Needs for Scientific Evidence Under the Basel, Rotterdam and Stockholm Conventions *Zhanyun Wang, ETH Zurich, Switzerland*

The Basel, Rotterdam and Stockholm Conventions are key intergovernmental instrument to addressing the global threats of chemical pollution to humanity and the environment. Since their establishment, they has identified many emerging issues such as new Persistent Organic Pollutants, but their national implementation remains challenging, particularly in low- and middle-income countries. Concerted action is needed to assist countries that are Parties to the Conventions in implementing their obligations, including enhancing scientific support. This analysis reviews various policy needs for scientific evidence under the Conventions that warrant attention and research from the broad scientific community, including disciplines of both natural and social sciences, as well as research funding agencies. For example, field studies measuring legacy and emerging contaminants under the Conventions are much needed. It further provides practical guidance to scientists and practitioners to ensure the visibility and accessibility of their work for the Conventions' implementation, in addition to conducting timely research.

3.04.P-Tu098 Multi-Stressor Approach on the Impact of Human Activities in Estuarine Systems - Occurrence of Emerging Contaminants in Fish Aquacultures and Concerns Regarding Human Consumption

Carolina Rocha¹, João Marques¹ and Ana M. M. Gonçalves², (1)University of Coimbra, MARE - Marine and Environmental Sciences Centre, Portugal, (2)University of Coimbra, MARE (Marine and Environmental Sciences Centre), Department of Life Sciences, Portugal

The need to understand pollutant mixtures' impacts on organisms is an ongoing discussion, being mixture experimental exposures with environmentally relevant concentrations encouraged. An approach to naturally occurring exposure conditions will allow to detect interactions between contaminants that can be overlooked when performing single-contaminant experiments. Coastal environments are truly rich environments, sustaining a multitude of intricate trophic relations, while providing numerous services for humankind. However, these systems are usually highly impacted by human activities. One common practise in coastal systems in Southern European countries is the use of land for aquaculture and, in some countries, semi-intensive fish rearing is common. If, on one side, this technique may provide a natural factor in fish production, potentially increasing its market value, it also means that the organisms are subjected to the cocktail of contaminants released into the waters by human activities. It is, then, urgent to understand how these contaminants may be, together, affecting fish, and, eventually, human health. Hence, a multi-stressor screening on three matrixes (fish, water and sediment) at semi-intensive fish aquaculture facilities in two Portuguese estuaries was performed, to provide a database of emerging contaminants (EC) found in the rearing systems, that may be used in further works to determine the metabolic impacts of EC in organisms and, eventually, in human-beings as consumers. Three main EC groups were defined for the screening – microplastics (MPs), polycyclic aromatic hydrocarbons (PAH) and pharmaceutical and personal care products (PPCP). The identification of MP polymers is being carried out through ATR-FTIR. The identification of PAH and PPCP is achieved through GC-MS. Identification and quantification of EC in all samples is ongoing. First results show that i) polyethylene (with different densities) and nylon are the most frequent MPs in all matrixes, found in higher amounts in fish gut and sediment; ii) PAH are more frequent in sediment; iii) a wide variety of PPCP can be found, such as additives, anti-depressive drugs and sunscreen, being apparently abundant in all matrixes. The fact that all EC are found in fish aimed for consumption contributes with further and alarming knowledge for legislative and regulatory processes that effectively act towards lowering the impact of human activities, safeguarding ecosystems and human health.

3.04.P-Tu099 Effect-Based Characterization of Polycyclic Aromatic Compounds (PACs) During In-Situ Thermal Remediation of a Former Gasworks Site

Ayan Au Musse¹, Anja Enell², Thanh Wang³, Magnus Engwall⁴ and Maria Larsson⁵, (1)School of Science and Technology, MTM Research centre, Örebro University, Örebro, Sweden, (2)Swedish Geotechnical Institute, Sweden, (3)MTM Research Centre, Örebro University, Sweden, (4)Örebro University, Sweden, (5)School of Science and Technology, Örebro university, Örebro, Sweden

In-situ remediation, in comparison to ex-situ remediation, is getting more and more attention as both research and technology advances as well as some advantages in-situ remediation poses over ex-situ remediation, e.g., limiting human exposure, lower cost etc. Soil remediation plays an integral role in achieving a healthy ecosystem. A group of compounds that are often present in high concentrations at industrial sites are polycyclic aromatic compounds (PACs). While polycyclic aromatic hydrocarbons (PAHs), especially the 16 US-EPA priority PAHs, have been studied pre- and post-remediation, little is known about the potential for thermal treatment to remove other PACs. In this study we are going to investigate changes in the composition of PACs, including PAHs, oxy-PAHs, alkylated PAHs, and heterocyclic compounds (NSO-PACs) and bioactivities in soil at a historically contaminated gasworks site in Sweden after in-situ thermal remediation. We will use a three-pronged approach, 1) targeted chemical analysis, 2) a battery of in-vitro reporter gene assays, and 3) effect-directed analysis (EDA). With the EDA approach, we aim to i) study the composition of the contaminants present in the samples (pre- and post-remediation), ii) determine any changes

in contamination profile, pre- and post-remediation, and iii) identify bioactive PACs, both novel and known. The results from this study will give a better understanding on degradation of PACs and formation of potentially toxic metabolites of PACs in soils during thermal remediation. Therefore, gaining more data and knowledge to further develop risk assessment models for PAC-contaminated soils.

3.04.P-Tu100 Calibrating a Passive Air Sampler for Semi-Volatile Organic Compounds Using Continuous Active Air Sampling and Long Deployment Periods

Yuening Li¹, Faqiang Zhan¹, Ying Duan Lei², Chubashini Shunthirasingham³, Hayley Hung⁴ and Frank Wania⁵, (1)Department of Physical and Environmental Sciences, University of Toronto, Scarborough, Toronto, ON, Canada, (2)University of Toronto, Canada, (3)Environment and Climate Change Canada, Canada, (4)Air Quality Processes Research Section, Environment and Climate Change Canada, Toronto, ON, Canada, (5)University of Toronto Scarborough, Toronto, ON, Canada

The use of passive air samplers (PAS) for atmospheric semi-volatile organic compounds (SVOCs) has expanded over the past decades. Confident use of a PAS requires knowledge of its uptake kinetics in their dependence on meteorological conditions and chemical properties and of the limits of linear uptake of more volatile SVOCs. Such knowledge is gained through calibration studies involving the side-by-side deployment of active and passive air sampling techniques. Here we describe a calibration of the XAD-PAS, which uses styrene-divinylbenzene-copolymeric resin as a sorbent. The resin's high capacity increases the likelihood of linear uptake, including for relatively volatile SVOCs and during long deployments. 24 XAD-PASs were deployed on the campus of the University of Toronto Scarborough in the Eastern suburbs of Toronto in June 2020 and duplicates retrieved at monthly intervals. From June 2020 to May 2021, 48 consecutive week-long active samples were taken with a mid-volume pump. The gas and particle phases were collected on PUF-XAD resin sandwiches and glass fibre filters, respectively. Numerous field blanks were collected. One duplicate of each pair of PASs, all blank samples and the PUF-XAD resin sandwiches have been extracted, concentrated, and are being analyzed for polycyclic aromatic hydrocarbons, halogenated flame retardants, polychlorinated biphenyls, organochlorine pesticides, organophosphate esters, and neutral per- and polyfluoroalkyl substances. Due to relatively low partitioning ratios between XAD resin and the gas phase, more volatile compounds may have reached equilibrium during the length of the calibration experiment. For example, the amount of 2-methylnaphthalene sorbed to the XAD-resin reached a maximum of ~5 mg after half a year of deployment and remained relatively constant during longer deployments. Whereas, the sorbed amount of less volatile PAHs, such as fluorene, increased with the deployment length throughout the entire year. Sampling rates can be derived using the slopes of the linear regressions through the curves of effective sampling volumes over the deployment period. For example, the sampling rates of β -TBECH, γ -TBECH and BDE-47 are 2.0, 1.7 and 0.8 m³ day⁻¹, respectively. It is hoped that this "gold standard" calibration experiment will succeed in greatly expanding the knowledge base on sampling rates and lengths of the linear uptake period for a great variety of legacy and emerging SVOCs in the XAD-PAS.

3.04.P-Tu101 The Role of Passive Sampling in Environmental Monitoring - Theory & Recent Advancements

David Cartmell¹ and Jan Peter Mayer², (1)Markes International, United Kingdom, (2)Markes International Ltd, Germany

Passive sampling is an established technique in the monitoring and characterisation of Volatile Organic Compounds (VOCs). Employed across various fields such as personal exposure monitoring, large-scale environmental studies and indoor air monitoring. Passive sampling provides a cheap, convenient and reliable method of characterising a range of VOCs across several samples in large-scale air monitoring programmes. Passive sampling possesses several favourable qualities to alternative methods, such as no pump requirements and a non-invasive design. Further to this, early sorbent-based passive samplers were required to undergo solvent extraction as a preparation step before analysis. The solvent extraction limited air-speed effects at the surface of the badge, preventing the stable conditions required for passive sampling. Recent developments allow analytes to desorb from the sampler via thermal desorption (TD), improving sensitivity and accuracy that were unachievable through earlier sorbent-based sampling devices. Within this presentation I will detail the latest TD-compatible passive samplers, exploring axial and radial sampling technologies and how these technologies are advancing environmental monitoring.

3.04.P-Tu102 Development of Active-Passive Sampling (APS) Strategies for Dynamic Speciation Analysis and Ecotoxicity Evaluation of Psychoactive Substances and Their Metabolites in Wastewater

Allen Anies¹, Raewyn Town¹ and Ronny Blust², (1)Systemic Physiological and Ecotoxicological Research (SPHERE), University of Antwerp, Belgium, (2)University of Antwerp, Belgium

Wastewater analysis of drugs and their metabolites can provide information on drug use and abuse in general populations. Conventionally, 24 h composite samples are analyzed and the chemical reactivity of the compounds within the wastewater matrix is ignored. In practice, these compounds are likely to associate with the diverse particles present in the wastewater matrix. Negligence of such interactions will lead to erroneous estimations of analyte concentrations. To address this issue, this project employs innovative active-passive sampling (APS) strategies to quantify psychoactive substances in wastewater, taking into account their chemo-dynamic behaviour. The interpretation framework will be supported by determination of analyte-particle interactions with a range of particles. The APS device incorporates a controlled hydrodynamic flow of the sample matrix across selective sorbents which accumulate the target compounds. APS can be used in equilibrium mode to estimate the equilibrium analyte concentrations, e.g., the freely dissolved form; and in non-equilibrium mode to provide information on the kinetic features of their chemical forms in wastewater matrices. The performance of the APS will be compared with conventional 24 h composite sampling in both influent and effluent flows of wastewater treatment plants. A novel passive dosing strategy will also be explored for the ecotoxicological risk assessment of the drugs and their metabolites via a battery of toxicological tests.

3.04.P-Tu103 Beyond 1,2,4-Triazole - Extending the Field Scale Leaching Assessment of Triazole Fungicides by Suspect-/Non-Target-Screening

Ulla Bollmann¹ and **Nora Badawi²**, (1)Geological Survey of Denmark and Greenland, Denmark, (2)Geological Survey of Denmark and Greenland (GEUS), Copenhagen K, Denmark

Triazole compounds are commonly used fungicides used both for combating fungal diseases in crops and as seed dressing. Recently, there has been increasing concern that 1,2,4-triazole, a major degradation product of several triazole fungicides, may leach to groundwater in concentrations exceeding the 0.1 µg/L threshold limit of the European Union. 1,2,4-triazole is detected in 21% of Danish monitoring wells with exceedance of the 0.1 µg/L threshold in 3.4% of the wells. However, this is the only transformation product hitherto included in targeted monitoring of the triazoles although several transformation products are mentioned in the respective triazole EFSA conclusions. The aim of this study was therefore two-fold: i) to monitor closely the leaching of triazoles and the transformation product 1,2,4-triazole to drainage and groundwater following multiple triazole applications on different crops (target-analysis by LC-MS/MS), and ii) to study the presence of both suspected and hitherto unknown transformation products from the triazole fungicides in drainage and groundwater by HRMS suspect- and non-target analysis. The study was performed on drainage and groundwater samples collected from five fields included in the Danish Pesticide Risk Assessment Programme (PLAP). Since 1999, the PLAP programme has been monitoring leaching of pesticides and transformation products to drainage and groundwater. Additional information about monitoring design and sampling methods is available online (www.pesticidvarsling.dk). The five test fields included in the PLAP programme are cultivated with crop rotations in accordance with conventional agricultural practice in the area and triazole fungicides have been applied consecutive times at the maximum permitted dose.

3.04.P-Tu104 Anthropogenic Gadolinium in Surfacewaters, Determination of Mri-Contrasts Using Ic-Icp-Sf-Ms

Marcel Kotte, RWS, Netherlands

Gadolinium-based contrast agents used in magnetic resonance imaging are difficult to impossible to remove in wastewater treatment plants, and may enter groundwater production wells and hence municipal tap water via bank filtration. As Rijkswaterstaat is responsible for surface-waters used in the production of drinking water, it has interest in knowledge about substances in its water-management area. Over a period of time, starting from January 2021, RWS has gathered information on the presence of Gd-based contrast agents. Together with information on the concentrations of other rare earth elements in surface water, RWS can provide an insight in the anthropogenic Gd. The poster will go into the analytical method used to determine Gd-based agents. Ion chromatography coupled with inductively coupled plasma, sector field mass spectrometry is used. Results will show that mostly macrocyclic Gd-based agents are present. This is in line with expectations, because these substances are used in the Netherlands. One linear compound is present which is also in line with expectations as this compounds is still used in Germany.

3.04.P-Tu105 Air-Sea Exchange and Atmospheric Deposition of Phthalate Esters in the South China Sea

Lijie Mi¹, **Wenyang Mi²**, **Lulu Zhang³**, **Lulu Zhang⁴**, **Ralf Ebinghaus⁵**, **Thomas Pohlmann⁶** and **Zhiyong Xie⁷**, (1)Helmholtz-Zentrum hereon, Geesthacht, Germany, (2)MINJIE Institute of Environmental Science and Health Research, Germany, (3)Chinese Academic of sciences, China, (4)VU University Amsterdam, China, (5)Helmholtz-Zentrum hereon, Germany, (6)Hamburg University, Germany, (7)Helmholtz-Zentrum Hereon, Germany

Phthalate esters (PAEs) are synthesized organic chemicals and have been used on a large scale as plasticizers and additives for more than 80 years. Upon their excellent characteristics, PAEs are extensively applied in manufacturing of resin and polymer products, building materials, personal care products. As PAEs are physically added in the products, they can leach out during the production and application, and especially from disposition of plastic waste. The continuous emissions of PAEs have led to their ubiquitous distribution and abundance in the global environment. In this study, we have determined nine PAEs in air and seawater samples from the South China Sea. Stationary air sampling has been performed at the Yongxing Island Marine Research Station of the South China Sea Institute of Oceanology from 17 May 2018 to 21 July 2019. Ship-bound sampling was carried out on board German research vessel Sonne along the transect from Singapore to Hong Kong from 2 August to 2 September 2019. All air and seawater samples were spiked with internal standards and extracted using a modified Soxhlet system in a clean lab. The sample analysis was performed with Agilent 8890A gas chromatography coupled to Agilent 7010B tandem mass spectrometry (GC-MS/MS). The concentrations of PEs are from below the method detection to 13 ng/m³ in air samples, and from 1.1 to 23ng/L in seawater, respectively. DiBP, DnBP and DEHP are the predominate PAEs in both air and water samples. Concentrations of PEs in air samples from Yongxing Island were supposed to be impacted by the monsoon, which leads to significant seasonal variations. Air-sea exchange and atmospheric particle deposition fluxes are calculated with paired gas/water concentrations and particle-bound fractions. The results showed air-to water deposition is the major process, which make the Southern China Sea being an important sink for PAEs.

3.04.P-Tu106 Accumulation and Chronic Effects of Cobalt on the Gastropod *Radix balthica*

Maëva Marimoutou¹, **Gilles Bareille¹**, **Patrick Baldoni-andrey²**, **Amiel Boullemant³**, **Cécile Courreges¹**, **Clementine Gelber⁴**, **Sandra Mounicou¹**, **Helene Tabouret¹** and **Severine Le Faucheur⁵**, (1)E2S-UPPA, CNRS, IPREM, Chaire Ecotox, France, (2)TOTALENERGIES, France, (3)Rio Tinto Aluminium Pechiney, France, (4)TOTAL ONE TECH S.E., France, (5)Université de Pau et des Pays de l'Adour, France

Gastropods are widespread mollusk living at the bottom and in shallow water of freshwater systems. First consumers of periphyton and plants, they represent an important source of food for large crustacean and fish. Toxic effects due to contamination such as metal increase might thus impede food sustainability of ecosystems. Gastropod shell has the interesting feature to grow

throughout their life by integrating some of the chemical elements present in their environment, including metals. Moreover, direct correlations have been observed between metal concentrations in the soft bodies of mollusks and those present in their ambient environment. The present study aims thus to examine the relationships between metal concentrations in the environment, in the gastropod soft tissue and in their shell. Here, cobalt (Co) is the metal of interest due to its increasing use in recent technologies of transport or energy production. Co effects towards gastropod growth and reproduction are also examined. To that end, the gastropod *Radix balthica* was exposed to increasing Co concentrations (6, 30 and 60 $\mu\text{g}\cdot\text{L}^{-1}$ Co) during 28 days using outdoor mesocosms (PERL, TotalEnergies) filled with the Gave de Pau water. Water and organisms were collected after 7, 14, 21, 28 days of exposure. The physicochemical parameters (pH, conductivity, oxygen and turbidity) were also monitored. Water was analysed for anion, cation and dissolved organic matter concentrations. Gastropod shell measurements (length and width) were performed at each sampling step whereas the number of egg masses was additionally monitored. Total metal concentrations were analyzed in the whole shells and soft bodies using acid digestions. Finally, microchemical analyses of metals in the shells are currently performed using Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS) and Time-of-Flight Secondary Ion Mass Spectrometry (TOF-SIMS). At day 28, the mortality (13, 19, 22 and 27 %) and the number of egg masses (21, 30, 44 and 56) increased with the Co concentrations (control, 6, 30 and 60 $\mu\text{g}\cdot\text{L}^{-1}$ Co, respectively). The number of neonates was higher in the control (193) than in Co enriched mesocosm (113, 10 and 58 for 6, 30 and 60 $\mu\text{g}\cdot\text{L}^{-1}$ Co, respectively). Finally, Co was measured by LA-ICP-MS at a concentration of $1.24 \pm 0.27 \mu\text{g}\cdot\text{g}^{-1}$ in the gastropod shell exposed to 60 $\mu\text{g}\cdot\text{L}^{-1}$ Co at day 28. Those results will allow us to determine if gastropod shell can be a good bioindicator of metal in freshwater.

3.05 Advancing analytical and experimental approaches for organic chemicals (Part I)

3.05.T-01 Characterising the Organohalogen Iceberg: Comprehensive, Multi-Halogen Mass Balance Determination in Sludge

Kyra Spaan¹, Bo Yuan², Merle Plassmann², Jonathan Benskin² and Cynthia de Wit³, (1)Department of Environmental Science, Stockholm University, ACES, Stockholm, Sweden, (2)Stockholm University, Sweden, (3)Stockholm University, Stockholm, Sweden

Organohalogen compounds (OHCs) comprise a wide range of fluorine-, chlorine-, and/or bromine-containing substances which are mostly anthropogenic and often have persistent, bioaccumulative and toxic properties. Currently, more than 30 000 individual OHCs, containing one or more halogens, are registered with a unique CAS number. Capturing this large number and diversity of chemicals in a single targeted method is challenging, leading to concerns that exposure to OHCs is underestimated. For this reason, there is growing interest in so-called “organohalogen mass balance” experiments, which seek to quantify the fraction of unidentified organohalogen in samples through a combination of mass spectrometry-based targeted analyses (both gas and liquid chromatography) and combustion ion chromatography (CIC)-based extractable organohalogen measurements. In this study we developed a multi-halogen CIC method for simultaneous determination of extractable organofluorine, -chlorine and -bromine in wastewater treatment plant (WWTP) sludge. The method was applied together with targeted analyses on samples from a WWTP in Stockholm. Targeted analyses included 16 per- and polyfluoroalkyl substances (PFAS), chlorinated paraffins (CPs), and 5 chlorinated and 38 brominated flame retardants (Cl-FRs and BFRs). Known extractable organohalogen (EOX) concentrations were calculated by summing the halogen equivalent concentrations from all OHCs measured by targeted analysis and then comparing these values to CIC-based EOX concentrations. 16PFAS contributed only ~2% of the EOF concentration, with the greatest contribution attributed to perfluorooctane sulfonate (PFOS; $7.0 \pm 0.6 \text{ ng/g dw}$). Likewise, 64% of organobromine levels were accounted for by 38BFRs, with BDE209 ($130 \pm 16 \text{ ng/g dw}$) and bis(2-ethylhexyl)tetrabromophthalate (BEH-TEBP; $83 \pm 6 \text{ ng/g dw}$) representing the most dominant substances. To the best of our knowledge, this study represents the first multi-halogen mass balance experiment conducted on sewage sludge samples. These data provide a comprehensive picture of both the known and unknown portions of the OHC “iceberg” in sludge and show that organohalogen concentrations are severely underestimated, especially for organofluorine and -chlorine compounds. Future work will apply high resolution mass spectrometry-based non-target screening to elucidate this unknown fraction.

3.05.T-02 Unravelling Chlorinated Paraffins; Characterising an UVCB and Evaluating Its Hazard Potential

Louise van Mourik¹, Elwin Janssen², Quinn Groenewoud², Martin van Velzen², Jessica Legradi², Jeroen Kool² and Pim Leonards², (1)E&H, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (2)Vrije Universiteit Amsterdam, Netherlands

UVCBs are compounds of unknown or variable composition, including complex reaction products and biological materials. The complex composition makes the characterisation and assessment of their (bio)degradation, bioaccumulative and toxic potential very challenging. The hydrophobic nature of most constituents further complicates the hazard and risk assessment. This study presents a novel approach for the isolation, collection, enrichment and characterisation of UVCB constituents. As proof of principle chlorinated paraffins (CPs) are used. Our approach applies GC fractionation in combination with various analytical methods, including nuclear magnetic resonance spectroscopy and GC×GC. With this approach it is possible to analyse a whole GC chromatogram by NMR and it lays the foundation to develop methods for obtaining purified single UVCB constituents. We also explored the possibility of generating biodegradation kinetics data for CPs and linking the fate data to toxicity data, a so called fate-directed toxicity approach. For generating biodegradation kinetics data a promising existing partitioning-based method has been applied that is able to determine biodegradation kinetics of hydrophobic organic hydrocarbons at environmentally relevant low concentrations. For generating toxicity data the Zebrafish (*Danio rerio*) early life test was applied to assess developmental toxicity and neurotoxicity.

3.05.T-03 Pyrolysis-Gc-Hrms an Application for the Identification and Quantification of Organic Plastic Additives

Fleurine Akoueson¹, Chaza Chbib², Armance Brémond³, Sebastien Monchy⁴, Ika Paul-Pont⁵, Périne Doyen⁴, Alexandre Dehaut³

and Guillaume Duflos³, (1)ANSES, France, (2)Aix-Marseille Université, France, (3)Agence nationale de sécurité sanitaire de l'alimentation, de l'environnement et du travail (Anses), France, (4)Université du Littoral Côte d'Opale, France, (5)LEMAR UMR 6539 CNRS, France

Environmental pollution from plastics and microplastics (MPs) is a threat to the environment and wildlife on multiple aspects regarding exposition of different hazards. One of them is due to the chemical impact of the organic plastic additives (OPAs). Various additives can be added to polymers during the manufacturing process to modify and improve their physical properties. The analysis of OPAs has shown a growing importance since their use has become controversial as some of the additives were found to be toxic to marine organism and humans. In order to have a better understanding of the chemical impact of those additives, it is important to identify and, ideally quantify the additives included in the polymeric matrices. The analysis of OPAs and polymers is an analytical challenge due to the diversity of their chemical composition, the fact that they are most of the time mixed, and the numerous steps needed for the sample preparation with "conventional" approaches such as solvent extraction (SE). Thus, implementing easy and quick screening analysis methods, able to analyse plastic additives, have become a focus of interest. Pyrolysis coupled to a gas chromatography and a high-resolution mass spectrometer (Py-GC-HRMS) is an analytical tool that enable a relatively quick and easy analysis. This technique minimize or even remove the steps for sample preparation, limiting their potential contamination prior the analysis. The goal of this study is to develop a method using Py-GC-HRMS to identify and, if possible, quantify OPAs included in a polymeric matrix. A single method for the analysis of various selected plastic additives has been implemented and benefits the constitution of a database in GC/MS-Orbitrap with a wide variety of plastic additives. This method has shown its ability to characterise several additives in plastic packaging samples. The development of the quantitative method is still on going.

3.05.T-04 Why DO Some "Blank" Samples Show Toxicity in Effect Directed Analysis?

Nina Cedergreen¹, Mafalda Castro², Yan Wang², Selina Tisler² and Jan Christensen², (1)Plant and Environmental Sciences, University of Copenhagen, Frederiksberg, Denmark, (2)University of Copenhagen, Denmark

Testing toxicity on environmental aquatic samples and using different approaches of effect directed analysis (EDA) to identify the substances causing toxicity, is an important tool to identify new and emerging toxicants of environmental concern. To measure toxicity, however, samples have to be up-concentrated to obtain an extract of the organic pollutants that can then be diluted into the media designed for the biological toxicity test. For the upconcentration of the environmental sample, different materials for solid phase extraction (SPE), and different solvent compositions are typically used for optimal elution of the sample. Paramount for the quality control of the EDA is the ability to run non-polluted water samples through this sample preparation procedure without detecting any toxicity in the biological assays at the relative enrichment factors (REF) used. In an ongoing project exploring the potential of virtual EDA (Vandalf-project), we have observed toxicity in both algae and daphnid bioassays from blank samples dosed at REF values up to 20-30. These results rose the question of what was causing the toxicity in our "blank" samples? We discovered that both ammonium added in the eluent mixture, and metals occurring in blanks could induce toxicity to algae and daphnids, respectively. We will present data on the frequency of blank sample toxicity, sources of the toxicity, and how it can be avoided and or dealt with when doing effect directed analysis.

3.05.T-05 TIMFIE Sampler - a New time-integrating, Active, Low-Cost Sampling Device for Quantitative Determination of Organic Micropollutants in Whole WATER

Ove Jonsson¹, Vera Franke², Wiebke Dürig², Oksana Golovko³, Thomas Andersson⁴ and Mikaela Gönczi⁴, (1)Swedish University of Agricultural Science, Sweden, (2)Swedish University of Agricultural Sciences, Sweden, (3)University of South Bohemia in CB, Sweden, (4)Swedish University of Agricultural Sciences (SLU), Sweden

Sampling techniques that enable quantitative determination of whole water concentrations are vital to assess the status of different waterbodies with respect to organic micropollutants (OMPs). Since OMP concentrations in aquatic environments are episodic, time integrated sampling is needed to estimate average concentrations and chronic exposure of biota. Time integrated sampling with automatic, electric samplers can be prohibitively expensive thus limiting the number of locations sampled and decreasing operational flexibility. Time integrated measurements based on passive sampling do not measure total concentrations and are not convincing for quantitative analysis. As a result, grab sampling is still the dominant sampling technique, despite its inadequacy for estimating average concentrations. To address these shortcomings, the Time Integrating, Micro Flow, In-field Extraction (TIMFIE) sampler was developed. This quantitative sampler is constructed from inexpensive laboratory consumables and requires no battery or power supply. A 120-mL single use syringe, connected to a flow restrictor, is set under negative pressure by pulling and locking the piston. This enables a low ($\mu\text{L}/\text{min}$) flow through SPE cartridges, where target compounds are continuously extracted over one or two weeks. The extracted water ends up in the syringe where sample volume can be determined, thus enabling quantitative analysis. The large number of available SPE adsorbents enable simultaneous extraction of compounds having very different physicochemical properties. TIMFIE was originally developed for pesticides but has been used to measure other OMP classes in whole waters, i.e., PFAS, pharmaceuticals, industry chemicals and personal care products, using four different LC-MS/MS multimethods. Furthermore, the water collected in the syringe opens up new possibilities to determine average free concentrations of other substance classes, e.g., metals, and possibly nutrients. Thanks to its small format and robust, low-tech construction the TIMFIE sampler can be mounted in many different ways, to support various needs, including winter sampling. Experiences from method development and validation, as well as a field study performed in five different regions in Sweden during 2021 will be presented.

3.05 Advancing analytical and experimental approaches for organic chemicals (Part II)

3.05.T-06 In Situ Vertical Profiles to Measure Seasonal Variation in Dissolved HOC Concentrations at the Sediment-Water and Air-Water Interphases

*Inna Elina Nybom*¹, *Janneke van Grimbergen*², *Mari Forsell*² and *Anna Sobek*², (1)University of Eastern Finland, Finland, (2)Stockholm University, Sweden

Hydrophobic organic contaminants (HOCs) are ubiquitously present in the aquatic environment, and cycle in the environment between different environmental phases. In this study low density polyethylene (LDPE) passive samplers were used to attain *in situ* vertical profiles from sediment-water and air-water interphases, to study the seasonal variation in air and water concentrations of polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs), and to assess their diffusive mass transfer at the air-water and sediment-water interphases. Seasonal variation in surface water and air concentrations was observed, with higher concentrations of PAHs in the autumn. The observed difference is likely induced by higher combustion-derived PAHs sources during autumn. The opposite was observed for PCBs, which implemented higher concentrations in surface water and air during the summer period. Elevated PCB concentrations in air during summer may be due to mass transport from urbanized areas or from re-volatilization from water. Upward diffusive fluxes from water to air for PCBs (excluding CB-28 and CB-110) were observed in this study, potentially contributing to the elevated air concentrations at the sampling site. Desorption fluxes from air to water was observed for PAHs at both seasons. Enrichment of the HOC concentrations near the water surface was observed, indicating that the air-water profilers can provide high resolution vertical measurement of HOCs in the subsurface waters, sea-surface microlayer and in the air above. Thermodynamic disequilibrium was observed between sediment pore-water and bottom water, with upward release fluxes from the sediment. These results indicate that when the primary emissions of HOCs have decreased, sediments at the coastal areas can start acting as a secondary sources of HOCs to the water phase. Passive sampling at the sediment-water and air-water interphases proved as an effective method to assess the concentrations and fluxes of HOCs in the coastal Baltic Sea and to detect seasonal variation in concentrations. *In situ* passive sampling campaign using the same passive sampling polymer in multiple environmental phases provides advantages for assessing the environmental fate, for example by allowing direct comparison of the equilibrium polymer concentrations to assess the direction of the air-water and sediment-water exchange.

3.05.T-07 Probing the Thermodynamics of Biomagnification in Captive Polar Bears by Equilibrium Sampling of Dietary and Fecal Samples

*Yuhao Chen*¹, *Ying Duan Lei*², *Jaap Wensvoort*³, *Sarra Gourlie*³ and *Frank Wania*⁴, (1)University of Toronto, Scarborough, Canada, (2)University of Toronto, Canada, (3)Toronto Zoo, Canada, (4)University of Toronto Scarborough, Toronto, ON, Canada

Biomagnification is the process through which organisms can have higher lipid-normalized concentrations of hydrophobic contaminants in their bodies than are prevalent in the food they eat. The underlying mechanism is a decrease in volume (V) and fugacity capacity (Z) of the food for the biomagnifying contaminants during digestion and assimilation in the gastrointestinal tract. In an earlier proof-of-concept study, we used equilibrium sampling with silicone films to noninvasively derive the thermodynamic limit to a canine's biomagnification capability (BMF_{lim}) by determining the ratio of the $V \cdot Z$ products of undigested and digested food. Low contaminant levels prevented the determination of the fugacity (f) or chemical activity of contaminants in food and feces. For polar bears from the Toronto Zoo, fed on fish and seal oil, we were not only able to measure the Z -value of diet and feces by equilibrium sampling, but also the increase in the f of native polychlorinated biphenyls (PCBs) upon digestion, providing incontestable proof of the process of gastrointestinal biomagnification. We could also confirm that equilibrium sampling yielded similar Z -values for PCBs originally present in food and feces and for isotopically labelled PCBs spiked onto those samples, so that the determination of f even in samples with small size and low contaminant levels becomes possible as long as the concentration of the compound in the sample (C_{native}) can be quantified (i.e. $f = C_{native}/Z_{spiked}$). For zoo bears eating a diet rich in lipids (24 %, as fed basis), an observed BMF_{lim} of ~171 indicates a very high biomagnification capability, which can be attributed to reductions in both Z (Z_D/Z_F from 53 to 113) and V ($V_D/V_F = 2.4$). Our study highlights the importance of a high fat diet and a high lipid assimilation efficiency (99 %) for achieving high BMF_{lim} . A PCBs uptake efficiency of 98 % indicates that contaminant concentrations in the zoo bears are still far from steady state, thus resulting in a biomagnification factor ($BMF = f_{feces}/f_{food} = 3$) that is much smaller than the BMF_{lim} .

3.05.T-08 In-Tube Passive Dosing for Flow-Through and Large-Volume Experiments

*Haotian Wang*¹, *Heidi Birch*², *Karina Knudsmark Sjöholm*³, *Xinghui Xia*⁴ and *Philipp Mayer*⁵, (1)Beijing Normal University, China, (2)DTU Environment, Lyngby, Denmark, (3)Technical University of Denmark (DTU), Denmark, (4)School of Environment, Beijing Normal University, China, (5)DTU Environment, Denmark

Passive dosing is increasingly used to control exposure concentrations of hydrophobic organic chemicals (HOCs) in small sized and short term aquatic tests. However, there are increasing demands for conducting aquatic toxicity and bioconcentration experiments in larger test systems and for longer test durations. The challenge of upscaling passive dosing to larger test systems is that mass transfer from the passive dosing donor to the exposure medium is diffusion limited. Longer test durations can lead to the formation of biofilm that can limit mass transfer or even degrade the test substance. This study introduces in tube passive dosing (in tube-PD) as an approach to control HOC exposure in larger test volumes and flow-through experiments: Aqueous medium is dosed by pushing it through a tube holding HOC loaded silicone rods. We equipped a 6 meter PTFE tube (ID 10mm) with four parallel silicone rods (OD 3mm) to accommodate water flows from 0.2-120 L/h, and developed a mass transfer kinetic model to capture the chemo-dynamics in the system. The first experiment was conducted with fluoranthene, where aqueous concentrations were measured by molecular fluorescence at different (1) flow rates, (2) water volumes and (3) positions within the tube. The second experiment was conducted with a complex petroleum mixture (cracked gas oil, UVCB), where concentrations of 22 mixture constituents were measured by solid phase microextraction coupled to GC-MS. The results showed that the system

provided very stable and reproducible concentrations over extended periods of time, which were at equilibrium for flows < 10 mL/min and steady state at higher flows. The results were consistent with the mass transfer kinetic model. A long-term test showed that approximately 1.5 m³ water can be dosed before fluoranthene concentrations declined by 20%. The developed in tube-PD can easily be combined with various types of toxicity, bioconcentration and other experiments. The physical separation of dosing system and test vessel can here minimize biofilm formation on the PD donor. A mass transfer kinetic model was developed, which not only was used to fit the experimental data but also provided mechanistic insight of the partitioning kinetics. This model can guide the future design and optimization of in tube-PD systems to meet the various demands in aquatic testing and research.

3.05.T-09 Expanding the Applicability Range of the Generator Column Technique for Measuring the Octanol-Air Partition Ratio to Volatile Substances

Sivani Baskaran¹, Ying Duan Lei² and Frank Wania³, (1)University of Toronto - Department of Chemistry, Canada, (2)University of Toronto, Canada, (3)University of Toronto Scarborough, Toronto, ON, Canada

Bioaccumulation modelling has identified a lower limit of ~5 for the log of the octanol-air partition ratio ($\log K_{OA}$) of chemicals that potentially bioaccumulate in air-breathing organisms. While hundreds of measured $\log K_{OA}$ values exist, few are close to that threshold, because existing techniques are not well suited to this volatility range. Here, we modified the generator column method to allow for K_{OA} determinations of more volatile compounds. In a generator column experiment, octanol saturated air flows through a column containing an octanol solution of the analytes of interest. Chemicals evaporate into the air stream until equilibrium is reached. They are collected from air and quantified. The K_{OA} is calculated from the concentration in octanol (C_O) and the volume of air passing through the column (V_A). For less volatile compounds a large V_A is equilibrated with the octanol so that the amount of chemical in air can be quantified. This necessitates high flow rates of 50-100 mL/min and long experimental run times. For volatile chemicals, a smaller V_A needs to be equilibrated with octanol to prevent chemical depletion from the column. We reduced flow rates to 5-15 mL/min and experimental run times to 30-60 minutes. The concentration of less volatile chemicals in the octanol in the generator column is assumed to remain constant during multiple experiments lasting many hours; it is often not even measured but inferred. Because volatile chemicals are more likely to be lost from the octanol, we extract and measure the amount of chemical in the column at the end of an experiment and calculate the C_O during each run by interpolating between the initial and final C_O . By recording K_{OA} values for hexachlorobenzene that agree with earlier measurements we confirmed our ability to obtain reliable data with the generator column technique. $\log K_{OA}$ values for tri-isopropyl phosphate, tetradecene, 1,3-dichlorobenzene, 1,2,3,4-tetramethylbenzene, *trans*-decalin, 2,6-dimethyldecane, and hexylcyclohexane have been obtained with the modified technique. Good agreement with predictions made with poly-parameter linear free energy relationships lends confidence to these data. Reducing gas flow rates and experimental run times and quantifying the concentration in the octanol phase are key to obtaining reliable K_{OA} data when applying the generator column technique to volatile compounds.

3.05.T-10 Understanding the Effects of Temperature on Pesticide Plant-Air Partitioning and Foliar Penetration

Kimberly J. Hageman, Ashlie Kinross and Calvin Luu, Utah State University, United States

Plant-air partition coefficient ($K_{\text{plant-air}}$) values are needed to understand and predict pesticide volatilization and persistence in agroecosystems. While temperature is expected to increase chemical volatilization from surfaces, there are several competing processes on the leaf surface and each is affected by temperature in different ways. Of particular interest, increasing temperatures can lead to increased sorption to the leaf surface but can also increase diffusion into inner leaf layers. Since both of these processes could result in less chemical available for volatilization, the effects of temperature on volatilization may not be as easy to predict as expected. The objectives of this work were to measure $K_{\text{plant-air}}$ values and foliar penetration for two current-use insecticides on alfalfa (lucerne) leaves at a range of temperatures and to use this data to better understand how sorption and foliar penetration effect plant-air partitioning. The insecticides investigated were chlorpyrifos (an organophosphate, studied as both the active ingredient alone and in a formulation) and γ -cyhalothrin (a pyrethroid, studied as the active ingredient alone). $K_{\text{plant-air}}$ values were measured using a solid-phase fugacity meter. Following the 16-h experiments, a portion of the leaves were used for foliar penetration experiments. This method involved successive extractions in which ethanol-extractable (surface associated), hexane-extractable (cuticle associated), and remaining (tightly bound) fractions of chemical were collected. We found that temperature had an opposing effect on the $K_{\text{plant-air}}$ and foliar penetration trends for the two pesticides. In sum, chlorpyrifos behaved as expected, with both increasing volatilization and diffusion to inner leaf layers with increasing temperature. However, γ -cyhalothrin displayed decreasing volatilization and increasing sorption to the leaf surface with increasing temperature. Nonetheless, we found that $K_{\text{plant-air}}$ values increased as the amount of chemical in the ethanol-extractable layer increased for both chemicals. Thus, we concluded that increasing temperature leads to changes in leaf surface properties that have complex effects on the interplay of volatilization, sorption and diffusion, resulting in different possible trends in $K_{\text{plant-air}}$ with temperature for different chemicals.

3.05 Advancing analytical and experimental approaches for organic chemicals (Virtual Only)

3.05.V-01 Freely Dissolved Concentration Analysis of Cationic Surfactant Benzalkonium in Sediment Toxicity Test Using Passive Sampling Method

Sakura Yoshii¹, Kyoshiro Hiki¹, Haruna Watanabe² and Satoshi Endo¹, (1)National Institute for Environmental Studies (NIES), Japan, (2)National Institute for Environmental Studies, Japan

A cationic surfactant benzalkonium chloride (BAC) has been used in household stuff such as antimicrobials, detergents, and fabric softeners. The impact of BAC on the environment has been of concern in ecotoxicological and environmental studies in recent

years because of its relatively high toxicity and strong adsorption property to negatively charged surfaces (e.g. soils and sediments). For assessing the toxicity of a chemical in sediments to benthic organisms, the freely dissolved concentration (C_{free}) in pore water is regarded as a key factor. C_{free} is usually measured using passive samplers such as solid phase microextraction (SPME) fibers. However, passive sampling methods have not been widely applied to C_{free} determination of cationic surfactants in sediments yet, and the suitability of C_{free} as a measure of exposure to cationic surfactants in sediments is still not clear. In this study, we measured C_{free} of benzyldimethyldodecylammonium (C12-BAC) in sediment toxicity test systems with a passive sampling method using polyacrylate (PA) coated glass fibers and compared the C_{free} with the total dissolved concentration (C_{diss}) in pore water collected by centrifugation. The organic carbon/water partition coefficient ($\log K_{\text{oc}}$) of C12-BAC estimated in passive sampling tests using a river sediment was 6.55 ± 0.04 , comparable to literature values. The results from the preliminary sediment toxicity tests using an amphipod *Hyalella azteca* as test organisms show that $\log K_{\text{oc}}$ of C12-BAC in OECD sediments was 5.25 ± 0.24 , and that the C_{free} in pore water was ca 10 times higher than the C_{free} in overlying water, partially as a consequence of a semi-flow through exchange with fresh water. In addition, C_{free} in pore water was 2–25 times lower than C_{diss} , which may be explained by significant binding of C12-BAC to dissolved organic carbon in pore water. These results indicate that C_{free} measurement can illustrate the distribution behavior of cationic surfactants in sediment test systems and suggest that pore water C_{free} has the possibility to be as a measure of the toxicity of cationic surfactants in sediments.

3.05.V-02 Method Validation for the Determination of Pesticides in Human Blood by Laminar Flow Mass Spectrometry

Celine De Montigny¹, Amelie Estienne¹, Dr Laurence Pellegrina¹ and Philippe Boniteau², (1)EUROFINS-BIOMNIS, France, (2)PerkinElmer, Villebon-sur-Yvette, France

Discussions about pesticides focus on the risks they pose to health and the environment. Many studies are being carried out to better understand the impact of pesticides on health, often by establishing a link between the area of use and the proximity to the individual. However, little correlation has been established between exposure to pesticides (through the environment or food) and the presence of residue in the body. Often this study is performed on urine samples which may be distorted by diuresis or issues with the shelf life of pesticides. We have chosen to analyze the pesticides on a serum matrix on a normal population regardless of environmental exposure, focusing on the pesticides most found in our food and the most regulated according to EFSA to ensure high safety for consumers. The objective of the study is to validate an LCMSMS analysis including the QuEChERS sample extraction and cleaning method and to obtain an accurate, reliable, and robust quantification of 19 targeted pesticides using a new technology LCMSMS. This analysis makes it possible to supplement existing epidemiological analysis and to observe a correlation between the exposure of a population to a pesticide, its detection and its persistence in the human body. The 19 molecules chosen are the most found in analyses of pesticides in food and water. Some molecules analysed: Carbendazim, Chlorpropham, Chlorpyrifos, Piperonyl Butoxide, Atrazine The goal was to find a single extraction method to dose these 19 pesticides simultaneously and provide the patient with a comprehensive report on his exposure to pesticides. The LCMSMS method and the use of the QuEChERS extraction was chosen because of its sensitivity and the existence of a single method allowing simultaneous identification and quantification of the 19 molecules Performance to be achieved:- Recovery on a control at 2 µg/L: 70-130% - S/N ratio for qualification transition >3- Limits of quantification: between 0,5µg/L and 10µg/L depending on the molecules- Variability of the internal standard in control solutions and patients: < 3 SD- Repeatability: < 20% or < 10% depending on the concentrations and RSD< 20% on internal standard pic area- Intermediate precision for 30 days: RSD< 20% on concentrations and peak area of Internal Standard and molecules Inter component contamination< 1%

3.05.V-03 Post-Acquisition Data Mining for Fungicides and Their Metabolites in an Inter-City Study Using Ultra-Performance Liquid Chromatography Coupled With High Resolution Tandem Quadrupole Time-Of-Flight Mass Spectrometry

Rawiwan Wattanayon¹ and Barbara Kasprzyk-Hordern², (1)Chemistry, University of Bath, Bath, United Kingdom, (2)University of Bath, United Kingdom

The presence of antifungal agents in the aquatic environment is a concern in many countries because antifungals are widely used as human pharmaceuticals, in household products and in agriculture. Fungicides are widely detected in wastewater treatment plants, sludge and river surface waters. Antifungals are found in surface waters and wastewater at up to $\mu\text{g/L}$ levels. The purpose of this study was to develop an analytical framework utilising retrospective data mining and full quantification with ultra performance liquid chromatography coupled with high resolution QTOF mass spectrometry for selective and sensitive multi-residue analysis of antifungals. The linearity of calibration curves (r^2) were generally > 0.997 for the concentration range 0-1000 ngmL⁻¹. The accuracy in the same day and different three days was typically within the range 83–117% and showed precision below 23% RSD. The SPE recoveries of most of antifungal agents were between 80-119%. However, some compounds provided low or high recoveries due to matrix effect. This method provided low (ng/L) MQs for most analytes and was applied to investigate their usage and fate of antifungals in catchment located in South-West England.

3.05.V-04 Quantification of Polyaromatic Hydrocarbons (PAH) by Online Spe-Lc/Ms/Ms in Drinking WATER

Derek Mattern¹, Roberto Bozic² and Aristide Ganci², (1)PerkinElmer, Germany, (2)PerkinElmer, Italy

Regulatory water directives from around the globe have implemented environmental quality standards for drinking water and in particular in the European Union, they have defined a list of more than 30 priority substances that have been determined to be high risk to humans (1). One class of compounds included are the polyaromatic hydrocarbons (PAH) that are of concern because of their potential adverse effects to our health (2). In the present work we demonstrate a robust and highly sensitive method using online SPE-LC/MS/MS to quantify the five PAHs (Benzo(a)pyrene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(ghi)perylene, indeno(1,2,3-cd) pyrene) listed in the latest EU drinking water directive (1). The goal of the present work is

to show an alternative to current methods such as LC-FLD (Fluorescence) or even GC/MS in analyzing the regulated PAHs and still meet the strict limits set forth. Moreover, this method needs no further offline sample preparation, because we used PerkinElmer's QSight SP50 Online SPE System. This module in addition to the UHPLC facilitates sample clean-up, enrichment and concentration, obviating the need for elaborate and time-consuming sample preparation procedures. A good example of how we could reach the required sensitivity was with Benzo(a)pyrene, the PAH with the lowest required amount. We could reach 0.002 µg/L, five times lower than the required limit of 0.01 µg/L. Additionally, with the other four PAHs, we could also reach levels of 0.002 µg/L, where the regulation states 0.1 µg/L as a sum of the four. This also easily meets the sensitivity requirements with some room to spare. References: 1. EU COUNCIL DIRECTIVE 98/83/EC [cited 2020 Dec. 10]. Available: <https://eur-lex.europa.eu/legal-content/EN/TXT/PDF/?uri=CELEX:31998L0083&from=EN> 2. 3.05.V-05 Seasonal Occurrence and Risk Assessment of Endocrine-Disrupting Compounds in Tagus River Estuary Biota Antía Lestido¹, Mateus Petrarca², Jose Fernandes³, Isa Marmelo⁴, António Marques⁵ and Sara Cunha⁶, (1)Faculty of Pharmacy, University of Santiago de Compostela, Spain, (2)LAQV-REQUIMTE, Portugal, (3)REQUIMTELAQV, Portugal, (4)IPMA, I.P., Portugal, (5)Portuguese Institute of Sea and Atmosphere IPMA, Portugal, (6)LAQV-REQUIMTE, Porto, Portugal

Water pollution in our seas and rivers has a direct impact in flora and fauna and, consequently, on human health. One essential aspect in food safety is to determine health risks associated with the presence of chemical contaminants in food. Such contamination includes, for example, bisphenols from industrial sources, pesticides from crop treatments, or personal care products, which are synthetic organic chemicals frequently used in cosmetic and hygienic products, such as musk fragrances, disinfectant, surfactants and ultraviolet (UV) filters, among others. Most compounds can be classified as endocrine disrupting chemicals (EDC). In this study, the simultaneous analysis of four types of EDC (21 pesticides, 4 polycyclic musk fragrances, 4 UV-filters and 7 bisphenols) in 296 samples including fish, bivalves, crustaceans, earthworm and macroalgae samples collected in Tagus River estuary biota to assess the environmental contamination and dietary exposure to these chemicals. Samples were collected in different seasons (winter, spring, summer, and autumn). In addition, the risk assessment for humans were evaluated. The analysis was achieved by Quick, Easy, Cheap, Effective, Rugged, Safe (QuEChERS) extraction combined with dispersive liquid-liquid microextraction-derivatization, followed by gas chromatography-single quadrupole mass spectrometry (GC-MS). A total of 14 of the 36 chemical compounds analysed could be identified and quantified in the studied biota, including 5 pesticides (alachlor, ethion, DDT, bifenthrin and γ -chlordane), 2 musk fragrances (galaxolide and tonalide), 4 UV-filters (EHS, IMC, EHMC, BP3), and 3 bisphenols (BPF, BPA and BPB). In general, the highest level of analytes in the different species was found in summer. Estimated dietary intakes (EDI) was calculated using the available consumption data of the Portuguese population obtaining a mean EDI of musks ranged between 0.2-5.9 µg/kg bw/day, 0.3-1.8 µg/kg bw/day for pesticides, 0.3-5.2 µg/kg bw/day for UV-filters and 0.1-3.8 µg/kg bw/day for bisphenols. Among fish liver samples analysed in this study, only residual amounts of galaxolide, tonalide, chasmeran, EHS and BPF were detected. In conclusion, based on the risk assessment performed, it is unlikely that there is a potential health risk because the exposure to these compounds is much lower than the tolerable day intake established. Funding: This work was supported by FEDER (Programa Operacional Competitividade e Internacionalização - COMPETE 2020), from PIDDAC through FCT/MCTES project POCI-01-0145-FEDER-028708, by UIDB/04423/2020 and AgriFood XXI R&D&I project, operation No. NORTE-01-0145-FEDER-000041, co-financed by the European Regional Development Fund (ERDF) through NORTH 2020 (Northern Regional Operational Program 2014/2020).

3.05 Advancing analytical and experimental approaches for organic chemicals (Poster)

3.05.P-Tu107 RAINBOWflow CHIP: Ensuring Stable Chemical Concentrations for Toxicity Assessment by a Miniaturised Flow-Through System With Fish Cells

Jenny Maner¹, Carolin Drieschner², Rene Schonenberger³, Christian Ebi³, Philippe Renaud⁴ and Kristin Schirmer³, (1)Environmental Toxicology, Eawag, Switzerland, (2)HSE AG, Switzerland, (3)Eawag, Switzerland, (4)EPFL, Switzerland

Fish form an integral part of aquatic ecosystems, and as such comprise a compulsory constituent of toxicity testing for chemical risk assessment and effluent testing; millions of fish are sacrificed annually in this context. One *in vitro* alternative is the use of fish cells. Cell lines of different species and organs exist, and have shown good correlation with *in vivo* results. In the RAINBOW_{FLOW} CHIP project, we use an intestinal cell line of the rainbow trout (*Oncorhynchus mykiss*), RTgutGC, for impedance sensing: cells are seeded on a microfluidic electrode chip and their adherence creates a resistance to the electric current flow, which reflects the health status of the cells. A decrease in resistance is an indicator for loss of cell viability as can be elicited, for example, by exposure to chemicals. Impedance sensing is non-invasive and can be measured in real-time, allowing for time-resolved analysis of cell viability. The aim of this project is thus to employ impedance sensing for chemical hazard assessment. A multi-channel microfluidic setup allows several concentrations to be tested in parallel by flow-through dosing. The flow of medium creates a shear stress which is a positive stimulus for these epithelial cells. In addition, the flow-through dosing allows for constant replenishment of the test substance. This is especially important for difficult-to-test (i.e., volatile and hydrophobic) chemicals, which are prone to losses by sorption and evaporation, thus potentially leading to underestimation of toxicity. Our first results show that stable exposure concentrations could be maintained for three model substances with different physico-chemical properties for at least 24 hours. In the next step, RTgutGC cells will be exposed to these substances for time- and concentration-dependent toxicity testing. Overall, the RAINBOW_{FLOW} CHIP biosensor will allow the investigation of toxicity of chemicals with stable or purposefully fluctuating concentrations over time without the need to conduct animal experiments. Moreover, extensions of this setup – specifically for applications to on-line effluent monitoring in the field – are also currently being implemented.

3.05.P-Tu108 Hydrophobic Organic Chemicals in Sediment Toxicity Tests - Optimizing Passive Dosing by 3D Printing Techniques

Nathalie Iris Grau¹, Andreas Schäffer² and Felix Stibany, Dr.², (1)Institute for Environmental Research, RWTH Aachen, Aachen, Germany, (2)RWTH Aachen University, Germany

Ecotoxicological tests of hydrophobic organic chemicals (HOC) come with different challenges. HOC tend to strongly sorb to organic material in the test system as well as to test vessels, materials and/or test organisms which complicates the exposure control of the freely dissolved concentration and might finally lead to an underestimation of the measured effects. In sediment toxicity testing the high amount of organic material can result in strong sorption effects, and a freely dissolved pore-water concentration (effective concentration) much lower than the total concentration. Also, analysis of the pore-water concentration is not straightforward, but information about the distribution of the chemicals and the resulting pore-water concentration is crucial for the ecotoxicological assessment of HOC in sediment toxicity studies. Passive dosing (PD) is a method that offers a reliable exposure control and leads to a constant dissolved concentration of the test compound over time. By applying an inert reservoir to the test system, loaded with the HOC, PD can make up for any losses of the test compound over the course of the experiment. PD reservoirs are often made of silicone and can have different shapes such as O-rings, tubes, or sheets. However, in a sediment toxicity test, the use of these forms is problematic due to their inhomogeneous distribution in the sediment. Here, a more complex form with a high surface-area-to-volume ratio was selected to ensure a homogenous distribution throughout the sediment layer and fast release kinetics. The design of the new passive dosing device was developed *in silico* in an adaptive manner and produced by 3D printing a casting form using a polylactic acid (PLA) filament. The used PLA is transparent, biocompatible, and food-safe to ensure no contamination of the silicone from colours or other additives. The 3D printed PLA negative form was finally casted with a food-grade 2-component silicone to create the final device. The distribution of selected hydrophobic model compounds in standard sediments was tested as well as their release kinetics from the new silicone forms. Furthermore, we will report the distribution coefficients between silicone, water and sediment which allow to estimate the pore-water concentration.

3.05.P-Tu110 Bioaccessibility of Persistent Organic Pollutants From Indoor Dust in Human Gastrointestinal Tract

Simona Rozarka Jilkova¹, Hidenori Matsukami², Natsuyo Uchida², Tatsiana Rusina³, Go Suzuki², Branislav Vrana⁴, Klara Hilscherova⁴ and Lisa Melymuk⁵, (1)Research Centre for Toxic Compounds in the Environment, Faculty of Science, Masaryk University, Czech Republic, (2)National Institute for Environmental Studies, Japan, (3)Masaryk University, Czech Republic, (4)Masaryk University, Faculty of Science, RECETOX, Czech Republic, (5)RECETOX, Masaryk University, Brno, Czech Republic

Indoor dust ingestion is considered one of the main human exposure routes for many chemicals, particularly consumer product additives such as flame retardants and plasticizers. Bioaccessibility of chemicals from ingested dust has been defined as the fraction of a compound that is released from its matrix within the gastrointestinal tract and thus becomes available for intestinal absorption. Bioaccessibility in terms of ingestion and risk assessment is frequently discussed and the understanding of the process for individual chemicals can help to improve risk assessment for human health. For this purpose, numerous tests have been developed which simulate transfer from the matrix to the gastric or intestinal fluids. One commonly used test is the modified physiologically based extraction test (PBET), which simulates processes in the stomach (for one hour) and small intestine (for four hours). In this study, the bioaccessibility of a set of chemicals of concern (halogenated flame retardants, polychlorinated biphenyls, organochlorine pesticides) from dust samples was tested with PBET. Dust samples were collected in seven microenvironments: (1) pre-fab apartment blocks, (2) new houses built after 2005, (3) kindergartens, (4) schools, (5) offices, (6) public spaces, and (7) cars. The finest fraction (< 0.25 mm) of the dust was used because it is the most relevant fraction for ingestion. The bioaccessible fraction of chemicals of concern varied based on dust origin (e.g., higher bioaccessibility of some compounds in public spaces) as well as on the chemical itself. Bioaccessible fractions were mostly under 10 % of total concentrations extracted by organic solvents, which suggests using total dust concentrations overestimates the internal exposure of pollutants from dust, e.g., when performing risk assessment. Supported by the grant 19-20479S from Grant Agency of the Czech Republic.

3.05.P-Tu111 Evaluation of Different Solid-Phase Extraction Methods for Effect-Based Assessment of Hazardous Chemicals in WATER - Differences in Recovery and Background Activities

Kim Frieberg¹, Viktor Stensson² and Johan Lundqvist³, (1)BVF, Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden, (2)Swedish University of Agricultural Sciences (SLU), Sweden, (3)Swedish University of Agricultural Sciences, Sweden

Solid-phase extraction (SPE) is commonly used for enrichment of different water samples (e.g. drinking water, wastewater and surface water) as preparation for effect-based assessment of hazardous chemicals in the sample. There is a wide range of sorbent materials available for solid-phase extraction, capturing different classes of pollutants. Further, different sorbents can be combined in multi-layer columns. It is well-known that environmental and drinking water samples can be polluted with a very complex mixture of chemicals. Effect-based water quality assessments are commonly run in a battery of bioassays, with each a specificity to one endpoint. As water samples can be contaminated with a very complex mixture of chemical pollutants, it is desirable to use SPE sorbents that can capture as broad range of pollutants as possible, to gain a holistic understanding of the hazardous chemicals in a sample and potential cocktail effects. At the same time, it is of utmost importance to ensure that the sorbent material is not contaminating the sample with any compounds that might interfere with the effect-based assays and cause false positive results. In this study, we have evaluated three commercially available SPE columns as well as one custom-built SPE column to observe the recovery of bioactivity of hazardous chemicals in both environmental water samples as well as spiked pure water. Additionally, we evaluated the potential contamination of water samples from sorbent materials by processing pure water controls. The extracts were then assessed in a battery of commonly applied bioassays for water quality assessment. Endpoints as xenobiotic metabolism,

hormone-receptor mediated effect as well as adaptive stress response were included. The results show differences in recovery between the sorbent materials and also indicate that some sorbent materials might contaminate samples with bioactive compounds which might interfere with the bioanalysis. It is evident that the choice of sorbent will greatly affect the outcome of the bioassay.

3.05.P-Tu112 Chemical Activity As a Quantitative Measure to Assess the Effects of Contaminant Mixtures on Phytoplankton

*Talles Oliveira*¹, *Sebastian Abel*², *Elin Lindehoff*³, *Clare Bradshaw*⁴ and *Anna Sobek*⁴, (1)ACES, Stockholm University, Stockholm, Sweden, (2)Helmholtz-Zentrum für Umweltforschung GmbH - UFZ, Germany, (3)Linnaeus University, Sweden, (4)Stockholm University, Sweden

Phytoplankton cells accumulate organic contaminants from the water phase through passive partitioning. The accumulating rate of these compounds is modulated by the physicochemical properties of both contaminants and phytoplankton cells. Understanding the mechanism that regulates phytoplankton's sensitivity towards a mixture of organic contaminants will better predict the effects of chemicals on biodiversity and productivity in aquatic ecosystems. Previous studies demonstrated the applicability of the chemical activity concept for different organisms; however, there is a lack of studies on primary producers. Our aim is to assess (eco)toxicological responses to chemical activities ranging from 0.01 to 0.2 of mixtures of four PAHs in the model phytoplankton species *Rhodomonas salina* (KAC 30). The concentration of each chemical is maintained below its established no effect concentration (NOEC) for any specific toxicity mechanism. A passive dosing method is used to obtain stable exposure levels. The concentrations in both water and biota are measured with GC-MS methods to confirm actual exposure levels to the chemicals. Growth and yield inhibition, membrane integrity, and photosynthetic activity will be assessed. We hypothesize that the chemical activity in the mixture and the observed effects in *Rhodomonas salina* follow a dose-response curve and that membrane integrity stands out as a sensitive and valuable early-warning signal to catch PAH-baseline toxicity.

3.05.P-Tu113 Questioning the Appropriateness of Sieving for Processing Indoor Settled Dust Samples

*Lisa Melymuk*¹, *Simona Rozarka Jilkova*², *Michal Kolar*³, *Petra Svobodová*³, *Branislav Vrana*⁴ and *Klara Hilscherova*⁴, (1)RECETOX, Masaryk University, Brno, Czech Republic, (2)Research Centre for Toxic Compounds in the Environment, Faculty of Science, Masaryk University, Czech Republic, (3)Masaryk University, Czech Republic, (4)Masaryk University, Faculty of Science, RECETOX, Czech Republic

Indoor settled dust is a common matrix for assessing human exposure to organic chemicals of concern (e.g., flame retardants, plasticizers). However, many of the techniques commonly used to collect and process indoor dust samples are not standardized, and are based on techniques adapted from other matrices. In this study, we consider the implications of sieving for pre-processing dust samples and the impact of this technique on measurements of chemicals in dust. Using composite dust samples from seven different microenvironments (pre-fab apartment blocks, new homes, kindergartens, schools, offices, public spaces, and cars), we investigated the effect of sieving by comparing individual size fractions of dust (1-2 mm, 0.5-1 mm, 0.25-0.5 mm, < 0.25 mm). Analyses of polycyclic aromatic hydrocarbons (PAHs) in dust fractions was combined with carbon analysis and optical microscopy to better understand the impact of sieving on observed distributions. The technique of sieving to pre-process dust samples developed from soil science, and is appropriate for dry, non-fibrous particles. However, microscopy analysis suggests that dust is not effectively separated by size fraction with this technique. Dust forms aggregates, which contain fine particles and are retained by coarser sieves, particularly due to the content of fibres, which are not found in e.g., soils. Thus, fine dust fractions will be biased towards non-fibrous particles, and coarse dust fractions will contain substantial fine particles. This was supported by measurements of carbon (total and organic) in individual size fractions of dust, which showed a high contribution of organic carbon (21±10%) across all dust size fractions without systematic variation with particle size. PAHs, rather than being predominantly found in the finest fractions, also had no systematic increase with finer size fractions, unlike typical distributions in aerosols or soils, where finest fractions also contain the highest levels of lipophilic organic compounds. This observed heterogeneity, attributed to the formation of aggregates during vacuuming and sieving, has implications for how dust samples are collected and processed for the purpose of exposure assessment. We emphasize the importance of carefully questioning techniques adapted from other matrices to understand how new factors (e.g., fibrous dust particles) can impact study outcomes. This work was supported by grant 19-20479S from the Grant Agency of the Czech Republic.

3.05.P-Tu114 Comparing Non-Invasive Passive Sampling Approaches to Monitor Human Exposure to Environmental Contaminants

*Sebastian Abel*¹, *Fanny Rosello*² and *Annika Jahnke*³, (1)Helmholtz-Zentrum für Umweltforschung GmbH - UFZ, Germany, (2)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (3)Helmholtz Centre for Environmental Research - UFZ GmbH, Germany

Around the globe, human health is affected by exposure to a wide range of harmful xenobiotics from diverse sources and uptake routes. Emerging chemicals, compounds generated as industrial byproducts and also legacy contaminants are of concern. Monitoring human exposure to these pollutants, however, relies heavily on invasive sampling methods. Non-invasive sampling approaches using silicone passive samplers have been developed to replace these invasive methods for large-scale monitoring studies. This project aims at the comparison of passive sampling approaches designed to cover different exposure routes. Silicone wristbands, which sample airborne, but also dermally excreted compounds are compared to silicone skin patches that have a larger contact area to facilitate sampling of the excreted internal contaminant burden of study participants. Furthermore, the skin patches are shielded against airborne particle deposition by an isolation layer and are worn on the upper thigh, hence usually covered by clothes. The contaminant-blocking capability of different materials for such isolation layer was tested in "sandwich" partitioning tests. Fabric layers, creating a passive, physical barrier, and activated carbon textiles that can trap compounds before they reach

the silicone sampler, were placed between a donor silicone disk spiked with model contaminants, and the clean receptor silicone disk. The results of a partitioning trial lasting 5 days (i.e., the intended sampling time) showed that for most hydrophobic contaminants, a simple gauze layer sufficiently slowed down the mass transfer between donor and receptor to substantially reduce the impact of airborne particles on silicone skin patches. Low molecular weight PAHs and more hydrophilic substances could still partly penetrate this isolation layer in a wet environment (emulating sweat). This penetration could be prevented to some extent by an added activated carbon layer. However, the benefits were considered too small to make up for the added discomfort to participants and increased challenges during the chemical analyses of samplers containing activated carbon particle traces.

3.05.P-Tu115 Passive Sampling to Detect Resuspension-Induced Increases in Dissolved WATER Concentrations of HOCs *Inna Elina Nybom¹, Ursula Strandberg¹, Clare Bradshaw², Cynthia de Wit³, Annika Jahnke⁴ and Hans Peter Arp⁵, (1)University of Eastern Finland, Finland, (2)Stockholm University, Sweden, (3)Stockholm University, Stockholm, Sweden, (4)Helmholtz Centre for Environmental Research - UFZ GmbH, Germany, (5)NGI, Norway*

Sediments near urban and industrial centers are historically contaminated with diverse environmental pollutants. Resuspension of these sediments, e.g. during construction activities, leads to an increase of contaminated sediment particles in the water, which consequently can drive an increase in freely dissolved water concentrations of sediment-associated pollutants. Low-density polyethylene (LDPE) passive samplers were applied to measure the freely dissolved water concentrations of hydrophobic organic contaminants (HOCs) in the water column during a large-scale bridge construction work, known to induce sediment resuspension. Passive samplers were deployed at different water depths; 1m from the bottom, middle of the water column and 1m from the surface. Two sampling campaigns were executed, over the period of 3-6 weeks before the construction work (May-July) and over 6 weeks during the construction (September-October). Despite the relatively short sampling time, polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs) from the water column were detected, and their freely dissolved water concentrations were derived. The changes over time in the freely dissolved concentrations were demonstrated with the applied sampling technique. Resuspension induced increase in water concentrations was observed specifically near the sediment surface for analytes with $\log K_{OW}$ 5-6. Factor of 1.7-4.6 increase in the dissolved water concentrations was observed during the sediment resuspension event compared to the previous deployment. Measurements at the reference site, beyond the influence of the construction activities, demonstrated seasonal variation in the dissolved water concentrations. For analytes with $\log K_{OW}$ 5-6, a factor of 0.7-1.7 difference in water concentrations was observed between the two sampling times near the sediment surface. However, the influence of the sediment resuspension at the construction site on the freely dissolved concentrations was evident and up to a factor of 3 higher than the observed seasonal variation.

3.05.P-Tu116 Applying Solid Phase Microextraction to Determine Biodegradation Kinetics of Chemical Mixtures in WWTP Sludge

Heidi Birch¹, Alexandre Teixeira², Chris Sparham³, Roger van Egmond³ and Philipp Mayer⁴, (1)DTU Environment, Lyngby, Denmark, (2)Unilever, UK, (3)Unilever, United Kingdom, (4)DTU Environment, Denmark

Biodegradation tests are traditionally designed for single chemicals. Testing of chemicals in mixtures and tracking the degradation of each chemical has the advantages that it improves the internal comparability of biodegradation data and their environmental relevance. Recently, we developed a platform for biodegradation testing of hydrophobic and volatile chemicals. The biodegradation and the analytical step were aligned by using headspace vials as test systems and automated Solid Phase Microextraction (SPME) coupled to GC-MS to measure substrate depletion relative to abiotic controls. The platform works well for biodegradation testing in lake, sea and river water that all have a limited suspended solids (SS) content. This study was directed at extending the applicability domain of the approach to media with higher SS content such as WWTP sludge. Activated sludge from a Danish wastewater treatment plant were filtered using (1) 0.5 mm sieve, (2) 0.125 mm sieve and (3) 25 μ m filter. The first filtration removed larger particles, the second reduced SS content from 2.4 g/L to 0.25 g/L, the third reduced SS to 0.0027 g/L. Abiotic test systems were prepared with autoclaved sludge and 0.1% NaN_3 . 13 test chemicals in methanol (fragrances, UV filters, plasticizer, PAHs) were added to 240 mL test systems by microvolume spiking (5 μ L) for μ g/L concentrations. Test systems were incubated at 12°C and subsampled in time-series covering 17-115 min, 1-48 hours or 1-29 days. Samples were diluted 1:1 in ethanol and stored at -18°C. The ethanol conserved the sample, avoided breakage of vials due to ice formation, and extracted chemicals from the sludge. This solution was filtered (0.2 μ m) and diluted in pure water to ~10% ethanol concentration before analysis using SPME. DNA extraction and microbial community analysis were performed on the three inocula and after 48 hours incubation with/without test chemicals. A markedly different microbial composition was seen in the 0.0027 g SS/L filtrate compared to the 0.25 g SS/L and 2.4 g SS/L sludge, for which minor differences were observed. Incubation for 2 days did not affect the microbial composition. Linalool, naphthalene, citronellol, α -isomethylionone, phenanthrene, and 2-ethylhexyl 4-methoxycinnamate degraded within 48 hours in the 0.25 g SS/L and 2.4 g SS/L sludge. Drometrizole, dicyclohexyl phthalate, homosalate and anthraquinone required longer incubation. Advantages and disadvantages of the test method will be discussed.

3.05.P-Tu117 Effects of Algae and Fungicides on the Fate of a Sulfonylurea Herbicide in a Water-Sediment System

Christiaan Wijntjes¹, Yanik Weber², Wolfgang Völkel², Stefan Hoger³, Henner Hollert⁴ and Andreas Schäffer¹, (1)RWTH Aachen University, Germany, (2)Innovative Environmental Services (IES) Ltd, Switzerland, (3)Innovative Environmental Services (IES) Ltd, Witterswil, Switzerland, (4)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany

The impact of pesticide mixtures on various soil parameters has been extensively studied, whereas research on effects in the

aquatic environment is scarce. Furthermore, investigations on the consequences of chemical mixtures on the biodegradation kinetics of parent compounds remain deficient. Our research intended to evaluate potential effects by combined application of an agriculturally employed tank mixture to aquatic sediment systems under controlled laboratory conditions. The mixture contained two fungicides and one radiolabelled herbicide of which the route and rate of degradation was followed. One set of aquatic sediment samples was incubated in the dark. A second set of samples was controlled under identical conditions, except for being continuously irradiated to promote algal growth. In addition, the algal biomass in irradiated aquatic sediment was monitored to determine its effects and a potential role in the biodegradation of iodosulfuron-methyl-sodium. The study results showed that the herbicide, although hydro- and photolytically stable throughout the experiment, metabolised faster (DT50 1.1 to 1.2-fold and DT90 2.8 to 4.5-fold) when continuously irradiated in comparison to dark aquatic sediment. Both fungicides had a significant prolonging effect on the biodegradation rate of the herbicide. In the presence of fungicides, DT90 values increased 1.5-fold in the irradiated, and 2.5-fold in the dark systems. Additionally, algae may have influenced the metabolism of the herbicide in the irradiated systems, where shorter DT90 values were evaluated. Even so, the algal influence was concluded to be indirect.

3.05.P-Tu118 Collision Cross Section (CCS) Value As an Additional Identification Point for Chemical Characterization: Development of a Lc-Esi-Tims-Qtofms Database for Environmental (Bio)monitoring Studies

Konstantina Diamanti¹, Dimitrios E. Damalas², Georgios Gkotsis², Eleni Panagopoulou², Maria-Christina Nika², Carsten Baessmann³, Bob Galvin³ and Nikolaos Thomaidis², (1)Department of Chemistry, National and Kapodistrian University of Athens, Athens, Greece, (2)National and Kapodistrian University of Athens, Greece, (3)Bruker Daltonik GmbH, Germany

Thousands of chemicals are estimated to be dispersed throughout the environment and may pose a threat to ecosystems and human health. Exposure to chemicals can be assessed by the monitoring of environmental contaminants in the ambient environment (air, water, soil), in organisms from various trophic levels, and in human biological samples (blood, urine). The increased availability of high resolution mass spectrometric (HRMS) techniques in the chemical analysis allows the wide-scope screening of complex samples. The hyphenation of ion mobility spectrometry (IMS) with HRMS has come to add a new dimension for compound separation and identification; namely collision cross section (CCS). This additional dimension enhances the identification confidence in target screening. To date, very few studies are available in the literature providing integrated LC-IMS-HRMS databases of organic contaminants. Here, a database containing more than 1,000 environmental contaminants (pharmaceuticals, illicit drugs, pesticides, industrial chemicals, etc.) was built by utilizing liquid chromatography coupled to electrospray ionization—quadrupole-time-of-flight mass spectrometry equipped with trapped ion mobility spectrometry (LC-ESI-TIMS-QTOFMS). The overall aim of this study was the establishment of a CCS-aware database for wide-scope target screening. For the database development, a quality control protocol was followed to ensure high-quality CCS measurements based on the guidelines for the Unified CCS Compendium. Accuracy was assessed by analyzing a standard solution with reference CCS values before, during and after the analyses, and the individual CCS error was found to be below 1%. To assess CCS values reproducibility, all solutions were analyzed in triplicate resulting in $\%CCS < 0.7\%$ being achieved in most cases. Therefore, beyond molecular formula (accurate mass, isotopic pattern), retention time, and qualifier ions (adducts, fragments etc.) information for each compound, the developed database was enriched with ion mobility derived CCS values. To the best of our knowledge, this is the first study reporting such an extensive dataset incorporating CCS values for a broad range of environmentally relevant compounds. Wide-scope target screening with the developed database was applied in different samples. Selected examples unveiling the performance of adding another dimension for analyte separation and sample characterization are presented.

3.05.P-Tu119 Advancing Electron Spin Resonance (ESR) Spectroscopy of Spin Labelled Organic Compounds in Environmental Chemistry

Heinz-Jürgen Steinhoff¹, Tamás Kálai² and Michael Matthies¹, (1)University of Osnabrueck, Germany, (2)University of Pécs, Hungary

Electron spin resonance (ESR) spectroscopy has successfully been applied since many years for investigating the structure and dynamics of biological macromolecules and assemblies, particularly membranes and proteins. However, its potential for investigating the various abiotic and biotic interaction processes in soil or sediment has not yet fully been utilized. ESR spectroscopy of tailored organic compounds labelled with stable paramagnetic nitroxides is a non-destructive method, which delivers direct information of their interaction processes with the soil or sediment environment on a molecular scale. Strong and weak adsorption, covalent binding and physical entrapment can be distinguished *in situ*. Moreover, the accessibility of immobilized spin labelled compounds for antioxidant such as sodium ascorbate and the polarity in the close vicinity of the nitroxide can be investigated [1]. The line shape of the continuous wave (cw) ESR spectrum reflects the reorientational motion of the nitroxide spin label, which in case of restricted Brownian motion can be characterized by its rotational correlation time, anisotropy, and (angular) amplitude. The rotational correlation time is a measure of the duration over which molecules maintain a particular orientation before random thermal motion reorients them. Cw ESR at different frequencies (9 – 95 GHz) spans the sensitivity for rotational correlation times from picoseconds to hundreds of nanoseconds [1]. Weak restrictions of the nitroxide reorientation, as e.g. found for small spin labels dissolved in water, result in nearly isotropic reorientational motion with correlation times less than 1 ns. Restriction of the nitroxide reorientational motion upon binding or sorption results in the decrease, e.g., of the rate or amplitude of the reorientation due to sterical hindrance yielding increased apparent hyperfine splitting and line widths. Time resolved investigations of spin labelled aromatic amines (aniline, sulfadiazine) with humic acid in solution and with model clay and soil suspensions demonstrate the potential of ESR spectroscopy for elucidating the interaction processes of organic compounds with soil and sediment (see platform presentation Ricke et. al.). References: [1] Klare JP, Steinhoff H-J in:

3.05.P-Tu120 Interaction Kinetics and Accessibility of Sulfadiazine in Model Clay-Humic Acid Suspension: Electron Spin Resonance Investigations With Nitroxide Spin Label

Adrian Ricke¹, Heinz-Jürgen Steinhoff¹, Tamás Kálai² and Michael Matthies¹, (1)University of Osnabrueck, Germany, (2)University of Pécs, Hungary

Electron spin resonance (ESR) spectroscopy of spin-labelled organic compounds is a microscale technique for the investigation of interaction processes in soil and sediment (see poster Steinhoff et al.). In the present work, the interaction of model clay-leonardite humic acid (LHA) suspensions with nitroxide spin-labelled antibiotic sulfadiazine (SL-SDZ) was studied. The objectives of our work are to (1) distinguish between adsorbed, entrapped and covalently bound species; (2) investigate the influence of the clay mineral on the kinetics of immobilization of SL-SDZ in model clay-LHA suspensions; (3) determine the accessibility of SL-SDZ in model clay-LHA suspensions important for remobilization and bioavailability. SL-SDZ and its spin labelled metabolite SL-N-acetyl-SDZ were synthesized. LHA was incubated with laccase to enhance the amount of reactive quinone groups of LHA and then mixed with the smectite mineral clay Ca-hectorite. The Ca-hectorite-LHA suspension was incubated with SL-SDZ or with SL-N-acetyl-SDZ, which is not susceptible for covalent binding of the aniline moiety to LHA. Upon incubation of SL-SDZ with the Ca-hectorite-LHA suspension ESR spectra were recorded in short time intervals over 46 d. The three sharp hyperfine lines of the free nitroxide decreased with time, whereas the broadened ESR signal, which indicates strong restriction of the reorientational motion of the spin probe, increased simultaneously. The amplitudes of the broadened ESR signal were fitted with an exponential model with pseudo first-order time constant of 82.6 ± 25.0 h for the immobilization of SL-SDZ. A fraction of SL-SDZ was obviously covalently bound to LHA as it was observed without Ca-hectorite, but with a reaction rate 4.7 times slower. An offset indicated a very rapid immobilization of SL-SDZ directly after mixing with the suspension due to strong adsorption to LHA. The fast decrease of the signal of the unbound SL-SDZ corroborates this observation. Ca-hectorite-LHA suspensions were incubated with SL-SDZ or SL-N-acetyl-SDZ. The suspensions were mixed with the hydrophilic antioxidant Na-ascorbate. The fast reduction of the unpaired electron of the immobilized and mobile fractions disproved physical entrapment. Covalent binding of SL-SDZ reduces the accessibility compared to strong adsorption. ESR investigations of spin labelled SDZ revealed unspecific adsorption and covalent binding in model soil suspensions of LHA with Ca-hectorite, but no physical entrapment.

3.05.P-Tu122 MALDI Mass Spectrometry Imaging As a New Tool in Biotic Systems

Michael Kubicki¹, Breanne Holmes¹, Benoît Salinier², Gregory F. Lemkine³, Laurent Lagadic¹ and Marc Lamshöft¹, (1)Bayer Crop Science, Germany, (2)Laboratoire Watchfrog S.A., France, (3)Watchfrog S.A., France

The OECD test guidelines for testing of chemicals combine a collection of 150 of the most relevant internationally agreed testing methods used by government, industry and independent laboratories to identify and characterize potential risks of chemicals. Over the last few years, there was a growing interest in developing test guidelines using fish and amphibian embryos, most of them being dedicated to the identification of endocrine active chemicals. Among these, the *Xenopus* Eleutheroembryonic Thyroid Assay (XETA, OECD Test Guideline 248) deliver data used for assessing the capacity of chemicals to activate or inhibit the transcription of a genetic construct thereby allowing the identification of chemical potentially active on thyroid axis. These guidelines, on the one hand, have many common methodological features with those applied for the testing of pharmaceuticals or plant protection products, but information about the distribution in- or outside of specific tissues of tested animals is limited. Matrix assisted laser desorption/ionization mass spectrometry imaging (MALDI MSI) provides, *in situ*, label-free molecular and spatial information of a range of compounds like pesticides and endogenous compounds (e.g., hormones, lipids, amino acids). The combination of morphological data with mass spectrometric data leads to a new tool for a better understanding of the behavior of test items in biotic model systems. *X. laevis* was selected as the representative test organism and exposed according to OECD TG 248. First MS imaging experiments of selected animal tissues were carried out on a Q-Exactive™ Hybrid-Quadrupole Orbitrap mass spectrometer, coupled to an AP-SMALDI5AF ion source. Mass spectra with high mass accuracy and high mass resolution were acquired for the precise identification of target molecules by the detection of monoisotopic masses of interest. Measurements were performed with a high spatial resolution of 30 μ m step size to distinguish the distribution of selected test items in particular areas of interest. *X. laevis* cryo-sections (25 μ m thickness) were optically assessed after optimization of the sample preparation protocol and characteristic anatomical structures (eyes, brain, intestine, tail) were identified. The test items in *X. laevis* were traceable by MALDI MSI and revealed a particular distribution in different sections of the animals and allowed a better understanding into the mechanistic behavior of the test item in the XETA.

3.05.P-Tu123 Polychlorinated Biphenyls in Mine Water - Miniaturized Approaches for Congener Specific Analysis and Palladium Catalyzed Dechlorination

Katrin Wiltchka¹, Rolf-Alexander Düring² and Leonard Böhm², (1)Institute of Soil Science and Soil Conservation, Justus Liebig University Giessen, Giessen, Germany, (2)Justus Liebig University Giessen, Germany

Polychlorinated biphenyls (PCBs) are among the persistent organic pollutants (POPs) that have been banned worldwide since 2001, due to their persistence, bioaccumulation and chronic toxicity even in very low concentrations. Produced as industrial chemicals, PCBs were used as insulating oil in transformers and capacitors, including underground mining. Due to high salt and metal concentrations, mine water represents one of the largest pollutant streams by volume in the world. However, until today especially inorganic pollutants are considered and treated. But as a legacy of mining, (closed) mines can contain relevant quantities of PCBs. Mine water must be pumped out regularly, and is discharged into rivers. When monitoring of PCB contamination takes place, it is mainly targeted at receiving waters. From the group of PCBs with theoretically 209 different

congeners, only six indicator PCBs and one dioxin-like PCB are considered. The aim of the study was both to determine concentrations of the most relevant PCB congeners in mine waters and to develop a treatment approach to reduce these concentrations. Catalysis promoted by palladium nanoparticles (Pd-NPs) is seen as a promising strategy to efficiently remove reducible contaminants in water treatment approaches. For PCB analysis, a solid-phase microextraction (SPME) method coupled to gas chromatography-mass spectrometry (GC-MS) was optimized for the sensitive and solventless extraction and detection of numerous PCB congeners directly from untreated mine water. Dechlorination experiments were carried out with the main detected PCB congeners. The SPME method was highly suitable for simultaneous extraction of the reactants and dechlorination products directly from miniaturized reaction vessels. As a result, more than 20 PCB congeners were quantified in water from five different mines in Germany. The presented method allows a comprehensive and labor saving analysis of PCBs even in lowest volumes of 10 mL untreated, matrix rich mine waters. Given the detected concentrations and the estimated annual load, action is needed even at very low levels of PCB occurrence due to their persistence and bioaccumulative properties. Hydrodechlorination using Pd-NPs can convert PCBs to the easier biodegradable biphenyl within minutes. Future experiments aim at protecting the Pd-NPs during dechlorination reactions for better stability and continuous usage.

3.05.P-Tu124 Synthesis and Certification of New Standards for Chlorinated Paraffins

Jon Eigill Johansen¹, Solveig Valderhaug¹, Huiling Liu¹, Alexey Gorovoi¹, Jiri Tuma¹, Jenny Button², Craig McKenzie¹, Jonathan Nygren¹, Louise van Mourik³, Sicco Brandsma⁴, Jacob de Boer⁵, Marina Ricci⁶ and Odd Reidar Gautun⁷, (1)Chiron AS, Norway, (2)Chiron, Norway, (3)E&H, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (4)Vrije Universiteit Amsterdam, Netherlands, (5)VU University, Netherlands, (6)European Commission - Joint Research Centre, Belgium, (7)NTNU, Norway

Introduction Chlorinated paraffins (CPs) represent a class of industrial chemicals used as high-temperature lubricants in metal-working machinery. The total global production remains largely unknown but is believed to exceed at least two million metric tonnes per year. Short-chain CPs (SCCPs) have been prohibited in the EU since 2017. Recently the European Chemicals Agency (ECHA) has added the medium chain CPs (MCCPs) to the list of Substances of Very High Concern. The validation of analytical methods for the identification and quantification of chlorinated paraffins in environmental matrices and foodstuff is being hindered due to a lack of certified reference materials (CRMs). As a result, errors in measurements within individual laboratories can occur. The principal goals of the current projects is to develop reference standards with a defined response factors, which can be used to mimic the industrial mixtures. Such reference standards will then be used to certify the SCCP content in a fish CRM offered by the EU Joint Research Council (JRC). **Materials and Methods** CRMs of individual single SCCPs, ¹³C labelled SCCP internal standards were prepared by synthesis. Single chain congener mixtures have been made by UV light catalyzed chlorination. Single individual compounds have been analyzed for chlorine content using an accredited titration method and of NMR and the results are compared with the theoretical values. Individual compounds and the single chain mixtures were analyzed by GC-MS-MS, high resolution GC-MS and by GC-GC.. Water, solvent and ash content was determined by TGA. **Results** To date, we have produced approximately 40 individual single chain CPs, ¹³C-labelled individual CPs, and 10 single chain CP congener mixtures. Further single component mixtures will be prepared for quantification together with defined mixtures and single chain mixtures. The chemical purity is established by one or several of the following GC-based methods: GC-FID/MS, GC-MS-MS, high resolution GC-MS and GC-GC-MS. Various NMR techniques were developed for chlorine content determination and are compared with theoretical values for single components. **Conclusions** We have prepared a range of CP reference standards and these will be used to prepare the CP CRMs urgently required to support reliable analytical methodologies. These materials will be characterized by a combination of certified analytical methods including purity determination by GC-FID, identity by NMR and excess water, solvent and ash by TGA in addition to stability and homogeneity assessments.

3.05.P-Tu125 The VANDALF Project: Linking Chemical Detection and Toxicological Endpoints From Wastewater

Mathias Jørgensen¹, Selina Tisler², Mafalda Castro², Kristoffer Kilpinen³, Jason Devers Mr⁴, Giorgio Tomasi⁵, Peter Bondgaard Mortensen³, Nina Cedergreen⁶ and Jan Christensen², (1)Development, BIOFOS A/S, Hvidovre, Denmark, (2)University of Copenhagen, Denmark, (3)EUROFINS, Denmark, (4)Analytical Chemistry Group, PLEN, Univeristy of Copenhagen, Copenhagen, Denmark, (5)University of Copenhagen, Department of Plant and Environmental Sciences, Denmark, (6)Plant and Environmental Sciences, University of Copenhagen, Frederiksberg, Denmark

In Europe alone, more than 70.000 different chemicals are used and many of these enter the wastewater system on daily basis. Conventional wastewater treatment plants (WWTPs) are not designed to remove complex mixtures of organic chemicals present at trace concentrations ($\mu\text{g L}^{-1}$ to ng L^{-1}) in wastewater, and only a minor part of total toxicity (1-5%) from wastewater was prior explained by chemicals included in target screening. Hence, there is an increasing necessity to combine analytical and bioanalytical tools with the potential to address and identify unknown chemicals posing a risk to the aquatic environment. In the ongoing project VANDALF, the goal is to develop tools to identify chemicals of emerging concern (CECs) in wastewater. An overall workflow was established, including representative sampling of wastewater from several WWTPs at different timepoints and state of the art sample preparation techniques to prepare wastewater samples for further chemical and toxicological investigations. The sample extracts were analyzed on several chromatographic platforms for chemical composition using both target, suspect, and non-target screening methods. Concurrently, these samples were screened for toxicity using both *in vivo* and *in vitro* assays. Multivariate approaches are then used to identify the chemical fingerprints contributing to observed toxic effects. Via the analysis of both influent and effluent wastewater samples, it is also possible to screen for persistent compounds and evaluate removal rates through the different treatment steps of the WWTP. In addition, we can also address formation of metabolites and pinpoint CECs to include in future monitoring and regulatory measures. At the SETAC poster session specific

chemical and toxicological results will be presented: Our present results agree with previous studies on toxicity from target compounds. This was especially the case for estrogen agonist and aryl hydrocarbon reporter gene assays. However, we were able to explain a larger contribution from target compounds on toxicity in an algae growth assay. With the use of suspect and non-target screening in VANDALF, there is a potential to identify more toxicity due to identification of additional compounds. Additionally, certain trends were observed in chemical diversity (e.g. anti-psychotics and drugs of abuse) as well as trends in the concentration of chemicals (e.g. beta blockers) between WWTPs at different locations and regions of Denmark.

3.05.P-Tu126 Trace-Level Analysis of Organic Pollutants in Atmospheric Particulate Matter by GC Q-Exactive Orbitrap MS

Barend Leendert van Drooge¹, **Raimon Prats**², **Clara Jaén**³ and **Prof. Joan Grimalt**⁴, (1)Environmental Chemistry, IDAEA-CSIC, Barcelona, Spain, (2)Institute of Environmental Assessment and Water Research (IDAEA CSIC), Spain, (3)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (4)IDAEA-CSIC, Spain

Over the past decade, gas chromatography coupled to Q-exactive orbitrap mass spectrometry (GC-Orbitrap-MS; Thermo Fisher) was developed, offering compound identification and high-resolution mass-accuracy analysis [1]. GC-Orbitrap-MS (Thermo Fisher) was tested with standard reference material (SRM2260a) and organic tracer compounds, e.g. traffic and wood burning emissions, in ambient air PM_{2.5} in full scan mode and compared to conventional GCMS analysis. GC-Orbitrap-MS analysis of polycyclic aromatic hydrocarbons (PAHs) in standard reference material (SRM2260a) and organic tracer compounds in ambient air particulate matter (PM_{2.5}) gave very low instrumental uncertainties (1% - 15%) and high linearity over a wide concentration range (0.5 pg and 500 pg/ μ L). Good reproducibility was obtained with the GC-Orbitrap-MS compared to conventional GCMS method. The detection limit of the GC-Orbitrap-MS method for full scan analysis of PAHs in PM samples was 0.5 pg/ μ L (compared to 5 pg/ μ L in GC-MS method), allowing the analysis of small sample fractions (< 1m³) and/or samples with short sampling times (1.5 h), thus, increasing the temporal and spatial analysis of organic tracer compounds in ambient air PM. Punch samples (\varnothing = 3.4 mm) were taken from PM_{2.5} filter and filter strips of Aethalometer AE51 (AETHLABS). This pocket-sized instrument is designed for real-time Black Carbon monitoring. Analyses of filter strips that collected 0.14 m³ in 24 hours showed levels above the quantification limit for PAHs, among them the regulated and most toxic PAH: benzo[a]pyrene, as well as several organic tracer compounds for source apportionment (Figure 2). The correlations between PAHs and BC was very strong, although independent in the two sites due to their different dominating emission sources (traffic vs. biomass burning). The work we present shows that GC-Orbitrap-MS can be used for routine analysis of organic contaminants in atmospheric PM samples and exposure studies at high precision and accuracy, while saving time and consumables in the analysis [2]. [1] Eliuk S., Makarov A. 2015. Annual Review of Analytical Chemistry. 8, 61-80. [2] van Drooge BL., Prat M. R., Jaén C., Grimalt JO. Submitted. J. Chrom. A.

3.05.P-Tu127 Study of the Adverse Effects of the Insecticide Clothianidin on the Stingless Bee *Tetragonisca Angustula* L., Based on Toxicity Tests and Preliminary Analysis of Environmental Risk

Gabriela Biscassi¹, **Waleria Rabelo**², **Rafael Sardeli de Oliveira**³, **Janete Brigante**² and **Eny Maria Vieira**⁴, (1)Instituto de Química de São Carlos/Universidade de São Paulo, São Carlos, SP, Brazil, (2)São Paulo University, Brazil, (3)IQSC-USP, Brazil, (4)DQFM, São Paulo University, São Carlos, Brazil

The collection of scientific information about bees proves their importance as natural pollinators, not only for agricultural crops, but also for the genetic diversity of plants which, in a macro view, means maintenance the stratum of primary producers in the whole world's ecosystems. The excessive use of pesticides is one of the factors that can compromise the health, growth and survival of hives and bees. The present research focused on the chemical determination of clothianidin, a neonicotinoid, in the tissues of *Tetragonisca angustula* stingless bees by the optimized QuEChERS method, and analysis by UPLC-MS/MS and a C18 column (100 x 2.1 mm, 1.7 μ m). Were obtained chromatograms with 5 minutes runs, recovery percentages of 85.05%, 99.01% and 74.58% at three levels studied, 0.001, 0.01 and 0.05 mgL⁻¹, respectively, with RSD less than 20%. The detection and quantification limits obtained were 0.00077 and 0.00232 mgL⁻¹, respectively. The toxic effects were also studied from the acute oral exposure of adults of *Tetragonisca angustula*, the LD₅₀ was determined and shown to be 0.160 ng a.i./bee after 24 hours of exposure. From the data obtained in these studies, the risk quotient (RQ) was calculated for a preliminary analysis of the environmental risk in cotton crops, as well as the possible risk of product drift, based on the commercial product Zellus® SC. Therefore, the results showed that clothianidin represents a mortality risk for bees. And, together with the chromatographic method, we can confirm and quantify the presence of this pesticide in these insects.

3.05.P-Tu128 Batch Equilibrium Experiments Indicate Weak Temperature Dependence of Soil/Sediment-Water Sorption for Cyclic Volatile Methyl Siloxanes

Gary Kozerski¹, **Jeremy Durham**² and **Jaeshin Kim**³, (1)Dow Chemical Company, United States, (2)Dow Chemical Corporation, United States, (3)The Dow Chemical Company, United States

The organic carbon normalized partition coefficient, K_{OC} , describes the equilibrium distribution of a chemical between water and particulate organic matter, and it is a key parameter in many chemical fate and transport models. In recent years, numerous studies have been published pertaining to environmentally relevant physicochemical properties of cyclic and linear volatile methyl siloxanes (VMS), including K_{OC} . Studies of the sorption behavior of several VMS substances between water and soil or sediment have been reported, with K_{OC} values determined either directly using the batch equilibrium method, or indirectly from measurements of volatilization rates from particle-water slurries. So far, the temperature dependencies of K_{OC} values for the cyclic VMS compounds octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5) have been investigated only by the

indirect purge-and-trap method. The present study examined the K_{OC} temperature dependencies of D4 and D5 by the batch equilibrium method. Notwithstanding unknown variations arising from use of sediments of differing origin, empirical K_{OC} values reported for 25 °C by the different methods agreed to within approximately 0.5 and 0.7 log units for D4 and D5, respectively. However, at lower temperature of 4-5 °C, these differences increased significantly, with batch equilibrium K_{OC} values lower by 1.8 log units for D4 and 1.3 log units for D5. Whereas the K_{OC} values by the purge-and-trap method increased with decreasing temperature, giving sorption enthalpies (ΔH_{OC}) of -79 kJ/mol for D4 and -48 kJ/mol for D5, the new batch equilibrium K_{OC} values showed modest *decreases* at lower temperatures with corresponding ΔH_{OC} values of 0 (i.e., not statistically significant) to +13 kJ/mol. These findings could have significant implications for the predicted fate of D4 and D5 in cooler remote regions particularly. Ongoing work is exploring how experimental differences between the studies, such as sorbent-water ratios or preparation and spiking of sorbents, might influence the observed discrepancies in K_{OC} values. Additionally, the dynamic method is being assessed from a theoretical perspective to identify potential bias arising from assumptions about the behavior of VMS materials in the purge-and-trap system. It is expected that the current study will be an important step toward resolving these apparent discrepancies, and eventually defining consensus values of these important parameters for the VMS substances.

3.05.P-Tu129 Early Life Stage Development and Oxidative Stress Markers in Lake Trout Fry From a Lake Used to Conduct Model Oil Spills

Cody Jackson¹, Vince Palace², Jason Treberg¹, Kenneth Jeffries¹, Mark Hanson¹, Lisa Peters¹ and Adam Scott³, (1)University of Manitoba, Canada, (2)IISD Experimental Lakes Area (IISD-ELA), Canada, (3)University of Manitoba, Winnipeg, Manitoba, Canada

In Canada, and across the globe, oil production as a source of energy remains an important means of economic development, with oil and natural gas accounting for 57.5% of global primary energy consumption. While transportation safety records have steadily increased, some spills do occur. In the summers of 2018 and 2019, controlled and contained spills of diluted bitumen (dilbit) were introduced into enclosures installed in Lake 260 at the IISD-Experimental Lakes Area (IISD-ELA) in Northwestern Ontario. These additions were performed to examine the fate and behaviour of oil in freshwater systems and to compare the efficacy of selected cleanup techniques as part of the Boreal-lake Oil Release Experiment by Additions to Limnocoals (BOREAL) and Freshwater Oil-Spill Remediation Study (FOReSt) studies, respectively. These projects included rigorous containment and contingency measures. The efficacy of those measures and the potential for impacts to early development of lake trout arising from exposure to residual oil was examined by comparing morphology and oxidative stress in early life stages of lake trout obtained from the lake where oil studies were conducted and unimpacted reference lakes. Lake trout are a species known to be sensitive to oil constituents, most notably polycyclic aromatic compounds (PACs). Eggs and milt were collected from fish in the four study lakes (n = 3-7). After transport, dry fertilizations were performed, and the fish were reared in Heath trays until swim-up. A subsample of fry from each lake (n = 6-30 per maternal clutch) were evaluated for spinal, craniofacial, edema and finfold deformities, with no increase in deformity rates being observed in the study lake, compared to the unimpacted reference lakes. Fertilization success, egg mortality and hatching success were also similar among lakes (p > 0.05). While no phenotypic changes were observed in fish from the lake where oil studies were conducted, we also evaluated genetic and biochemical markers of PAC exposure. Cytochrome p4501A (CYP1A), a common biomarker of PAC exposure in fish, and the ratio of oxidized and reduced glutathione, an indicator of oxidative stress, were measured in a subsample of whole swim-up fry and levels were found to be similar between the study lakes (p > 0.05). Results from this study will be used to evaluate the efficacy of containment and contingency measures and the trajectory of recovery in oil spill impacted freshwaters.

3.05.P-Tu130 Simultaneous Determination of Allium Compounds (Propyl Propane Thiosulfonate and Thiosulfinate) in Animal Feed Using Uplc-Ms/Ms

Antonio Lira¹, Ana Isabel Prieto¹, Remedios Guzman-Guillen¹, Giorgiana Catunescu², Jose Manuel de la Torre³, Enrique Guillamon³, Angeles Jos¹ and Ana Camean¹, (1)Universidad de Sevilla, Spain, (2)University of Agricultural Sciences and Veterinary Medicine, Cluj-Napoca, Romania, Romania, (3)DMC Research Center, Spain

Propyl-propane-thiosulfonate (PTSO) and Propyl-propane-thiosulfinate (PTS) are organosulfur compounds present as secondary metabolites in many plants of the genus *Allium*. They are used to supplement the diet of livestock because of their beneficial effects on palatability, antimicrobial and antimethanogenic activities in order to reduce the greenhouse gas levels in the environment, and to improve the livestock efficiency. Furthermore, since antibiotics used in livestock as growth promoters were forbidden by European legislation due to the unwanted residues they generated, additives that come from a natural origin are considered the best alternative. However, to guarantee the safety of these sustainable additives, a correct analytical validation is necessary. For this reason, the objective of this study was to optimize the extraction parameters for the analysis of PTSO and PTS in feed matrices by performing a solid-liquid extraction and quantification by Ultra performance liquid chromatography coupled to tandem mass spectrometry (UPLC-MS/MS). Optimization was performed using the Response Surface Methodology on a Box-Behnken experimental design, optimizing the following parameters: solvent:sample ratios and evaporation temperature set for the rotary evaporator. The method was validated for 3 concentration levels for both PTSO (100, 500, 1000 ng g⁻¹) and PTS (500, 1150, 2300 ng g⁻¹). The highest recoveries of PTSO and PTS were obtained using 12.5 mL of 100% acetonitrile, stirring for 15 min, and an evaporation temperature of 20°C. The validated method was further applied to detect and quantify these compounds in different feed matrices (ruminants, broilers, pig, lactating pig, hens and fish). In conclusion, this is the first study to simultaneously analyse PTSO and PTS at low concentrations, employing a sensitive technique such as UPLC-MS/MS. This suggests the possible application of the proposed method in the industry and monitoring programs of feed additives, to ensure safety and efficacy. Acknowledgements: Spanish Ministerio de Ciencia, Innovación y Universidades (RTC-2017-6199-2) and

Junta de Andalucía (transference action AT-17-5323 and Project P18-TP-2147) for its financial support. Antonio Cascajosa Lira thanks the Spanish Ministerio de Universidades for the funding FPU grant (FPU2019-01247).

3.05.P-Tu131 Investigation on Selection Efficient Representative Matrices for Multi-Residue Analysis of Pesticides in Agricultural Products

JeongYoon Choi¹, Hun Ju Ham¹, Yeong-Ju Jo¹, Syed Wasim Sardar¹, Abd Elaziz Sulieman Ahmed Ishag¹ and Jang Hyun Hur², (1)Kangwon National University, Korea, South, (2)Kangwon National University, Chuncheon, Korea, Republic of (South)

Recently, simple and efficient multiresidue pesticides analytical methods using QuCHERS and mass spectrometry have been developed in many countries for the safety management of pesticides residues in food. However, the accurate quantification of pesticide residues requires the preparation of the same matrix for each sample of agricultural products therefore there is difficulty in using a mass spectrometer in such analysis. In addition, nowadays, matrix matched analysis is important in pesticides analysis and essential technique in quantitative analysis of pesticides residues using a mass spectrometer. However in the case of simultaneous multi-residue analysis, various agriculture samples should be prepared, but it is almost impossible to prepare a blank matrix for all agricultural sample matrices. Therefore, this study is proposed to investigate the possibility of selecting a representative matrix that can be used in the multi residue analysis of 460 pesticides active ingredients in various agricultural products. Fifty highly consumed types of agricultural products in South Korea will be selected and analyzed for the residues of 460 pesticides ingredients included in the Korean Food Code and to calculate the matrix effects (%) for the various agricultural products and pesticides components as well. The Organization for Economic Cooperation and Development (OECD) and Korean Ministry of Food and Drug Safety (MFDS) guidelines will be followed to secure the validation of the analytical method, linearity, accuracy, repeatability, instrument limit of detection (I-LOD), and limit of quantification (LOQ). The expected findings of the proposed work could explore representative matrices that can be used to analyze 460 pesticide components in various types of agricultural products, and minimize the percentage of matrix effect. The expected output of this investigation could improve the applicability and efficiency of multi component residue analysis of pesticides in food and significantly contribute to the safety management of pesticide residues in Korea and worldwide.

3.05.P-Tu132 Determination of Ethylene Oxide and 2-Chloroethanol in Food and Food Additives

Lucy Hearn¹, Jan Peter Mayser², Carlos Gil³ and Rachael Szafnauer¹, (1)Markes International, United Kingdom, (2)Markes International Ltd, Germany, (3)Markes International GmbH, Germany

Within the EU ethylene oxide (EtO) and its degradation product 2-chloroethanol (2-CE) have been banned since 1991. However, in many parts of the world it is still regularly used as a fumigant to kill bacteria and fungus on food and food additives, known as cold gas sterilization. The ban in the EU is based on EtO's toxicity and reactivity, causing mutagenic effects. Therefore, the EU has defined that there is no safe level of exposure for consumers and implemented Regulation 396/2005, stating that EtO must be determined above an LOQ of 0.05 mg/kg. This has led to numerous recalls of foods across the EU and the need to determine EtO from food and food additives. EtO poses several challenges during analysis, leading to complex sample preparation steps required to analyse EtO and 2-CE reliably. These challenges include EtO's high volatility and its high reactivity causing a transformation of EtO to 2-CE very rapidly. Other methods circumvent this challenge by transforming EtO into its degradation product. New advancements in headspace sampling technology by linking it to a backflushed focusing trap have made it possible to extract both compounds from the food matrix, by extracting the food sample multiple, sequential times. This multi-step enrichment headspace-trap (MSE-HS-trap) technology allows the headspace of the sample to re-equilibrate, while other samples can be extracted. Here a new sample extraction technique is presented for the analysis of EtO and 2-CE from foods using MSE-HS-trap, where three enrichment steps were necessary to reach the required LOQs specified by the EU regulation. Unlike other methods, EtO and 2-CE are extracted, preconcentrated (on a sub-ambient, cryogen-free focusing trap) and analysed at the same time, with no conversion step required to transform either EtO into 2-CE or vice versa. The calibration range for each of the compounds ranged from 0.013–0.25 mg/kg, which bridges the 0.05 mg/kg cut-off for EtO. With this methodology sesame seeds were obtained from a rejected batch bound for Germany. EtO, within the batch by itself, was found to be just above the limit of 0.05 mg/kg (0.057 mg/kg) and the concentration of 2-CE was found to exceed the limit by far (8.760 mg/kg EtO equivalent). This methodology offers a fast and low manual labour approach to determining EtO and its corresponding degradation product from sesame seeds. Headspace-trap with MSE is well suited and can be adapted to many kinds of sample matrices.

3.05.P-Tu133 Method Development for the Analysis of C₆₀ and C₇₀ Fullerenes and Their Derivatives in Aerosol and Settled Dust

Mathieu Galmiche¹, Eden Esslinger², Olivier Delhomme³, Philippe Schaeffer⁴, Pierre Adam⁴, Estelle Motsch⁴, Emmanuelle Leize-Wagner⁴, Yannis François² and Maurice MILLET⁵, (1)Institute of Chemistry and Processes for Energy, Environment and Health (ICPEES), Université de Strasbourg, Strasbourg, France, (2)Université de Strasbourg, France, (3)Université de Lorraine, France, (4)Université de Strasbourg / CNRS, France, (5)University of Strasbourg (UdS), France

Even if their effects on human health and environment are still debated, as their industrial production reaches around tens of tons per year, fullerenes and their derivatives should be considered as emerging contaminants (Astefanei et al., 2014; Carboni et al., 2016). For further toxicological risk assessment studies, more analytical data reporting the occurrence of these novel pollutants in various environments are critically missing. To our knowledge, only three previous works assessed their occurrence in aerosols, two of them focusing only on the sole C₆₀ fullerene (Benn et al., 2012; Encinas and Gómez-de-Balugera, 2018; Sanchís et al., 2012). In our work, we developed a single method for the simultaneous analysis of C₆₀ and C₇₀ together with three fullerene derivatives, frequently used for industrial applications (Sanchís et al., 2012). The very high hydrophobicity of fullerenes requires special analytical conditions. Above all, we report the necessity of using toluene both as extracting solvent and as liquid

chromatography (HPLC) eluent as it seems to be the best solvent for fullerenes. Therefore, we applied Pressurized Liquid Extraction (PLE) with a Toluene / Acetonitrile (1:1, v:v) mixture to extract quantitatively our analytes. Extraction yields measured on a real particulate matter (PM) matrix were found to be from 67% to 104% for our five target compounds. HPLC was successfully applied to separate our fullerenes on a C₁₈ stationary phase (150 x 3 mm, 3 µm) in 10 minutes. In this work, we extensively compared the performance of the three most common atmospheric pressure ionization techniques: ESI, APCI and APPI, in both positive and negative modes. The electron capture electrospray negative ionization was found to be less robust and sensitive than APCI and APPI. Negative APPI was finally selected as the optimal ionization method for most compounds, except NMFP which showed a higher signal in positive mode. As fullerenes show very little fragmentation, the pseudo-MRM mode was implemented for fullerenes monitoring, which means that the selected m/z transitions did not exhibit any mass loss from parent ion to daughter ion. LC-APPI-MS/MS instrumental quantification limits (LOQs) were from 10 to 50 pg injected for the five fullerenes, enabling to reach method LOQs down to 1 µg/g in settled dust and down to 0.02 ng/m³ in airborne PM. Thanks to these low LOQs, the developed ASE-LC-MS/MS method was successfully applied to aerosol and settled dust samples collected in indoor urban environments in the area of Strasbourg, France.

3.05.P-Tu134 Increasing the Sensitivity for 1,4-Dioxane Analysis in Drinking WATER

Lucy Hearn¹, Jan Peter Mayser² and Rachael Szafnauer¹, (1)Markes International, United Kingdom, (2)Markes International Ltd, Germany

In past water investigations at solvent release sites, 1,4-dioxane was typically not included as a target analyte because it was not detectable at low concentrations in a standard laboratory scan for volatile organic compounds. However, 1,4-dioxane has emerged as a likely human carcinogenic compound, and as it is highly soluble and does not readily biodegrade it tends to accumulate in the aquatic environment. This has led to a large spread in 1,4-dioxane contamination sites. Further, attitudes towards 1,4-dioxane have changed in recent years. This is reflected in the recent decrease of regulatory detection limits, in some cases to 25 ng/L (Bayerischer Landtag 17/16517). Reliable low-level detection of 1,4-dioxane is challenging because of its high solubility, which makes it particularly difficult to extract from water. A combination of solid-phase microextraction (SPME Arrow) with further preconcentration on a sub-ambient trap allows for multi-step enrichment (MSE), wherein analytes from multiple SPME Arrow extractions from a single sampling vial are concentrated prior to trap desorption. With this technique, 1,4-dioxane is removed from the headspace of the sample with each extraction, and time is then allowed for a new equilibrium to establish prior to the following extraction, forming a semi-dynamic headspace approach, dramatically improving extraction efficiency overall. SPME Arrow-trap with MSE thus allows analysis of 1,4-dioxane at trace levels far surpassing what is possible with traditional SPME Arrow while maintaining peak shape, excellent linearity, low MDLs and highly reproducible results. During the development of the method it was determined that three enrichment steps of MSE-SPME Arrow-trap were necessary to obtain results with the required sensitivity, while allowing the cycle time of the methodology to remain below one hour. Furthermore, by encompassing the sub-ambient trap with SPME Arrow, this method can perform re-collection and archiving of SPME Arrow extracts for later re-analysis if required on thermal desorption tubes. Here we demonstrate the fully automated sampling and detection of the 1,4-dioxane at ng/L levels in water using a multi-phase (DVB/CWR/PDMS) Arrow for MSE-SPME Arrow-trap.

3.05.P-Tu135 Chromatographic Determination of Selected Carbamate Pesticides in Soil Samples: Degradation and Bioavailability

Luleka Luzi-Thafeni¹ and Vernon S Somerset², (1)Department for Environmental Food & Rural Affairs, South Africa, (2)CPUT, South Africa

Pesticides are generally applied to agricultural crops for protection but their residues present a potential risk to non-target organisms, affecting aquatic ecosystems and posing risks to human health. Organophosphates and carbamates impair nerve transmission in insects and poses even higher human health risks if left undetected. Recent advances have shown that these pesticides can be extracted and pre-concentrated from aqueous samples by liquid-phase micro-extraction (LPME), solid phase extraction (SPE) and headspace solid phase micro extraction (HS-SPME), while supercritical fluid extraction (SFE) and pressurised fluid extraction (PFE) can be employed for sediments. This study has shown that improved extraction allows for sensitive detection of carbamates in soil and fruit samples. The study involves the testing of a rapid, reliable and low-solvent extraction procedure for selected carbamate pesticides of carbaryl, carbofuran, and methomyl from soil and fruit samples. It involves an investigation to determine how much of the applied carbamates are found in the fruit, compared to the soil in the same geographical location. This study is currently investigating the chemical behaviour of the carbamates in soil under environmental conditions and aims to examine if a sonicated SPE procedure promotes the release of the carbamates in the soil, before samples are subjected to a GC-MS/MS or LC-MS analysis procedure.

3.05.P-Tu136 Analysis of OTA and OTB in Urine Employing Lc-Q TOF MS and Exposure Assessment Study

Noelia Pallares¹, Emilia Ferrer¹, Maria-Jose Ruiz² and Houda Berrada¹, (1)Faculty of Pharmacy, University of Valencia, Spain, (2)Laboratory of Toxicology, Faculty of Pharmacy, University of Valencia, Burjassot, Spain

Traditional evaluation exposure to mycotoxins is often carried out combining chemicals analysis in foodstuffs with data of food consumption. This indirect approach presents some disadvantages such as the lack of information related to individual exposure situation, toxicokinetics and mycotoxins bioavailability and the difficult to obtain accurate data on food consumption. Human biomonitoring constitutes a suitable alternative to assess toxins exposure overcoming the limitations of the indirect approach (1,2). Mycotoxins are secondary metabolites produced naturally by filamentous fungi that produce a wide range of adverse health effects. *Aspergillus* and *Penicillium* genera are responsible of Ochratoxin A (OTA) production (3). OTA constitutes a toxic compound with relatively rapid absorption and slow elimination, being the kidney and liver, the principal organs involved in its

biotransformation. The OTA metabolite, Ochratoxin B (OTB) is considered less toxic than the parent compound (4). The aim of the present work was to evaluate the presence of OTA and its metabolite OTB in human urine samples and to estimate the potential risk of exposure. For this purpose, 56 urine samples were extracted by QuEChERS method and determined by LC-ESI-QTOF-MS. The samples were acquired from 24 males and 32 females in a wide age group. The results revealed that OTA was not detected in any of the analyzed samples, while OTB was observed in 9% of samples with concentrations ranging from < LOQ and 38.88 µg/L, and mean of positives of 18.17 µg/L. Comparing between genders, the mean amount detected in male samples (38.88 µg/L) was higher than those detected in females (12.99 µg/L). The risk assessment study revealed that PDIs calculated for OTB exceeded the TWI established for OTA. Moreover, the margin of exposure (MoE) obtained employing the BMDL10 established for OTA also revealed a potential health risk with MoE values

3.05.P-Tu137 Identification and Characterization of Non-Petroleum Oils in Support of Emergency Response and Ecosystem Assessment

Laura M. Basirico¹, Maggie Knight² and Kevin Armbrust¹, (1)Louisiana State University, United States, (2)Department of Environmental Sciences, Louisiana State University, Baton Rouge, LA

With the advent of containerized trade and the streamlining of supply chains between container ports globally, oceans and waterways have becoming increasingly important transport routes for cargo ships. The volume of seaborne trade has nearly doubled over the past 20 years, reaching 11 billion tons loaded in 2019. The upward trend continues with a current estimation of 80 percent of good transported by ships. Even as non-petroleum oils are growing component of global bulk transport, there are minimal data on the chemical and physical properties of these oils. The increase in global transport as well as recent spill incidents involving non-petroleum products highlight the need for advancements in extraction methods and analytical identification of biogenic and non-petroleum oils. In 2020, the Alaska Sea Grant Marine Advisor in Nome reported a mystery substance on the beach and coating a number of seabirds in the village of Savoonga. Initial responses suggested the substance was likely a non-petroleum oil such as a vegetable oil, fish oil, spent cooking oil, or type of rendered fat, released, then solidified in the cold water. Samples were analyzed via standard GC/MS methods for semi-volatile compounds and the results determined the constituents in the unknown matrix were of non-petroleum origin. In addition to qualitative differences, including patterns of alkanes and PAHs unlike from typical petrogenic fuels and oils, the unknown substance contained undetectable concentrations of the 16 EPA Priority PAHs and no high molecular weight aromatic compounds. As a result, it was recognized that additional analytical tools were necessary and research has begun to develop an effective extraction method for the identification and characterization of non-petroleum oils via GC/MS. In addition to the characterizations of chemical properties of non-petroleum oils, biogenic oils will be analyzed for bulk physical properties such as density, viscosity, emulsification, and more. The current research attempts to characterize chemical and physical profiles for high priority, novel non-petroleum oils, ultimately building a reference library to aid in source identification of spilled substances in nearshore and coastal environments.

3.05.P-Tu138 QualiMon LaMa - Live Quality Monitoring of Non-Targeted Analysis Through Utilization of Landmarks

Anton Ribbenstedt¹, Olle Hartvigsson² and Carl Brunius³, (1)Biology and Biological Engineering, Chalmers University of Technology, Gothenburg, Sweden, (2)Chalmers University of Technology, Sweden, (3)University of Gothenburg Sweden, Sweden

Technological advancements have taken mass spectrometry into the omics realm, enabling non-targeted analysis of thousands of compounds within a single sample. Like all new technologies, high resolution mass spectrometry faces several obstacles on the road to reach its full potential: While high resolution and sensitivity are what make these techniques attractive for nontarget analysis, it also makes the instruments susceptible to drift-related disturbances that are detrimental for data quality. Unfortunately, these disturbances are generally not detected during instrument analysis and inadequate instrument performance or data quality is often discovered during data processing of individual batches or full experiments, potentially comprising thousands of samples. This can lead to severe consequences, such as precious sample material being wasted and increases in required instrument-time and burdens for technicians. To address this problem, we have developed “QualiMon – LaMa”, a near-real-time Quality Monitoring software. At the core, the software monitors LandMarks (LaMas), i.e. unique, easily distinguishable features that are present in virtually all samples and/or quality control standards of a particular matrix. LaMa characteristics (such as rt, m/z, intensity, s/n) are automatically extracted on an injection-by-injection basis into a local database structure. QualiMon then detects any significant deviations from the previous injections as well as violations of instrument-specific cut-off limits. Transgressing samples activate real-time warnings through web services, so that instrument technicians can take appropriate measures immediately. LaMas also have the benefit of providing a framework for improved retention time alignment between samples, batches and can be utilized to improve matching to in-house databases for identification purposes. QualiMon is developed in open source (R and SQLite) and will be available for free under license. In conclusion, QualiMon offers assessment of instrument performance and data quality mid-sequence and the possibility to minimize waste of resources through live monitoring of non-targeted data.

3.05.P-Tu139 Are Natural Deep Eutectic Solvents Always a GREEN Option? A Bioassay-Based Study

Matilde Vieira Sanches¹, Matteo Oliva², Lucia De Marchi³, Alessia Cuccaro⁴, Rosa Freitas⁴, Andrea Mezzetta⁵, Lorenzo Guazzelli⁵ and Carlo Pretti⁶, (1)Universidade de Aveiro, Portugal, (2)CIBM, Italy, (3)University of Pisa, Portugal, (4)University of Aveiro, Portugal, (5)University of Pisa, Italy, (6)University of Pisa, San Piero a Grado, Italy

The traditional use of organic solvents in various branches of industry is being rethought as these compounds (e.g., dimethylsulfoxide (DMSO)) very often display high volatility, toxicity and lipophilicity (related to the ability to interact with biological membranes). More recently, developments in the field of Green Chemistry are focusing on the design of more sustainable and cost-effective solvent alternatives like Ionic Liquids (ILs), bio-based solvents and natural deep eutectic solvents

(NADESs). The present study aimed to perform an ecotoxicological screening of 15 NADESs compounds using an extensive set of marine and freshwater bioassays, which aimed at different endpoints: immobilization of the freshwater crustacean *Daphnia magna*, inhibition of growth of the freshwater alga *Raphidocelis subcapitata*, and of the marine alga *Phaeodactylum tricoratum*, alteration in larval development on the brackish water serpulid *Ficopomatus enigmaticus* and the inhibition of bioluminescence in the marine bacteria *Aliivibrio fischeri*. The latter was performed using both freshwater and marine water protocol. What emerged was a clear absence of effect of all samples against *D. magna*. Regarding *F. enigmaticus*, highest effects were observed with 2 choline acetate- based compounds, in particular the one with imidazole and the one with citric acid. *A. fischeri* showed, in general, differences between the marine and the freshwater assay on same compounds. Specifically, for marine assay, bacteria showed a low degree of bioluminescence inhibition, while for freshwater assay a stimulation of bioluminescence was observed. Both marine and freshwater algae showed a certain degree of biostimulation. *P. tricoratum* growth was stimulated mainly by proline-based compounds, while *R. subcapitata* growth was stimulated by almost all tested compounds. Since biostimulation of algal growth is actually considered as an effect, samples which exhibited an increase of cellular concentration over 40% respect to control, were retested. The new assays were performed in the range 1-100 mg/L (8 dilutions) in order to find statistically significant NOEC and LOEC. Despite no ecotoxicological parameters, such as EC20/50, were calculable, biostimulation endpoints may underline a potential risk linked to substances considered “green”, in terms of environmental degradation.

3.05.P-Tu140 A Cost- and Time-Effective Screening Method for Determining Biodegradability Using Non-Invasive Optical Oxygen Sensors

Dennis Becker¹, Jens Bietz², Robin Coers³, Reinhard Kreiling² and Dirk Scheerbaum⁴, (1)Clariant Produkte (Deutschland) GmbH, Sulzbach, Germany, (2)Clariant Produkte (Deutschland) GmbH, Germany, (3)NOACK-Laboratorien, Germany, (4)DR.U.NOACK-LABORATORIEN, Germany

Improved biodegradability of chemicals in the environment is a key element for all actors in the supply chain as well as for the assessment of substances in existing and evolving regulatory frameworks. Especially, but not exclusively, for polymers it is and continues to be increasingly important to avoid persistent residues that could harm the environment and human health.

Hence, there is a world-wide research effort to increase the biodegradability of organic substances and polymers. Already, during the development of new polymers sustainability and sustainable-by-design plays a crucial role.

However, the state-of-the-art process to assess the biodegradability of substances is time consuming and expensive. With the presented screening method established by Noack and Clariant, it is possible to obtain an initial indication of the percentage biodegradability of several substances and polymers at a time. The turnover time is significantly reduced, by reducing the time for preparation and evaluation and the costs are decreased compared to the standard process.

For this purpose, up to ten different substances can be tested within a variable duration under flexible conditions in the innovative measuring system. The biodegradation is calculated via the oxygen concentration in the test vessels, which is determined via non-invasive optical oxygen sensors. This allows any form of substance or polymer to be tested, regardless of whether it is water-soluble or not.

The functionality of the test system has already been demonstrated in tests with various reference materials with known degradation behavior (fast, medium and slow biodegradation and polymeric alcohol ethoxylates) as well as with promising candidates from research and development activities to improve the biodegradability of polymers from different classes.

In summary, the established screening system offers the opportunity to assist the sustainability-focused innovation-pipeline by helping to decide about promising candidates for better biodegradable substances and polymers with reduced time-demand and costs.

3.06 Air pollution: exposure and effects on human and environmental health

3.06.T-01 Why Is the Air Toxic? Virtual Effects-Directed Analysis (vEDA) to Identify Human Health Hazards in Fine Particulate Matter (PM_{2.5})

Jean Froment¹, Jong-Uk Park², Sang-Woo Kim², Yoonjin Cho³, Soobin Choi³, Ji Eun Lee³, Young Hun Seo⁴, Seungyun Baik⁵ and Jonathan Martin⁶, (1)Department of Environmental Science (ACES), Stockholm University, Sweden, (2)Seoul National University, Korea, South, (3)Korea Institute of Science and Technology, Korea, South, (4)KIST Europe, Germany, (5)Environmental Safety Group, KIST Europe, Saarbruecken, Germany, (6)Stockholm University, Sweden

Air pollution causes major threats to human health across the globe. The air quality in South Korea is an increasing concern and is highly affected by continental outflows of neighboring countries. Depending on the source of the air, weather, and season, the composition of fine particulate matter (PM_{2.5}) is highly variable. Therefore, the present study uses a *virtual effects-directed analysis (vEDA)* approach to identify toxic chemicals. In the vEDA approach, each sample does not need to be fractionated. Rather, many samples are tested directly with bioassays and each sample is also comprehensively characterized with non-targeted mass spectrometry analysis. Through this ‘big data’ approach, the study aims to identify chemical features that correlate with toxicity in relevant human cells. PM_{2.5} samples were collected continuously from the Korean Climate Observatory at Gosan (33.29° N, 126.16° E), located in the Yellow Sea on the South Korean island of Jeju. Collection period of PM_{2.5} samples was over 17 months and the water-soluble component of the filters was extracted. A battery of bioassays and chemical analyses were carried out on the extracts. The samples were tested in cellular cytotoxicity and reactive oxygen species (ROS) assays (in primary human nasal epithelial and lung fibroblast cells) and an cellular assay (the dithiothreitol, or DTT, assay). Comprehensive screening of the water-soluble extracts was performed by HPLC-HRMS (in data independent acquisition mode) while trace metal analysis was carried out by ICP-MS. Two days back-trajectories of the air reaching the sampling station was modelled every hour, and aerosol scattering coefficients as well as particle sizing were measured during the sampling campaign. The bioassays showed

a high variability of the toxicity depending on the sampling days justifying the vEDA approach. The non-targeted analysis of PM_{2.5} extracts detected thousands of features. The deconvoluted MS2 spectra were compared against high-resolution spectral databases. The unmatched features were processed with high-throughput software workflows to predict their molecular formulas, and molecular networking was then applied to group molecules which have similar structures, based on spectral similarities. Together with the atmospheric parameters, the list of toxic candidates is being refined. This project is a unique opportunity to understand the challenges we are facing in terms of atmospheric exposure to toxic compounds.

3.06.T-02 Nontarget Mass-Spectrometry and In-Silico Molecular Characterization of Air Pollution From the Indian Subcontinent

*Stefano Papazian*¹, *Lisa D'Agostino*², *Ioannis Sadiktsis*¹, *Jean Froment*³, *Bénilde Bonnefille*⁴, *Kalliroi Sdougkou*¹, *Hongyu Xie*⁵, *Ioannis Athanassiadis*¹, *Krishnakant Budhavant*¹, *Sanjeev Dasari*¹, *August Andersson*¹, *Örjan Gustafsson*¹ and *Jonathan Martin*¹, (1)Stockholm University, Sweden, (2)Geosyntec Consultants, Sweden, (3)Department of Environmental Science (ACES), Stockholm University, Sweden, (4)ACES, Stockholm University, Sweden, (5)Stockholm University, ACESx, Sweden

Airborne fine particulate-matter (PM_{2.5}) is a major component of air pollution that contains unresolved complex mixtures of organic compounds. A deep molecular characterization of PM_{2.5} would contribute to improved understanding of air pollution impacts on global climate and human health. Here, we collected PM_{2.5} for 3 months at a remote receptor site in the Maldives that regularly intercepts polluted air outflows of the Indian subcontinent, and occasional pristine air from the Southern Indian Ocean. To achieve a broad molecular characterization of organic compounds, each PM_{2.5} sample ($n = 40$) was extracted with a range of solvents and analyzed by combining gas- and liquid chromatography high-resolution mass-spectrometry, i.e. (GC)- and (LC)-HRMS. A wide range of known anthropogenic contaminants were confirmed, including legacy persistent organic pollutants, polycyclic aromatic hydrocarbons (PAHs), plasticizers, flame retardants, pharmaceuticals, pesticides and associated transformation intermediates, some of which were detected in air for the first time. Unprecedented complexity was observed by nontarget analysis (>60,000 features). However, only a minor proportion of features (0.5%) could be annotated with spectral databases (318 compounds) or identified with authentic standards (53 compounds at Level 1, and 36 compounds as closely related isomers) - thus leaving vast 'molecular dark matter' structurally uncharacterized. An integrated workflow that leveraged on molecular networking and *in-silico* fragmentation predictions allowed us to reach a structural-level characterization for over 10,000 molecules, of which over 1,000 were hallmarks distinguishing polluted air of the Indian subcontinent from pristine air of the Indian Ocean. Clean air from the Indian Ocean primarily contained simple organooxygen molecules (O_x class; x=1-3) while polluted air was dominated by organodinitrogen (i.e. N₂, N₂O_x class), organosulfur and highly-oxygenated molecules (O₄-O₇ class). Overall, molecules associated with polluted regions occupied a broader and highly oxidized chemical space with physicochemical properties of high relevance to human toxicity and regional climate. Altogether, these results highlight how nontarget analyses and *in-silico* structure predictions can be implemented as advanced tools to explore deeper molecular-level insights and hypotheses on the health and climate impacts of complex organic compound mixtures in airborne PM.

3.06.T-03 New Approach Methodologies (NAMs) and Chemometrics to Study the Health Effects of Air Chemical Mixtures on Lung Cells

*Carmen Bedia*¹, *Paula Villasclaras*², *Clara Jaén*², *Athina Pavlidou*², *Fulvio Amato*², *Barend Leendert van Drooge Sr*³ and *Roma Tauler*², (1)Environmental Chemistry, Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Barcelona, Spain, (2)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (3)Environmental Chemistry, IDAEA-CSIC, Barcelona, Spain

Airborne particulate matter (PM) pollution has raised great concern since its exposure has been associated with adverse respiratory outcomes, such as exacerbations of asthma and chronic obstructive pulmonary disease, pulmonary fibrosis and lung cancer. However, the causality between specific chemical exposures and their effects on lungs health and their mechanism of action remain mostly unknown. To avoid the use of animals, a variety of approaches called New Approach Methodologies (NAMs) have been developed and progressively introduced to improve understanding of toxic effects of chemicals. In this work, we propose the use of NAMs, i.e. 3D cell cultures, HTS methods (viability assays, ELISA) and lipidomics to assess the biological effects of chemical extracts from environmental air samples. In addition, we apply chemometrics methods (PCA, MCR-ALS) to find relationships between the chemical composition data of air samples and the biological effects on cell cultures. Filter samples from an air quality monitoring station of Barcelona (collected from June to December 2019) were characterized using ICP-MS and GC-MS, and source apportionment was carried out using Positive Matrix Factorization. The results about the biological effects showed that sample extracts caused important changes on the release of pro-inflammatory cytokine IL-8 and on the lipidomic profile of 3D lung cell cultures. Different patterns of lipid changes and distribution along time were observed in the MCR-ALS analysis of lipidomics data from PM1 and PM10 treated cells. Data fusion of chemical analysis of PM1 and PM10 filters, and the biological effects data was performed to find a relationship between specific compounds or sources of pollution and changes in lipids and phenotype. Correlation maps and MCR-ALS analysis were applied to this fused data showing specific lipid patterns associated to pollution sources. Overall, the use of three dimensional lung cell cultures, HTS assays, omics and chemometrics in this work provided information about the biological mechanisms induced by PM1 and PM10 air pollution samples. The application of MCR-ALS on the chemical and biological fused data provided insight about the chemical pollutants and sources of pollution that contribute to the changes observed in lung cells. Additional data is being generated to produce more robust models that enable the prediction of biological outcomes using the chemical composition of samples.

3.06.T-04 Influence of Temperature Inversions on Organic Aerosols and Human Exposure: Measurement by Using Meteorological Balloons

Clara Jaén¹, Isabel Díez Palet², Barend Leendert van Drooge Sr², Esther Marco³, Prof. Joan Grimalt⁴ and Pilar Fernández⁵, (1)Environmental Chemistry, Spanish National Research Council (CSIC), Barcelona, Spain, (2)Environmental Chemistry, IDAEA-CSIC, Barcelona, Spain, (3)CSIC/IDAEA, Barcelona, Spain, (4)IDAEA-CSIC, Spain, (5)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain

Outdoor air pollution constitutes a global threat to ecosystems and human health. In 2016, around 4.2 million premature deaths worldwide were attributed to this cause and, still in 2019, 99% of the world population was breathing air which does not fulfil the WHO air quality guidelines levels. The highest human exposure to airborne pollutants occurs in cities which is usually more related to atmospheric conditions than to changes in emission sources. Atmospheric temperature inversion conditions often involve precautionary health warnings as they increase the concentration of atmospheric pollutants. Restricted dispersion of organic compounds and photooxidation in the upper air layers lead to qualitative and quantitative changes of aerosols with formation of secondary organic aerosols (SOA), involving processes that are still largely unknown. Understanding the main changes in composition of these compounds at molecular level will help to define the best strategies to deal with the improvement of air quality and reduction of health risks. The present study is devoted to the analysis of the vertical distribution of particle-associated organic pollutants and Black Carbon (BC), which was performed with the use of captive balloons equipped with particulate matter (PM) samplers and BC monitors. The qualitative and quantitative vertical distribution of organic pollutants was studied under standard environmental lapse rates and temperature inversion conditions. The organic pollutants present under several types of temperature inversions in urban and rural environments in different seasons were studied. One of these environments was located in the semiurban area of Osona (Catalonia) where the highest winter benzo[a]pyrene concentrations have been observed among those recorded in the Iberian Peninsula. The other site is a rural background site surrounded by fruit fields. The temperature inversions in the plain systems and associated atmospheric transport of organic pollutants, prior and after photooxidation, have been studied. The particle-associated pollutants involved polycyclic aromatic hydrocarbons (PAHs), anhydrosaccharides, hopanes, phthalates, and SOA compounds. Some of them were used as tracers to identify the contribution of emission sources and secondary formation to PM. The chemical analysis was performed with a high-resolution Q Exactive GC Orbitrap GC-MS/MS (GC-Orbitrap-MS).

3.06.T-05 Ecotoxicity of Atmospheric Particles' Deposition on Marine Organisms

Andreia Filipa Matos Ventura¹, Susana Loureiro², Regina Duarte³ and Roberto Martins⁴, (1)CESAM & Department of Biology, CESAM & University of Aveiro, Portugal, (2)Universidade de Aveiro, Portugal, (3)University of Aveiro, Portugal, (4)CESAM & Department of Biology, Department of Biology, University of Aveiro, Aveiro, Portugal

Currently, air pollution is a growing problem globally, mostly due to industrialization and urbanization. Anthropogenic activities can contribute to the emission of several pollutants into the atmosphere, including particulate matter (PM). Despite the few existing studies on literature, it can be predicted that the deposition of such atmospheric PM on the water bodies can affect marine biota performance. The magnitude of these effects depends on the atmospheric concentration and composition of PM and the wet/dry status of this PM in the deposition process. Using the NIST SRM® 1648a material as a surrogate for urban PM, this work considered the deposition of PM equivalent to one year of oceanic deposition (11.4 mg NIST/L) in an attempt to understand the toxicological effects on different marine organisms. Producers (microalgae and diatoms) and primary/secondary consumers (rotifers and polychaete) were used aiming to partially cover the current knowledge gaps on this topic. Thus, growth inhibition of primary producers and survival of rotifers and polychaetes were assessed. In addition, biochemical changes in polychaetes were measured, regarding oxidative stress (LPO-lipid peroxidation), antioxidant enzymes (CAT-catalase, GPx-glutathione peroxidase, GR-glutathione reductase), detoxification enzymes (GST-glutathione-S-transferases), neurotransmission impairment enzyme (AChE-acetylcholinesterase). Significant differences were observed between the control organisms (artificial saltwater with salinity 35) and exposed organisms in primary producers. Effects differed between diatoms and golden-brown microalga *I. galbana*, with diatoms being stimulated to grow while microalgae being inhibited. One possible explanation was hypothesized regarding the presence of silicon in NIST particles ($12.8 \pm 0.4\%$), which could promote the growth of diatoms since the chemical and structural composition of their frustules is highly dependent on this element; on the other hand, the presence of contaminants in the NIST particles may justify the growth inhibition on *I. galbana*. Furthermore, no acute effects were observed in the tested animals, however significant oxidative stress (LPO) and glutathione peroxidase activity (GPx) impairment were detected. The results suggest that PM does indeed cause effects on marine biota.

3.06 Air pollution: exposure and effects on human and environmental health (Poster)

3.06.P-Tu141 Source Apportionment and Toxicity of PM in Urban, Sub-Urban and Rural Atmospheres in Catalonia

Barend Leendert van Drooge Sr¹, Clara Jaén², Paula Villasclaras², Carmen Bedia³, Prof. Joan Grimalt⁴ and Pilar Fernández⁵, (1)Environmental Chemistry, IDAEA-CSIC, Barcelona, Spain, (2)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (3)Environmental Chemistry, Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Barcelona, Spain, (4)IDAEA-CSIC, Spain, (5)Institute of Environmental Assessment and Water Research IDAEA CSIC, Spain

Exposure to air pollution is a global threat to human health and ecosystems. Effective action to reduce air pollution requires a good understanding of sources, transport and transformation mechanisms and the effects of these atmospheric pollutants on humans and ecosystems. The contributions of biomass emissions to PM₁₀ and BaP, as well as the formation of secondary organic aerosols (SOA) and their influence on PM and their toxicity are still pending of clarification. PM₁₀, NO₂, O₃ and BaP and several molecular organic tracer compounds (e.g. levoglucosan, hopanes, SOA) were evaluated in three geographically different sites in Catalonia (Spain) that often exceed the limit values in the past decade. The organic compounds were analyzed by GC-MS and toxicity was evaluated by the pulmonary lung cells A549 assay. The PM samples were collected in an urban traffic site, a sub-

urban background site, and a rural background site, from summer to winter 2019. Source apportionment of the organic aerosol confirmed the traffic related air pollution in the urban site, and showed that biomass burning and secondary organic aerosols impact the air quality in the sub-urban and rural background sites, with substantial differences between summer and winter. Toxicity tests of the PM extracts with lung cells show higher toxicity (Inhibition of Cell growth) in wintertime samples in the sub-urban and rural sites, compared to the urban site and summertime sample with high biogenic SOA contributions. The inhibition of cell growth (IC50) was observed at equivalent air volumes between 4 and 30 m³, which were relevant volumes for daily respiratory volumes in humans. IC50 correlated best with biomass burning indicators, PAH, and quinones. These results that there is a need for different mitigation strategies for urban and rural sites in order to improve the air quality and reduce health effects. In urban areas traffic emissions are still the dominant factor influencing urban air quality and may directly be responsible for part of the SOA and O₃ levels in suburban and rural areas, while these later areas cope with putative air quality from local biomass burning emissions, essentially in the colder period of the year. *Reference* - Clara Jaén, et al. 2021, doi: 10.3390/atmos12060744 *Acknowledgement* - Financial support for this study was provided by the research projects from the Plan Nacional de I+D of the Spanish Ministry of Science and Innovation CUANTOX (CTM2015-71832-P) and INTEMPOL (PGC2018-102288-B-I00).

3.06.P-Tu142 Cytotoxicity of Human Lung Cells (A549) After Exposure to a Gaseous Bio-Hybrid Fuel Blend at Air-Liquid Interface (ALI)

Jonas Daniel¹, Ariel Schönberger², Stefan Pischinger², Martina Roß-Nickoll² and Miaomiao Du², (1)Department of Ecosystem Analysis, RWTH Aachen University, Institute for Environmental Research, Aachen, Germany, (2)RWTH Aachen University, Germany

Emissions from the transport sector contribute to air pollution and lead to exposure of humans to a variety of gaseous chemicals. Recently, several studies have shown that gaseous chemicals induce adverse effects, e.g., programmed cell death, inflammatory responses, or DNA damage on cell level. However, most studies focussed only on single substance exposure whereas mixtures of several chemicals are present in the environment. In addition, the investigated exposure pathway, e.g., using cell suspensions might lack relevance to human lung physiology. Therefore, we exposed human lung cells to a gaseous bio-hybrid fuel blend mixture at air-liquid interface (ALI) conditions. Briefly, A549 cells were cultivated on microporous membranes supplied with media from the basal side. Then A549 cells were exposed apically to a 20 mL/min flow of undiluted or diluted gaseous fuel blend (components: methanol, ethanol, methyl acetate, ethyl acetate, 3-methyl-2-butanone and n-pentane) for 1 h at ALI in a humidified air at 37 °C. The investigated fuel blend was chosen based on previous work from Ackermann *et al.* 2021. After exposure, cells were post-incubated for 24 hrs and cell viability/toxicity endpoints were investigated. Microscopic investigation revealed a damaged cell layer of exposed cells compared to controls (qualitative). Furthermore, our results indicated a slightly lower cell viability of exposed cells for both undiluted and diluted exposures compared to controls (quantitative). Our experiments resembled an exposure scenario, e.g., to simulate inhalation of highly concentrated fuel vapours at the gas station or in low-ventilated areas. For future research, other factors such as the oxidation products of the chemicals and the involvement of other gaseous compounds in the tested mixture could contribute to a more realistic exposure scenario. This work was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy – Cluster of Excellence 2186 „The Fuel Science Center” – ID: 390919832.

3.06.P-Tu143 Relationship Between Airborne Pollen Concentrations and Air Pollutant Levels in a LOW Polluted City

Juan Jesús Hidalgo Barquero¹, Santiago Fernández-Rodríguez¹, Raúl Pecero-Casimiro¹ and Eduardo Pinilla-Gil², (1)University of Extremadura, Spain, (2)Universidad de Extremadura, Spain

Scientific studies on health impacts caused by air components focus on the independent effects of the levels of atmospheric pollutants and aerobiological particles. In contrast, there are less studies that relate both types of data. The objective of this study is exploring statistical relationships in Badajoz (SW, Spain) among airborne pollen concentrations of different pollen types such as Quercus, Olea, Poaceae, and Pinus, and air pollutants as O₃, CO, NO, NO₂ and SO₂. The relationship between atmospheric pollutants and pollen grains was studied using Spearman's correlation (r) (significance level of 95%), from 2010 to 2019. The levels of the different pollen types were obtained from aerobiological sampling using a volumetric sampler. The levels of atmospheric pollutants were acquired from the city's air quality monitoring unit. The correlations results vary according to the pollen type and pollutant. The correlations of O₃ with the different pollen types are higher than reported data [1]. Poaceae presents the maximum value of r for O₃ (0.46); in cited study the correlation is between 0.10 and 0.24. However, NO₂ presents similar negative correlations, between -0.10 and -0.20 [1]. Olea pollen type also presents negative values for CO, NO₂ and SO₂. On the contrary, O₃ and CO show positive values. For Pinus there is no agreement between the negative value obtained for NO₂ and the reported positive values [1,2]. Quercus shows correlations similar to published data, except for the relationship between Pinus and NO₂ levels. The interrelations between the levels of pollen and atmospheric pollutants present a high variability, and multiple factors such as meteorological factors may be involved, as well as synergies between pollutants or time lags.[1] P. Cariñanos, I. Foyo-Moreno, I. Alados, J.L. Guerrero-Rascado, S. Ruiz-Peñuela, G. Titos, A. Cazorla, L. Alados-Arboledas, C. Díaz de la Guardia, Bioaerosols in urban environments: Trends and interactions with pollutants and meteorological variables based on quasi-climatological series, Journal of Environmental Management. 282 (2021). <https://doi.org/10.1016/j.jenvman.2021.111963>. Kumar, Influence of atmospheric PM_{2.5}, PM₁₀, O₃, CO, NO₂, SO₂, and meteorological factors on the concentration of airborne pollen in Guangzhou, China, Atmospheric Environment. 212 (2019) 290–304. <https://doi.org/10.1016/j.atmosenv.2019.05.049>.

3.06.P-Tu144 The Effects of Traffic Pollution Are Changes in Lichens Caused by Road Salt and Lead Stress

Gintare Sujetoviene, Vytautas Magnus University, Kaunas, Lithuania

Road transport is responsible for a large proportion of air pollution in urban ecosystems. With the increase in car use, road traffic pollution is considered to be a major threat to ecosystems. The impact of salinity and heavy metals as lead on physiological parameters of lichens was determined. Lichens *Evernia prunastri* and *Ramalina fastigiata* were exposed to different NaCl in combination of lead. The results of the experiment showed that both exposures affected the lichen membrane damage as indicated by increase in conductivity. The potential photosystem II efficiency (F_v/F_m) was not so susceptible to the impact of stressors compared to membrane integrity. The results show that combination of the traffic-related factors have negative effect on sensitive lichens. The results of the study supplemented the knowledge on the effects of transport-related pollution on organisms, such as salts and heavy metals, on lichens and provided a better understanding of the mechanisms of toxicity.

3.06.P-Tu145 Development of Extraction and Sample Preparation Methods for the Application of Metaproteomics to Bioaerosol

*Mathieu Galmiche*¹, *Lauriane Kuhn*², *Maurice MILLET*³ and *Yannis François*⁴, (1)Institute of Chemistry and Processes for Energy, Environment and Health (ICPEES), Université de Strasbourg, Strasbourg, France, (2)Plateforme Protéomique Strasbourg-Esplanade, France, (3)University of Strasbourg (UdS), France, (4)Université de Strasbourg, France

The biological fraction of aerosols is of growing concern regarding its adverse health effects because of the airborne allergens and pathogens it contains [1,2]. Up to now, most analytical methods employed for the characterization of bioaerosols are either restricted to a particular type of biological source (such as optical microscopy for pollen grains and fungal spores), or they only give broad information on the whole bioaerosol without any selectivity (such as total protein content or molecular tracer quantification methods) [3,4]. Therefore, metaproteomics seems to be a very appropriate analytical tool for the characterization of bioaerosol [1,2]. Indeed, shotgun bottom-up analysis of the protein content of such environmental samples enables a large-scale characterization of their expressed phenotype regardless of their taxonomy, thus it can lead to the identification of the main protein sources in bioaerosols. However, the application of metaproteomics to bioaerosol samples is associated with two major analytical challenges: the data interpretation with bioanalytical tools and database searches, and the sample treatment, including extraction and further preparation steps. In this work, we describe the influence of various parameters such as: - the extraction time, - the number of extraction cycles, - the composition of the extraction solution in terms of detergents, pH buffers, etc... on the efficiency of ultrasound-assisted in-solution extraction of the proteinaceous content of bioaerosol samples. We also discuss the necessity of further sample preparation, including detergent removal, concentration and purification steps, which are often necessary but can also lead to protein loss. All the optimizations presented in this work were found to be critical for the enhancement of the detection of proteins present at very low levels in airborne particulate matter. **References** [1] F. 3.06.P-Tu146 Is There Any Potential Role of Essential and Toxic Trace Elements on COVID-19 Infection? An Observational Study in Catalonia (Spain)

*Montse Marques*¹, *Noemí Serra*¹, *Simona Iftimie*², *Jordi Camps*², *Jorge Joven*² and *Jose Domingo*¹, (1)Universitat Rovira i Virgili, Spain, (2)Hospital Universitari de Sant Joan, Institut d'Investigació Sanitària Pere Virgili, Universitat Rovira i Virgili, Spain

COVID-19 is the infection caused by the SARS-CoV-2 resulting in a massive outbreak in 2020. The most frequent symptoms include fever, cough, fatigue, sputum, and dyspnea. However, up to 20% of infected individuals undergo a severe disease, frequently leading to pneumonia, acute respiratory distress syndrome, organ dysfunction and death. Respiratory comorbidities, along with cardiometabolic diseases, cancer and long-term exposure to environmental pollutants are risk factors for the severity of COVID-19. Anyhow, the age is a key variable determining COVID-19 health outcomes due to the weakening of the immune system over the life course. Considering that both essential and toxic elements are responsible for immune responses, the present study was aimed at assessing their potential role on COVID-19 health outcomes. A retrospective observational study was performed with 214 individuals attending or admitted to the Hospital Sant Joan (Reus, Catalonia, Spain), which were classified into: i) individuals COVID-19+ with an asymptomatic infection course; ii) individuals suffering mild COVID-19; iii) individuals suffering severe COVID-19; iv) individuals COVID-19? (control). An *ad hoc* database with data on age, sex, toxic habits, comorbidities, blood test results, medication and clinical outcomes, along with the levels of As, Cd, Cr, Cu, Hg, Fe, Mg, Mn, Pb, Se, V and Zn in individual serum samples was created. Arsenic was < 0.1 µg/L in all individuals, while Hg showed a low detection rate (< 85%). None of the elements here assessed showed significant differences ($p > 0.05$) among the COVID-19 severity groups. However, the concentrations of Cd, Pb and V in infected individuals were significantly higher ($p < 0.05$) than the control group, while the levels of Zn in asymptomatic and mild COVID-19 were significantly lower ($p < 0.05$) than non-infected individuals. Although the occurrence of Zn in COVID-19 severe patients was higher than in COVID-19?, but with no significant differences ($p > 0.05$). Results revealed random correlations among analyzed elements. While Cd and Pb showed a significant ($p < 0.05$) positive correlation with C-Reactive Protein (CRP), glucose and aspartate transaminase (AST) in infected individuals. In conclusion, the present study indicates that exposure to Cd, Pb and V might weaken the immune system, and consequently, to increase vulnerability to develop COVID-19 in case of infection with SARS-CoV-2.

3.06.P-Tu147 Analytical Developments for the Assessment of 120 Pesticide Compounds in Blood, Plasma and Feathers of Birds

Anaïs Rodrigues¹, Jérôme Moreau², Agathe Gaffard², Vincent Bretagnolle², Karine Monceau², Olivier Delhomme³ and Maurice Millet⁴, (1)ICPEES, CNRS, Strasbourg, France, (2)CNRS CEBC, France, (3)Universite de Lorraine, France, (4)Universtiy of Strasbourg I CNRS, France

More and more studies show the importance of biomonitoring as an evaluation tool to assess environmental contaminations by crop protection products. In this study we chose to analyze blood, plasma and feathers of *Perdix* to assess their potential contamination by those products. The group of pesticides is composed of a huge variety of compounds. Therefore, in this study, we optimized and validated methods to analyze around 120 compounds including herbicides, insecticides and fungicides. We compared various extraction methods found in the literature and we adapted the protocol of Goutner et al. (2011) for blood extraction and Hao et al. (2018) for the extraction of pesticides from plasma. To extract pesticides from feathers, we used a QuEChERS procedure following Humman-Guillemot et al. (2021). After extraction, samples were concentrated then injected simultaneously in LC-MS/MS and GC-MS/MS for quantification. Liquid chromatography was selected to separate non-volatile or thermolabile compounds such as neonicotinoids, being 38 compounds. Gas chromatography was selected to analyze non-thermolabile and volatile compounds - or semi-volatile compounds with a prior derivatization step - being 93 compounds. LC-MS/MS analyses were performed using the MRM mode with 2 mass transitions for each compound, one for quantification and one for qualification. GC-MS/MS analyses were preceded with a thermal desorption step. MRM mode was also used for detection and quantification. For both analytical methods, calibrations were done by spiking within the matrices using deuterated compounds as internal standards. Evaluation of reproducibility, repeatability and extraction yields were also performed with satisfactory results for most compounds. LOD and LOQ were determined as the concentrations giving signal to noise (S/N) ratios of 3 and 10 respectively. In this project, we developed and validated two distinct analytical methods which showed very good analytical characteristics. Those methods were successfully applied to 70 blood samples, 35 plasma samples and 22 feather samples collected in 2021 in the area of La Rochelle, France. The choice of several complementary matrices such as blood, plasma and feathers allowed a good assessment of environmental contaminations for a selected population of breeding birds. This study also showed the importance of biomonitoring combined with such analytical methods for more accurate evaluations of environmental pollution.

3.06.P-Tu148 Volatile Organic Compounds and Their Influence on Tropospheric Ozone Formation in Semi-Urban and Rural Areas

Isabel Díez Palet¹, Clara Jaén², Esther Marco³, Barend Leendert van Drooge Sr¹, Prof. Joan Grimalt⁴ and Pilar Fernandez⁵, (1)Environmental Chemistry, IDAEA-CSIC, Barcelona, Spain, (2)Environmental Chemistry, Spanish National Research Council (CSIC), Barcelona, Spain, (3)CSIC/IDAEA, Barcelona, Spain, (4)IDAEA-CSIC, Spain, (5)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain

In order to develop effective pollution control measures, it is essential to know the chemical composition of the atmosphere and the mechanisms of formation of air pollutants. Air pollution is one of the most pressing environmental issues for human health and its occurrence in semi-urban and rural areas cannot be underestimated. While traffic-related compounds are the main pollutants in most urban regions, agricultural phytosanitary compounds and biomass burning products could be the most relevant in semi-urban and rural areas. Besides direct emissions of contaminants to the atmosphere, the impact of air pollution is also related to weather changes. Atmospheric temperature inversion episodes imply stagnant conditions that restrict the dispersion of atmospheric pollutants fostering the transformation of chemical compounds through photooxidation and increasing the concentrations of toxic compounds and human exposure. Unfortunately, the knowledge on the qualitative and quantitative changes in the composition of atmospheric pollutants and their vertical transport under varying weather conditions is very limited and need to be elucidated. The present study is concerned with the vertical distribution of the chemical composition of Volatile Organic Compounds (VOCs) and its influence on O₃ formation within and above the temperature inversion layer in two different areas from Catalonia: Vic (semi-urban) and Mollerussa (rural). The former undergoes frequent temperature inversion conditions and shows one of the highest summer concentrations of ozone of the Iberian Peninsula. The second is a rural area with a high agricultural activity, where the application of phytosanitary products and pesticides can cause the increase of other pollutants like ambient VOCs and O₃. Sampling campaigns were performed in winter and summer to assess the seasonal variations of VOCs on molecular level, including both biogenic (isoprene and monoterpenes) and anthropogenic compounds (alkanes, alkenes, aromatic hydrocarbons and oxygenated compounds). The vertical distribution of VOCs was performed using meteorological balloons fitted with active sampling pumps and different adsorbent cartridges. The chemical analysis included thermal desorption-gas chromatography mass spectrometry (TD-GC-MS) and high-performance liquid chromatography (HPLC) techniques.

3.06.P-Tu149 Industrial Air Emission Impact on Human Exposure and Health - Towards Evidence-Based Decision Making

Lorenzo Marotti¹, Joonas Koivisto², Patrick Van Sprang², Violaine Verougstraete³ and Hugo Waeterschoot⁴, (1)Eurometaux, BRUXELLES, Belgium, (2)ARCHE Consulting, Belgium, (3)Eurometaux, Belgium, (4)Chemicals Management, Eurometaux, Hove, Belgium

Better air quality would significantly improve European population well-being, which is why the European Commission recently launched the Zero Pollution Action Plan “to reduce the health impact of air pollution by more than 55%”. The non-ferrous metal sector (NFM) is committed to continuing lowering its emissions of air pollutants in the most cost-effective and evidence-based approach. This can be achieved by quantifying source/sector specific health impacts and then assessing economic feasibility to reduce emissions from source/sector. Source/sector specific health impact can be quantified by using Burden of Disease (BoD) assessment as recommended by WHO. [1] The aim of the study is to quantify the impact of the NFM industry stack- and fugitive emissions on human exposure and health by quantifying factory emissions attributable fraction to ground level concentration

levels, population attributable exposure fraction and health impact by using the BoD concept. Key questions are: What is the NFM sector emissions impact on population level exposure and health (current situation)? What is the NFM sector emissions relative impact to population exposure and health compared to other sectors (can the NFM sector make a significant change)? What is the NFM sector potential to make air healthier for humans (what can be done)? Answering these questions is used to define what the NFM industry can do to contribute to air quality and identify cost-effective solutions associated with a significant impact on population exposure and health. The approach was tested with a virtual factory placed in a typical industrial site. Health impacts of Cadmium (Cd), Nickel (Ni) and Arsenic (As) metal emissions were evaluated in terms of Disability Adjusted Life Years (DALYs). First results showed that DALYs by Cd, Ni and As factory emissions were low compared to emissions attributable to transportation. The evaluation continues by moving towards the estimation of PM, NO_x and SO₂. The study outcomes will be extrapolated to estimate NFM industry health impact by scaling average emissions with total production volumes and assuming similar average population attributable fraction, and answer the above-mentioned scientific questions. References [1] WHO, 'Health risk assessment of air pollution - general principles.', World Health Organization Regional Office for Europe, Copenhagen, Denmark, 2016.

3.06.P-Tu150 COSMOtherm Estimates of Organophosphate Ester Oxidation Product Physico-Chemical Properties

Cassandra Johannessen¹ and J. Mark Parnis², (1)Chemistry, Trent University, Peterborough, ON, Canada, (2)Trent University, Canada

Chemicals released into the atmosphere have a finite lifetime, usually ending in transformation into other products by oxidation processes. As a result, it is insufficient to consider the fate of only the initially released chemical, but ultimately necessary to consider the fate and properties of their oxidation products. In this study, we present computational estimates of properties associated with organophosphate ester oxidation reactions, demonstrating the extent of variation in key physico-chemical properties such as partition ratios K_{ow}, K_{aw} and K_{oa}. These results are used to illustrate such variation using chemical space plots of log(K_{aw}) vs log(K_{ow}). In general, oxidation increases the polarity of such chemicals, resulting in increased hydrophilicity and corresponding lowering of K_{aw} and K_{ow}. Thus, oxidation of chemicals in the atmosphere can be seen as a driving force for oxidation products to leave the atmosphere and enter the hydrosphere. As well, propensity for long-range transport and bioaccumulation are lowered.

3.06.P-Tu151 Permeation of Chlorpyrifos in Ex Vivo Pig Skin - Experimental Conditions to Get Closer to Human Exposure

Dorinda Silva, Polytechnic Institute of Leiria, Leiria, Portugal

Exposure to air pollutants is not limited to inhalation risk and dermal contact is gaining increasing interest with the possibility to represent a risky carcinogenic route. Chlorpyrifos is a broad-spectrum organophosphorus pesticide used for aerial and ground-based treatments with different permeation values being reported for human skin. Despite the recommendations of the organisation for economic co-operation and development (OECD) to use 50% of ethanol in the receptor fluid for skin permeation of lipophilic compounds (as chlorpyrifos), this condition was suggested to exaggerate its permeation. Indeed, the definition of the appropriate receptor condition for lipophilic compounds is a common unmet need pointed by different research groups in the area. The aim of this study was to understand the most appropriate receptor fluid composition to be recommended for the permeation of chlorpyrifos in *ex vivo* pig skin that mimics human exposure. For this, several receptor fluid compositions were investigated. Permeation assays were carried with *ex vivo* pig skin mounted on Franz cells and different concentrations of ethanol in the receptor fluid were tested. Permeation assays were carried out at 32 °C and cumulative permeation of chlorpyrifos quantified by HPLC. The results were compared with kinetic parameters reported in the literature for human exposure to chlorpyrifos. Higher quantities of permeated chlorpyrifos are achieved when using the highest concentration of ethanol in the receptor fluid and the values obtained for the permeation kinetic parameters - flux and T_{lag} - are related to the percentage of ethanol in the receptor fluid. Indeed, the permeation flux is directly correlated with the ethanol concentration in the receptor fluid. Finally, when using the lowest concentration of ethanol in the receptor fluid, the permeation flux was 0.63±0.22 µg/cm²/h, which greatly approximates to the value of 0.46 µg/cm²/h reported in human studies. When using *ex vivo* pig skin, the experimental condition that best approximates to kinetic parameters obtained for human skin exposure to chlorpyrifos is the use of lower concentrations of ethanol in the receptor fluid. This work addressed a reported unmet need thereby supporting experimental conditions to be considered in this research field.

3.06.P-Tu152 Reduction of Odor Emitted From Swine Manure Facility by Bio-Foam Cover

Prakash Gautam¹, Subok Chae¹, Jongshin Jeong² and Seung-Woo Jeong¹, (1)Kunsan National University, Korea, South, (2)Girpoom Environmental Technology Inc., Korea, South

In this pilot-scale study for ammonia (NH₃) reduction from swine facilities, bio-foam was produced by surfactant solution and ammonia-degrading microbes using automatic foam generation unit and sprayed onto the manure surface. We report that the bio-foam spraying significantly suppresses the release of NH₃ from swine manure (located in the four different real swine manure storage facilities in Yongin city, South Korea) irrespective of the seasonal change. The designed biofoam spraying system was as effective as laboratory testing (previous study) for NH₃ masking/degradation and complete coverage of manure was ensured within 40-50 min. The applied biofoam in this study was very dry (Hexagonal, foam quality; 99.0-99.2% and foam density 0.0080 g/mL), medium expansion and stable (half-life; 120 min) with foam bubble density of 25 bubbles/cm² (small size bubbles). Furthermore, this study reduced NH₃ significantly higher (90%±100 %) compared to the control (without treatment; 25%±43 %). Considering this evidence, the bio-foam has two major functions; i.e. biofoam can act as a physical barrier to prevent early release of malodorous compounds into the atmosphere, and it ultimately degrades malodorous (bad odor gases) by the bacteria, after

breaking the foam. Furthermore, surfactant foam can also serve as an effective medium for bacteria to distribute themselves uniformly in the manure pits. (This work was supported by Korea Smart Farm R&D Foundation (Grant 421020-03)).

3.07 Influence of climate change on the fate of persistent organic pollutants and chemicals of emerging concern in the Arctic

3.07.T-01 Assessing Climate Change Influence on Persistent Organic Pollutants (POPs) and Chemicals of Emerging Arctic Concern (CEACs) in the Arctic Physical Environment

Hayley Hung¹, Crispin Halsall², Hollie Ball³, Terry F. Bidleman⁴, Jordi Dachs⁵, Amila De Silva⁶, Mark H. Hermanson⁷, Roland Kallenborn⁸, Derek C.G. Muir⁶, Roxana Suehring⁹, Xiaoping Wang¹⁰ and Simon Wilson¹¹, (1)Air Quality Processes Research Section, Environment and Climate Change Canada, Toronto, ON, Canada, (2)Lancaster University, Lancaster, United Kingdom, (3)Lancaster Environment Centre, Lancaster University, Lancaster, United Kingdom, (4)Chemistry, Umea University, Umeå, Sweden, (5)IDAEA-CSIC, Spain, (6)Environment and Climate Change Canada, Canada, (7)Hermanson & Associates LLC, United States, (8)Norwegian University of Life Sciences, Norway, (9)Ryerson University, Canada, (10)Institute of Tibetan Plateau Research Chinese Academy of Sciences, China, (11)Arctic Monitoring and Assessment Programme (AMAP), Norway

The physical environment in the Arctic has changed significantly as a result of climate change and such changes, e.g. increasing temperatures, sea ice retreat, slumping permafrost, changing sea ice regimes, glacial loss and changes in precipitation patterns, can impact contaminant distribution and subsequently affect the Arctic ecosystems. Evidence of the influence of climate change on contaminant circulation and transport among various Arctic environmental media, including air, ice, snow, permafrost, fresh water and marine environment, are summarized in this presentation. We will broaden the discussion on how climate change may influence contaminant fate in similar cold-climate ecosystems, including Antarctica and the Tibetan Plateau. Indirect effects of climate change on contaminants in the Arctic, including those of extreme weather events, increase in wild fires, and increased human activities leading to new local contaminant sources, have been identified as significant knowledge gaps. Intensified contaminant movements into marine and freshwater ecosystems were observed due to climate change, but better connections are needed with observed effects due to subsequent exposure and accumulation of contaminants in biotic species. Emerging issues, including potential enhanced impacts of higher molecular weight halogenated natural products (hHNPs) and microplastics under a changing climate will be explored and their implications discussed.

3.07.T-02 The Influence of Global Climate Change on Accumulation and Toxicity of Persistent Organic Pollutants and Chemicals of Emerging Arctic Concern in Arctic Food Webs

Katrine Borga¹, Melissa McKinney², Heli Routti³, Kim J. Fernie⁴, Julia Giebichenstein⁵, Derek C.G. Muir⁶ and Ingeborg Hallanger⁷, (1)UiO, Norway, (2)McGill University, Canada, (3)The Norwegian Polar Institute, Norway, (4)Environment and Climate Change Canada, Burlington, ON, Canada, (5)University of Oslo, Norway, (6)Environment and Climate Change Canada, Canada, (7)Norwegian Polar Institute, Norway

As it affects physical, biological, and ecological processes in the environment, global climate change has the potential to influence the uptake and fate of persistent organic pollutants (POPs) and contaminants of emerging Arctic concern (CEACs) in biota and food webs through multiple mechanisms. We summarize the current understanding of how climate change-driven physical and ecological processes influence the levels of persistent organic pollutants (POPs) and contaminants of emerging Arctic concern (CEACs) in biota and food webs within Arctic marine, terrestrial, and freshwater ecosystems. We also address how climate change may interact with other stressors to impact contaminant toxicity and the utility of modelling and newer research tools in closing knowledge gaps on climate change-contaminant interactions. In summary, the study reveals that climate change will impact the long-range transport of pollutants to the Arctic and within the Arctic by altering atmospheric, environmental, and ecological processes, and thus will influence the exposure and accumulation of POPs in Arctic wildlife. In detail; i) physical climate parameters, including climate oscillation indices, precipitation, water salinity, sea ice age, and sea ice quality, show statistical associations with POPs concentrations in multiple Arctic biota. ii) Permafrost thaw is influencing the concentrations of POPs in freshwater ecosystems. iii) Northward range-shifting species can act as biovectors for POPs and CEACs into Arctic marine food webs. iv) Shifts in trophic position can alter POPs concentrations in populations of Arctic species. v) Reductions in body condition are associated with increased levels of POPs in some biota. vi) Models are useful for predicting the net result of various contrasting climate-driven processes on POP and CEAC exposures; however, for some parameters, especially food web changes, insufficient data exists with which to populate such models. In addition to the impact of global regulations on POP levels in Arctic biota, we demonstrate that there are various direct and indirect mechanisms by which climate change can influence contaminant exposure, accumulation, and effects. Therefore, it is important to identify the actual factors that contribute to the variations in POPs to better inform future regulations and policies.

3.07.T-03 Does Climate Change Affect the Long-Term Time Series of Persistent Organic Pollutants (POPs) in Arctic Biota?

Katrin Vorkamp¹, Pernilla Carlsson², Simonetta Corsolini³, Cynthia de Wit⁴, Rune Dietz⁵, Matthew Gribble⁶, Magali Houde⁷, Vrinda Kalia⁸, Robert Letcher⁹, Adam Morris¹⁰, Frank Rigét⁵, Heli Routti¹¹ and Derek C.G. Muir⁷, (1)Aarhus University, Denmark, (2)Norwegian Institute for Water Research, Norway, (3)University of Siena, Italy, (4)Stockholm University, Stockholm, Sweden, (5)Aarhus Universitet, Denmark, (6)University of Alabama, Birmingham, United States, (7)Environment and Climate Change Canada, Canada, (8)Columbia University, United States, (9)Environment and Climate Change Canada, Ottawa, ON, Canada, (10)Northern Contaminants Program, Canada, (11)The Norwegian Polar Institute, Norway

Time series of persistent organic pollutants (POPs) in Arctic wildlife have been established under national monitoring

programmes, generally showing decreasing concentrations of POPs over time, although exceptions exist. These time series are also used to evaluate the effectiveness of international regulations, such as the Stockholm Convention on POPs of the United Nations, regarding decreases in POP concentrations as reflective of reduced primary emissions. However, climate change might affect the fate of POPs in the Arctic, and ultimately the long-term time series, through direct physical and chemical processes or complex ecosystem changes. This study was part of an assessment of the Arctic Monitoring and Assessment Programme (AMAP), analysing links between climate parameters and/or biological variables and the time trends of POPs in Arctic biota, with some additional information from the Antarctic. Several correlative relationships were identified between POP trends in Arctic freshwater and marine biota and climate parameters such as oscillation indices, sea ice extent and its time of formation, temperature and precipitation, but little is known of mechanisms behind these observations. Permafrost thawing seems to lead to increased inputs of POPs into Arctic lake systems. Biological data indicate changes in the diet and trophic level for some species, e.g. thick-billed murres (*Uria lomvia*) and polar bears (*Ursus maritimus*), with consequences for their POP exposure. Studies from the Antarctic suggested associations between iceberg calving and concentrations of POPs in fish, a phenomenon that has not been studied in the Arctic yet. The overall trends of long time series did not change substantially when climate and/or biological parameters were considered, indicating that primary emissions remain the main driver of time trends in Arctic biota. However, rates of annual change could be affected, and local and temporary perturbations occurred in the long-term time series. Effects appeared more pronounced in recent years and often showed a time-lag influence, suggesting that climate-related effects might gain importance in the future. The findings indicate a development towards a more dynamic and complex exposure situation for Arctic biota.

3.07.T-04 Influence of Climate Change on Persistent Organic Pollutants and Chemicals of Emerging Arctic Concern: Overview of the State of Knowledge

*Cynthia de Wit*¹, *Katrin Vorkamp*² and *Derek C.G. Muir*³, (1)Stockholm University, Stockholm, Sweden, (2)Aarhus University, Denmark, (3)Environment and Climate Change Canada, Canada

A recent Arctic Monitoring and Assessment Programme (AMAP) report addresses the influence of climate change on persistent organic pollutants (POPs) and chemicals of emerging Arctic concern (CEACs) based on empirical data available in the past 10 years. Higher temperatures are leading to release of stored POPs from melting ice, glaciers and thawing permafrost into aquatic systems, and are also affecting the uptake and elimination of POPs in cold-blooded organisms. Reductions in the amount and extent of sea ice are influencing air-water exchange of contaminants and prey accessibility. Northward movement of subarctic species from the Atlantic and Pacific leads to increased prey-switching, affecting POP exposure and tissue levels. Increasing temperatures and cryospheric changes have increased the mobility and transfer of POPs between physical environmental compartments of the Arctic through various mechanisms. Climate change and a diminishing cryosphere will likely increase human activity in the Arctic, including shipping, tourism, and industrial operations, as well as promote the expansion of urban areas, contributing to local releases of POPs and CEACs. Temporal trends of POPs in the Arctic are used in effectiveness evaluations of the Stockholm Convention, which regulates primary emissions of POPs. POP concentrations have generally decreased in the Arctic environment and biota, but some POP time series have shown recent perturbations in these decreasing trends associated with climate-related changes in physical processes or ecosystems. Variations in climate oscillation indices, which reflect changes in air mass movements, ocean currents, and thus contaminant transport, are correlated with changes in POP accumulation in some Arctic biota. Temporal associations between POP concentrations in air and biota and climate parameters (e.g. climate oscillation indices, sea ice extent, precipitation) are also seen. The reduction of primary emissions is still considered to be the main driver of POP time trends, however, for some compounds, the rate of concentration decline has been correlated (negatively or positively) with climate-related parameters. Although the assessment shows climate-change related influences on POPs and CEACs, considerable knowledge gaps exist and further monitoring and research are needed to fill these. The coordinated research and monitoring approach under AMAP will help provide new data to evaluate these emerging climate-contaminant issues.

3.07 Influence of climate change on the fate of persistent organic pollutants and chemicals of emerging concern in the Arctic (Virtual Only)

3.07.V-01 "Nothin' Like a DAME": Biogeochemistry of Drosophilin a Methyl Ether and Other Halomethoxybenzenes in the Nordic Region

*Terry F. Bidleman*¹, *Agneta Andersson*², *Sonia Brugel*², *Lars Ericson*², *Katherina Hansson*³ and *Mats Tysklind*², (1)Chemistry, Umea University, Umeå, Sweden, (2)Umea University, Sweden, (3)IVL Swedish Environmental Research Institute, Sweden

Drosophilin A (DA: 2,3,5,6-tetrachloro-4-methoxyphenol), drosophilin A methyl ether (DAME: 1,2,4,5-tetrachloro-3,6-dimethoxybenzene), and chlorinated anisoles are halogenated natural products (HNPs) of terrestrial fungi, particularly basidiomycetes. Tetrachloroveratrole (TeCV: 1,2,3,4-tetrachloro-5,6-dimethoxybenzene), along with DiCV and TriCV, are metabolites of chloroguaiaicols in bleached kraft mill effluent. We searched the Nordic ecosystem for these chloromethoxybenzenes, as well as for bromoanisoles (BAs) of marine origin. The sample set comprised air and atmospheric deposition from southern Sweden, air from Arctic Finland, rivers flowing into the northern Baltic, small Baltic estuaries, terrestrial fungi and forest litter. DAME and BAs were prominent in air, deposition, rivers and estuaries, while TeCV and pentachloroanisole (PeCA) was less abundant or absent. DAME in terrestrial fungi were 400 and 900 ng/g fresh weight in two species, 2-7 ng/g in eight species, and < 1 ng/g in sixteen species. Four samples of forest litter contained 2, 57, 68 and 900 ng/g of DAME. In estuaries, DAME was negatively correlated with salinity and BAs, and positively correlated with dissolved organic carbon, which is high in northern Baltic streams. These observations suggest that DAME is not produced within the estuaries, but

is of terrestrial origin. Fungi and forest litter containing fungal mycelia are suggested as sources to the atmosphere by volatilization, and to estuaries by precipitation, streams, surface runoff and possibly submarine groundwater discharge. Production and biogeochemical cycles of marine brominated HNP are influenced by climate change, and we suggest similar influence for DAME and other terrestrial HNPs.

3.07.V-02 Climate and Weather Factors of Influence on the Temporal Trends of Concentrations of Highly Bioaccumulative POPs in Seabird Eggs and Polar Bears From the Hudson Bay, Canada

Adam Morris¹, Birgit Braune², Jason Stow³, Jason O'Brien² and **Robert J. Letcher**⁴, (1)Northern Contaminants Program, Canada, (2)Environment and Climate Change Canada, Canada, (3)Fisheries and Oceans Canada, Canada, (4)Science and Technology Branch, Environment and Climate Change Canada, Ottawa, ON, Canada

Persistent organic pollutants (POPs) are found throughout the Arctic environment including in wildlife and in Northern people, and are monitored extensively in Northern Canada in order to assess temporal changes in concentrations. Incorporating climate or weather variables into temporal models of POP levels can identify consistent variables of influence and can also strengthen temporal components of the models. The present study investigated the comparative time series of concentrations of five bioaccumulative POPs in polar bear (*Ursus maritimus*) tissues (fat, liver) and thick-billed murre (*Uria lomvia*) eggs from Hudson Bay populations. Temporal trends were analyzed using log-linear regressions and multivariate general linear models with year and weather/climate variables. Log-linear regressions showed that *p,p'*-dichlorodiphenyltrichloroethane (DDT) and 2,2',4,4'-tetrabromodiphenyl ether (BDE-47) decreased significantly in murre eggs (1993–2015), though 2,2',4,4',5,5'-hexachlorobiphenyl (CB-153) increased slowly (1.6 % per year). γ -hexachlorocyclohexane (γ -HCH) and *p,p'*- DDT also decreased in polar bear fat from the Western Hudson Bay (WHB; 1991–2015), though BDE-47 increased relatively rapidly (9.6 % per year). None of the POPs showed significant trends in Southern Hudson Bay (SHB) polar bears (2007–2016), and perfluorooctane sulfonate (PFOS) did not change significantly in liver of WHB or SHB bears. Time-lagged Arctic and North Atlantic Oscillation indices (AO and NAO) were consistently related to POP levels in both species; sea ice freeze up dates, length of the ice free periods, air temperatures and wind speeds also produced consistently significant models. Relationship directions varied by season and time-lag length, sometimes within the same year, consistent with previous studies. Adding weather or climate variables improved the relationships with “year” in several multivariate models, producing interpretable temporal relationships from previously insignificant ones. E.g., In a multivariate model with 1-year time-lagged June AO, γ -HCH decreased significantly in murre eggs while γ -HCH and CB-153 also decreased significantly in SHB bear multivariate models. Some consistent climate and weather factors of influence have now been identified through this and similar studies, and these can improve temporal analyses of POPs levels. However, continued re-analysis as these time series is needed to deduce consistent directional change relationships.

3.07.V-03 Long-Range Transport and Temporal Trends of Emerging Organic Contaminants in the Arctic - Impacted by Human Activities and Climate Change

Zhiyong Xie, Helmholtz-Zentrum Hereon, Germany

Emerging organic contaminants (EOCs) may reach ecologically sensitive Arctic environment via atmospheric and/or oceanic long range transport. They are subject to a variety of processes in the Arctic environment such as degradation, bioaccumulation and interaction between the atmosphere, snow, water and soil. Additionally, climate change may significantly influence the transport and environment fate of EOCs in the Arctic. As a part of collaborative German-French program at joint French-German Arctic Research Base (AWIPEV) in Ny-Alesund, Svalbard, this project is proposed to investigate the occurrence and long term trends of EOCs in Arctic air, water and snow. Integrated high-volume air samples were taken on the platform of German Atmospheric Observatory using a high-volume pump operated for 7 days to obtain a volume of ~2500 m³. A glass fiber filter is used to trap the airborne particles and the gaseous contaminants are collected with a PUF/XAD-2 resin column. Surface snow samples were collected on the glaciers around Ny-Alesund and seawater samples were obtained in Kongs Fjord from 2011 to 2018. EOCs including poly- and perfluoro alkyl substances (PFASs), brominated flame retardants (BFRs) and organophosphate esters (OPEs) have been determined in all air, seawater and snow samples. Data achieved from this study may improve models to predict the environmental progression and assess the effect of human activities and climate change on remobilization and phase exchange for EOCs in the Arctic ecosystem.

3.07.V-04 Temporal Trends of Persistent Organic Pollutants in a High Arctic Seabird Over 15 Years: Influenced by Climate Variability and Dietary Plasticity?

Pierre Blevin¹, Olivier chastel², Frédéric Angelier³, Claus Bech⁴, Paco Bustamante⁵, Jan Ove Bustnes⁶, Don jean Leandri Breton⁷, William Jouanneau⁸, Børge Moe⁹, Kjetil Sagerup¹⁰, Manrico Sebastiano¹¹, Torunn Stople¹², Sabrina Tartu¹³, Igor Eulaers¹² and Geir Gabrielsen¹², (1)Akvaplan-niva AS, Norway, (2)CNRS UMR 7372, France, (3)La Rochelle University, CNRS, France, (4)Norwegian University of Science and Technology, Norway, (5)Université de La Rochelle, France, (6)Norwegian Institute for Nature Research, Norway, (7)Centre d'Etudes Biologiques de Chizé CEBC CNRS UPR, France, (8)University of La Rochelle, France, (9)NINA - Norwegian Institute for Nature Research, Norway, (10)Akvaplan-niva, Norway, (11)Centre d'études Biologiques de Chizé, CNRS - Université de La Rochelle, France, (12)Norwegian Polar Institute, Norway, (13)Centre d'études Biologique de Chizé, CNRS, France

Global change is currently inducing drastic changes in the Arctic ecosystem, which are highly suspected to ultimately impact contaminant exposure and health risks in Arctic wildlife. The dynamic of contaminant exposure over time can be monitored through the bioaccumulation in top predators being considered as relevant sentinels of environmental pollution. Long-lived apex species, such as the black-legged kittiwake (*Rissa tridactyla*) from the Norwegian Arctic, is chronically exposed to a complex cocktail of harmful contaminants. In this study, we describe and assess long-term trends of a wide range of legacy POPs in

Svalbard kittiwakes over 15 years (2007-2021), based on a unique collection of blood samples collected during the chick-rearing period in males and females (n=500). We also identify how these time trends may be impacted by biological factors (i.e., morphometry, body condition and sex), dietary ecology (inferred from stable isotope and stomach content analysis), and climate (climate teleconnections and local conditions), and oceanographic conditions in shaping the magnitude and profile of POP exposure in Svalbard kittiwakes. We were able to depict temporal trends of a wide range of organochlorine pesticides (OCPs) and polychlorinated biphenyls (PCBs). Preliminary results indicate overall stable or decreasing trends for most of the POPs, likely in response to reduced primary emissions. PCBs and OCPs have been regulated during the 1970s by national bans and were followed by international regulations under the Stockholm Convention of POPs, which entered into force in 2004. Interestingly, a few notable exceptions were pointed out, such as for p,p'-DDE and oxychlorane, which appear to increase in blood of kittiwakes over the studied period. In recent years, Kongsfjorden has been strongly influenced by the West Spitsbergen Current with increasing temperature, declining sea ice cover and prey community shifting with periodic arrivals of Atlantic species. There is also a considerable annual variation in the dietary composition and niche of the kittiwakes, both evidenced by spontaneous regurgitates as well as by stable carbon and nitrogen isotopes. Consequently, both climate variability and dietary plasticity could impact temporal trends of POP exposure in kittiwakes. Specifically, a shift in prey community associated to secondary emissions in response to melting sea ice due to climate warming may lead to increasing bioaccumulation of some POPs in Arctic kittiwakes.

3.07.V-05 Understanding the Fate of Microplastics in Sea Ice

Hollie Ball¹, Jack Garnett², Crispin Halsall³, Alice A. Horton⁴, Jan Kaiser⁵, Yueng Lenn⁶ and Andrew Mayes⁵, (1)Lancaster Environment Centre, Lancaster University, Lancaster, United Kingdom, (2)Lancaster University, United Kingdom, (3)Lancaster University, Lancaster, United Kingdom, (4)National Oceanography Centre, United Kingdom, (5)University of East Anglia, United Kingdom, (6)Bangor University, United Kingdom

In the Arctic, microplastic pollution has the potential to be a major threat. Although very few studies have been carried out thus far, their presence has already been discovered in sea ice, snow, surface and sub-surface waters and deep-sea sediment, as well as Arctic biota. Arctic sea ice has been recognised as a potential sink and mode of transport for microplastic particles. The purpose of this experiment was to provide a mechanistic understanding of plastic particle uptake and behaviour in forming sea ice using the Roland von Glasow Air-Sea-Ice Chamber (RvG-ASIC) at the University of East Anglia, UK. Applying polyethylene spheres (ranging ~50 – 300mm dia) to the chamber sea water, preliminary results show sea ice formation results in the entrainment of these microplastics into the ice. The highest particle concentrations were observed in the uppermost layer of sea ice (ice – atmosphere interface), with lower particle concentrations in the base of the ice and the surrounding seawater (surface and sub-surface). Microplastic release during simulated sea ice thaw was also tracked, with evidence of particle accumulation in a buoyant, lower-saline meltwater layer beneath the ice. The findings from this study provide insight into the accumulation and fate of relatively buoyant microplastic particles in sea ice. In turn, these will serve to improve oceanic modelling approaches to predict microplastic fate in ice-covered regions.

3.07 Influence of climate change on the fate of persistent organic pollutants and chemicals of emerging concern in the Arctic (Poster)

3.07.P-Mo139 Poly- and Perfluoroalkyl Substances (PFAS) in a Firn Core From Austfonna, Svalbard

Mark H. Hermanson¹, Elisabeth Isaksson², Sabine Eckhardt³ and Geir Gabrielsen², (1)Hermanson & Associates LLC, United States, (2)Norwegian Polar Institute, Norway, (3)NILU - Norwegian Institute for Air Research, Norway

In spring 2015 we drilled a 13.2 m deep firn core, representing years mid-2001 to early-2015, from Austfonna, the largest ice cap on Svalbard. The core was shipped frozen to the Norwegian Polar Institute in Tromsø where we separated it based on density into 18 samples of sufficient volume for analysis of 40 PFAS compounds in 9 groups, including perfluoroalkyl carboxylic acids, perfluoroalkyl sulfonic acids, fluorotelomer sulfonic acids, perfluorooctane sulfonamides, perfluorooctane sulfonamide ethanols, and perfluorooctane sulfonamidoacetic acids, per and polyfluoroether carboxylic acids, ether sulfonic acids, and fluorotelomer carboxylic acids, using USEPA Method 1633 (draft). The results show that 5 of the 40 PFAS compounds appear in at least one sample, mostly close to the detection limit. The most often observed was PFOA in 11 samples, 8:2 FTS in 5 samples, PFNA in 4 samples, and one observation each of PFOS and PFHpA. The most concentrated of any PFAS was consistently 8:2 FTS, with range of 1.48 – 2.77 ng L⁻¹, the latter in a sample from mid-2001 to early-2002. The appearance of 8:2 FTS is unusual because it is considered to be a biological decomposition intermediate that can further decompose to PFOA. Its origin at Austfonna is not clear. PFOA appeared the 6 surface samples from early-2011 to early-2015, and 5 deeper samples as early as mid-2001. PFOA concentrations range nearly a factor of 2 from 0.386 ng L⁻¹ to 0.744 ng L⁻¹, but there is no trend in the results: the deepest sample from mid-2001 was 0.592 ng L⁻¹ and the sample, from 13 years later was 0.553 ng L⁻¹. We assume that the source of PFOA and PFNA is oxidation of 8:2 FTOH, a volatile PFAS found in comparatively high concentrations in Ny-Ålesund air in 2013, with an 80-day atmospheric residence time. PFNA, had concentration ranging from 0.381 ng L⁻¹ from late-2013 to late-2014 up to 0.572 ng L⁻¹ from late-2003 to late-2004. The PFNA amounts, when found with PFOA, are similar, suggesting that both are oxidation products of 8:2 FTOH. However, atmospheric oxidation on Svalbard is limited to periods of UV-B input from late February to late October. PFOS was found once in the sample from late-2003 to late-2004, suggesting that it is not abundant in the Svalbard atmosphere. PFHpA, was found once from mid-2001 to early-2002. The results suggest that atmospheric deposition of PFAS at Austfonna is limited, largely to oxidation products, and to 8:2 FTS.

3.07.P-Mo140 POPs and Climate Change in Antarctic Ecosystems From a Bi-Polar Perspective

Simonetta Corsolini¹ and Nicoletta Ademollo², (1)University of Siena, Italy, (2)National Research Council, Italy

The climate crisis is affecting Antarctica and the Southern Ocean and effects have been already reported for the abiotic compartments of the ecosystems, e.g. ice loss and iceberg calving. The global warming can alter also the distribution of persistent organic pollutant (POPs) both at a global scale and in the Antarctic Region, due to their physical-chemical characteristics. Effects of climate changes have been already reported on feeding behavior and reproductive process of organisms. Another consequence for organisms includes the POP bioaccumulation. Here we review the literature reporting the linkage between recorded effects of climate changes and POP bioaccumulation in resident marine Antarctic species (fish and penguins). We focused our data revision on PCBs, *p,p'*-DDT, *p,p'*-DDE, DDTs, and HCB since other chemicals, including emergent contaminants, were reported only in very few articles not allowing any comparison. Notwithstanding Antarctica is a final sink for persistent contaminants due to the extreme cold climate, a general decreasing POP trend has been observed for some POPs, although they seems weak and inconstant. Their concentrations in marine biota are reported to be linked to ice melting and large iceberg calving; these effects have not been studied in the Arctic to any significant degree, despite they are likely to occur given the similarities of polar environments. The comparison with the Arctic biota is not always possible due to the lack of data in the Antarctic Region, both for terrestrial and marine ecosystems. The climate-driven changes may affect the marine Antarctic ecosystems, where the peculiar pelagic-benthic coupling may also contribute to alterations in the bioaccumulation processes. The peculiar ecosystems and trophic web structure and functioning make Antarctic biota vulnerable to effects of persistent contaminants; the impact of climate-driven environmental changes on POP bioaccumulation processes in marine organisms, not only top predators, is still to be understood. It remains an open question if the POP amount accumulated in the Antarctic ecosystems is decreasing or not depending on the variation of climate parameters.

3.07.P-Mo141 Influence of Climate on Long Term Trends of Brominated Flame Retardants and Perfluorinated Alkyl Substances in Landlocked Arctic Char in the Canadian Arctic

Derek C.G. Muir¹, Mary Williamson¹, Xiaowa Wang¹, Debbie Iqaluk², Günter Köck³, Amy Sett¹, Enzo Barresi⁴, Jane Kirk¹ and Ana Cabrerizo⁵, (1)Environment and Climate Change Canada, Canada, (2)Resolute Bay, Canada, (3)University of Innsbruck, Austria, (4)Environment & Climate Change Canada, Canada, (5)Valladolid University, Spain

Landlocked Arctic char are the only top predators in most high Arctic lakes and they can serve as a sentinel species for changes in atmospheric inputs of persistent organic pollutants (POPs) to remote freshwater environments. Previous work has shown that PCBs and other legacy POPs have been declining in Arctic air and in landlocked char from isolated lakes in the Canadian Arctic over the past 20 years. However, atmospheric measurements and studies of ice cap snow/firn/ice cores published over the past 10 years have shown continuing and, in some cases, increasing, inputs of polybromodiphenyl ethers (PBDEs) and poly/perfluoroalkyl substances (PFAS) to the high Arctic. Therefore, we were interested to see if these trends were reflected in the landlocked char as well. PBDEs (13 Br3-Br7 congeners), C6-C14-perfluoro carboxylates (?PFCAs) and perfluorooctane sulfonate (PFOS) were determined in muscle of Arctic char and compared results to published global emission estimates and to climate related parameters such as glacier runoff, air temperatures, summer ice free area of the lakes. Data was available for char from 4 lakes (Resolute, Char, Amituk and Hazen), spanning 12 to 19 sampling years from the early-1990s to 2019, with sample sizes ranging from 3 to 10 fish per year. ¹³PBDEs significantly increased in Char, Resolute and Hazen from the 1990s to 2017 (6.6 to 9.5%/y). The increase of PBDEs contrasts with phase out of PBDEs in the mid-2000s and modelled predictions of declining global emissions. ⁷C₇-C₁₄-PFCAs generally declined from 2007/08 to 2015 in all lakes and then showed increasing concentrations in the two most remote lakes in Hazen and Amituk (~ 40% /y) over the period 2015-2019. The increasing trends of ?PFCAs and PFOS in char were surprising given the phase-out of perfluorooctanoic acid and related PFAS by 2014 as well as PFOS in the early 2000s. Nevertheless, the general trends of ?PFCAs and PFOS in char are in agreement with published snow/ice and air measurements from the mid-2000s to 2015. Climate related factors could be important. PFOS in char was positively correlated with increasing glacial runoff in Lake Hazen while ¹³PBDEs were not. Annual summer ice free area or ice out date was not correlated with year to year variation of the PBDEs or PFAS. Further assessment of the influence of climate warming would be aided by having a more sampling years in order to increase statistical power as well as local rather than regional climate data.

3.07.P-Mo142 Influence of Climate Related Factors on the Temporal Trends of PCBs and Perfluoroalkyl Substances in Landlocked Char in Two High Arctic Lakes

Ana Cabrerizo¹, Derek C.G. Muir², Debbie Iqaluk³, Xiaowa Wang², Mary Williamson², Amila De Silva², Jane Kirk², Samantha Burke², Scott Lamoureux⁴ and Melissa Lafrenière⁴, (1)Valladolid University, Spain, (2)Environment and Climate Change Canada, Canada, (3)Resolute Bay, Canada, (4)Queens University, Canada

Temporal trends and climate related parameters affecting the fate of polychlorinated biphenyls (PCBs) and perfluoroalkyl substances (PFASs) were examined in landlocked Arctic char (*Salvelinus alpinus*) in two paired lakes, West and East lakes, on Melville Island in the Canadian High Arctic. Research over the past 15 years in the study area has revealed ongoing permafrost disturbances in the West Lake watershed and sub-aqueous sediment slumps in the lake, which have impacted lake turbidity. Adult char were collected in late July from 2008 to 2019, by gill netting. In total, more than 140 samples of char were collected and muscle analyzed for PCBs and PFASs. The study goals were to i) examine temporal trends of two classes of POPs differing in physical-chemical properties, ii) study which parameters are affecting the occurrence of these POPs in Arctic char, and iii) investigate the influence of climatic disturbances affecting the lake catchments, water chemistry, and fish growth rates, on the temporal trends of hydrophobic PCBs and hydrophilic PFASs. ⁷¹PCB (lipid adjusted) showed a declining trend in Arctic char from East Lake (-7.4 % /yr; P=0.058, 2008-19) as expected due to the past national and regional bans/ restrictions on use and emissions of these chemicals. However, PCBs were higher in char from West Lake and increased significantly from 2008 to 2015 (+10 % /yr; P=0.02, 2008-15). PCB concentrations declined in from their peak in 2015 but remained higher than in East Lake char in 2017. The increases of PCBs in char from West Lake in comparison to East Lake coincided with a large increase in lake

turbidity. The lake is undergoing greater inputs of PCBs bound to terrestrial carbon, due to permafrost disturbances, as well as to mobilization of PCBs from sediments into the water column during subaqueous slumps. Higher growth rates of East Lake char may also have contributed to the observed decline. On the other hand, total (C4-C14) perfluorocarboxylates (PFCAs) concentrations in char showed a decreasing (but non-statistically significant) trend of 8%/y in West Lake and 3%/y in East Lake over the period 2008 to 2019. Concentrations of PFASs in West and East lakes were similar in char muscle, despite major differences in water chemistry including turbidity. These results suggest that climate disturbances due to warming may affect, in different magnitudes, the exposure of Arctic freshwater biota to hydrophobic and hydrophilic POPs.

3.07.P-Mo143 Inputs of Organochlorine Pesticides, Organohalogen Industrial Compounds and Brominated Flame Retardants to Annual Surface Snow on the Juneau Icefield

Lisa Hoferkamp¹, Mark H. Hermanson², Richard Hann³, Elisabeth Isaksson⁴, Camilla Teixeira⁵ and Derek C.G. Muir⁵, (1)University of Alaska Southeast, United States, (2)Hermanson & Associates LLC, United States, (3)Norwegian Technical and Natural Sciences University, Norway, (4)Norwegian Polar Institute, Norway, (5)Environment and Climate Change Canada, Canada

In June 2006 we collected bulk annual surface snow from two sites on the Juneau Icefield (JIF), which straddles the Alaska-British Columbia border and is experiencing warming air temperatures and glacial loss. Samples were collected about 3 km apart and 366 m different elevation, at Summit (1646 m a.s.l., Lat 55.560666N, Long 134.408344W) and at North Branch (1280 m a.s.l., Lat 58.5457778N, Long 134.456139W). We analyzed the samples for 23 organochlorine pesticides (OCPs) and 16 organohalogen industrial compounds (OHICs, mostly chloro- and bromo-benzenes) and 19 brominated flame retardants (BFRs). Total OCP burden at Summit is 377 pg L⁻¹ while at North Branch it is 225 pg L⁻¹. Most of the difference is accounted for by a much higher amount of β -endosulfan at Summit. OCP maximum amount was 50.5 pg L⁻¹ for endrin at Summit. Total OHIC burden at Summit is 32940 pg L⁻¹, while at North Branch it is slightly higher at 34160 pg L⁻¹. These high values result from the high amounts of three dichlorobenzenes (diCBs) which peaked at 26600 pg L⁻¹ for 1,4-diCB at Summit. The 3 diCBs, 1,2-diCB, 1,3-diCB and 1,4-diCB comprise 99% of all OHIC at both Summit and North Branch. Without the diCBs, the OHIC burden at Summit is 303 pg L⁻¹ and at North Branch it is 397 pg L⁻¹, values more comparable to those of OCPs. The higher value at North Branch is again due to several of the non diCB OHICs having higher concentrations there. The comparatively high concentrations of the diCBs is typical in snow and ice in our earlier work on the Antarctic Plateau (2001) and at the Holtedahlfonna glacier (2005) on Svalbard. The OHIC results from JIF are consistent with earlier research, suggesting that these comparatively volatile contaminants are found throughout the global atmosphere at concentrations higher than most other chlorinated or brominated contaminants. They are known to be high production chemicals in the United States since the early 1920s. The total BFR burden at Summit is 223 pg L⁻¹, while at North Branch it is 617 pg L⁻¹ and is a result of most BFRs at higher concentrations at North Branch except polybrominated diphenyl ether (PBDE)-17, PBDE-28, 1,2-Bis(2,4,6-tribromophenoxy) ethane and pentabromo ethylbenzene. The maximum amount for an individual BFR was 312 pg L⁻¹ for PBDE-99 at North Branch. Clearly there is a different source at North Branch. The results for OCPs and BFRs suggest the influence of different sources at these sites.

3.07.P-Mo144 Chlorinated Paraffins in Polar Cod and Capelin From the Barents Sea During the Arctic Spring Bloom

Julia Giebichenstein¹, Nicholas Warner², Tom Andersen¹, Øystein Varpe³, Geir Gabrielsen⁴ and Katrine Borga⁵, (1)University of Oslo, Norway, (2)Norwegian Institute for Air Research, Norway, (3)University of Bergen, Norway, (4)Norwegian Polar Institute, Norway, (5)UiO, Norway

Chlorinated paraffins (CPs) are currently under intense regulatory scrutiny due to their widespread distribution in the environment and are listed as contaminants of emerging Arctic concern. As of 2017, short-chain chlorinated paraffins (SCCPs) have been added under the Stockholm Convention to restrict their production and use due to their long-range transport (LRT) potential, bio-accumulative and toxic properties. This highlights the need for additional data from the Arctic regions, which is understudied due to their challenges in trace level analysis of these compounds. Many Arctic animals have utilized their main energy reserves by March, before the onset of the spring bloom and upon return of the sun. By May, the spring bloom reaches its peak, and energy generated therein propagates through the entire ecosystem. With ongoing climate change, food web dynamics might change, and with that CP dynamics. However, little is known about seasonal partitioning and transfer of these emerging contaminants, making it challenging to understand and predict climatic change impacts. Two key species in the Arctic marine food web are Polar cod and capelin. They channel energy generated by lower trophic levels like phytoplankton and zooplankton to higher trophic levels like seals and sea birds. Here, we analyzed short-chain and medium chain chlorinated paraffins (SCCPs and MCCPs, respectively) in two key Barents Sea fish species, Polar cod, and capelin in March and May 2021. Preliminary results revealed similar CP levels between species and seasons. We observed dominant SCCP concentrations in Polar cod, whereas MCCPs dominate in capelin, suggesting that capelin acts as biovector for contaminants like CPs to Arctic waters.

3.08 Measuring, monitoring and modelling of pesticide fate and mitigation in a regulatory context

3.08.T-01 How Transparency of Pesticide Use Helps Farmers Meet Compliance Expectations and Introduces Realism in Risk Assessment: The CropLife Europe Digital Label Compliance Project

Anne Alix¹, Michal Kicinski², Dominic Widmer³, Susanne Lauck-Birkel⁴ and Krisztian Szegedi⁵, (1)Corteva Agriscience, Abingdon, United Kingdom, (2)CropLife Europe, Belgium, (3)Syngenta AG, Switzerland, (4)Bayer Crop Science, Germany, (5)BASF SE, Germany

The use of Plant Protection Products (pesticides) in agriculture is regulated through EC Regulation No. 1107/2009 that imposes preliminary risk assessments and the precise setting of directions of use and risk mitigation measures for the active substance at

EU level followed by the Plant Protection Product approval at EU member state level before placing them on the market (EC, 2009). The risk assessments rely on hundreds of guideline compliant studies and are performed to reflect worst-case use and exposure scenarios (EC, 2013a and 2013b). Directions for use and all precautions to be taken at all stages must be indicated on the label, thus making labels increasingly more complex to read. Label instructions are established based on the outcome of these worst-case scenarios considered for the risk assessments and thus rarely reflect the conditions under which products are actually used in the field. These reflect the diversity of application machinery, agro-environmental conditions and pest pressures faced by European farmers. Furthermore, modern technologies and stewardship measures are a central piece of a developing a more sustainable food production model as outlined by the EC's Communication on the EU Green Deal and specifically in the F2F and the Biodiversity strategies, reflecting consumers', policymakers' and society's expectations. This presentation will introduce the Digital Label Compliance (DLC) concept developed by CropLife Europe. The DLC aims to de-risk growers and reduce complexity in dealing with the handling and application of Plant Protection Products by increasing label comprehension via digital labels. The automated application of Plant Protection Products according to the digital label considering the geolocation and conditions of a growers field and the subsequent recording of spray operations is maintaining a high-level of protection for human health and the environment whilst de-risking growers.

3.08.T-02 Using GIS Overlay Methods to Determine Vulnerable Agricultural Areas in Europe

Gerco Hoogeweg¹, Natalia Peranginangin², Russell Kreuger¹ and Amy Ritter¹, (1)Waterborne Environmental, Inc., United States, (2)Syngenta Crop Protection LLC, United States

GIS enables the use of meta-models, weighted-overlay, and index methods are frequently used to assess the relative vulnerability of groundwater or surface water to contaminants. The application of these methods is driven in large part by data availability, and assessor expertise and familiarity. This may result in a bias in the models as certain criteria are over- or underemphasized; for example, pesticide behavior is often ignored in commonly used index methods, where environmental factors such as pH and organic carbon have been shown to affect the local vulnerability of groundwater and surface water. Furthermore, vulnerability index methods may feature subjective weights and rankings, which increases the likelihood of bias. Two overlay index methods were developed, applied, and tested to determine groundwater and surface water vulnerability for maize production areas in the Ukraine. Both methods follow a standardized approach in which the applicable data within the areas of interest are ranked and grouped using a cumulative distribution function. A weighting schema was developed by grouping the data in six classes with each class has fixed probability range. The classes were assigned weights, ranging from 1 to 6, with 1 being the lowest weight and 6 being the highest weight. Using this approach, the maximum vulnerability score is 36 and the results show the relative vulnerability for both groundwater and surface water. This approach has the advantage that the distribution of variables is accounted for and are unbiased. For groundwater, the following parameters were included: average annual rainfall, topsoil sand content, topsoil organic carbon content, topsoil pH, drainage class and depth to groundwater. For surface water, key variables included slope, days with more than 25.4 mm of rainfall, topsoil available water capacity, topsoil organic carbon content, topsoil pH and drainage class. The maize production areas falling in the most vulnerable category, aka having the highest score, represent 12% to 13% of the areas of interest. The maximum attainable vulnerable score of 36 was not achieved.

3.08.T-03 Degradation Kinetics on the Next Level

Johannes Ranke¹ and Janina Wöltjen², (1)Johannes Ranke, wissenschaftlicher Berater, Grenzach-Wyhlen, Germany, (2)German Environment Agency (Umweltbundesamt), Germany

The current procedure for deriving endpoints from chemical degradation data is based on separate evaluation of the available datasets and subsequent averaging of the parameters obtained. For each individual dataset, the most suitable degradation model is then selected based on statistical criteria and visual evaluation. In many cases the decision requires expert judgement, which frequently leads to discussions with an unpredictable outcome. In this contribution, we show simultaneous evaluations of all available datasets based on nonlinear mixed-effects models and highlight some of the advantages of this method with respect to regulatory degradation kinetics, namely a) the shift of the model selection step to the level of the complete available degradation data, and b) the improved handling of datasets in which certain kinetic parameters, such as the degradation rate constant of a certain metabolite, are ill-defined and where current guidance recommends to use a surrogate value such as a half-life of 1000 days. For illustrating the application of nonlinear mixed-effects models to chemical degradation data, synthetically generated data as well as experimental data were used. For each variant of synthetic datasets, degradation parameters were drawn from a specified distribution of degradation model parameters. In addition, a random noise component was added to the simulated data, with properties similar to the two-component random noise often observed in real datasets. Experimental datasets were obtained from regulatory dossiers published by the European Food Safety Authority (EFSA) on their website. The results presented in this contribution demonstrate that the application of nonlinear mixed-effects models to chemical degradation data is technically feasible. Results obtained for synthetically generated data suggest that this method provides more reliable and accurate representations of the information in the available data. The application of nonlinear mixed-effects models to experimental data shows that the use of surrogate values for previously ill-defined fits can be circumvented. [1] Ranke J, Wöltjen J, Schmidt J, Comet, E. 2021. Taking Kinetic Evaluations of Degradation Data to the Next Level with Nonlinear Mixed-Effects Models. *Environments* 8(8):71.

3.08.T-04 Size Matters: The Effect of Scale in Chemical Biodegradation Studies

Andris Grigorjevs¹, Gary Bending², Laurence Hand³, Rebecca Southwell⁴ and Jonathan Pearson², (1)School of Life Sciences, University of Warwick, Coventry, United Kingdom, (2)University of Warwick, United Kingdom, (3)Syngenta Limited, United Kingdom, (4)Syngenta, United Kingdom

Environmental persistence of synthetic chemicals is a significant ecological challenge for the industry and the public. However, current regulatory tests lack environmental realism, particularly when biodegradation of chemicals is assessed in a very small-scale laboratory systems and the results are then extrapolated to the real world. In this study, we hypothesised that the factor of scale plays a major role in the inconsistency of the rate of degradation between lab-based regulatory testing and field trials. For this study “OECD 308 Aerobic and Anaerobic Transformation in Aquatic Sediment” test guidelines were used to represent regulatory study microcosms ($v = 0.25$ l) and set a comparison with much larger flumes ($v = 25$ l). Five pesticides were used with different chemical properties, including a carboxamide, azole, benzoylurea and two triazine based compounds with a range of Log K_{ow} between 0.069 and 5.12, molecular masses between 166.18 and 511.1 and dissimilar degradation kinetics. We also studied how system scale affected the broader physico-chemical environment including rates of nitrogen and phosphorus biogeochemical cycling processes. The chemical degradation rates were found to be faster in larger test vessels compared to small, with decay rates significantly different with 4 out of 5 chemicals. A Single First-Order kinetics model was used to estimate half-life (DT_{50}) of chemicals in both systems and the DT_{50} of each chemical was found to be significantly shorter in flumes than in microcosms. Additionally, it was found that the biogeochemistry of larger systems was significantly more stable and consistent than smaller microcosms. Not only was the extent of variation over time much higher in smaller vessels, but the variability between replicates was also always higher than in flumes. Microcosms also showed significantly higher bacterial cell count, lower redox potential and oxygen levels and higher ammonium concentration than flumes. This study showed that the size of test system affects biogeochemical cycling in the incubation vessels, underlying microbial community and the rate of degradation of chemicals. The effect of scale also has an impact on test system stability and variation. To understand the effect of scale on microbial ecology, metagenetic analysis for ecological drift, diversity and relative abundance is necessary.

3.08 Measuring, monitoring and modelling of pesticide fate and mitigation in a regulatory context (Virtual Only)

3.08.V-01 Opportunities for Regulatory Decision Making Through Digital Agriculture: A Mapping Exercise

Anne Alix¹, John Becker², Francis P. Donaldson³, Joachim Dressel⁴, Edgars Felkers⁵, Martyn Griffiths⁶, Martin Herchenbach⁷, Thomas-Georg Hofmann³ and Sophie Hane-Weijman⁸, (1)Corteva Agriscience, Abingdon, United Kingdom, (2)FMC Corporation, United States, (3)BASF SE, Germany, (4)Syngent Crop Protection AG, Switzerland, (5)ADAMA, Denmark, (6)Bayer Crop Science, France, (7)Digitalisation, Industrieverband Agrar e.V., Frankfurt, Germany, (8)FMC Corporation, Switzerland

Crop Protection products are highly regulated in the EU. They are subject to thorough risk assessments following guidance developed by Member States and EFSA. These risk assessments rely on exposure estimates which reflect so called realistic worst case situations as well as increasingly conservative toxicity endpoints. The reality of environmental conditions, agronomic situations and hence the realities under which crop protection products are applied are much more diverse. The rapid developments of digital tools in agriculture now enable us to overlay existing data with in-situ measured data and model predictions. At the same time we observe an increasing pace in the development of hardware, i.e. precision application equipment for crop protection products. Both developments combined allow much more targeted applications of crop protection products, i.e. to apply crop protection products at the most appropriate application rate only where needed, exactly when needed. Machine readable digital labels will enable the computer aided planning, execution and documentation of applications, overlaying the spatial and agronomic information with the approved application conditions of the specific product as described on the product label (e.g. risk mitigation measures). With all this information, assessments of the risk to consumers, the environment or operators, workers and bystanders specific to location, time and available application equipment will be possible. EU regulators and industry have started considerations how to include these new opportunities the digitization of agriculture offers into regulatory decision making. Crop Life Europe has conducted a mapping of these activities across EU institutions, Member States and industry associations. An analysis of analogies and differences is presented as well as an identification of gaps where bespoke risk assessments should be developed.

3.08.V-02 The Casanova Drift Model (CDM): An Arable Crop Spray Drift Deposition Model

Eduardo Casanova¹, Naresh Pai¹, Andrew C. Chapple², Zhenglei Gao³ and Rena Jutta Irene Isemer⁴, (1)Bayer Crop Science, United States, (2)Environmental Safety, Bayer Crop Science, Germany, (3)Bayer Crop Science, Germany, (4)Crop Science, Bayer Crop Science, Germany

A mechanistic arable crop spray drift model is presented. The model, written in C++ with a Shiny R interface, is a mixture of ballistic tracking of droplets (Lagrangian transport of water droplets through air in time) combined with equations dealing with droplet evaporation, a representation of the horizontal wind profile (from two heights and variation from perpendicular), an approximation of canopy effects, a droplet size distribution (temporal measurement and using a minimum drop size of 18 μ m), and a simplified description of spray sheet breakup. The model has been calibrated and validated against Bayer (internal) USA field data but also European field data from Belgium, France, and Poland. Relative performance (i.e., relative changes in drift due to operational variables such as wind speed) and absolute performance (i.e., modelled drift curves that match results on the ground) have been assessed and will be presented. The model includes modules that may help address issues raised during the SETAC Drift Risk Assessment Workshops (e.g., sampler capture efficiency; locale). The model will be released after the 2022 meeting as publicly available code and interface, along with a nozzle droplet spectra library for standard flat fans commonly used in drift trials across the EU.

3.08 Measuring, monitoring and modelling of pesticide fate and mitigation in a regulatory context (Poster)

3.08.P-Th052 Amended Soil With Different Application Rates of Sugarcane Straw Biochar Interfere Sorption and Desorption of Metribuzin

Kassio Mendes, Kamila Mielke, Maura Gabriela Brochado, Alessandro Lima, Bruna Medeiros and Vanessa Freitas, Federal University of Viçosa, Brazil

Biochar is a carbon-rich material that comes from the partial carbonization of different feedstock under controlled conditions. The use of biochar has been evaluated as an alternative to improve the chemical, physical and biological quality of the soil. However, the application of this material to the soil has shown to directly influence the sorption, desorption, leaching and degradation of pre-emergence herbicides. The effects of biochar on herbicide behavior in soil depend directly on the type of feedstock, pyrolysis temperature and rate of application in the field. Furthermore, herbicides can behave differently depending on the physicochemical characteristics of the molecule. Therefore, the objective of the study was to investigate the sorption and desorption of metribuzin in an amended soil with different application rates of sugarcane straw biochar. The experimental design was entirely randomized with seven application rates of biochar (0, 0.1, 0.5, 1, 1.5, 5, and 10% w w⁻¹) produced in a pyrolysis temperature of 750°C. The sorption and desorption study were carried out in an equilibrium batch method with five concentrations of metribuzin (0.5, 1, 2, 4, and 8mg L⁻¹) where the average concentration corresponds to the highest recommended dose of the herbicide (1920g a.i. ha⁻¹) for sugarcane cultivation. The analysis of the herbicide was performed in High Performance Liquid Chromatography (HPLC). The sorption and desorption coefficient data were fitted to the Freundlich isotherm model (K_f). The K_f values of sorption (1.42mg^(1/21/n) L^{1/n} Kg⁻¹) and desorption (0.78mg^(1/21/n) L^{1/n} Kg⁻¹) were low in unamended soil compared to all amended soils. Application rates of 5 and 10% of biochar increased 6- and 10-fold the K_f values of sorption and decreased desorption between 15- and 45-fold relative to unamended soil. Application rates < 1.5% had no impact on sorption (K_f = 1.84mg^(1/21/n) L^{1/n} Kg⁻¹) and low interference with desorption (2.84mg^(1/21/n) L^{1/n} Kg⁻¹) of metribuzin. The biochar applied at 5 and 10% sorbed 77.8 and 89.4% and desorbed 14.2 and 3.7%, respectively, relative to the initially applied herbicide. The degree of linearity of sorption and desorption (1/n) of the unamended soil averaged 0.59 and varied from 1.0 to 0.4 with increasing biochar application rate. The application of rates >1.5% of sugarcane straw biochar strongly increased sorption and decreased desorption of metribuzin in the soil and can influence the residual effect and weed control.

3.08.P-Th053 Collation and Analysis of Public Environmental Monitoring Datasets for Regulatory Submissions

Gregory Hughes¹, Liz Whitworth² and Simon Mayer³, (1)Cambridge Environmental Assessments, United Kingdom, (2)RSK ADAS Ltd, United Kingdom, (3)Bayer Crop Science, Germany

For the authorization of plant protection products (PPP) under regulation 1107/2009/EC an overview and assessment of environmental monitoring data must be provided by the applicant. However, there are currently no guidelines for what data should be supplied or how the data should be processed, analysed, presented and interpreted. Data collection and analysis to meet this regulatory requirement draws on existing guidelines, guidance and directives e.g., FOCUSgw (EC, 2014), groundwater monitoring guidelines (Gimsing *et al.*, 2019), Water Framework (2000/60/EC) and associated directives, QA/QC directive (2009/90/EC) and associated guidelines (e.g. SANTE/2020/12830). The typical approach taken when preparing regulatory submissions utilises readily available public monitoring data from online data repositories, digital maps and reports. Public monitoring data sourced from different regions/Member States are collected for: · different purposes [e.g. incident investigation, surveillance, compliance assessment], · using different sampling strategies [e.g. flow proportional/grab, seasonal/monthly], · by different organisations [e.g. water company, environment agency] using different sampling protocols, · analysed to different standards [e.g. ISO17025] by different organisations/methods, · and reported differently [e.g. LOD or LOQ reported; data quality (un)reported]. These public monitoring data provide valuable insight into the state of the environment, emerging issues and possible impacts, and are therefore in principle good data sources to fulfil the regulatory requirement. However, caution is required when collating, analysing and interpreting these datasets. Extensive data exploration should be undertaken such that all aspects of the dataset characteristics are fully considered for the assessment of the data. This poster outlines key issues in this context, relating to (i) data quality and harmonisation, (ii) data analysis e.g. dealing with outliers and non-detects, (iii) selection of robust science-based thresholds and (iv) derivation of relevant exposure values for compliance/impact assessment. It also considers interpretation of the results, confounding factors, and key aspects of conclusions on management and mitigation measures, e.g. ensuring that relevant uses, sources and pathway are addressed. The use of public monitoring data for local issue detection and for definition of local measures and stewardship programmes is also discussed.

3.08.P-Th054 Sorption and Desorption of Metribuzin in Soils Amended With Sugarcane Straw Biochar Produced at Different Pyrolysis Temperatures

Kamila Mielke, Kassio Mendes, Maura Gabriela Brochado, Alessandro Lima, Mateus Silva and Rafael D'Angeri, Federal University of Viçosa, Brazil

Biochar is defined as a carbon-rich product that can be used as a source of nutrients, soil carbon sequestration, waste management, and energy production. It has a high sorptive capacity and is a potential sorbent for organic contaminants in soil and water. Residual herbicides applied directly to the soil, such as metribuzin, may have their bioavailability, leaching and agronomic efficacy reduced due to the increased sorption provided by soil amendment with biochar. The pyrolysis temperature factor has shown to directly interfere in the sorption and desorption of the herbicide in the modified soil; however, the results may vary with the type of raw material, the soil characteristics and the herbicide analyzed. Therefore, the objective of the study was to investigate the interference of the sugarcane straw biochar produced at different pyrolysis temperatures on the sorption and desorption of metribuzin in soil. The experimental design was entirely randomized composed with three pyrolysis temperature of biochar (BC350, BC550 and BC750°C) added to the soil at application rates 10% w w⁻¹. The sorption and desorption study were carried out in an equilibrium batch method with five concentrations of metribuzin (0.5, 1, 2, 4 and 8mg L⁻¹) where the average

concentration corresponds to the highest recommended dose of the herbicide (1920g a.i. ha⁻¹) for sugarcane cultivation. The analysis of the herbicide was performed in High Performance Liquid Chromatography (HPLC). The sorption and desorption coefficient data were fitted to the Freundlich isotherm model (K_f). Sorption and desorption of metribuzin were 1.42 and 0.78mg (1^{2/1/n}) L^{1/n} Kg⁻¹, respectively, in soil unamended. BC750°C increased the K_f value of sorption of metribuzin 11-fold and decreased the K_f of desorption 45-fold compared to unamended soil. However, for the BC350 and BC550°C, the K_f value of sorption increased 4- and 6-fold and decreased the K_f for desorption 18- and 35-fold, respectively, relative to the unamended soil. The percentage sorbed was 63.8, 75.5 and 89.4% and the desorbed was 8.3, 5.8 and 3.7% to BC350, BC550 and BC750°C, respectively, relative to the initially applied herbicide. A pyrolysis temperature of 750°C produced a sugarcane straw biochar with higher sorption potential of metribuzin, which can become an alternative for immobilization of metribuzin in soil. The high sorption and low desorption of herbicide can interfere with bioavailability in soil solution and influence weed control.

3.08.P-Th055 Degradation and Sorption of the Herbicide Pelargonic Acid in Agricultural Topsoils and in Subsoils Below Railway Tracks

Thomas Poiger, Joanna Müller, Julian Angst, Roy Kasteel and Ignaz Buerge, Agroscope, Switzerland

Herbicides based on pelargonic acid are becoming increasingly important in organic farming but also for weed control in sensitive areas where use of synthetic organic chemicals may be less acceptable. In recent years, pelargonic acid also gained interest for weed control on railway tracks, preferably in combination with the herbicidal active substance flazasulfuron. While data required to estimate potential leaching of pelargonic acid from treated agricultural fields to groundwater (i.e. on soil degradation and adsorption) has recently become available, such data are missing for proper assessment of potential leaching from use on railway tracks. Therefore, we conducted degradation and adsorption experiments with various subsoils sampled at railway tracks. For comparison, we also performed such experiments with a number of agricultural topsoils. Our experiments confirmed that dissipation of pelargonic acid in topsoils is very rapid with half-lives of a few hours, when applied to soils at concentrations corresponding to typical agricultural application rates. In subsoils from railway tracks, degradation was 3-10 times slower than in topsoils, but half-lives were still < 1 day. We also conducted experiments at different starting concentrations. These experiments showed that degradation of pelargonic acid is strongly concentration dependent. At high starting concentrations, degradation initially is slower and becomes more rapid over the course of the experiment. Adsorption of pelargonic acid to subsoils was weak with Freundlich adsorption constants (K_f) of 0.06 - 0.31 mL/g. However, when normalized to the organic carbon content of the soils, the K_{foc} values fitted well within the range of 11 topsoils selected to cover a wide range of soil properties, particularly pH. Adsorption of pelargonic acid is pH-dependent and the sigmoidal curve fitted to the K_{foc} vs. pH data indicated an apparent pKa close to the pKa values reported in the literature. Overall, our data indicates minimal risk of leaching of pelargonic acid to groundwater, not only from agricultural but also from railway use of pelargonic acid.

3.08.P-Th056 Losses of Plant Protection Products Via Drainage Over One Growing Season on a Potato Field

Simon Mangold, Nora Bartolomé Gutiérrez, Isabel Hilber and Thomas Bucheli, Agroscope, Switzerland

On a 0.2 ha sized and drained field, we grew potatoes and applied plant protection products (PPP) according to good agricultural practice. In total, 20 different PPP were applied during ten application events in the growing period from April to August. In the rather dry year (431 mm in comparison to 517 mm precipitation in the longtime mean for this time span) precipitation caused eight discharge events in the drainage. An autosampler with discharge monitoring allowed flow proportional sampling and discharge peaks could be sampled with high temporal resolution of down to 30 minutes. Over the entire season 151 samples were collected and frozen until analysis and were measured with large volume injection liquid chromatography coupled to tandem mass spectrometry with electrospray ionization (LVI-LC-ESI-MS/MS). Almost all applied and measured PPP could be detected in the water samples. However, concentrations and duration of their occurrence varied widely. For instance, the apolar trifloxystrobin was detected only immediately after application, while the more polar metribuzin, once applied, appeared over the whole cultivation period. Together with the water discharge and the known amount of applied PPP, the exported fraction was calculated. The span of the exported fractions ranged from almost zero for the apolar compounds up to more than 0.4% for metribuzin, the compound with the lowest organic carbon normalized soil-water distribution coefficient (K_{oc}) in our substance selection. Total exported loads and maximum concentrations from the field experiment were compared with such predicted by the EXPOSIT model, which is used in the registration process of PPP in Switzerland to predict PPP concentrations and toxicological risks in surface waters. Measured emitted loads were in the range of the predicted values. However, peak concentrations in the field were much higher than the predicted ones, although the model is supposed to represent a worst case scenario. The 24h averaged concentrations (according to the duration of the discharge event in the model calculation) in the water samples show already up to 17 times higher concentrations compared to the model values. This discrepancy gets even bigger (factor of 60) if predicted values are compared with real maximum concentrations during a discharge peak (sampling frequency ~30 minutes).

3.08.P-Th057 Aging Reduces Bioaccessibility and Explains Persistence of Triazole-Fungicides Accumulated in Agricultural Topsoil

Anders Johnsen¹, Ulla Bollmann², Christian Albers³ and Nora Badawi², (1)Geochemistry, Geological Survey of Denmark and Greenland, Copenhagen K, Denmark, (2)Geological Survey of Denmark and Greenland, Denmark, (3)Geological Survey of Denmark and Greenland, Copenhagen, Denmark

We investigated the fate of triazole fungicides in the plough-layer of an agricultural field that is managed by the Danish Pesticide Leaching Assessment Program. The field has a detailed record of spray-applications. Topsoil was sampled from the field at regular intervals for more than two years starting in 2019. Surprisingly, we detected tebuconazole, propiconazole and epoxiconazole in the soil 10 to 20 years after the last spray applications. They furthermore showed almost constant concentrations

over time during the two years sampling. Metconazole, in contrast, was applied twice in 2019 within the sampling period. Metconazole was not detected before spraying, but after spraying, soil concentrations peaked and then declined rather quickly, levelling off at a constant concentration instead of approaching zero. We determined the bioaccessible concentrations to investigate the mechanisms behind the observed triazole-fungicide concentrations. Bioaccessibility was estimated by extraction with the complexing agent hydroxypropyl-beta-cyclodextrin (HPCD) that mechanistically mimics the microbial uptake of hydrophobic compounds. Tebuconazole, propiconazole and epoxiconazole showed low bioaccessibility, whereas metconazole initially showed high bioaccessibility. Aging of triazole fungicides was also demonstrated in a lab-experiment where soil from three organic fields was spiked with triazole fungicides followed by incubation for up to 2 years under oxic conditions. Subsamples were analysed by sequential extraction of the concentrations that were either immediately bioavailable (CaCl₂ extraction), bioaccessible over time (HPCD-extraction) or non-bioaccessible (hard extraction). The lab-experiment confirmed the field observations. Due to strong sorption and low degradability, a fraction of applied triazole-fungicides may persist in the topsoil and may accumulate after repeated application. This persistent fraction may slowly “bleed” 1,2,4-triazole to the groundwater many years after spraying.

3.08.P-Th058 Global Sensitivity Analysis for a MACRO Meta-Model for Swedish Drinking Water Abstraction Zones *Stefan Reichenberger¹, Thorsten Pohler², Sebastian Multsch², Nicholas Jarvis³ and Mikaela Gönczi⁴, (1)knoell France SAS, Lyon, France, (2)knoell Germany GmbH, Germany, (3)Swedish University of Agricultural Sciences, Sweden, (4)Swedish University of Agricultural Sciences (SLU), Sweden*

In Sweden farmers are legally obliged to apply for permits for pesticide use if their land lies within a drinking water abstraction zone. The standalone modelling tool MACRO-DB 4 developed by the Swedish University of Agricultural Sciences (SLU) is available for risk assessment and decision support. MACRO-DB 4 is used by local authorities, farmers/landowners and consultants, and is based on the well-established leaching model MACRO 5.2. However, the software is costly to maintain and slow for end users. Hence, a robust meta-model of MACRO-DB 4 was developed and integrated in a web-based tool (MACRO DB Steg2 v.5) that is fast, easy to maintain, and easy to understand for stakeholders. The meta-model (implemented as an R package) is based on i) a large number of MACRO simulations for the whole agriculturally relevant area of Sweden, and ii) a trilinear interpolation tool. The simulations comprised 18 climates, 72 soils, 1 typical crop (spring cereals), 3 application seasons (spring, summer and autumn), and 150 dummy compounds consisting of a grid of normalized Freundlich coefficient Koc, degradation half-life at reference conditions DT50 and Freundlich exponent. Target variables were i) the mean leaching flux concentration over 20 years at 2 m depth (PEC_{gw}), and ii) the 20-year mean concentration in large surface water bodies (PEC_{sw}; based on pesticide inputs via drainage and baseflow). The meta-model performs a trilinear interpolation (in the three-dimensional space of Koc, DT50 and Freundlich exponent) for log₁₀ of PEC_{gw} or PEC_{sw}, respectively. Different crops are taken into account in the web-based tool by adjusting the pesticide interception fraction according to the BBCH stage of the crop to be modelled at the time of application. In order to identify the most important input factors for PEC_{gw} and PEC_{sw}, a variance-based Global Sensitivity Analysis (GSA) was performed for the MACRO meta-model using the Sobol’ method. This method allows to i) identify first-order (direct) and higher-order (interaction) effects for each input factor (climate, soil, application season, Koc, DT50 and Freundlich exponent), and ii) rank the input factors according to their importance.

3.08.P-Th059 Agrochemical Exposure in Sri Lankan Inland Water Systems

Emma Shipley¹, Penny Vlahos¹, Rohana Chandrajith² and Prasanna Wijerathna², (1)University of Connecticut, United States, (2)University of Peradeniya, Sri Lanka

Sri Lanka has undergone a number of development efforts over the last few decades, including the development of a series of water reservoirs in the central dry zone resulting in the expansion of primarily rice growing agricultural communities. These rapidly developed communities were built with shallow wells that are impacted by surface water runoff composition, which may intermittently contain significant amounts of agrochemicals as they are applied onto the fields. Chronic kidney disease of unknown etiology (CKDu) has been a growing threat in tropical low-land agricultural regions globally, including Sri Lanka, and agrochemical pollution is suspected as one of the factors in this disease. This study compares water quality parameters including target agrochemicals in a transect along the major Mahaweli River and from wells in the local rice farming community of Wilgamuwa in the dry zone. Simultaneous health data was collected from CKDu patients who consumed water from these wells. This study shows elevated phosphate levels, with an average phosphate concentration of 0.47 mg/L in Wilgamuwa wells compared to the US EPA water quality criteria of 0.05 mg/L. This study also shows 68% of sampled Wilgamuwa wells and 20% of Mahaweli water samples had agrochemicals above water quality guidelines. While no direct relationships could be drawn between CKDu progression and water quality, these results indicate concern of both Mahaweli water quality and localized water contamination sources, and may help inform other studies of agrochemical exposure and CKDu globally.

3.08.P-Th060 Transport of WATER and Pesticides Through Sloping Vegetated Filter Strips on Macroporous Soil

Roger Holten¹, Attila Nemes², Randi Bolli³, Kathinka Lang⁴, Hans Ragnar Norli⁵, Dominika Krzeminska⁴, Mona Pauer⁶ and Marianne Stenrød⁵, (1)Norwegian Institute of Bioeconomy Research (NIBIO), Ås, Norway, (2)Norwegian University of Life Sciences NMBU, Norway, (3)Norwegian Institute of Bioeconomy Research (NIBIO), Norway, (4)Norwegian Institute of Bioeconomy Research, NIBIO, Norway, (5)Norwegian Institute of Bioeconomy Research NIBIO, Norway, (6)Norwegian Institute of Bioeconomy Research, NIBIO, Norway

Vegetated filter strips (VFS) are well-known mitigation measures applied to reduce particle transport, soil, nutrient, and pesticide loss from agricultural fields. Transport of pesticides through vegetated filter strips have not been studied much under Norwegian conditions though, hence a field study was initiated in 2020 to generate more knowledge about the transport of water and

pesticides through vegetated filter strips and to generate data for model calibration. Two field runoff simulation experiments were performed to investigate surface runoff of water spiked with pesticides and bromide through sloping (9-14 %) vegetated filter strips (well established grass) and a plot with bare soil. The two trials were performed on strips of 3x6 and 1x3 meters respectively. Approximately 1000 litres of water were applied at the top of each plot and the runoff rate was set to 3 L/min in both trials. Very little surface runoff was generated as most of the applied water quickly infiltrated and leached out of the soil, applying to both trials. Subsurface flow along denser subsurface soil layers, through macropores and/or down to drainpipes dominated the transport patterns. In the first trial the water sampled showed very high concentrations of pesticides even after passing through the subsurface of 6-meter-wide vegetated buffer strips. Measured concentrations were as high as 42 and 74 % of the applied concentrations for the most sorbing (benzovindiflupyr) and the most mobile pesticide respectively (clopyralid). In the second trial 40 % of the amount of applied water was sampled and all about 300 samples will be analysed for bromide and pesticides. Here we present results from these trials and discuss factors that affect the transport of water and pesticides as surface runoff and/or by leaching in vegetated filter strips in sloping terrain, based on the results from two field-scale experiments in a loam soil.

3.08.P-Th061 Development of a Surface- and Groundwater Modelling Risk Assessment Tool for Predicting Exposure From Pesticides Used in Major Crops in Norway

Amy Ritter¹, Mark Cheplick², Roger Holten³ and Randi Bolli⁴, (1)Waterborne Environmental, Inc., United States, (2)Waterborne Environment Inc, United States, (3)Norwegian Institute of Bioeconomy Research (NIBIO), Ås, Norway, (4)Norwegian Institute of Bioeconomy Research (NIBIO), Norway

The risk assessment tool WISPE (The World Integrated System for Pesticide Exposure) was developed which includes the environmental fate and transport models winPRZM and EXAMS. WISPE is a computer modelling tool developed to evaluate the potential impact of crop protection products on the environment in Norway. WISPE makes it possible to estimate pesticide exposure in surface- and groundwater resources considering Norwegian conditions for 11 different crops. Originally developed in 2013, WISPE was updated in 2021 to be more flexible with adding scenarios, outputs, weather files and to utilize the most recent enhancements to winPRZM. This version of WISPE also includes two northern FOCUS groundwater scenarios. This poster presents the new user input interface and shows examples of the results.

3.08.P-Th062 Evaluation of the Effect of Band Application on Groundwater Concentration Using Two-Dimensional Leaching Modelling

Shanghai Li and Bernhard Jene, BASF SE, Germany

The leaching of agro-chemical substances in soil to groundwater for regulatory purpose in the EU and other regions is usually assessed by using 1-D (one-dimensional) models which exclusively considers vertical transport. One-dimensional modelling can be considered sufficient and appropriate for homogeneous field application (e.g. surface spray treatment to whole fields) since for this application type lateral transport and mixing effects are of minor importance. However, with the adaptation of innovative application techniques, such as precision farming including band and spot application, it is unclear if partial area application leads to locally higher ground water concentration under the applicated bands or spots or if lateral transport and dispersion processes compensate for the partial area treatment which results in a homogenous transport after a certain transport depth after complete lateral mixing. Two-dimensional (2-D) spatial modelling is used to investigate the influences of lateral mixing on the solute transport after partial area application. Different aspects are considered such as size of the applicated bands or spots, influence of distances between the bands or spots as well as influence of transport distance and lateral dispersion length. The 2-D modelling is performed with the HYDRUS-2D model using implementations of the FOCUS scenarios in HYDRUS 2-D as presented in Diamantopoulos et al 2017 (doi:10.2136/vzj2017.04.0070). Conclusions will be presented for which situations 1-D modelling can cover partial area treatment and under which circumstances 2-D modelling is necessary to consider the additional effects of band or spot application on the predicted concentrations in groundwater.

3.08.P-Th063 Transcriptomic Points of Departure Calculated From Rainbow Trout Gill, Liver, and Gut Cell Lines Exposed to Fluoxetine and Methylmercury

Krittika Mittal, Jessica Ewald and Nil Basu, McGill University, Canada

There is great interest in the development, validation, and application of resource-efficient new approach methods (NAMs) in toxicity testing (e.g., in vitro models; toxicogenomics data). To this end, in vivo rodent and aquatic studies have documented that transcriptomics data may be analyzed using the benchmark dose-response (BMD) method. While the combination of BMD analysis and transcriptomics data has been used for in vitro studies on human cells, this approach has yet to be explored for in vitro studies with ecological species. The OECD standardized test #249 for cytotoxicity in gill cells from rainbow trout (RT), a key test organism used in ecological risk assessment, has garnered much attention as a NAM. Thus, the objective here was to establish an in vitro, transcriptomic-based BMD assay using RT gill, liver, and gut cell lines. Cells were exposed to fluoxetine (Flx; 0–1000 ppb) or methylmercury chloride (MeHg; 0–12,500 ppb) for the cytotoxicity assay, and subsequently with Flx (0–1000 ppb) or MeHg (0–250 ppb) for RNA Sequencing. Cell viability decreased to 78.1% in liver cells at 1000 ppb Flx, and < 24% across all three cell lines at > 2,500 ppb MeHg. The MeHg LC50 values for gill, liver, and gut cells were 301 ppb, 840 ppb, and 328 ppb, respectively. There were no differentially expressed genes (DEGs) in RT cells exposed to Flx, hence BMD analysis was not possible. The MeHg exposures resulted in 5,376, 3,714, and 7,236 DEGs, the maximum 1st peak of the BMD density plot was 14.46, 20.47, and 17.75 ppb, and pathway-level BMD analysis identified 16,8, and 21 enriched pathways in the gill, liver, and gut cells, respectively. No pathway overlapped across all three cell lines, however, ferroptosis, phagosome, and PI3K-Akt signaling pathway were common across gill and the liver, while apoptosis, peroxisome, and Fanconi anemia pathway were common across gill and gut. Overall, the liver was least sensitive, whereas the gill was marginally more sensitive in terms of cytotoxicity and the

gut was marginally more sensitive in terms of gene- and pathway-level BMDs. This study shows that several NAM concepts (i.e., in vitro, toxicogenomics, transcriptomics BMD) can be pulled into a single study design and can yield valuable dose-response information on both cell viability and molecular responses. Moving forward, there is a need to scale up this approach to test a diverse range of chemicals to determine if the information gathered is in line with expectations.

3.08.P-Th064 Developing a Data Table Tool for Farmers to Assess the Leaching Potential of Pesticides Under Different Soil and Climate Conditions in Norway

Roger Holten¹ and Randi Bollt², (1)Norwegian Institute of Bioeconomy Research (NIBIO), Ås, Norway, (2)Norwegian Institute of Bioeconomy Research (NIBIO), Norway

Farmers in Norway have very few tools to assess the potential for leaching of the pesticides they apply to their fields. Some pesticides come with a general warning on the label stating that they may be prone to leaching and that caution must be taken. For farmers it is difficult to know when and how to follow this warning. In this project we wanted to make a tool where farmers can look up and identify the degree of leaching potential of all registered plant protection products for their crop under the soil and climatic conditions relevant for the field or area in question. In cases there are several alternatives, the idea then is that the farmer can choose the product with lowest leaching potential. In this project we identified the biggest agricultural regions in Norway and the dominating climatic and soil conditions in these regions and simulated the leaching potential of all approved plant protection products in the biggest crops (cereals and potatoes) in Norway using the groundwater leaching model MACRO-DB. Here we present the development of the table tool and some of the results generated in this project.

3.08.P-Th065 Harmonised Framework for Spatially Distributed Leaching Modelling of Pesticides Initiative: A 2022 Update

Anton Poot¹, Aaldrik Tiktak², Bernhard Jene³, Gerco Hoogeweg⁴, Erik van den Berg⁵, Abdul Ghafoor⁶, Michael Klein⁷, Michael Stemmer⁸, Paul Sweeney⁹, Robin Sur¹⁰, Jutta Agert¹⁰, Marnik van Clooster¹¹, Gerard Heuvelink¹², Gregory Hughes¹³, Stephan Marahrens¹⁴, Stefan Reichenberger¹⁵ and Nicoleta Suciuc¹⁶, (1)Ctgb, Netherlands, (2)PBL Netherlands Environmental Assessment Agency, Netherlands, (3)BASF SE, Germany, (4)Waterborne Environmental, Inc., United States, (5)Alterra Wageningen University and Research Centre, Netherlands, (6)KEMI, Sweden, (7)Fraunhofer IME, Germany, (8)Austrian Agency for Health and Food Safety, Austria, (9)Syngenta, United Kingdom, (10)Bayer Crop Science, Germany, (11)Université Catholique de Louvain, Belgium, (12)ISRIC, Netherlands, (13)Cambridge Environmental Assessments, United Kingdom, (14)German Federal Environment Agency (UBA), Germany, (15)knoell Germany GmbH, Germany, (16)Universita Cattolica del Sacro Cuore, Italy

Spatially distributed leaching modelling (SDLM) of pesticides is a methodology to estimate leaching potential over a large spatial extent such as national or European level. SDLM can help setting groundwater monitoring programs in context. It is described in the FOCUS groundwater report and foreseen to be used as higher tier leaching risk assessment as well as supporting monitoring studies. SDLM is already used as a higher tier assessment in the national authorization procedure in some EU countries and will probably become more important in future. At the SETAC Europe 2020 online meeting, the initiative was officially formalised as a SETAC working group, consisting of a triad of members from regulatory agencies, academia, and industries. A steering committee manages the effort to develop harmonized guidelines for spatial distributed leaching modelling across Europe and published a problem definition document describing the aim and scope of the work. In 2021 subgroups for Geodata and Modelling were established with each a specific focus. The Geodata subgroup is evaluating datasets that can be used to generate a spatial modelling scheme and associated scenarios. Data reviewed fall in several established INSPIRE metadata categories such as Agricultural, Meteorological, Land Cover, Hydrography, Soil, and many other categories. All data are evaluated for spatial coverage, resolution, temporal aspects, period covered, version control, accuracy, and frequency of updates. Data availability is assessed as well to ensure that all SDLM stakeholders can use the same datasets when developing their SDLM framework. The Geodata group primarily focusses on pan-European datasets that cover the EU27 and the UK. The modelling subgroup is evaluating the models to be used in the SDLM context. Specific attention is paid to runoff processes and the interaction with substance transport to groundwater. Pesticide leaching models developed for regulatory purposes do not consider these processes. In a spatial context, ignorance of runoff may lead to unrealistic leaching patterns, so options were evaluated how to include runoff in a harmonised way into the models (e.g., using the runoff curve number approach). The modelling subgroup is further investigating how other lateral loss processes, such as drainage, can be included. As the SDLM teams continue to work, this presentation provides an update to interested parties.

3.08.P-Th066 Spatial Variability of POPs in Air at European Background Sites

Mrs. Helene Lunder Halvorsen¹, Pernilla Bohlin-Nizzetto², Knut Breivik³, Sabine Eckhardt², Claudia Moeckel⁴, Alexey Gusev⁵, Victor Shatalov⁵ and Lovise Pedersen Skogeng², (1)Environmental Chemistry, NILU - Norwegian Institute for Air Research, Kjeller, Norway, (2)NILU - Norwegian Institute for Air Research, Norway, (3)Norwegian Inst. for Air Research, Kjeller, Norway, (4)Stockholm University, Sweden, (5)Meteorological Synthesizing Centre East, Russian Federation

The atmosphere is an important pathway for environmental transport of persistent organic pollutants (POPs) across national boundaries and into remote areas. While a limited number of atmospheric monitoring stations within Europe report concentrations of POPs in background air using active air sampling techniques, data on the spatial distribution of POPs across Europe remains limited. This limits our understanding of the main sources controlling the atmospheric burdens within Europe. The key objective of this study was to measure the spatial variability of concentrations of POPs in background air across Europe, and to use observations and models in concert to assess if the measured concentrations are mainly governed by secondary emissions or continuing primary emissions. In our study, polyurethane foam based passive air samples were collected at 101 sampling sites across 33 countries along a European-Arctic transect (35 °N to 81 °N, 51°W to 47 °E) during summer 2016. The samples were

analyzed for 31 polychlorinated biphenyls (PCBs) and 29 organochlorine pesticides (OCPs) by using a gas chromatograph coupled to a high resolution mass spectrometer. The Global EMEP Multi-media Modelling System (GLEMOS) was used to obtain further insight into source-receptor relationships of selected POPs. HCB and γ -HCH were detected in all samples and with the highest concentrations. PCBs, p,p'-DDE, Dieldrin and Endosulfan I were also detected frequently (>72%). Differences in spatial pattern were observed between the targeted POPs, e.g. γ -HCH was found to be highest at sites in eastern Europe whereas concentrations of γ -HCH were highest in western Europe. HCB was the only POP that was positively correlated to latitude, and also the only POP that had significantly increased over the last decade. The highest concentrations of PCBs were observed in central parts of Europe. Model predictions of PCB-153 by the GLEMOS model for each site suggest that secondary emissions are, on average, four times more important than primary emissions in controlling atmospheric burdens. The model predictions furthermore suggest that the relative importance of primary emissions are more influential in southern Europe compared to northern Europe. Our results illustrate the utility of combining observations and mechanistic modelling to provide insights on the relative importance of primary vs. secondary emissions for individual POPs, as well as on their main source regions.

3.08.P-Th067 Groundwater Modelling of Volatile Substances in the EU

Steven Andrews, Compliance Services International, United Kingdom

The modelling of volatile active substances leaching to groundwater and further refinement of these estimations can be complex, particularly when higher tier environmental fate studies are required either as inputs or to support a hypothesis on which a refinement relies. For active substances with indoor (e.g., permanent glasshouse) and open field uses, consideration must be given to the design and conduct of the higher tier studies to ensure they will be beneficial in the context of the current data package. This poster will look at groundwater models: comparing the input assumptions and potential for experimental refinement of these; the limitations of the models and the potential for higher tier modelling options. It also aims to outline the current state of applicable guidance in this area for relevant formulation types and uses.

3.08.P-Th068 Seed Dressing - an Overlooked Source of Pesticides and Their Transformation Products in Groundwater?

Christian Albers¹, Ulla Bollmann², Nora Badawi³ and Anders Johnsen⁴, (1)GEUS, Denmark, (2)Geological Survey of Denmark and Greenland, Denmark, (3)Geological Survey of Denmark and Greenland (GEUS), Copenhagen K, Denmark, (4)Geochemistry, Geological Survey of Denmark and Greenland, Copenhagen K, Denmark

1,2,4-triazole is of emerging concern regarding groundwater contamination. In Denmark, 3.4% of the groundwater monitoring wells are polluted with concentrations exceeding the European threshold of 0.1 $\mu\text{g/L}$. Spray application of the most common triazole fungicides, propiconazole, tebuconazole, epoxiconazole and difenoconazole, has been restricted by the Danish EPA. However, seed dressing, i.e., coating of seeds with a thin layer of pesticide formulation, has not been considered a potential source for 1,2,4-triazole formation. In the present study, we carried out laboratory column experiments to determine the leaching potential of 1,2,4-triazole from commercial barley seeds, coated with the triazole fungicides tebuconazole and prothioconazole. In addition, we followed the release of difenoconazole in an agricultural field site, after sowing of difenoconazole coated winter wheat. The results show, that 1,2,4-triazole leaches from soil columns with barley seeds coated with the two fungicides. Both, tebuconazole and prothioconazole, added to the leaching of 1,2,4-triazole, which reached concentrations up to 0.8 $\mu\text{g/L}$. However, at the end of the experiment after 63 days, only 1% of the total fungicide was recovered as 1,2,4-triazole. Extraction of the remaining fraction of tebuconazole and prothioconazole revealed that the parent compounds are released into soil but are rather immobile and stay close to the sow depth. Similarly, difenoconazole concentrations in the agricultural field site increased shortly after sowing of coated seeds to 0.8 $\mu\text{g/kg}$, while it was below 0.1 $\mu\text{g/kg}$ prior. It is evident from our results that not only the spray applications but also seed dressing contributes to the leaching of 1,2,4-triazole. It is therefore advised to include seed dressing when assessing the leaching risk of pesticides and their transformation products.

3.08.P-Th069 OECD Round Robin Test to Evaluate a New Test Design to Determine Plant Root Uptake for Regulatory Environmental Fate Modelling

Marc Lamshöft¹, Maximilian Küppers¹ and Konstantin Kuppe², (1)Bayer Crop Science, Germany, (2)Umweltbundesamt, Germany

In 2018, the the German Environment Agency (UBA) initiated an OECD project to establish a new test design for the determination of plant root uptake for environmental fate modelling. The intended outcome is an OECD test guideline. The key part of the validation process is a round robin test that aims to evaluate the intra- and inter-laboratory accuracy and reproducibility of the new test protocol. The test design was based on a protocol developed by stakeholders from academia, regulatory authorities and industry [1]. An OECD experts group recommended to modify the preliminary design with regard to several experimental parameters and suggested to test plants with different growth stages (14- and 28-days old plants), three test item concentrations (0.5, 1.0 and 2.0 $\mu\text{mol/L}$) and suggested to reduce the incubation period to 48 h. In 2020, a pretest was conducted in one laboratory to check whether the proposed changes are feasible. The pre-test was performed with oilseed rape and wheat. 14- and 28-days old plants were incubated for 48 h with the test items [¹⁴C]-1,2,4-triazole and [¹⁴C]-TFA (trifluoroacetic acid). The plant uptake factor (TSCF, Transpiration Stream Concentration Factor) varied mainly depending on the test item concentration and the age of the plants. Keeping these parameters constant yielded rather homogeneous TSCF values. Based on this outcome, the round robin test with 10 labs was planned and started in 2021. If the results of the validation process prove the reliability of the test design, the protocol will be proposed for implementation as a new OECD Test Guideline in 2022/23. [1] Lamshoef, M., Gao, Z., Ressler, H., Schriever, C., Sur R, Sweeney, P., Webb, S., Zillgens, B., Reitz, M., 2018. Evaluation of a novel test design to determine uptake of chemicals by plant roots. *Sci. Total Environ.* 613, 10-19.

3.08.P-Th070 Collation and Analysis of Regulatory Field Trial Data for the Validation and Refinement of Crop Development Dates Used in Pesticide Exposure Modelling and Risk Assessment

Gregory Hughes¹, Andrew Eatherall², Michael Bird³, Anastasiia Bolekhan⁴, Philip R Branford⁵, Sebastian Gebler⁶, Anthony Lozano⁷, Paul Massey⁸, Liz Whitworth⁹ and Jonathan Blake⁹, (1)Cambridge Environmental Assessments, United Kingdom, (2)Corteva Agriscience, United Kingdom, (3)Syngenta, United Kingdom, (4)Bayer AG, Germany, (5)Environmental Safety, ADAMA, United Kingdom, (6)BASF SE, Germany, (7)Sumitomo Chemical Agro Europe SAS, France, (8)FMC Agricultural Solutions, United Kingdom, (9)RSK ADAS Ltd, United Kingdom

Determining appropriate pesticide application windows is an important component of pesticide exposure modelling; increasingly, regulators are constraining these application windows using estimates of the timing of BBCH crop growth stages from AppDate. For example, the “repaired” version of the FOCUS SW models will have AppDate integrated directly into the software shell to remove “subjectivity” from the selection of application windows. The AppDate (Klein, 2012) software calculates consistent application dates for use in FOCUS SW and GW modelling with the purpose of aligning the product GAP being assessed with the fixed model crops described by the FOCUS models. The dates for major crop development stages, e.g., BBCH 10, captured in AppDate are based on various sources, differentiated for GW and SW, with linear interpolation used for BBCH growth stages between these. Given exposure assessments are a function of the application dates this software generates, it is important to understand how realistic and representative they are; however, there is currently no comprehensive, quality-controlled, readily available, pan-European crop phenology dataset available to undertake such an assessment or for use in regulatory risk assessment refinement. The crop protection industry holds large quality-controlled datasets of BBCH crop growth stages within their efficacy and residue trials datasets that span the required crop types as well as the agronomic and pedoclimatic diversity of Europe. A Crop Life Europe (CLE) project has sourced efficacy trial datasets from 7 members and created a harmonised crop development dataset that allows for the assessment and, where required, the justification of more realistic and location specific dates in regulatory risk assessment refinements. The data collection process has highlighted that residue trial datasets are not typically stored in a format that makes them easily combined with the efficacy trials datasets. The harmonised database spans two decades (2000-2020), comprises >250 crops (combinable, top/soft fruit, pasture/grass, ornamentals, vegetables and herbs amongst others) and covers 25 EU Member States, 3 EEA countries as well as Switzerland and the UK. This poster describes the database created in more detail, presents preliminary results for representative crops and outlines opportunities for the further development of exposure science to allow for more accurate and realistic risk assessment.

3.08.P-Th071 The Underground of the Crops - Representative Agricultural Soils in Brazil Through a GIS Based Approach

Rafael Ramon¹, Leticia Scopel Carniel², Alex Tornisielo¹, Carolina Wolff¹, Romulo Scorza Junior³, Pablo Torrado⁴, Rafael Marques Pereira Leal⁵ and Bernhard Jene⁶, (1)BASF SA, Brazil, (2)Regulatory Sciences - APS, BASF SA, São Paulo, Brazil, (3)Embrapa, Brazil, (4)ESALQ USP, Brazil, (5)Instituto Federal Goiano, Brazil, (6)BASF SE, Germany

Environmental fate assessment of plant protection products (PPPs) for regulatory purposes requires soil studies to characterize route and rate of degradation, sorption, and mobility. Considering the unfeasibility of performing such tests on all soil classes that occurs in a country, and the lack of a clear definition about required local soil classes and characteristics, it is necessary to choose those which are the most representatives of relevant agricultural areas. In Brazil, the representative soils suggested by the authorities dates from 1996 (Portaria Ibama nº 84, de 1996), which were selected based on its mineralogical, chemical, and physical characteristics, in order to cover the clay mineralogy, pH, texture, and organic matter variability of main Brazilian soils (verbal communication, no official document published). Since 1996, Brazil’s agricultural area has increased by 105% (27.2 Mha in 1996 to 55.7 Mha in 2020). Recently, advances on satellite images to identify agricultural areas and the availability of high-resolution soil maps, it has been possible to estimate the main soils in use for agriculture by using geoprocessing (GIS) tools. The objective of this study is to identify the most representative soil types under agricultural use in Brazil nowadays based on a GIS analysis. Using updated soil maps on the scale of 1:250.000 from the Brazilian National Program of Soils (Pronasolos) and the land use maps provided by the Mapbiomas Initiative, it will be possible to identify the main soil types currently used for agriculture and inquire about the spatial representativeness of these soils in the studies to characterize sorption, mobility, and degradation of PPPs for regulatory purpose in Brazil. Moreover, this database can be used in a near future to generate more representative scenarios for PPPs exposure assessment as well as to support the choice of the most appropriated soils to be used in studies required for PPPs registration in Brazil.

3.08.P-Th072 Know Your Drift Facts

Rena Jutta Irene Isemer¹, Clare Butler Ellis², Clive Tuck², Andrew Lane², Jenny Baumann³ and Andrew C. Chapple⁴, (1)Crop Science, Bayer Crop Science, Germany, (2)Silsoe Spray Applications Unit Ltd, United Kingdom, (3)Bayer Crop Science, Germany, (4)Environmental Safety, Bayer Crop Science, Germany

Drift from pesticide application is a (if not the) major route of exposure for non-target organisms (NTOs). But how much do we actually know about factors that determine the quantity of spray drift reaching vertical collectors in the off-field (i.e., the NTO of interest)? These factors are (1) application technique (nozzle, spray volume, pressure, formulation, etc.), (2) environmental factors, i.e., wind and T°-plus-humidity and (3) specific characteristics of the NTO. Modelling, wind tunnel, and field experiments will be presented giving insights into the effects of some of these factors. Some conclusions so far are listed below. · Nozzle design (i.e., initial droplet size distribution) has a surprisingly small effect on downwind droplet size reaching an NTO at a given location. However, it does affect how much of the spray reaches the NTO (e.g. for conventional hydraulic nozzles, reducing volume by switching to smaller nozzle sizes with lower flow rate, droplets become smaller and drift quantity increases). · The distance downwind of the NTO and the wind speed are the main factors influencing the size of the droplets impacting on the NTO (largest changes in droplet size are between 1 and 5 m downwind). · There can be a noticeable effect of changing application

volume on NTO exposures, but this correlation is complex and depends on the method of changing volume (*e.g.*, changing speed *v.* changing pressure), type of nozzle used, and distance between crop and nozzle. It is hardly possible to change volume without changing other parameters like nozzle size or sprayer speed. However, given the use of drift-reducing nozzles, the effect is small enough for ground deposits to be considered independent of volume; airborne spray is independent of volume down to 50 L/ha. We generally hypothesise that only small changes in drift depending on volume will occur if droplet size remains approximately constant. The quantity of spray captured by NTOs with vertical structures appears to be correlated with the quantity (mass flux) and quality (drop size spectra) of the airborne spray, as well as the characteristics of the NTO (*e.g.* size and structure) and wind speed. Thus, a spray drift model combined with some description of the collection efficiency of NTOs should be sufficient to predict the quantity of spray reaching NTOs. Models like SiMoD (SSAU) are suitable as shown by comparing model results to field data. SiMoD confirms that the initial droplet spectrum has little to no effect on the droplet size distribution reaching the NTO and that distance and wind speed are the main factors influencing the size of the droplets impacting on the NTO.

3.08.P-Th073 Lessons Learned: A Regulators Experience of Applying the OECD 106 Evaluators Checklist

Michelle Morris¹ and James Hingston², (1)CRD, HSE, York, United Kingdom, (2)HSE, Chemical Regulation Division, United Kingdom

The OECD 106 checklist was developed by EU Member State experts in collaboration with ECPA and EFSA to provide supplementary information to aid consistency in the conduct, evaluation and reporting of batch sorption/desorption studies. The checklist is a tool for applicants and regulators to help identify where deviations from the OECD 106 guideline could lead to significant and systematic errors in fitted parameters. It is not intended to replace the quality checks outlined in the OECD 106 guideline. K_{foc} and $1/n$ are critical input parameters to FOCUS modelling for groundwater and surface water. The models are sensitive to these input parameters. For example, a 10 % change in $1/n$ can lead to a 100 % change in PEC_{GW} . Therefore, robust studies performed to standardised guidelines are needed to have confidence in the modelled predictions. HSE's Chemicals Regulation Division has been applying the OECD 106 checklist to pesticide active substance evaluations for several years. Presented here are the key lessons learned from a regulatory perspective. The soil adsorption coefficient is normally derived using the 'indirect method' based on solution depletion. However, decisions made regarding the study set-up often result in the study not fulfilling key parts of the checklist and not being relied upon during the active substance evaluation. For example, a soil:solution ratio greater than 1:1 is used in cases where % adsorption is low; a long equilibrium time is used for volatile substances meaning the mass balance is unacceptable; or mass balance is calculated incorrectly by measuring % radioactivity not the test item. Altering the study design to account for these issues could result in the more cost-effective indirect method study being accepted. However, where these issues cannot be resolved by altering the study design, the 'direct method', where both soil and aqueous phases are analysed, is recommended. A common error for studies using the direct method include not accounting for the liquid entrained in the soil pellet.

3.08.P-Th074 New Tools for Predicting Environmental Concentrations in Soil in Regulatory Context - an Impact Assessment

Sebastian Multsch¹, Krisztian Szegedi², Klaus Hammel³, Agnes Schimera⁴, Olga Irene Guevara Montemayor¹, Frank Voss¹, Bernhard Gottesbueren⁵, Neil Mackay⁶ and Frances Pool, MMath⁷, (1)KNOELL CONSULT GmbH, Germany, (2)BASF SE, Germany, (3)Bayer Crop Science, Germany, (4)ADAMA Deutschland GmbH, Germany, (5)Environmental Modelling, BASF SE, Germany, (6)FMC Corporation, United Kingdom, (7)Syngenta, Afghanistan

In 2017 the European Food Safety Authority (EFSA) published a new guidance with four tiers for exposure assessment of pesticides in soil. Tier-1 and Tier-2 procedures can be calculated with the software tool PERSAM, which generates input for Tier-3A calculations which are performed with the PEARL and PELMO tools. The final tier, Tier-4 addresses post-registration monitoring. We present an impact assessment of these future requirements for calculations of predicted environmental concentrations (PEC) and the associated ecotoxicological regulatory acceptable concentrations for soil organisms. 56 chemicals (parent substances and metabolites) covering a broad range of environmental fate parameters and several different uses were considered. PEC values calculated with the new tools were at all tiers substantially higher than corresponding values calculated according to the current FOCUS approach. Soil bulk density was identified as a main driver of the concentration increase. Soil bulk densities at geographic locations selected by the PERSAM tool for the calculations appear to not necessarily represent locations relevant for agricultural practice. Foliar interception and simulated wash-off, determined by crop growth stage at time of application, were identified as other main drivers for the increase in concentrations. Exposure increases were more significant for uses with higher interception, due to larger impact of simulated foliar wash-off on the amount of substance reaching the soil. Obligatory model and scenario specific correction factors embedded in the framework contributed to an increase of PEC values over all compounds and uses. Risk assessments for soil organisms were performed using PEC values from FOCUS and EFSA Tier-3A calculations, respectively. The comparison showed a substantial change in overall pass/fail ratios. In future roughly seven times more higher tier risk assessments will be triggered than currently arise, including necessity for field studies. Further refinement options need to be developed and implemented to obtain a new, workable soil risk assessment scheme. Time needed for performing such studies shall be considered in the implementation plan of the new assessment scheme. Please refer to the poster of Schimera et al for further details. Practical experience with the new models revealed a highly inefficient workflow, which will increase future workload for evaluators and applicants. This must be considered for the implementation plan: some additional usability features would be necessary, including improved reporting, access and operation with a substance database and automation of calculations. We propose a stakeholder discussion to resolve practical concerns related to the new tools.

3.08.P-Th075 Comparing PNEC to Swedish Pesticide Monitoring Data - How Reliable Is the Registration Process?

Bodil Lindstrom¹ and Mikaela Gönczi², (1)Department of aquatic sciences and assessment, Swedish University of Agricultural Sciences, Uppsala, Sweden, (2)Swedish University of Agricultural Sciences, Sweden

In the registration process for Plant Protection Products, one of the assessments of a substance is calculating PNEC (Predicted No Effect Concentration) based on laboratory studies and comparing to PEC (Predicted Environmental Concentration), to ensure no unacceptable effects on aquatic organisms. In this abstract, we used PNEC values from the latest EFSA Conclusion for each substance (June 2021) and compared with measured environmental concentrations from Swedish pesticide monitoring data. The aim was to evaluate how well the registration process prevent negative effects on the aquatic environment. The Swedish national pesticide monitoring started 2002 and is mainly carried out in four small agricultural catchments (>90% arable land; 8-16 km²; Boye *et al.* 2019). Surface water is sampled automatically May to October, 100 subsamples per week, giving weekly average concentrations per substance analysed. These concentrations (E_i in Equation 1.) was divided with PNEC ($PNEC_i$) and summarized per year for all analysed substances ($=n$), giving an annual pesticide toxicity index (PTI; Figure 1). The results show that of the approximately 150 substances analysed annually, the majority of substances found (78) contributed with < 0.1% to total PTI during 2002-2020 (they have not been categorized into “approved for use (2021)” or year of ended approval). The four substances with highest total PTI are imidacloprid and picoxystrobin (approval ended during 2016-2018 in Sweden) and metiocarb and metazachlor (approval ended 2009-2015). Of the substances approved for use (2021) diflufenican and MCPA contribute most to PTI, with diflufenican having the highest PTI the last few years whereas annual PTI for MCPA show a decline. We conclude that 1) PNEC values seldom are exceeded for most pesticides measured in Sweden, although 2) some substances regularly exceeds PNEC and can be seen as problematic, but, 3) most of these substances have not got a renewed approval. Equation 1. $PTI = \sum E_i / PNEC_i$ Figure 1. Pesticide toxicity index (PTI) calculated for surface water from four intensively farmed catchments in the Swedish monitoring program of pesticides. Substances with total PTI higher than 0.1% categorized according to approval in Sweden or year approval ended. A lower total PTI than 0.1% are uncategorized. In 2009 the analytical method improved with more substances and lower detection limits. Boye, K., Lindström, B., Boström, G. & Kreuger, J. 2019. Long-term data from the Swedish national environmental monitoring program of pesticides in surface waters. Journal of Environmental Quality. DOI:10.2134/jeq2019.02.0056.

3.08.P-Th076 Modelling the Impacts of Climate and Socio-Economic Changes on Pesticide Use and Fate

Poornima Nagesh¹, Rudrani Gajraj², Josef Eitzinger² and Stefan Dekker¹, (1)Copernicus Institute of Sustainable Development - Utrecht University, Netherlands, (2)University of Natural Resources and Life Sciences (BOKU), Austria

Agricultural use of pesticides helps to control a range of pests and diseases that threaten crops and thereby avoid yield losses and improve the quality of the food produced. However, pesticides applied on agricultural fields dissipate with time. The export of pesticides and their transformation products after application from the agricultural fields threatens the water quality of aquatic systems in many world regions. Climate change is further expected to intensify pest pressures and potential pesticide use by affecting agriculture in many ways. Changing climatic conditions can increase pesticide leaching due to increased and frequent rainfall, higher degradation rates due to higher temperatures or soil moisture contents. The indirect effects are changes in land use, the timing of crop cultivation, selection of other crop types, new pests and changed pest behaviour, etc. Additionally, several socio-economic factors influence pesticide use at the farm and national level, including regulation and legislation, economy, technology and crop characteristics. In order to better understand the pesticide risk to surface waters in the future, it is our aim to understand the influence of both climate and socio-economic change on pesticide use and fate. To assess pesticides and their impacts on water bodies, a variety of catchment scale models are available. However, most modelling approaches solely concentrate on the total amount or concentration of pesticide exported from a catchment and do not necessarily analyse the future change of pesticide and transformation products. We propose an integrated modelling framework to answer the research questions: What are the current significant climate and socio-economic drivers influencing pesticide use and emissions? How can climate change influence pesticide and transformation products emission trends? How will socio-economic change influence pesticide emissions? The integrated modelling framework helps to include adapting agricultural production to climatic (e.g., temperature, precipitation) and socio-economic drivers (e.g., land use, crop type, pesticide regulation) and quantifying pesticide emissions with the Zin-AgriTRA pesticide fate model. The ZIN-AgriTra is a catchment scale reactive transport model which can simulate agrochemical and transformation products exported from agricultural catchments. We use the Eur-Agri-SSP scenarios that extend and enrich the basic Shared Socio-economic Pathways with a regional and sectoral component on agriculture to explain the socio-economic change and climate projections for Representative concentration pathways to adopt climate change scenarios. The integrated modelling framework links the future scenario results from independent, standalone models that present crop rotation, land use, pesticide regulation and climate to the pesticide fate model (Zin-AgriTRA). The framework is applied to an agricultural catchment in Burgenland, Austria, to quantify pesticide pollution under future climate and socio-economic change up to 2050.

3.08.P-Th077 Pesticide Transformation Product Occurrences in Surface Waters As Ground Water Pollution Risk Indicators in the Context of an Extended Residence Time Aquifer

Tom Galle¹, Julien Farlin², Michael Bayerle³, Denis Pittois³ and Viola Huck³, (1)ERIN, Luxembourg Institute of Science and Technology, Esch sur Alzette, Luxembourg, (2)Water Management Administration Luxembourg, Luxembourg, (3)Luxembourg Institute of Science and Technology LIST, Luxembourg

Luxembourgish groundwater aquifers have recently been impacted by high concentrations of several pesticide transformation products that led to regulatory issues for about 1/3 of the drinking water supplies (Luxembourg considers all transformation products to be relevant and applies the 100 ng/L legal threshold). The consequent application restrictions or complete bans of

certain pesticides triggered switches in compound uses in several cultures. A leaching risk analysis had been conducted to orient agricultural counselling on the least impacting parent compounds and transformation products. However, since the leaching simulations relied on literature environmental property data of the pesticides (like fraction of TP generated), there was some uncertainty on the true impact of the identified TPs. Residence times of groundwaters in the main aquifer spanning on average between 10 and 20 years (with proportional recovery times once these waters are contaminated), a faster validation approach was needed. The hypothesis was established that the interflow component in surface waters would be a good indicator to estimate the amount of transformation products available for groundwater leaching. In that perspective passive sampling campaigns were established on four river basins of distinct hydrogeology to quantify the masses of parent compounds and transformation products transported during an entire season. All the predicted transformation products were identified and their occurrence varied in amount and timing in the different catchments. This poster discusses the influences of spatial use variability and hydrological connectivity of agricultural source plots to the magnitude of the occurrences as well as its potential link to the leaching modelling and its parametrization

3.08.P-Th078 Interpretation of Public Surface Water Monitoring Datasets: Characterising Pollutant Sources and Their Exposure Pathways to Assess Their Relative Importance

Gregory Hughes and Claire McMillan, Cambridge Environmental Assessments, United Kingdom

Public surface water monitoring datasets are increasingly used within the regulatory process either directly (e.g. registration requirement under plant protection products [PPP] directive 1107/2009/EC) or indirectly (e.g. pharmacovigilance initiatives under the veterinary medicines [VM] directive 2001/82/EC). This public monitoring data provides valuable insight into the state of the environment, emerging issues and possible impacts. However, caution is required when collating, analysing and interpreting these datasets, especially where active substances are registered under multiple directives and used in a wide range of sectors. Interpretation of the results, considering confounding factors and understanding what might be concluded from such datasets is key to ensuring that policy responses and mitigation measures are targeted at the correct sector, use, source, pathway and use-period. This poster collates observations from several insecticide investigations where such a multi-sectoral assessment of sources and pathways was conducted. The number of direct and indirect sources and pathways to surface water can be quite complex and the range of indirect/direct sources and their pathways to surface water are identified and described. Some uses in certain sectors are difficult to characterise as information on the ingredients/treatments used in the production of imported/domestic products are poorly documented and little or no data is often collected/available. One such sector is that of textiles where raw fibres, fabric and garments may have been treated with insecticides at different stages of production for different purposes in countries with different regulatory control and compliance. Potential gaps in source and pathway characterization, their impact on interpretation of surface water monitoring datasets and the requirement for and role of additional legislation to address these is discussed.

3.08.P-Th079 First Outcomes of Glyphosate and AMPA Pesticides in Surface and Groundwater Bodies of the Puglia Region (Italy)

Claudia Campanale, Carmine Massarelli, Mariangela Triozzi and Vito Felice Uricchio, Italian National Research Council, Italy

There is a growing need to study the chemical quality of water bodies concerning Plant Protection Products (PPPs). Particular attention is paid to Glyphosate and its metabolite AMPA. Glyphosate is the world's best-selling herbicide for weed control. Its toxicity to ecosystems and human health is widely discussed worldwide. The excessive use of this herbicide promotes continuous monitoring in environmental matrices, particularly in surface and groundwater bodies. With the Water Framework Directive, each Member State of the European Union has adopted a National Action Plan (NAP) to combat water pollution for the use of pesticides. In agreement with the Italian National Institute for the Protection of the Environment (ISPRA), in the Puglia region (Southern Italy), a monitoring program of the residues of PPPs in surface and groundwater bodies has been approved. This study presents the results related to the analytical activities on Glyphosate and Ampa, provided by the Monitoring Program for 2018. A total of 216 samples were analysed, 98 of which were taken from surface water bodies and 118 from groundwater ones. Their particular chemical-physical properties and consequent analytical difficulties led to developing a method for better retention and separation. A pre-column derivatisation with FMOC-Cl coupled to Ultra High Performance Liquid Chromatography-Mass Spectrometry (UHPLC-MS/MS) has been applied. In surface water bodies, Glyphosate was present at 39.5% of stations, and in 20.8%, it exceeded the regulatory limit (0.1 µg/L). The AMPA was revealed with a percentage of 39.5%, while in 36.4%, it exceeded the legal limit. The mean concentration of Glyphosate was 0.28 µg/l, with a maximum concentration of 2.2 µg/l detected in Cervaro river and a minimum value of 0.03 µg/l. For Ampa, the average quantity was 1.32 µg/L with a maximum of 9.72 µg/L observed in the same river and a minimum concentration of 0.025 µg/L. For groundwater bodies, Glyphosate was present in 14% of cases, and 1.7% exceeded the legal limit. For Ampa, the presence was 3%, while the 0.4% exceeded the legal limit. The overall results showed a diffuse presence of the two pesticides along the whole Region. In order to predict their damaging effects on the delicate balance of ecosystems, develop models of sustainable management of environmental resources, and provide more environmentally friendly solutions over time, continuous and updated monitoring campaigns is crucial.

3.08.P-Th080 Environmental Monitoring and Risk Assessment of Pesticides Applied in an Agricultural Watershed Dominated by Avocado Orchards: East-Michoacan, Mexico

Ana Edith Merlo Reyes¹, Céline Duwig², Christine Baduel³ and Isabel Ramírez⁴, (1)Université Grenoble Alpes, Saint Martin D'hères, France, (2)IRD / CNRS, France, (3)CNRS IGE UMR 5001, Univ. Grenoble, France, (4)Centro de Investigaciones en Geografía Ambiental, Universidad Nacional Autónoma de México, Mexico

Worldwide the increase of pesticides is a serious environmental and human health concern, even more in developing countries, where the use and application of pesticides are not regulated. Mexico is the largest avocado producer in the world, and Michoacan

the main producer state, representing 70% of the total land planted in avocados in the country. In the last 10 years, eastern Michoacan has experienced an expansion and intensification of avocado monoculture, mainly at the expense of traditional crops, and to a lesser extent in priority conservation forests. Hence, there is a need to assess surface and groundwater pollution risks as well as health risks due to pesticides used in avocado monoculture. To address this need, we first inquire the agricultural practices through interviews applied to 30 local farmers, asking them about the use and frequency of pesticides application. Weather data was obtained from six stations around the study area, and soil data from official cartographic sources and by examining the physicochemical parameters of five soil profiles. We assessed the concentrations of 23 pesticides in water from samples collected in 15 sites during the dry and wet seasons. The analysis involved an extraction step using solid phase extraction (Oasis HLB cartridges) and pesticides identification/quantification by liquid chromatography coupled with mass spectrometry triple quadrupole (LC-MS/MS). The risks for the ecosystem and mobility of pesticides in the basin is being evaluated using the Pesticide Impact Rating Index (PIRI) and Hydrus-1D model. Results show that most farmers apply at least six main pesticides every month (glyphosate, benomyl, paraquat, chlorpyrifos, cypermethrin and imidacloprid), as a “preventive treatment”. The soil types are dominated by volcanic soils: andosols in the productive zone, and lithosols and vertisols at the basin outlet. The final analysis is under process and results are expected by January. The chemical concentrations will then be confronted to the survey. The results of field survey, of the index calculation and modelling will show the potential risks linked to pesticides use and mobility in soils, which will be useful to support the need of regulated agricultural practices, to prevent health issues and pollution of natural resources.

3.08.P-Th081 A Field Study Protocol for Collection of Human and Environmental Data on Pesticide Use in Europe and Argentina

Current farm systems rely on the use of Plant Protection Products (PPP) to secure high yields and the quality of crops and agricultural products. However, PPP may have considerable impacts on human health and the environment. We prepared a study protocol to determine the occurrence and levels of PPP residues in humans, plants, animals and other non-target species for exposure modelling and impact assessment. This was linked to a cross-sectional study to compare conventional and organic farm systems across Europe. Environmental and biological samples were collected during the 2021 growing season at eleven case study sites: ten in Europe (covering a range of climate zones and crops), one in Argentina (to inform the impact of PPP on growing soybean, an important European protein-source in animal feed). We monitored PPP fate in environmental media (soil, water and air) and in the homes of farmers, and complemented it by the collection of samples from humans, farm animals (cow, goat, sheep and chicken), and other non-target species (earthworms, fish, aquatic and terrestrial macroinvertebrates, bats, and farm cats). Data of PPP residues in environmental and biological matrices will be used to estimate exposures by modelling. These exposure estimates together with health and toxicity data will be used to predict the impact of PPP use on environment, plant, animal and human health. The outcome of this study will be integrated with socio-economic information leading to an overall assessment used to identify transition pathways towards more sustainable plant protection and inform decision-makers, practitioners and other stakeholders regarding farming practices and land use policy.

3.08 Measuring, monitoring and modelling of pesticide fate and mitigation in a regulatory context (Poster Corner)

3.08.PC-We13 Landscape Level Modelling for Derivation of Dilution Factors at Drinking Water Abstraction Locations *Shanghai Li, Sebastian Gebler and Tom Schröder, BASF SE, Germany*

The exposure assessment of plant protection products (PPPs) at drinking water (DW) abstraction locations is of growing interest for authorities, water suppliers, industry, and other stake holders and hence particularly addressed in the EU regulatory framework (regulation 1107/2009). From a landscape level exposure perspective, the target is amongst others to derive dilution factors from edge-of-field surface water (SW) concentrations (PEC_{sw}) to a potential drinking water abstraction location at the catchment

outlet. This dilution factor depends on various variables, e.g. the agricultural use area, the hydrology, connectivity and other processes that determine the fate of a chemical substance in a catchment. Currently, no generic guidance is available on the derivation of drinking water abstraction concentrations for conducting exposure assessments in the EU. An exception is the national approach of the Netherlands DROPLET, a simplistic but very solid first Tier approach. However, the Dutch approach underlies worst-case assumptions, e.g. all agricultural land is connected and releases water instantaneously to a water body, further it only considers the topographical characteristics of the Netherlands. Our work explores the feasibility of using a step-wise EU approach to derive realistic dilution factors at drinking water abstraction locations which are potentially prone to high exposure of PPPs. This involves, first, identifying potentially vulnerable drinking water catchments using a GIS-based approach. This was presented at SETAC 2021 by Gebler et al. showing the identification of potentially vulnerable drinking water catchments based on high resolution upstream agricultural land use and surface water distribution within a catchment. Second, evaluation of the dilution factor of PPPs at drinking water abstraction points using the spatially distributed eco-hydrological model - SWAT (Soil and Water Assessment Tool). The SWAT tracer experiments, which considers all these different processes that determine the dilution factors in a holistic manner, evaluates the dilution factor of PPPs in a conservative and yet realistic manner. Future work includes identifying proper temporal scales, the impact of connectivity as well as application timing on the quantification of the dilution factor within drinking water catchments in the EU.

3.08.PC-We14 Deterministic Modelling of Effectiveness of Runoff Mitigation in the Netherlands at Field Scale

Wim Beltman¹, Pim Dik², Piet Groenendijk², Marius Heinen², Harry Massop³, Martin Mulder², Ab Veldhuizen², Robin Sur⁴ and tom smit⁵, (1)Wageningen Environmental Research, Netherlands, (2)Wageningen Environmental Research, Nederland,

(3)Wageningen University and Research, Netherlands, (4)Bayer Crop Science, Germany, (5)Bayer Crop Science, Nederland

Runoff from agricultural fields may affect surface water quality due to the presence pesticides. In areas densely populated with water courses, as common in the Netherlands, farmers need effective tools to manage runoff events. Emissions to surface water can be mitigated by reducing the number and size of the runoff events. The aim of the study was to quantify the effect of mitigation measures on runoff reduction, parameterized for typical Dutch landscapes, crop, soil, and weather conditions. Two measures were considered: micro-dams in ridged fields and an infiltration trench at the edge of the field. The Soil-Water-Atmosphere-Plant (SWAP) simulation model describes deterministically the hydrological processes (Richards equation combined with the Darcy-Buckingham equation) at field scale, including estimates of runoff. 30 Years of rainfall events were simulated for different soil-crop combinations with and without mitigation measures. All arable fields in the Netherlands were attributed to one of 57 standard situations. The simulated runoff volume was plotted against precipitation volume for each unique SWAP simulation run for the 30-year period. The plotted data were then used to determine two parameters in the rainfall-runoff relationship for the reference and for the mitigation situations. The optimized rainfall-runoff relationships were then used to determine the effectiveness as a function of the precipitation, applicable for any precipitation event. With the effectiveness function and the set of 57 standard situations the effect of the mitigation measures for all arable fields in the Netherlands can be determined individually. The results of the study can be used to advise farmers for which crops and for which fields the mitigation measures help to reduce runoff from their fields. The deterministic modelling of runoff is appropriate for river delta areas with relatively little slope and for areas with shallow groundwater levels and where measures are mostly taken at the field scale.

3.08.PC-We15 The Integrated Drift Management Sprayer As a Use-Case for the Digital Label Infrastructure

Andrew C. Chapple¹, Frank Dietz², Dennis Goeke², Josy Bravidor², Yves Jaschinski², Susanne Lauck-Birke², Walter Mayer² and Robert Puhl², (1)Environmental Safety, Bayer Crop Science, Germany, (2)Bayer Crop Science, Germany

Farming is moving rapidly towards digitalization, ranging from control systems (e.g., self-driving vehicles in the field), to mapping of yields with respect to cropping variables (e.g., pest pressure, seed and soil quality) and digitally enabled risk mitigation measures, and to the overall integration of all inputs and outputs into planning software to drive decisions and document them. These changes need to be considered in the registration of plant protection products and will have to include, for example, changing application techniques and digitally enabled risk mitigation measures implemented on the label of plant protection products. However, labels are already complicated and further label complexity is in no-one's interest. A running project at Bayer AG – the Integrated Drift Management sprayer [IDM] – demonstrates a solution to increasing label comprehension and compliance by implementing the right label recommendations for products applied to a crop using automated spray application. This helps manage the complexity of dealing with multiple spray drift risk assessment compartments for vulnerable off-target areas (e.g., a residential area downwind from a stream next to a cropped field). In addition, the IDM applies a very simple change in the decision process by taking into account the wind direction and applying the label requirements automatically in a customised way in the field *during spray operation*. The software and the sprayer prototype have been developed integrating the customised software into an Amazone 28 m towed sprayer and uses the FieldView Drive system (also being developed by Bayer / Climate Corp) for documentation. The first proof of concept (PoC) for this approach to in-field application of label requirements modified to consider local wind conditions has been successfully completed at the ARVALIS research station at Boigneville, France in 2021 and will have been demonstrated, live, to the French regulatory authorities (ANSES and the Ministries of Agriculture, Health, Environnement). Thus, we have demonstrated the possibility that, eventually, all aspects of the regulatory oversight of pesticide spray application can follow a digitalized, in situ or field-localised risk assessment and integrate customized risk mitigation in real-time for local field conditions. The IDM PoC is a stepping-stone towards a vision of a fully integrated digital label.

3.08.PC-We16 Using Degradation Kinetics to Improve Our Understanding of Substance Behaviour to Support Regulatory Assessments

Claire Anderson and James Hingston, HSE, Chemical Regulation Division, United Kingdom

For over a decade, regulatory scientists across Europe have collaborated to develop and utilise a harmonised approach to consider the degradation of parent compounds and breakdown products. Currently the main purpose of kinetic assessment is to produce key regulatory endpoints (DT₅₀, DT₉₀, formation fraction) for the use in environmental risk assessments or for comparison against trigger values in hazard-based classification systems. At the same time, there has been an increasing requirement to consider other behaviour observed in laboratory studies (for example non-extractable residues and stereoisomerism). Approaches are developing to support the interpretation of OECD laboratory studies but can vary across the regulatory regimes for pesticides, biocides, and general chemical under REACH. Whilst the new approaches look promising the practical implementation of the schemes into standard laboratory testing programs remains uncertain. In the past decade, our collective applied knowledge and understanding of degradation kinetics in various regulatory regimes have increased and kinetic analysis procedures and associated easy-to-use tools have been improved to the extent that there is now an opportunity to extend the standard kinetic approach to consider other observed chemical behaviours (where mass measurements are taken). With adaptations to the conceptual model, valuable insights could be gained to behaviours other than dissipation and/or degradation in environmental matrices. This insight can provide evidence to support refinements to produce more realistic regulatory risk assessments or better inform decisions on substance persistence. Additionally, these developments may potentially negate the need to conduct much more complex laboratory methodologies or decision-making frameworks in some circumstances. Case studies considering issues around handling non-extractable residues and stereoisomers are presented alongside conceptual models illustrating how data sets from standard OECD simulation studies could be analysed to provide this extra information and how it may help inform future regulatory assessments.

3.08.PC-We17 Improving and Implementing Passive Sampling Techniques to Monitor Pesticides in Rivers

Naomi Reymond¹, Vick Glanzmann², Nicolas Estoppey² and Céline Weyermann², (1)University of Lausanne, Lausanne, Switzerland, (2)University of Lausanne, Switzerland

Active sampling, e.g. with an autosampler, is usually the method of choice to monitor pesticides in water streams. However, it requires specific and costly infrastructure (security, electricity). Passive sampling can be a good alternative or a complementary approach to monitor pesticides in diverse locations. However, the hydrodynamic conditions influence polar passive sampling and thus, need to be taken into account to obtain time-weighted average concentration over the sampling period. The mass transfer coefficient of the water boundary layer (k_w) is a key parameter that is mainly dependant of the water velocity. Determining k_w for laboratory calibration and field exposure will improve the understanding of the uptake process for polar compounds and thus the reliability of the results obtained by passive sampling. This presentation will discuss the calibration of polar samplers and the field application of a dual device comprised of non-polar and polar samplers. Experiments were done in a 4-channel system at four different water velocities and two temperatures. In a preliminary experiment, alabaster plates were deployed in a home-made Chemcatcher housing to determine k_w based on the mass loss of CaSO₄. Silicone disks were spiked with performance reference compounds (PRC) and deployed in the same conditions as the alabaster plates. Preliminary experiments demonstrated that PRC-spiked silicones can be used to determine in-situ k_w . Then, the polar samplers (Chemcatcher) were calibrated in the channel system to determine the sampling rates (R_s) for various pesticides. A relationship was established between R_s and k_w , allowing the calculation of in-situ time-weighted average (twa) concentration of the contaminants in water streams. This method was implemented in the field (two rivers) to test its feasibility. To do this, the non-polar and the polar samplers were co-deployed in a dual device (two weeks exposure). The non-polar sampler allows determining in-situ k_w , and the polar sampler accumulates the analytes. The practical aspects of the method were approved in the field.

3.08.PC-We18 Factors Affecting Spring Pesticide Spray Operations in Central Sweden: Towards Refining the FOCUSsw D1 Scenario Pesticide Application Timing

Gregory Hughes¹, Neil Mackay², Liz Whitworth³, Katarina Kyllmar⁴, Nicholas Jarvis⁴ and Kristin Piikki⁴, (1)Cambridge Environmental Assessments, United Kingdom, (2)FMC Corporation, United Kingdom, (3)RSK ADAS Ltd, United Kingdom, (4)Swedish University of Agricultural Sciences, Sweden

Determining appropriate pesticide application windows and dates of application is an important component of pesticide exposure modelling and can have a marked impact on the outcome of surface water (SW) risk assessments, especially where these windows are on the fringe of the drainflow period. The current FOCUSsw pesticide application timer (PAT), considers patterns of rainfall to define a realistic worst-case application date. In certain cases an application window recommended by AppDate v3.0, also lacks realism. In the real-world farmers have to consider a range of other climatic and soil condition factors when deciding the practicality to spray pesticides. For example, can they actually access the field and traffic their land with a sprayer on any given day. A review of scientific publications considering soil workability/trafficability identified a range of soil moisture as well as plastic limits of deformation that might contribute to constraining pesticide applications in the PAT to days where a sprayer could access agricultural land. Incorporation of soil moisture deficit and plastic deformation limits into the FOCUSsw D1 scenario PAT showed promise but lacked sufficient direct applicability having been defined for other soil series, regions or continents. The Swedish University of Agricultural Sciences have collected detailed field level information of field operations within their O18 research catchment for >2 decades. The soils/weather in this catchment are closely aligned with that of the D1 scenario offering a good opportunity to explore factors affecting farmer decision making regarding spray operations. This poster outlines the approach taken to modelling soil moisture using MACRO v5.2 for 3 representative soil profiles and 7 representative crops assigned to each field in each year such that a spatio-temporal database of pesticide application dates, daily weather conditions and soil moisture metrics could be compiled. Analysis of this database allowed for the definition of factors and associated thresholds that affect the trafficking of soils and application of pesticides in central Sweden. Opportunities for use in the current and "repaired" FOCUSsw D1 scenario are discussed.

3.09 Micro- and nanoplastics: Towards the harmonized analysis for monitoring, effect studies and risk assessment (Part I)

3.09.T-01 Using Biological Traits to Identify Organisms Most at Risk of Microplastic Ingestion

Adam Porter¹, Ceri Lewis², Tamara Galloway³, Martin Solan⁴ and Jasmin Godbold⁴, (1)Biosciences, University of Exeter, Exeter, United Kingdom, (2)Biosciences, University of Exeter, Exeter, United Kingdom, (3)University of Exeter, United Kingdom, (4)University of Southampton, United Kingdom

With plastic contamination of the environment now considered a planetary boundary threat, it is pertinent for us to understand which ecosystems and organisms are most at risk so as to best conserve our environment for the future. With levels of marine plastic contamination predicted to increase 50 fold by the year 2100 the seabed is acknowledged as one of the areas of great concern as ninety-nine percent of ocean plastic is predicted to sink to the seabed. Benthic sampling for microplastic contamination is under-represented in the literature due to the cost and equipment required to sample the benthic realm across the globe and the difficulties experienced in processing these samples. Hence, an alternative approach is urgently required to assess the potential impact of microplastics on this ecosystem. Our understanding of the impact of plastic contamination in these seafloor environments is paramount in elucidating the threat microplastics play to marine ecosystems. Given the challenges of monitoring the benthos, a organism focussed framework to assess uptake and risk of uptake of microplastics might be more appropriate. Traits based approaches offer one such framework. Here we test the hypothesis that biological traits can be used to assess the risk to benthic species and habitats from microplastics pollution. Traits can help disentangle interspecies differences and instead allow the prediction of the effects microplastics may exert at an individual to ecosystem level. We hope identifying species at higher risk from ingesting or interacting with microplastics will in turn, enable the field to undertake more targeted laboratory exposures and environmental sampling programs to investigate “at risk” species and create evidence for change. We addressed this hypothesis using a global meta analysis based on 1471 primary research articles returning 74 articles for final analysis; identifying 285 benthic associated species and over 17000 individuals who have been recorded to ingest microplastic. We present to what extent species traits (and other factors) confer vulnerability to microplastic ingestion, demonstrate organismal selectivity of plastic particulates and identify species groups that require further investigation in the hope that this will provide a roadmap for further research.

3.09.T-02 Systematic Development of Extraction Methods for Quantitative Microplastic Analysis in Soil Using Metal-Doped Plastics

Alissa Tophinke¹, Urs Baier², Akshay Joshi² and Denise M Mitrano³, (1)Zurich University of Applied Sciences, Switzerland, (2)Zurich University of Applied Sciences (ZHAW), Switzerland, (3)Environmental Systems Science, ETH Zurich, Zurich, Switzerland

Monitoring microplastics (MP) in soil is crucial, not only to assess current exposure but also to evaluate possible mitigation measures. However, there are no standard methods for analyzing MP in soil - a very heterogeneous matrix that includes various inorganic and organic components. The plethora of approaches currently suggested in literature typically follows the pattern of 1. sampling 2. extraction and 3. detection and chemical identification. Previous studies overlooked evaluating the efficiency of such extraction methods on the dependence of sample content. Therefore, we focus explicitly on validating extraction methods to isolate MP from complex soil matrices by systematically investigating specific subgroups (sand, silt, clay, non-lignified and lignified biomass). To improve sample throughput when assessing extraction procedure(s) for individual or multi-component systems, MP with a passive inorganic tracer (Indium, 0.2% w/w) were used. Due to the selectivity of the metal tracer, the recovery rate of MPs from spiked samples could be quantitatively assessed using ICP-MS. Extraction procedures examined here include approaches that have been published in the literature and were complemented with new and extended concepts, including biotechnological advances for the degradation of lignocellulosic biomass. This covers density and lipophilic separation (for sand/silt), filtration through stainless-steel filters (for clay particles), Fenton's reaction (for non-lignified biomass) and a novel radical-enzyme treatment using enzymes from an anaerobic fungus strain (*Neocallimastix frontalis*), isolated from feces of Gaemse (for lignified biomass). Based on the results of the individual subgroups, sample-specific extraction chains were designed for lab-produced and standardized soil mixtures. The overall goal was to select a suitable extraction chain based on defined characteristics of the soil sample in question. Finally, a Nile Red staining protocol was developed to assess how appropriate these extraction chains would work for non-metal-doped MPs, which requires a filter with minimal background residues for chemical identification using e.g. FTIR-spectroscopy. This allows a distinction between the number of residues in brightfield mode from MPs counted in fluorescence mode. These systematically developed methods thus open new perspectives on soil microplastic analysis and are a step towards further harmonization of extraction protocols in solid matrices.

3.09.T-03 Towards Reproducible Microplastic Quantification: Advanced Automation of Raman Microscopy Enhanced by Machine Learning

Dieter Fischer¹, Kristina Enders¹, Robin Lenz¹, Franziska Fischer¹, Elisavet Kanaki¹, Lucie Marx², Benedikt Hufnagl³, Lukas Wander³ and Hans Lohninger⁴, (1)Leibniz Institute of Polymer Research Dresden, Germany, (2)University of Applied Sciences Dresden, Germany, (3)Purency GmbH, Austria, (4)Vienna University of Technology, Austria

Microplastic (MP) analysis is a complex, multi-step process that includes sampling, sample treatment, measurement and data analysis. For each step, a multitude of protocols has been developed, but mandatory standards do not yet exist. Thus, comparability of results is an issue, even if the same methods are used. Result deviations can occur at each point in the process, but to ensure precision and accuracy, it is necessary to evaluate the contribution of each step. Here, we investigate measurement and data analysis. For the measurement, we focus on a combination of optical particle detection and Raman microspectroscopy. We compare the MP quantification in riverine surface water (particle sizes > 50 µm) and aquatic reference samples (particle sizes

> 10 µm) obtained with the software tools ParticleScout, which is commercially available, and GEPARD, which is an open source program developed at the IPF Dresden. Both tools allow a highly automated analysis. ParticleScout as the proprietary software of the Raman microscope manufacturer WITec fully utilizes the instrument's capabilities, which results in optimized analysis speed, precision and ease of use. The GNU GPL-licensed GEPARD can be adapted to a broader range of instruments. Furthermore, it provides a unique annotation module for correcting inaccuracies in the particle detection. To illustrate the result variations that occur when measuring the same sample with different settings, we compare the results obtained by varying the software, the Raman parameters and the type of Raman instrument. For the analysis of the Raman spectra, a common method is an automated library search that uses comparison algorithms, such as the Pearson correlation coefficient, to assign the spectrum with the best match. This is sensitive to effects such as fluorescence or a poor signal to noise ratio. Especially single component library searches, which are suitable for fast analyses and highly automated workflows, may misidentify spectra that contain bands of more than one component. Hence, the result often requires a manual follow-up control, which is time-consuming and prone to introducing human bias. As an alternative, we present first results for a machine learning-based approach for the analysis of Raman spectra. In a proof of concept, we train a model to identify several of the most common polymer types and compare its performance to the routinely used spectra analysis on the same samples.

3.09.T-04 Evidence of Underestimation in Microplastic Research: A Meta-Analysis of Recovery Rate Studies

Chloe Way¹, Malcolm Hudson², Ian Williams² and John Langley², (1)Environmental Science, University of Southampton, Southampton, United Kingdom, (2)University of Southampton, United Kingdom

Society is increasingly interested in the levels of microplastics in the environment and the possible associated risks. The success of the research is dependent on how accurate and reliable the methods are when isolating microplastics from an environmental matrix. However, complicated, multi-staged methods are now being developed at an increasingly fast rate to combat the discovery of microplastics in new complex media. As a way of validation, these new methods should be subject to a recovery rate study. This involves 'spiking' the study matrix with known amounts of microplastics, running the method in question and calculating the amount of microplastics recovered. However, an issue in the study of microplastics is that this type of method validation is rarely undertaken. Here, 71 recovery rate studies were pooled for a meta-analysis. Sediment was found to be the most-studied environmental medium and saline solutions were the most frequently used reagent to isolate the microplastics. Polyethylene and polystyrene were most commonly used as spiking polymers, which is representative to highest polluting microplastics in the environment. The highest recovery rates were found with plant material, excrement, and whole organisms (>88%) and lowest recoveries from soil, fishmeal and water (58-71%). We have provided what we believe to be the first (to our knowledge) indication for an approximate general underestimation of environmental microplastics of 14%, based on the studies we reviewed. Furthermore, to improve the current lack of standardisation in microplastic research we recommend improvements in the use and quality of reporting in recovery rate studies.

3.09.T-05 Production of Micro and Nanoplastic Reference Materials

Elena Martinez-Frances¹, Anastasia Georgantzopoulou², Ralf Kaegi³, Marie-Louise Tambo Magni⁴, Craig McKenzie⁴, Jon Eigill Johansen⁴, Luca Nizzetto⁵, Rachel Hurley⁶, Nina Buenaventura², Amy Lusher⁷, Bert Van Bavel⁵ and Svetlana Pakhomova¹, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)NIVA - Norwegian Institute for Water Research, Norway, (3)Swiss Federal Institute of Aquatic Science and Technology (EAWAG), Switzerland, (4)Chiron AS, Norway, (5)NIVA, Norway, (6)Norwegian Institute for water research, Norway, (7)Norwegian Institute of Water Research, Norway

The validation of analytical methods for the identification and quantification of micro and nanoplastics in environmental matrices is hindered by a lack of standard reference materials (SRM). These materials are required for the harmonisation of analytical methods and the generation of comparable and reliable data. As a result, uncertainties associated with the measurements from individual laboratories can occur due to contamination, over-estimation, and under-estimation of nano and microplastics from environmental samples affecting the comparison and interpretation of analytical data from different laboratories. Until now, the Norwegian Institute for Water Research (NIVA) has focused on making reference materials (RMs) in the microscale, i.e., from 50 µm and up to 1 mm of the following polymer types: polyvinyl chloride (PVC), polyethylene (PE), polyethylene terephthalate (PET), polystyrene (PS), as well as polymer mixtures, in the form of effervescent soda tablets. These RMs have been used in inter-laboratory comparison studies worldwide as well as in microplastic recovery tests in pyrolysis gas chromatography mass spectrometry (Pyr-GC/MS). The RMs have been analysed by different laboratories using different techniques, including light microscopy, micro-Fourier transform infrared spectroscopy (µFTIR), Raman and Pyr-GC/MS. The next step in generating relevant RMs is to focus attention on the size fractions below < 50 µm. This is of importance as the detection of small particles will allow the generation of data relevant e.g. for the impact of nano and microplastics on biota. These materials will be generated by cryo milling and size fractionation and will be characterised by several techniques. The materials will be made available through the NORMAN network and the EU project EUROQCHARM.

3.09 Micro- and nanoplastics: Towards the harmonized analysis for monitoring, effect studies and risk assessment (Part II)

3.09.T-06 Raman Microspectroscopy-Based Analysis of Micro- and Nanoplastics: Ready for Harmonization and Standardization?

Natalia P. Ivleva, Technical University of Munich, Germany

Microplastics (MPs) and nanoplastics (NPLs) are found in the environment all around the globe as well as in drinking water and food, raising concerns about their impacts on the environment and human health. To adequately address these issues, reliable

information on their ambient concentrations is needed. Here, vibrational spectroscopy methods which allow for the chemical identification and quantification of plastic particles, providing information on the particle number, size/size distribution, and shape can be applied. The size range is determined by the detection limit of the method, i.e., 1 μm or even below (down to approx. 300 nm) for Raman microspectroscopy (RM). Thus, RM is suitable for the analysis of both MPs and (partially) NPLs. Since a very high number of MP particles has to be measured in order to achieve representative results, automation is necessary. Therefore, we introduced open source program *TUM-ParticleTyper* (doi.org/10.1371/journal.pone.02347), which enables the detection, quantification, and morphological characterization of fragments, including particles and fibers in images from optical microscopy. It can be used to randomly select targets for subsequent RM analysis of up to 7000 particles/fibers on the entire filter. For the analysis of fragments down to 1 μm , we propose to choose windows for the subsampling randomly, and to apply a bootstrap method to provide an error quantification with confidence intervals from the available window data (doi.org/10.1007/s00216-021-03326-3). To enable the representative analysis of NPLs, we developed the online coupling of field-flow fractionation (FFF) with RM (doi.org/10.1021/acs.analchem.9b05336). The FFF system is used for the separation of particles, while chemical identification is performed by RM. The online detection in flow cell is enabled by utilizing an optical tweezer-based particle retention. The online coupling has been realized for asymmetric flow FFF (AF4) and centrifugal FFF (CF3) and validated for the size range of 100 nm – 5 μm and for different polymer and inorganic materials. Thus, RM can be efficiently applied for the reliable and representative MP analysis in the entire size range (down to 1 μm). Here, not only harmonization (doi.org/10.1007/s00216-021-03498-y), but also standardization is in progress. The RM-based analysis of NPLs will, however, require further development and validation of the procedure, before the steps towards harmonization and standardization can follow.

3.09.T-08 Reproducible Analytical Pipelines (RAPs) in Environmental Plastics Analysis: First Outputs From the EU EUORqCHARM Project

Stefano Aliani¹, Amy Lusher², Sebastian Primpke³, Bavo De Witte⁴, Vladimir Nikiforov⁵, Jakob Strand⁶ and Bert Van Bavel⁷, (1)Section of Lerici, CNR ISMAR, Lerici, Italy, (2)Norwegian Institute of Water Research, Norway, (3)Alfred Wegener Institute, Germany, (4)Flanders Research Institute for Agriculture, Fisheries and Food (ILVO), Belgium, (5)NILU - Norwegian Institute for Air Research, Russian Federation, (6)Aarhus Universitet, Denmark, (7)NIVA, Norway

Plastic pollution has become a global environmental and societal concern in recent years. Numerous protocols have been developed to monitor plastic debris, but these are rarely comparable. This has hindered gathering of knowledge regarding pollution sources, development of monitoring programmes and risk assessments and implementation of mitigation measures. To develop long-term solutions to reduce plastic pollution, it is essential to establish methodologies that are harmonised, or at least interoperable. EUORqCHARM addresses this by critically reviewing state-of-the-art analytical methods. The number of articles published in the scientific literature about plastic monitoring methods has increased exponentially in recent decades and scientists face a huge amount of scientific literature when designing studies and monitoring programs about litter in the environment. Review articles are a solution to reduce this amount to a digestible summary. Traditional reviews based upon readers experience may lack rigorously defined criteria to identify and select the vast number of studies in an area and two different authors may reach different conclusions depending on the chosen articles. Systematic reviews are used to quickly and accurately identify scientific discoveries and to mitigate the biases often found in traditional review. A Systematic Review is a research summary that uses a structured, reproducible approach, often supplemented by a meta- analysis. It has been carried out and matrix- and size-adapted methods have been highlighted, which may eventually be incorporated into plastic monitoring programmes. Harmonisation for large scale monitoring requires flexibility, comparability and reliability, therefore Reproducible Analytical Pipelines (RAP) are proposed based upon Systematic Review data, resulting in a catalogue of RAP procedures for nano-, micro- and macro-plastics for sediments, water, biota and air target matrices. Each RAP is validated in terms of Technology Readiness Level and SWOT analysis.

3.09.T-09 Hierarchical Analysis for Microplastic Classification Applying Fourier Transform Infrared Imaging System

Vitor Hugo da Silva¹, Jose Amigo² and Jakob Strand¹, (1)Ecoscience, Aarhus Universitet, Denmark, (2)University of Basque Country UPV/EHU, Spain

Microplastics (MPs) are defined as microscopic plastic particles in the range of 1 μm - 5 mm. These particles are recognized as emerging pollutants that are broadly present in the environment. Although this emerging pollutant needs to be addressed, the field is still relatively young, and robust standardized analytical approaches for sampling, treatment, and analysis are still in development. This work aims to develop an analytical method for the classification of MPs using Fourier Transform Infrared imaging system (?-FTIR) and hierarchical analysis (HA). Principal Component Analysis (PCA), Soft Independent Modelling of Class Analogy (SIMCA) and Partial Least Squares Discriminant Analysis (PLS-DA) models were evaluated in order to retrieve the three major information of ?-FTIR imaging measurements (Cary 620 FTIR microscope from Agilent Technologies) for MP analysis: background (membrane), MPs (target information) and Natural Matter (interfering particles, which often occur despite sample processing). This strategy was evaluated to classify the most common polymers produced worldwide (PE, PET, PMMA, PVC, PC, PUR, PA, PS, PP, ABS and PBT). Statistic models assessment were realized using the misclassification error, specificity and sensibility for cross-validation and prediction steps. PCA successfully selected the region of interest by removing any pixels not related to the particles in the image. Both SIMCA and PLS-DA showed great average sensitivity ($S_n \approx 1$) and specificity ($S_p \approx 1$) for sorting natural matter and discriminating the polymers, respectively. As for misclassification error, an average of 3% and 0.2% were obtained for SIMCA and PLS-DA, respectively. The hyperspectral images were also analyzed to quantify particle abundance and size automatically. This approach was validated and could classify particles tested on a sample with a mixture of MPs spiked with natural matter (cellulose and protein of different kinds). The proposed method demonstrated a

fast and efficient automated approach for microplastic polymer characterization, abundance numeration and size distribution. Moreover, a more detailed description of the particle was provided using the spatial information of the image to determine the size of MP particles and their frequency. In addition, HA is faster than the traditional library searching method, with results obtained in seconds once the models have been developed, improving the MPs throughput analysis.

3.09.T-10 Microplastics in Waste Water Treatment Plants: Monthly Analysis With FTIR and Py-Gc/Ms and Methodological Improvements

Lisa Roscher¹, Maurits Halbach², Minh Trang Nguyen³, Martin Hebel⁴, Franziska Lushtinetz⁵, Barbara Scholz-Böttcher⁶, Sebastian Primpke¹ and Gunnar Gerds⁷, (1)Alfred Wegener Institute, Germany, (2)Carl-von-Ossietzky University Oldenburg, Germany, (3)Leesu - Enpc, France, (4)hanseWasser Bremen GmbH, Germany, (5)KASSELWASSER, Germany, (6)ICBM, Carl-von-Ossietzky Universitaet Oldenburg, Germany, (7)Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Germany

Microplastics (MP) were shown to be present in various environments around the world. In order to better understand distribution patterns and to provide a solid basis for risk assessments of this organic pollutant, comprehensive datasets on MP concentrations and chemical compositions are needed. This study focussed on the effluents of two German wastewater treatment plants (WWTP) and investigated the temporal input of MP into the receiving river systems by performing a year-long sampling campaign with monthly sampling events. MP item data (minimum size: 11 µm) were generated using Fourier Transform Infrared (FTIR) spectroscopy, under the application of an improved polymer database. The database adaptation allowed for an improved data quality, as it counteracted matrix interferences due to residual plant material on measurement filters. Beside item data, complementary MP mass data were gained by the application of pyrolysis gas chromatography-mass spectrometry (Py-GC/MS) (for one WWTP). Both item and mass data showed homogeneous polymer compositions over the sampling year, generally dominated by polyolefins. Elevated MP item and mass concentrations occurred during winter months, and were accompanied by either heavy rainfall (resulting in increased discharge), total organic carbon or elevated turbidity values. These findings underline the necessity for the integration of background parameters in MP monitoring studies. Finally, by providing monthly data over one year on MP masses and items, this work contributes to the current knowledge on temporal MP dynamics in WWTP effluents, and can therefore be a useful baseline for future monitoring studies.

3.09 Micro- and nanoplastics: Towards the harmonized analysis for monitoring, effect studies and risk assessment (Part III)

3.09.T-11 Development of an Open-Source Hyperspectral Database and Model for Microplastics Classification and Comparison to Nile Red Staining

Andrea Faltynkova¹, Win Cowger², Martin Wagner³ and Geir Johnsen³, (1)Biology, Norwegian university of science and technology, Trondheim, Norway, (2)Moore institute for plastic pollution research, United States, (3)Norwegian University of Science and Technology, Norway

Microplastics (MP) analysis is time-consuming, which limits our ability to monitor and respond to plastic pollution. Hyperspectral imaging is a rapid spectroscopic technique that can be used to image relatively larger surface areas than µFT-IR and Raman imaging systems. In this work, we develop a database and classification model for four polymer types (PP, PE, PET, PS) based on pristine, consumer product sourced and environmentally weathered plastics. A SIMCA chemometric model is used to classify hyperspectral images of spiked microplastic samples on glass fiber filters. Model performance parameters vary based on polymer type; however, specificity, sensitivity and accuracy are all greater than 85%. The quantification of MP sizes (area, Feret diameter, perimeter, circularity) is determined in parallel by HSI and Nile red staining with fluorescence microscopy to assess the performance of HSI. MP < 150 µm Feret diameter are not consistently detected by HSI when compared with results from Nile red staining; however, estimates for Feret diameter are consistent with Nile red staining for MP > 500 µm. HSI is shown to be a rapid method to accurately identify MP above 500 µm. With a simple user-friendly interface on an open-source application, this MP analysis workflow minimizes the need for expertise in spectroscopic methods enabling more researchers to rapidly carry out MP analysis. The workflow for analyzing hyperspectral images is open source and will be integrated into OpenSpecy, an existing database and analysis tool for MP spectral analysis. HSI could be a key technology for environmental monitoring frameworks where rapid imaging (< 30 seconds per sample) and analysis of multiple samples is required, however MP size ranges of interest must be above the limit of detection for the hyperspectral instrument being used.

3.09.T-12 Detection and Identification of Microplastics in Biota Using Nile Red and Machine Learning: Validation of an Innovative, Cost-Effective Approach

Nelle Siele Meyers, MSc¹, Bavo De Witte², Gert Everaert³, Kris Hostens² and Colin Janssen⁴, (1)ILVO, VLIZ, Belgium, (2)Flanders Research Institute for Agriculture, Fisheries and Food (ILVO), Belgium, (3)Flanders Marine Institute, Belgium, (4)University of Ghent, Belgium

Plastic pollution has become one of the most ubiquitous threats the oceans are facing nowadays. Microplastics (MPs) are of special concern as it has been shown these are ingested by a wide range of marine species from different trophic levels. However, the environmental implications of MPs ingestion, coupled to the toxicological relevance of different MP polymers and their chemical composition, remain poorly understood. This highlights the need for standardized, cost- and time-effective monitoring procedures to accurately and routinely determine the abundance, composition and distribution of MPs in the marine environment, to allow for effective management strategies. We developed an innovative approach for MP analysis in biota, thereby combining the advantages of both high-throughput screening and automation. We evaluated the method in mussel and different fish

gastrointestinal tracts (GIT) samples. The pretreatment involved a two-step digestion (10% KOH and 15% H₂O₂) at 50°C, with a stainless steel filtration step in between and an optional density separation step (NaI) to remove sediment, followed by filtration over a PTFE-filter and staining with the fluorescent dye Nile red (1 µg/ml acetone). MP detection and identification of the polymer types was done using two machine learning decision models. The first model predicted with high accuracy whether a particle was plastic or of natural origin. The second model allowed to identify the MP polymer type on the base of RGB colour data, which are extracted from Nile red-stained MPs, photographed through a fluorescence microscope under blue, green and UV filters. The efficiency and suitability of our approach was validated by spiking six MP types into the mussel and fish GITs, each one varying in the combination of polymer type (PAN, PET, PP, PS and PVC), size (250 – 1000 µm) and shape (particle/fibre). The validation took into account the accuracy, precision, limits of detection and quantification, selectivity, specificity, and robustness. This unique approach of high-throughput screening and machine learning automation, proved to be promising for the cost- and time-effective routine analysis of MPs in mussel and fish GITs in a simple, yet reliable way.

3.09.T-13 Characterization of Micro- and Nanoplastic Exposure in Human Tissues Using an Exposomic Framework

Anna Robuck¹, Zoe Coates Fuentes¹, Brooklynn McNeil¹, Mariona Bustamante², Virissa Lenters³, Martine Vrijheid², Tim Nawrot⁴, Roel Vermeulen⁵ and Douglas Walker¹, (1)Icahn School of Medicine at Mount Sinai, United States, (2)Barcelona Institute for Global Health, Spain, (3)Universitair Medisch Centrum Utrecht, Netherlands, (4)Hasselt University, Belgium, (5)University of Utrecht, Netherlands

Despite rapid advances in our understanding of micro- and nanoplastics (MNPs) in environmental matrices, significant data gaps hinder our understanding of MNP exposure in humans. Studies involving small sample sets investigating specific tissues have thus far established the presence of MNPs in human feces and placenta^{1,2}. Further work is required to more fully understand MNP exposure across a range of human tissues to deduce associated health outcomes. However, this goal is hindered by analytical challenges associated with the heterogenous and complex nature of MNPs. Most environmental studies of MNPs focus on a few candidate polymers or chemicals that capture only a small fraction of MNP complexity. To overcome these and other limitations we have developed an untargeted HRMS analytical framework to characterize known and unknown MNPs, their monomers and additives, and related exposure biomarkers and biological response. This analytical framework combines 1) pyrolysis (GC) gas-chromatography with HRMS (Pyr-HRMS) to characterize MNP levels, 2) alkaline-assisted hydrolysis with liquid chromatography HRMS (AAH-HRMS) to measure particle monomers and additives, and 3) untargeted liquid chromatography with HRMS (LC-HRMS) to characterize the metabolome for the presence of MNP constituents and additives and biological response profiles. This framework was applied to placenta samples, virgin plastics, and weathered plastics to validate our approach. Pyr-HRMS detected a range of common MNP types in placenta tissue, including PS, PE and PMMA which were detected at a range of concentrations from 10-2650 ng/g. LC-HRMS revealed that free and particle-bound small molecule profiles were significantly different between virgin and weathered particles. Results to date validate the application of this framework to contemporaneously characterize polymers, free monomers, additives, and biomarkers of disease in human tissues; this framework provides an important toolset to expand our understanding of MNP exposure in humans and other biological receptors.

3.09.T-14 Quantification of NanoPlastics Association With Cells: Advances in Single-Cell Inductively Coupled Plasma Time of Flight Mass Spectrometry (sc-ICP-TOFMS) for Fast and Sensitive Detection of Metal Doped NanoPlastics

Lyndsey Hendriks¹, Tina Buerki-Thurnherr², Yvette Hannig², Olga Borovinskaya³ and Denise M Mitrano⁴, (1)TOFWERK, Thun, Switzerland, (2)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (3)TOFWERK, Switzerland, (4)Environmental Systems Science, ETH Zurich, Zurich, Switzerland

Plastic pollution is a growing environmental issue and has triggered a need for appropriate hazard assessment strategies. Particulate plastic is present in the environment along a size continuum (macroplastics, microplastics and nanoplastics), and different size classes will dominate different fate and transport routes, as well as possibilities for biological interactions. Nano-sized plastics may pass through biological barriers and enter cells. Unfortunately, analytical tools for sensitive and quantitative detection of nano-sized plastics in cells and tissues are largely lacking. Indeed, the assessment of nanoplastics association with cells is more analytically challenging than other metal-based nanomaterials (e.g. engineered nanomaterials) considering that (nano)plastics chemical composition is more difficult to distinguish amidst high concentrations of organic matter with lower analytical detection limits. Therefore, assessing risks of (nano)plastic pollution demands creativity and requires innovative analytical methods, even in a laboratory context. An elegant approach is to dope nanoplastics with an inorganic tracer, thereby allowing for a more effective detection and tracking in complex matrices using common analytical techniques appropriate for metal analysis, such as ICP-MS. In this work, we synthesized nanoplastics particles with an embedded inorganic fingerprint (Pd) and used them to investigate the association of nanoplastics with human cells grown in culture using single-cell ICP-TOFMS. The simultaneous elemental detection of ICP-TOFMS enables the measurement of the full mass spectrum, thereby allowing the simultaneous detection of a cell elemental “fingerprint” together with the metal tag of the nanoplastics particles. Consequently, this method offers a direct quantitative measure of the nanoparticle-cell association. The potential for this approach is highlighted by analysing human cells (THP1 monocytes and A549 lung epithelial cells) exposed to low concentrations of Pd-doped nanoplastics (0, 5 and 50 mg/L; 24h). Additional challenges and improvements related to sample preparation, sample introduction and transport efficiency were also overcome to develop a robust and reliable method. Collectively, the study presents a strong foundation for a powerful analytical method to explore nanoplastics exposures in a variety of conditions, ranging from ecotoxicological studies to human health related questions.

3.09 Micro- and nanoplastics: Towards the harmonized analysis for monitoring, effect studies and risk assessment (Virtual Only)

3.09.V-01 Arctic Seabirds: Tools to Support Spatial, Temporal and Source Monitoring of Litter and Microplastics Across the Pan-Arctic

Jennifer F Provencher¹, Amy Lusher², Julia Baak³, Liz Pijogge⁴, Max Liboiron⁵, Katrin Vorkamp⁶, Jannie Fries Linnebjerg⁷, Mark Mallory⁸, Maria Gavrilov⁹, Geir Gabrielsen¹⁰, Ingeborg Hallanger¹⁰, Bonnie Hamilton¹¹, Madelaine Bourdages¹² and Sjurdur Hammer¹³, (1)Environment and Climate Change Canada, Canada, (2)Norwegian Institute of Water Research, Norway, (3)McGill University, Canada, (4)Nunatsiavut Government, Canada, (5)Memorial University of Newfoundland, Canada, (6)Aarhus University, Denmark, (7)Aarhus Universitet, Denmark, (8)Acadia University, Canada, (9)Arctic and Antarctic Research Institute, Russian Federation, (10)Norwegian Polar Institute, Norway, (11)University of Toronto, Canada, (12)Carleton University, Canada, (13)Faroese Environment Agency, Faroe Islands

Plastic pollution has been reported to affect birds in the Arctic over the last few decades. There are strengths and limitations to monitoring litter and microplastics using Arctic birds. Spatial and temporal trends of plastic pollution can be based on northern fulmars (*Fulmarus glacialis*) as an environmental indicator. Similarly, the use of gulls and skuas across the Arctic can be used to track sources of litter and microplastics in the region as they regurgitate pellets that include indigestible material that has been recently consumed. We also recommend the monitoring of plastic additives in consumed species and tissues, preferably coordinated with other contaminant monitoring, to inform questions related to human health. We recommend that future programs consider a range of monitoring objectives, and consider monitoring birds as part of the suite of tools for monitoring plastic chemical additives and effects, as well as understanding the source and surveillance of litter and microplastics. Local and Indigenous researchers and community representatives are critical to decision-making processes for priority species and research questions in their areas, and should be involved in every step of the research. An important consideration is the ethics of reporting and publishing contamination results for wild food species, even if the results are null or low, as Arctic birds are an important food for many communities across the Arctic region.

3.09.V-02 Assessment of Photocatalytic Degradation of Engineered Polystyrene Nanoplastics (PS-NPs) in the Aqueous Medium Using Titanium Dioxide (TiO₂) Nanoparticles

Ahmad Morid Khurami and **Hatice Şengül**, Hacettepe University, Turkey

Natural and engineered NPs are emerging pollutants that pose risks to human and ecosystem health due to their persistent nature and bioaccumulation potential. Traditional water and wastewater treatment methods may treat NPs; however, these methods cause secondary pollution by transferring the pollutants to other mediums in concentrated forms. Photocatalytic degradation using TiO₂ nanoparticles is a green method that treats organic pollutants in water by mineralization through direct oxidation and formation of free radicals. In this study, anatase form of TiO₂ (10-20 nm, 80 m²/gr) and a mixture of 80/20% anatase/rutile form of TiO₂ (18 nm, 60-90 m²/gr) nanoparticles were used for degradation of engineered PS-NPs with an average size of 22 nm as a model for NP pollution in water. Preliminary results indicated that the mixture of anatase/rutile form of TiO₂ had greater treatment efficiency resulting in up to 90% degradation and mineralization of PS-NPs under optimum operating parameters: 96 mg/L dose for TiO₂, water pH of 6.35, and irradiation time of 6 hours under UVC from 4.5 cm distance and at 300 rpm magnetic stirring. Initial results for potential reuse of TiO₂ nanoparticles indicated that they have high potential for reusability after five reuse cycles without recovery. High photocatalytic degradation efficiency for reuse cycles should be further investigated to be applied at commercial scale for treating NP pollution in water.

3.09.V-03 Finding Microplastics in Hyperspectral Images - a Guide Through Current Methods

Jana Weisser¹, Teresa pohl², Natalia P. Ivleva³, Thomas Hofmann⁴ and Karl Glas³, (1)Chair of Food Chemistry and Molecular Sensory Science -Technical University of Munich, Germany, (2)Technical University of Munich, Germany, (3)Technical University of Munich, Germany, (4)Chair of Food Chemistry and Molecular Sensory Science-Technical University of Munich, Germany

The identification of microplastics (MP) in vibrational spectra is challenging due to method- and sample specific variables and large datasets. Several automatization approaches have been proposed for analysis of vibrational spectra, making it an important topic in the ongoing discussion about harmonizing MP research. We here aim to provide a critical overview on the methods proposed and hint at remaining challenges [1]. A common method is to compare query spectra to a database of reference spectra. It has been shown that not only the selection of database entries but also of the metric for spectral similarity substantially influences the results. For instance, inclusion of weathered particle spectra is highly recommended [2]. Both supervised and unsupervised machine learning (ML) have been proven suitable for interpreting vibrational spectra. While unsupervised ML allows exploring the data and to extract particle spectra from larger hyperspectral images [3], supervised ML was shown to be a reliable and quick tool for assigning particle spectra to a substance class [4]. Up- and downsides of database matching, supervised and unsupervised ML are critically discussed regarding their applicability for MP research. This includes time, staff and computational resource resources, as well as a discussion of evaluation methods for the techniques proposed, including tests on real-world data. The latter is a key factor in developing harmonized and comparable methods. 1. 3.09.V-04 How to Test Weathered Microplastics of Various Sizes

Annegret Potthoff¹, Kathrin Oelschlägel², Silke Aulhorn³ and Dana Kühnel³, (1)Fraunhofer IKTS, Dresden, Germany, (2)Topas GmbH, Germany, (3)Helmholtz-Centre for Environmental Research- UFZ, Germany

Although, the number of studies focusing on potentially harmful ecotoxicological effects of microplastics has been increasing, there remains a lack of environmentally relevant data. Mostly uniform and pristine materials are used for toxicity testing. At the same time, there is an ongoing discussion about potential size-related effects, assuming that the smaller the particles, the higher the potential effects on organisms might be. In our study, we addressed two issues: (1) more environmental realism by subjecting the test polymer particles to wet weathering (UV and shaking) and (2) potential size-related effects by applying a fractionation approach subsequently to the weathering. Appropriate characterisation of applied suspensions with regard to particle size, shape and number is the key for interpretation of toxicological data. In our study we investigated three types of polymers, low density polyethylene (LDPE) and polyethylene terephthalate (PET) and a consumer product. All materials were cryo-milled down to a range of below 250 µm. To mimic the weathering of polymer particles in the aquatic environment, polymer particle suspensions were exposed to UV radiation and stirring. For comparison, the corresponding original pristine particles were used. In order to test the potential size-dependency of toxicological effects, the samples were dispersed in water and fractionated by wet sieving. We received five fractions (> 140 µm, 140 – 60 µm, 60–40 µm, 40 – 20 µm, < 20 µm), whereas their mass amount was calculated. For quantification of particle sizes and shapes, dynamic imaging techniques were applied. A further advantage of these measuring method is that particles are counted. This gives the opportunity to consider both, number and mass-based concentrations in in-vitro studies. The effect of the different fractions of weathered and unweathered polymer suspensions on the 48 h immobilisation of *Daphnia magna* was assessed subsequently. It revealed little effect of polymer type, particle size, as well as aging status on toxicity in the concentrations tested. Dose metrics were challenging, as not for all fractions the same characterisation methods were applicable. Our study demonstrated that the fractionation approach works for all types of polymer particles, artificial microplastics and realistic materials such as consumer products. Further, it is applicable independently from the weathering status of the materials.

3.09.V-05 Microplastic Pollution Around Svalbard - CTD Samples Give First Evidence of Microplastic Distribution and Pathways Within the WATER Column

Carolinn Philipp¹, France Collard², Ingeborg Hallanger² and Geir Gabrielsen², (1)Norwegian Polar Institute, Tromsø, Norway, (2)Norwegian Polar Institute, Norway

Several studies have already revealed microplastic pollution in different matrices, e.g., snow, ice, water, and sediment in the Arctic environment around Svalbard. In contrast, knowledge on the microplastic distribution and transport pathways within the water column at different depths is still lacking. To address this issue, the Norwegian Polar Institute (NP) conducted a research cruise focusing on microplastic pollution in the Barents Sea in June 2021. Among other sample types and techniques to collect ice, water, and sediment samples, a CTD casts equipped with a rosette of Niskin bottles was utilized to collect water samples at different stations (N = 5) and various depths (0 – 1,430 m). Three replicates of 30L⁻¹ at each depth per station were taken to cover a sample volume of approximately 1m⁻³ to assess valuable results on microplastic contamination in this Arctic area. The collected water samples were directly sieved (50 µm) onboard to decrease the sample volume. The sieved and rinsed samples are stored at -20°C until further processing. For a reliable evaluation of the amount and composition of considered anthropogenically synthesized particles (including fragments and fibres), µRaman spectroscopy will be utilized for further identification. Procedural blanks and other safety measures were applied and considered to control and evaluate the potential contamination through the field and working environment (incl. ship and laboratories). This study focuses on acquiring a harmonized protocol to ensure no particle loss and the avoidance of an overestimation based on secondary contamination. Furthermore, this study will give first evidence on the microplastic distribution (quantity and quality) in different water depths of the Barents Sea and the west coast of Svalbard, including the Isfjord. In accordance, this analysis will be the first outcome out of this plastic dedicated research cruise, and thus the very first hint of the actual microplastic burden in different matrices around Svalbard.

3.09.V-06 Innovative Technology for In Situ Quantification of Nano and Microplastics in Water Media

Lara Dronjak¹, Andrés Álvarez Perez², Nora Exposito Lorenzo², Joaquim Rovira², Jordi Sierra¹, David Coral², Francesc Díaz², Xavier Mateos² and Marta Schuhmacher³, (1)Universitat Rovira i Virgili, Spain, (2)University Rovira i Virgili, Spain, (3)Rovira i Virgili University, Spain

Plastic pollution is ubiquitous in the environment. Micro and nanoplastics pose a threat for the health of living organisms. Although the literature provides a wide range of analytical techniques for the identification and quantification of microplastics in environment samples until now, there is a not standardized protocols and the methodologies developed have drawbacks as time consuming, expensive and low robustness. Furthermore, for nanoplastics identification there are not practical methodologies for its application in routine analysis. Therefore, there is an urgent need for new robust automated tools for fast micro-nanoplastics identification in routine analysis for short-term decision-making. This work shows early-stage research of an innovative technology for in situ and automatic analysis of small microplastic (< 125 µm) and nanoplastics in water samples. A microfluidic chip has been computationally designed by means of COMSOL Multiphysics software considering complex processes involved in microplastics fluid dynamics. The device is working under the following principles: microfluidics to sort the micro/nanoplastics by size and concentrate the samples; staining of micro/nanoplastics with solvatochromic dye (Nile Red) and, finally, detection with fluorescence-based techniques. The fabricated device was made of poly (dimethylsiloxane) (PDMS) material since it is the most widely used silicon-based organic polymer due to its versatility and characteristics leading to very large number of applications. The fabrication of the microfluidic device was done with photolithography providing high precision and resolution. Validation of geometry of the device such as separators and focusers has been performed with PS microbeads of different size

standards. Additionally, we report on for the first time to the best of our knowledge the staining of microplastic particles using Nile Red as a dye for short time in aqueous media, never reported before. The device has been used successfully in a case study employing low-density polyethylene (LDPE) microplastics previously collected from La Pineda beach (located in Tarragona-Spain). The pellets were grounded and sieve by size, the smaller ones were selected and tested with a successfully characterization of fluorescent signals. Further research is being conducted to improve the promising performance of the fabricated device and to solve additional challenges.

3.09 Micro- and nanoplastics: Towards the harmonized analysis for monitoring, effect studies and risk assessment (Poster)

3.09.P-Mo145 The Power of Multi-Matrix Monitoring in the Pan-Arctic Region: Plastics in Water and Sediment

Amy Lusher¹, Jake Martin², Maria Granberg³, Jennifer F Provencher⁴, Max Liboiron⁵, Liz Pijogge⁶, Kerstin Magnusson³, Ingeborg Hallanger⁷, Melanie Bergmann⁸, Stefano Aliani⁹, Alessio Gomiero¹⁰, Bjørn Einar Grøsvik¹¹, Jesse Vermaire¹² and Sebastian Primpke¹³, (1)Norwegian Institute of Water Research, Norway, (2)Norwegian University of Science and Technology (NTNU), Norway, (3)IVL Swedish Environmental Research Institute, Sweden, (4)Environment and Climate Change Canada, Canada, (5)Memorial University of Newfoundland, Canada, (6)Nunatsiavut Government, Canada, (7)UiT The Arctic University of Norway, Norway, (8)Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Germany, (9)Italian National Research Council, Italy, (10)International Research Institute of Stavanger, Norway, (11)Havforskningsinstituttet/Institute of Marine Research, Norway, (12)Carleton University, Canada, (13)Alfred Wegener Institute, Germany

Assessing Arctic ecosystems for litter and plastic pollution is high on the agenda of the Arctic Council and Arctic Monitoring and Assessment Plan (AMAP) nations. Coordinated efforts by all parties will contribute to a combined knowledge of the distribution and fate of this global pollutant and aid in identifying priority areas/regions where mitigation efforts should be focused. When we focus on our knowledge of microplastics, there are increasing reports of their presence in the Arctic. Yet, efforts to track microplastics have been uncoordinated with little follow-up on the state of the ecosystem where they were initially found. Further, the data that is currently available from these environmental compartments is sporadic, collected with different methods and processed with different approaches, generating results that are not currently comparable across the Arctic region. Without baseline data that are comparable across the Arctic region - collected from water bodies and sediment - it becomes far too complicated to compile the data required by policy and researchers who want to model the movement and consequences of plastic pollution. Through this work, we have used the framework of the AMAP to illustrate how scientists, governments, and Arctic Peoples can work together to address microplastic pollution. Specifically, our focus is on linking efforts together to build an understanding of this pollutant from the local scale to the full breadth of the Arctic. To achieve this, it will be necessary to obtain data from more than one sample matrix. Quantifying microplastics in sediment and water from the same region will facilitate a three-dimensional picture of microplastics, not only as a snapshot in time, but as an ongoing process of pollution within the Arctic. By implementing systematically designed and harmonised monitoring programmes and research activities to investigations of the rivers, beaches, seas, and seafloor along a track that links our communities to the deepest parts of the Arctic Ocean we can gain the most complete picture of the spread of plastic pollution to date. We highlight the latest technical recommendations for monitoring microplastic pollution across the pan-Arctic and consider how the challenges of conducting research in the polar environment may be overcome in this endeavour. Effort must be directed toward harmonizing these approaches and validating the extent to which data can be used in combination.

3.09.P-Mo146 Accurate Microplastics Identification From <500nm to mm's : Particle Shape/Size Artefact-Free Submicron IR and Simultaneous Raman

Mustafa Kansiz¹ and Christoph Krafft², (1)Photothermal Spectroscopy Corp., United States, (2)Leibniz Institute of Photonic Technology, Germany

Whilst the scientific and even public interest in microplastics continues to see rapid growth, thanks to the explosion of research in the field, there remains several key analytical challenges, limitations, even misconceptions and misunderstandings when it comes to determining which analytical techniques are most suited for microplastics analysis. The recent development of a new approach to IR microspectroscopy, termed "Optical Photothermal Infrared (O-PTIR)" spectroscopy has demonstrated a unique ability to generate submicron IR spectra in reflection mode (that are fully compatible with FTIR transmission mode) and thus to take the best properties of Infrared microscopy and Raman, whilst leaving behind all the issues of those techniques. Furthermore, this technique is also able to generate simultaneous Raman spectroscopy from the same spot, at the same time with the same submicron IR resolution. The application of both traditional IR and Raman microscopy to MPs suffers from a number of drawbacks, some of which are intuitively obvious (such as limited IR spatial resolution of >20µm), but other issues are not, hence many a MPs analysis practitioners may be unaware of the issues at play. In fact, the IR microscopy field has been clouded with the emergence of new instrumentation types, based on direct measurements with IR QCLs operating with both widefield (camera) based detection and also rapid scanning single point detection schemes. Whether an MP analysis is conducted with a traditional FTIR instrument or the emerging direct QCL based techniques, the issues, challenges, and pitfalls are all the same. Beyond the key issue of limited spatial resolution of direct IR microspectroscopy (>20µm), is the potentially very troublesome issue of particle shape and size dependent scattering artefacts which can interfere with the spectra so severely that accurate classification is made very difficult. In this presentation we will introduce, with examples, the various types of artefacts observed, from dispersive Mie-Scattering, diffuse/specular mixtures to band saturation issues. The issues with Raman spectroscopy, though it possesses excellent (and equivalent to O-PTIR) spatial resolution at the submicro level, are quite different, with it is often being plagued by auto-fluorescence interference and poor sensitivity, necessitating longer and sometime prohibitively measurement times. Through the use of a single frequency probe beam (532nm), the wavelength dependent dispersive scattering (Mie-scattering) issues

associated with variable IR probe wavelengths (such as in FTIR and direct QCL measurements) are circumvented. Additionally, the other issues often encountered with such methods of band saturation and competing specular and diffuse reflectance are also eliminated. The end result is a series of measurements that are now no longer confounded with particle morphology (shape/size) but are only dependent on their chemistry, which is what is needed for robust and repeatable MP analysis, independent of particle shape and size.

3.09.P-Mo147 Arctic Mammals and Plastic Pollution: Monitoring Efforts Directly Relate to the Monitoring Objectives

Amy Lusher¹, Jennifer F Provencher², Liz Pijogge³, Max Liboiron⁴, Ingeborg Hallanger⁵, Katrin Vorkamp⁶, Julia Baak⁷, Bonnie Hamilton⁸, Sjurdur Hammer⁹, Maria Gavrilov¹⁰, Jesse Vermaire¹¹, Jannie Fries Linnebjerg¹², Mark Mallory¹³ and Geir Gabrielsen¹⁴, (1)Norwegian Institute of Water Research, Norway, (2)Environment and Climate Change Canada, Canada, (3)Nunatsiavut Government, Canada, (4)Memorial University of Newfoundland, Canada, (5)UiT The Arctic University of Norway, Norway, (6)Aarhus University, Denmark, (7)McGill University, Canada, (8)University of Toronto, Canada, (9)Faroe Environment Agency, Faroe Islands, (10)Arctic and Antarctic Research Institute, Russian Federation, (11)Carleton University, Canada, (12)Aarhus Universitet, Denmark, (13)Acadia University, Canada, (14)Norwegian Polar Institute, Norway

Effects monitoring is a critical component for understanding the impacts of plastic pollution on the environment. Studies on mammals are important for addressing questions related to regional food security and safety. Given the important and prominence of mammals in the diets of many communities across the Arctic, effects monitoring should focus on species that are 1) consumed, and 2) experience high levels of plastic accumulation. The currently available knowledge in the Arctic has been mostly driven by opportunistic collections, and not specifically for monitoring purposes. Monitoring of litter and microplastics in the pan-Arctic requires a multi-matrix approach which can build on existing monitoring programmes and modify methods accordingly. The AMAP monitoring guidelines suggest that mammals might not be the priority target matrix, but they may be useful as part of a suite of tools needed to better understand pollution in the Arctic. Future monitoring programs should consider a range of monitoring objectives, and consider monitoring mammals as part of the suite of tools useful for monitoring plastic chemical additives and effects, as well as understanding the source and surveillance of litter and microplastics. That said, local or regional efforts are not being discouraged; rather further research is required to considering scaling to the pan-Arctic. Using mammals to study plastic pollution requires much larger sample sizes than typically collected for consumption, or for some other research programs. Here, the benefit is that hunter-collected samples can inform studies on plastics and plastic additives in relation to species regularly consumed by humans. Such assessments could also be conducted in parallel to the monitoring of plastic additives, preferably coordinated with other contaminant monitoring programmes and potentially associated biological effects. Local and Indigenous researchers and community representatives should be part of decision-making processes for priority species and research questions in their areas. The ethics of reporting back and publishing contamination results for wild food, even if the results are null or low, is an area of crucial importance and should play a central role in monitoring projects moving forward. Tissues regularly consumed by humans should also be selected to provide information on human exposure to plastic additives via the consumption of country foods.

3.09.P-Mo148 EUROqCHARM - Assuring Reproducible, Harmonised and Quality-Controlled Assessments of Plastic Pollution

Bert Van Bavel¹, Amy Lusher², Stefano Aliani³, Jacob de Boer⁴, Ike van der Veen⁵, Francois Galgani⁶, Elena Stoica⁷, Joan Fabres⁸, Marinella Farre⁹, Vladimir Nikiforov¹⁰, Bavo De Witte¹¹, Sebastian Pimpke¹², Jakob Strand¹³, Jon Eigill Johansen¹⁴, Ralf Kaegi¹⁵, Alessandra Giorgetti¹⁶ and Corinne del Cerro¹⁷, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Norwegian Institute of Water Research, Norway, (3)Italian National Research Council, Italy, (4)VU University, Netherlands, (5)Vrije Universiteit, Amsterdam, Netherlands, (6)IFREMER, France, (7)RMRI, Romania, (8)SALT, Norway, (9)IDAEA- CSIC, Spain, (10)NILU - Norwegian Institute for Air Research, Russian Federation, (11)Flanders Research Institute for Agriculture, Fisheries and Food (ILVO), Belgium, (12)Alfred Wegener Institute, Germany, (13)Ecoscience, Aarhus Universitet, Denmark, (14)Chiron AS, Norway, (15)Swiss Federal Institute of Aquatic Science and Technology (EAWAG), Switzerland, (16)OGS, Italy, (17)AFNOR, France

Plastic pollution (macro to nano) has become a global environmental and societal concern. Numerous protocols have been developed to monitor plastic debris, but these are rarely comparable. This has hindered the gathering of knowledge regarding pollution sources, development of monitoring programs, risk assessments, and the implementation of mitigation measures. To develop long-term solutions to reduce plastic pollution, it is essential to establish harmonised methodologies. EUROqCHARM, a European Commission H2020 Coordination and Support Action (CSA) project, is addressing this by critically reviewing state-of-the-art analytical methods and validating them through an interlaboratory comparison (ILC) study. Outputs will be integrated into recommended procedures for policy, legislation and risk assessment, as well as capacity building exercises, and knowledge transfer and dissemination. The EUROqCHARM consortium consists of 15 partners, a scientific advisory board composed of international experts, and a network of more than 25 associated laboratories. EUROqCHARM recognises that harmonisation for large-scale monitoring requires flexibility, comparability and reliability. As this is a CSA, our aim is to provide a cross-Europe and international platform to validate several methods for monitoring plastic in the environment and put forward recommendations for monitoring. In more detail, we aim to identify, test and optimise monitoring approaches through quality assured and rigorously validated methods based on current state-of-the-art techniques which cover all relevant environmental matrices. EUROqCHARM is focused on harmonizing and the possibility of standardising methods and reporting formats to facilitate data comparability and meta-level analysis on regional, national and international scales. EUROqCHARM is now entering an intensive phase with the results from the systematic review of more than 3000 papers being evaluated to identify commonly used and reproducible approaches. Moving harmonization forward, the identified methods will be incorporated into the

ILC taking place in 2022. By including multiple national and international organisations, and working groups currently participating in the proposal of harmonisation and standardised methods for research and monitoring, EUROqCHARM brings these players together to merge working group ideas and facilitate a framework for urgently required procedures for monitoring and assessment of plastics in our environment.

3.09.P-Mo149 Screening of Suspected Micro(Nano)Plastics in the Barcelona Metropolitan Area

Albert Vega-Herrera¹, Marta Llorca², Xavier Borrell-Diaz¹, Cristina Villanueva³, Esteban Abad¹ and Marinella Farre⁴, (1)IDAEA-CSIC, Spain, (2)IDAEA, CSIC, Spain, (3)ISGlobal-CREAL, Spain, (4)IDAEA- CSIC, Spain

Plastics are recognised by the scientific community as an emerging risk for the environment and human health. The most important sources of plastic pollution come from industrial and anthropogenic activities (primary plastics). This plastic litter undergo continuous degradation processes (secondary plastics) generating a broad amount of microplastics (MPLs; particles size up to 5 mm) and nanoplastics (NPLs; plastic particles less than 1 µm). Main problems associated with micro(nano)plastics (MNPLs) are the lixiviate of contaminants used in their formulation, their small sizes, wide occurrence and long life in the natural environments. In addition, due to their properties, MNPLs can also enhance the transport of many organic chemical contaminants by adsorption/desorption processes, acting as a passive carriers of hydrophobic organic substances [1]. This work reports the micro and nanoplastics (MNPLs) with size ranges from 0.7 to 20 µm found in tap water samples of the Barcelona metropolitan area (BMA) collected during a sampling campaign carried out in September and October 2020. Tap water samples were collected from home pipes of volunteers distributed in the zip codes of the BMA. To identify and quantify the polymers in the samples, a suspected screening validated method based on high-performance liquid chromatography coupled to high-resolution mass spectrometry (HPLC-HRMS) using an advanced polymer chromatography column (Acquity APC XT45 1.7 µm) and atmospheric pressure photoionization (APPI) source under negative and positive conditions was used taking into account a previous method developed and validated in our research group for MNPLs in seawater compartments [1]. The acquisition was performed in full scan mode, and the subsequent tentative identification was based on the Kendrick Mass Defect analysis (KMD). The main results of the samples showed that polyethylene (PE), polypropylene (PP), polyisoprene (PI), polystyrene (PS), polybutadiene (PBD), polyamide (PA) and polydimethylsiloxanes (PDMS) were most commonly found. In particular, PE, PP and PA, while the polymers found at high concentrations were PI reaching 39 µg/L and PBD reaching 27 µg/L. A principal component analysis (PCA) was performed to assess if there are significant differences (confidence level 95%) between districts. Despite the fact that significant differences were not found among the studied area, there is a trend indicating that the samples collected at the west part of BMA presented a higher number of polymers and at higher concentrations.

3.09.P-Mo150 Monitoring Guidelines for Polymer Identification, Quality Assurance/Quality Control QA/QC and Data Reporting for Monitoring of Microplastics in the Arctic Environment

Sebastian Primpe¹, Stefano Aliani², Andy Booth³, Francois Galgani⁴, Gunnar Gerds⁵, Alessio Gomiero⁶, Tanja Kögel⁷, Amy Lusher⁸, Shreyas Patankar⁹, Jennifer F Provencher¹⁰, Chelsea Rochman¹¹, Jakob Strand¹², Barbara Scholz-Boettcher¹³ and Katrin Vorkamp¹⁴, (1)Alfred Wegener Institute, Germany, (2)Italian National Research Council, Italy, (3)Climate and Environment, SINTEF Ocean, Trondheim, Norway, (4)IFREMER, France, (5)Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Germany, (6)International Research Institute of Stavanger, Norway, (7)Havforskningsinstituttet/Institute of Marine Research, Norway, (8)Norwegian Institute of Water Research, Norway, (9)Ocean Wise Conservation Association, Canada, (10)Environment and Climate Change Canada, Canada, (11)University of Toronto, Canada, (12)Ecoscience, Aarhus Universitet, Denmark, (13)University of Oldenburg, ICBM, Germany, (14)Aarhus University, Denmark

The increasing pollution of the environment with plastics is of growing concern, also in the Arctic region. Larger plastic litter items, such as fishing gear or plastics bags, are a visible pollution issue in the environment. Their presence can have negative impact for economic factors like tourism or for recreational quality, while it further poses a threat to animals by entanglement and ingestions. In contrast, microplastics are not readily visible in most cases, but of concern for animal health and products for human consumption as accumulation in animal tissue can occur, including Arctic food items. For their analysis, these small plastic particles need a series of dedicated preparation steps, including sampling, sample extraction, clean up and advanced analysis in order to robustly identify and quantify them. Due to the small size of these microplastic particles and a variety of possible sample contamination sources, our study presents a set of general guidelines for their sampling, laboratory extraction and analysis. These guidelines outline and evaluate the different methods and tools available and include a series of recommendations. We start with a focus on general and specific quality assurance and quality control (QA/QC) measures related to microplastic sampling in different environmental matrices. Recommendations for QA/QC measures for the handling of samples in the laboratory, both on land or on ship, including an assessment on the scope and use of laboratory and procedural blanks are the second step. The final component of the study focuses on a general overview and discussion of suitable analytical tools for the identification, quantification and characterization of microplastics, considering a cost efficient and high throughput application. The recommendations proposed are anchored in the provision of mandatory data for reporting and in the generation of additional information that is of high value for scientists, stakeholders and legislators. Relevant data platforms are discussed with a view to their suitability to include Arctic data on microplastics.

3.09.P-Mo151 Current Status of the Quantification of Microplastics in Water

Susanne Belz¹, Ivana Bianchi², Caludia Cella², Hakan Emteborg³, Francesco Fumagalli⁴, Otmar Geiss⁴, Douglas Gilliland⁵, Andrea Held⁶, Ulf Jacobsson⁷, Dora Mehn⁸, Yannic Ramaye⁹, Piotr Robouch⁷, John Seghers⁷, Birgit Sokull-Kluettgen¹⁰, Rita La Spina¹¹, Elzbieta Stefaniak¹² and Joerg Stroka⁷, (1)European Commission - Joint Research Centre, Italy, (2)European

Commission, Joint Research Centre, Italy, (3)European Commission, Joint Research Centre, Belgium, (4)European Commission Joint Research Centre, Italy, (5)European Commission, Joint Research Centre / Directorate F Health, Consumers and Reference Materials, Italy, (6)European Commission - Joint Research Centre, Belgium, (7)European Commission Joint Research Centre, Belgium, (8)European Commission-Joint Research Centre, Italy, (9)European Commission - Joint Research Centre, Benin, (10)European Commission - Joint Research Centre, Italy, (11)JRC, European Commission, Joint Research Centre, Italy, (12)EC JRC, Belgium

We present here an overview of an inter-laboratory comparison (ILC) that aimed to investigate the current status of microplastic quantification in water and to support the development of microplastic reference materials. Measurement results were produced by almost 100 participating laboratories who also provided detailed technical information about the instrumental methods and experimental procedures used. The reported number and mass concentrations were evaluated in relation to the technical details provided and analysed for possible correlations. As a result, our study gives a broad picture of methods and procedures currently utilised in the measurement of microplastics in water. Sixteen different analysis techniques appeared in this ILC, but no (group of) methods could be identified that systematically seem to give results that are more consistent with the indicative ranges of expected values than others. The reported measurement data scattered around the centre values of the indicative ranges but the spread was quite large, even when looking at individual techniques. Furthermore, a great variety of experimental practices was applied, making it difficult to identify individual factors that significantly influenced the measurement outcome. Nevertheless, the outcome of this comprehensive study provides valuable input for further harmonisation and standardisation efforts towards reliable quantification of microplastics in water and other matrices.

3.09.P-Mo152 Meta-Analysis As a Tool for Combining Evidence of Micro and Nano Plastic Effects

Ana Leticia Antonio Vital¹ and Magdalena M. Mair², (1)Junior Research Group Statistical Ecotoxicology, University of Bayreuth, Bayreuth, Germany, (2)Statistical Ecotoxicology, University of Bayreuth, Bayreuth, Germany

Micro- and nanoplastic particles (MNP) are found worldwide, even in the most remote regions, from deserts to the Arctic, and the number of studies reporting adverse effects of MNPs on organisms is increasing rapidly. The scientific literature supports policymakers and stakeholders in understanding and predicting these adverse effects and establishing an environmental risk assessment for MNPs. The increasing number of publications on MNP effects on organisms covers a wide variety of test species and MNP traits: for example, MNPs in these studies differ in polymer type, size, shape, and degradation stage; they are chemically modified, weathered artificially or tested in combination with surfactants or other plastic-associated chemicals; and in some studies the tested MNPs are produced directly from plastic products. To get a better overview of the general effects of MNPs, it is necessary to aggregate all this information in a combined analysis. One means by which such a data aggregation can be achieved is the use of meta-analyses. Meta-analyses combine statistical results or effect sizes of several studies to summarise the evidence in a particular topic and are widely used for example in medical and epidemiological research. Although meta-analyses have become more broadly used in ecotoxicology in recent years as well, their use in risk assessments is still limited. We discuss the importance of meta-analyses for aggregating evidence in ecotoxicological risk assessment in general and argue that datasets produced by systematic data extractions from the literature are a valuable resource for predictive modelling approaches. To demonstrate this, we use a dataset on effects of MNPs on *Daphnia magna* that we extracted from the literature and discuss how meta-analyses can help to identify MNP traits associated with toxic outcomes.

3.09.P-Mo153 Fate and Transport in Wastewater Treatment PLANTS: Adapting a Draft OECD Guideline to Assess Heteroaggregation of Micro- and NanoPlastics

Patrizia Pfohl¹, Till Gründling¹, Thilo Hofmann², Frank Von der Kammer³ and Wendel Wohlleben, Dr.⁴, (1)BASF SE, Germany, (2)University of Vienna, Austria, (3)Vienna University, Austria, (4)Material Physics & Analytics AND Experimental Toxicology & Ecology, BASF SE, Germany

Recent research reveals various environmental scenarios (including road run-off and textile washing) in which microplastics end up in wastewater treatment plants (WWTP). Their ability to remove microplastic particles from influent via aggregation and adsorption processes to sludge is essential to reduce microplastic pollution of effluents and rivers. However, the scientific knowledge on heteroaggregation processes of microplastics is limited, which is why it is important to investigate to which extent microplastics are retained in the sewage sludge. Here we adapted a draft OECD guideline, that was originally proposed for WWTP removal of nanomaterials, to become a standardized process simulating the fate of micro- and nanoplastics in a WWTP. The process itself is focussed on heteroaggregation between natural colloids (sewage sludge) and microplastics only and does not include WWTP pre-treatments. The simplified and standardized process is applicable in the laboratory and is therefore suitable for a material comparison, providing a simple pre-screening possibility for potential retention efficiencies in WWTPs. The process includes standardization of sewage sludge from a municipal wastewater treatment plant for experimental reproducibility. PA-6 (< 5 µm) and two types of controls (anionic and cationic solid, insoluble polymer particles, made by emulsion polymerization) were monitored by a batch experiment based on mixing and sedimentation with and without sludge colloids, determining the remaining amount of polymer in the supernatant, which would be the effluent. Pyrolysis GC-MS was used for identification and quantification, in accord with the increasing use of pyrolysis GC-MS for environmental monitoring. We successfully developed a reliable and simplified process for simulating the fate of micro- and nanoplastics in wastewater treatment plants, including sample treatment protocols for pyrolysis GC-MS. The process in combination with suitable controls can serve for a material comparison and to determine heteroaggregation attachment efficiencies between micro- and nanoplastics and sewage sludge. However, the relevance of the measured retention still needs to be assessed against retention in real-world WWTPs. Additional settling processes and flocculating agents would increase retention, and could be added to the guideline in a tiered testing strategy.

3.09.P-Mo154 Determination of Microplastics in Soil and Water Samples From a Managed Aquifer Recharge System With Wastewater Treatment Plant Receiving Waters

Albert Contreras Llin¹, Silvia Diaz-Cruz² and Jesus Carrera³, (1)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Barcelona, Spain, (2)QA, IDAEA-CSIC, Barcelona, Spain, (3)Institute fo Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain

Plastic materials are extremely versatile due to their low density, low thermal and electric conductivity, and resistance to corrosion, which allow these materials to serve as a water and oxygen barrier. Their low price also contributes for their easy and widespread manufacture, where they are used in a wide range of applications from food packaging to medical and technological applications. Environmental conditions such as solar radiation, abrasion and diverse interactions with organisms, among many others, cause plastic to degrade and fragmentate into smaller particles commonly known as microplastics (MPs). MPs might accumulate in the natural environment, considering the low degradability of most plastics, thus their analysis and determination is of utmost importance. Wastewater treatment plants (WWTPs) have been identified as one of the highest sources of plastic release into the environment. In the present work, a simple analytical method for the simultaneous determination of MPs, including polyethylene (PE), polypropylene (PP), polystyrene (PS), polyvinylchloride (PVC), and polyethylene terephthalate (PET), in water and soil samples from a managed aquifer recharge (MAR) system which receives water from a WWTP has been optimised and validated. The method is based on a density separation of the MPs using a salt saturated floatability solution, followed by an oxidative treatment using hydrogen peroxide in presence of iron (II) sulphate heptahydrate (Fenton's reagent) in order to eliminate the organic matter present in the samples. After the oxidation, the solution is allowed to settle, before collecting the supernatant, which is filtered through a 1 x 1 cm² silicon filter. Once particles are retained onto the filter, it is analysed by FTIR imaging, using a Nicolet™ iN™ 10 MX infrared imaging microscope. An exhaustive pretreatment of the sample is needed in order to obtain cleaner supernatants with less organic matter and sediments, thus improving the posterior characterisation by FTIR *imaging*. The improved method will be applied to the analysis of barrier material as well as water samples from the MAR pilot system.

3.09.P-Mo155 A Novel Methodology for the Removal of Microplastics From Deep Sea Sediments

Katherine Shaw¹, Rachel Sandquist², Cameron Fairclough³, Ray Aivazian III⁴, Jesse Black⁵, Alex Fitzgerald³, Scott Gallagher³, Jennifer Lynch¹ and Jessica Reiner¹, (1)National Institute of Standards and Technology, United States, (2)HPU Center for Marine Debris Research, United States, (3)Coastal Ocean Vision, United States, (4)Seed World, United States, (5)Hawaii Pacific University Center for Marine Debris Research, United States

One of the main challenges in identifying and quantifying microplastics is extracting the microplastics from the matrices in which they are found. This is a feat that is currently lacking efficiency, reproducibility, and standardization throughout the field of microplastic research. Current methods for removing microplastics from the environment use inefficient glassware and expensive density separation devices that require transferring samples between glassware, with each transfer increasing the likelihood of sample loss. Harsh chemicals including Fenton's reagent, sodium hydroxide, and potassium hydroxide are often used to remove the organic matter in a sediment sample but can be damaging, potentially leading to the loss or misidentification of the microplastics. The objective of our study was to design a readily accessible and affordable density separation device (DSD) to optimize and harmonize research in the microplastics community. A DSD was built with two 1.5 inch diameter sight glasses connected by a stainless steel ball valve. In a novel approach to dealing with organic matter in the sample, a vacuum was applied prior to density separation which reduced the amount of organic plant matter in the sample by 93%. Stainless steel balls were used inside the DSD to mix only the bottom chamber in order to release plastic particles bound to sediment and increase recovery. Furthermore, all steps of the separation process, until filtering, take place inside the DSD, eliminating the need for sample transfer and greatly reducing the chances for sample loss. The recovery potential of our DSD was tested by spiking samples of deep sea sediment in triplicate with eight polymers (fragments of polypropylene (PP), high density polyethylene (HDPE), polystyrene (PS), nylon-6 (PA6), polyvinyl chloride (PVC), crumb rubber from tires (CR), and two fibers, polyester (PEST) and cellulose acetate (CA)) between 100 and 300 μm in size. Separation was achieved with 2.0 g/mL sodium polytungstate. Recoveries of all fragments exceeded 80%: PP: 81.6 ± 25.7%, HDPE: 96.1 ± 13.4%, PA6: 91.4 ± 19.2%, and PVC: 101.4 ± 9.7%. The recovery of CR was greater than expected (212.4 ± 115.3%) due to the fragmentation of the CR during processing. Fiber recoveries were lower than expected (PEST: 41.1 ± 35.6%, CA: 34.8 ± 8.3%) and require further investigation. Overall, the DSD has proven to be an efficient, easily accessible, and affordable solution to microplastic extraction.

3.09.P-Mo156 Determination of Microplastics in Macroalgae Using FTIR Microspectrometry

Adrián López-Rosales¹, José Andrade-Garda², Verónica Fernández-González², Purificación López-Mahía² and Prof. Soledad Muniategui-Lorenzo¹, (1)Universidade da Coruña (UDC), Spain, (2)Universidade da Coruña, Spain

Algae are an important source of food and a refuge for marine species because they form marine forests of huge ecosystem importance. They also emerged as an economic resource (food, cosmetics). However, it was reported that they could retain large amounts of microplastics (MPs). Further, they may transport MPs and, so, have implications for the food chain. This work focuses on developing a reliable method to characterize and quantify MPs in two types of matrices: seawater containing macroalgae and plain surface stranded algae. For this purpose, several digestion methods were tested, where from an enzymatic-oxidative protocol was selected and validated, with good results. It uses cellulase, protease and H₂O₂. Validation was made by preparing a mixture of 5 algae (usually sold in supermarkets; namely, *Undaria pinnatifida* spp, *Porphyra* spp, *Ulva* spp, *Laminaria ochroleuca* and *Himantalia elongate*). The two phases of seawater-containing algae were separated and subsequently digested. A comparison with a traditional method that washes the algae was made. It is concluded that the digestion procedure results in better recoveries than the washing protocol. In addition, studies were made to reduce the measurement time required when an IR microscope (Perkin Elmer Spotlight 200i) is used to characterize the suspicious particles. The characterization of the particles in a filter was

made in a two-stage approach. First, larger (>100 µm) particles were transferred to dedicated multi-well aluminium plates [1] (this is a quite fast step and the subsequent semiautomatic measurement with the microscope is straightforward) and, then, the filter (47 mm diameter) was scanned following a helical subsampling pattern. [1] López-Rosales A., et al., Development of a fast and efficient method to analyze microplastics in planktonic samples. *Marine Pollution Bulletin*, 168:112379. 2021.

3.09.P-Mo157 Recent Developments, Applications, and Future Perspectives for siMPle, a Freeware Tool for the Manufacturer-Independent Analysis of Microplastics

Sebastian Primpke¹, Alvis Vianello², Gunnar Gerds³ and Jes Vollertsen², (1)Alfred Wegener Institute, Germany, (2)Aalborg University, Denmark, (3)Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Germany

Microplastics analysis is an emerging and challenging topic for laboratories worldwide due to the various steps involved. These steps range from sampling, work up/purification, to analysis, and each has its own challenges. Additionally, the final analytical step can be carried out using different methods based on spectroscopy or thermoanalysis available, which provide different data quality, comparability, and mass or number-related results. Among these, the analysis via Raman or Fourier-Transform Infrared (FTIR) spectroscopy is often applied to determine the chemical nature of these particles. In the case of FTIR imaging, the procedure allows the measurement of complete filter areas independent of human bias in a short amount of time. In the scope of recent approaches to determine standardized operational protocols (SOPs), access to comparable data determination is in many cases difficult due to a large number of different manufacturers as well as commercial software solutions and spectral libraries available. Hence, siMPle was developed to overcome this limitation and allow the harmonization of data analysis. It allows the analysis of datasets measured on different machines from the manufacturers Agilent, Bruker, DRS Day Light Solutions, Perkin Elmer, and Thermo Fisher (further imports in development). In the current stage, every spectrum can be selected individually or analyzed via two pipelines for the automated analysis, which can handle a large dataset with more than 11 million spectra with relative ease. This study will present recent developments of the software tool focusing on usability, improved function ability, and spectral libraries. The generated data by this additional tool was benchmarked and validated in accordance with standard analysis approaches and libraries within siMPle to allow a harmonized comparison of results. In addition, the influences on calculation time for a reference data set containing 1 million spectra were monitored and evaluated. This tool and its further updates and spectral libraries are available as Freeware on www.simple-plastics.eu for the harmonization of MP data analysis for spectroscopic data.

3.09.P-Mo158 Fast Microplastic Classification Using µFTIR and Random Forest

Jordi Valls Conesa, Bruker Scientific LLC, Ettlingen, Germany

Fourier-transform infrared micro-spectroscopy (µFTIR) is a commonly used non-destructive probing technique for Microplastic (MP) analysis. It allows for both chemical identification and geometric analysis of MP particles in a MP sample. Analysing the spectral information of a MP sample renders data acquisition and analysis challenging and time consuming. One promising path for fast and reliable automated analysis of µFTIR data from MP samples are Machine Learning (ML) classification methods such as Random Forest (RF). RF is a supervised ML method, meaning that it requires training with labelled data, i.e. spectra that have been tagged as a certain type of MP by a human expert or equivalently reliable means. In the present work, µFTIR data from lab-created MP samples are semi-automatically labelled. This data consists on labelled MP spectra and is used to generate a training dataset and an independent test dataset. The RF forest is trained until convergence using only the training dataset, the training progress is validated using the test dataset. Another test case is the measurement of sediments from environmental wastewater samples using fast MP detection. The RF classifier is able to detect the MP types that it has been trained to classify, including some MP particles that have been missed by using other state-of-the-art classification methods.

3.09.P-Mo159 Investigation of Microplastics in the Tropical Indian Ocean Using Laser Direct Infrared (LDIR) Chemical Imaging and Microwave-Assisted Sample Preparation

Fadi El Gareb¹, Lars Hildebrandt², Andreas Kerstan³, Tristan Zimmermann², Kay Emeis⁴ and Daniel Pröfrock², (1)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Geesthacht, Germany, (2)Helmholtz-Zentrum hereon, Germany, (3)LSAG, Agilent Technologies, Inc., Germany, (4)University of Hamburg, Germany

In this study we introduce a novel in-house-built fractionated water filtration system (Geesthacht Inert Microplastic Fractionator, GIMPF) to sample large water volumes and extract high loads of suspended particulate matter out of water bodies. It was thoroughly tested for its efficiency to retain small-sized microplastics ($d > 300 \text{ ?m}$ and $10 \text{ ?m} < d < 300 \text{ ?m}$) with metal doped model microplastic particles using Inductively Coupled Plasma – Tandem Mass Spectrometry (ICP-MS/MS). The GIMPF was applied on real environmental samples taken during SO270 cruise (*RV Sonne*) in the tropical Indian Ocean. 21 Samples ($10 \text{ ?m} < d < 300 \text{ ?m}$) were subjected to a microwave-assisted one-pot sample preparation protocol. The validated microwave-assisted matrix removal protocol showed quantitatively high matrix removal rates ($94.3\% \pm 0.3\%$ (1 *SD*, $n = 3$)) using a certified reference material and high recovery rates ($95\% \pm 4\%$ (1 *SD*, $n = 3$)) for model microplastics, using in-house HDPE and PET model particles in the size range between 20 ?m and 63 ?m . Furthermore, model microplastic particles were investigated using Scanning Electron Microscopy (SEM) analysis after and before matrix digestion, which showed no significant changes in surface morphology and particle integrity. Microplastics were chemically identified and physically characterized using recently introduced Laser Direct Infrared (LDIR) Chemical Imaging based on a quantum cascade laser (QCL) source. This novel infrared imaging technique enabled fast and automated analysis of each entire sample, combined with a new efficient sample preparation

method, and reduced uncertainty introduced by any extrapolation. Microplastic particle number concentration of 21 analyzed tropical Indian Ocean samples (20 μm – 300 μm) ranged from 8 to 132 particles/fibers m^{-3} (mean: 50 ± 30 MPs m^{-3}) along the sampled transect at 6 m depth. The most abundant polymer clusters were acrylates/PU/varnish (49%), PET (26%), PP (8%), PE (4%) and EVA (4%). 96% of the microplastic particles/fibers had a diameter < 100 μm . The samples were collected along a previously unexplored transect and cover a large ocean area for which, according to our current state of knowledge, there is a poor data situation. Though inter-study comparison is difficult, the sampled area exhibits a high contamination with marine plastic debris compared to other open ocean regions. A distinct spatial trend was observed with an increasing share of the particle size class 20 μm – 50 μm from east to west.

3.09.P-Mo160 Microplastics in Beach Sands and Sandy Sediments: Comparative Analysis of Infrared and Fluorescence Methods

Nora Exposito Lorenzo¹, Cristina Herrero², Jordi Sierra¹, Joaquim Rovira³, Jaume Folch¹ and Marta Schuhmacher⁴, (1)Universitat Rovira i Virgili, Spain, (2)Universitat de Barcelona, Spain, (3)University Rovira i Virgili, Spain, (4)Rovira i Virgili University, Spain

Microplastics (MPs) are plastic particles of less than 5 mm that accumulate throughout ecosystems. The scientific community aims to standardize methods for the identification and quantification of MPs. This study proposes a method for the analysis of MPs in beaches and sandy sediments, based on visual sorting for MPs larger than 0.5 mm and a density separation method with a ZnCl_2 solution followed by Fenton's reagent oxidation for MPs smaller than 0.5mm. Infrared spectroscopic techniques, such as ATR-IR and micro-FTIR, and fluorescence microscopy with Nile red dye are used for polymer type identification. This method was applied to 32 samples, including 26 beaches and 6 sediments distributed along the Catalan coast (western Mediterranean). MPs larger than 0.5 mm were mostly fragments and fibres of polypropylene (50%) and polyethylene (31%), while MPs smaller than 0.5 mm were mostly fibers (400 μm in length) and particles (100 μm in diameter) of cellulose derivatives (42%), polyethylene (18-26%), polyamide, polyvinyl chloride, etc. Along the Catalan coast, the highest incidence of MPs is in the province of Tarragona, at points where rivers and wastewater treatment plants discharges coincide. In addition, urban and industrial pressure, marine currents, coastal line morphology and fine granulometries are conditioning factors of the distribution of MPs, making it heterogeneous along the coast. High pollution levels were detected in Ebro's Delta region such as the Bay of Fangar with 8406 items/kg dw as well as in the city of Tarragona with hot spots with more than 10000 items/kg dw. The proposed method is a strong candidate to be a standard method in microplastic analysis. However, the study found up to 30% items/kg dw difference between fluorescence microscopy and quantification by micro-FTIR spectroscopy on fine sand beaches, which should be further studied to ensure data quality.

3.09.P-Mo161 Evaluation of Weathering of Freshwater Environmental Microplastics by Fourier Transform Infrared Spectroscopy

Claudia Campanale, Carmine Massarelli, Mariangela Triozzi and Vito Felice Uricchio, Italian National Research Council, Italy

Fourier transform infrared (FTIR) is a spectroscopy technique widely used to identify organic materials. It has recently gained popularity in microplastic (MP) pollution research to determine the chemical composition of unknown plastic fragments, but it could also be used to evaluate the degree of ageing of MPs collected from the environment. In this context, the principal aim of our research has been to qualitatively evaluate the natural weathering of environmental MPs collected in an Italian freshwater body (Ofanto river) during Spring 2018 using ATR-FTIR technology. FTIR spectra were acquired using a Nicolet Summit FTIR (ThermoFisher Scientific) equipped with an Everest ATR with a diamond Crystal plate and a DTGS KBr detector (wavenumber range 4000-500 cm^{-1} , 32 scans per spectrum, spectral resolution of 4 cm^{-1}). The degree of ageing was assessed using three different indices known to be related to changes in MPs: Carbonyl Index (CI), Hydroxyl Index (HI) and Carbon-Oxygen Index (COI). The three indexes were calculated as the ratio of the absorbance peaks at 1770-1700/1495-1423, 3553-3021/1504-1467 and 924-1197/2987-2866 respectively. The overall results showed that the regions reflecting ageing-related changes (hydroxyl groups, peaks from 3100 to 3700 cm^{-1} , alkenes or carbon double bonds, 1600 and 1680 cm^{-1} and carbonyl groups, 1690 and 1810 cm^{-1}) appeared greatly modified compared to the pristine materials in each type of MPs. Moreover, new peaks are present almost all in the fingerprint region (1500-500 cm^{-1}). Differences in CI, HI and COI were evidenced among the different morphological MP shapes. On the one hand, the CI calculated for the PE pellet samples showed values ranging from 0.05 to 0.26 with a mean value of 0.17 ± 0.10 . The majority of samples (57%) presented a CI with values between 0.16 and 0.30. On the other hand, fragments presented slicer modifies in the carbonyl region with CI values lower than pellets (0.05 ± 0.05). This index is helpful to evaluate the degradation of PE MPs by UV light, and it increases with enhancing residence time in the environment. Conversely, fragments showed greater values of HI (5.90 ± 2.57) and COI (1.04 ± 0.48) than pellets, as well as lines, which presented the maximum value of HI (11.51). HI is attributed to the bond vibrations of hydroxyl, carboxyl or phenol groups, while COI is frequently attributed to the vibrations of C-O bonds found in carbohydrates, as well as to alkanes, secondary alcohols and ketones.

3.09.P-Mo162 Development of a Reliable Method to Analyze Microplastics in Fish Stomach Using an Infrared Tunable Quantum Cascade Laser System

Adrián López-Rosales¹, José Andrade-Garda², Verónica Fernández-González², Purificación López-Mahía² and Prof. Soledad Muniategui-Lorenzo¹, (1)Universidade da Coruña (UDC), Spain, (2)Universidade da Coruña, Spain

The presence of microplastics (MP) in fish stomachs causes great environmental concern due to the damage they cause to the specific individual and the possibility of trophic transfer. Infrared spectrometry is a common workhorse for chemical characterisation of MPs, but it is time-consuming. In this work, a IR device based on a quantum cascade laser is used to accelerate the characterisation step (Agilent 8700 Laser Direct Infrared (LDIR) chemical imaging system). Its novelty poses new challenges

for sample processing and particle handling, as the particles must be unfolded on a reflective slide without losing representativeness. This study compares three sample digestion protocols (alkaline-oxidative with H₂O₂, alkaline-oxidative with NaClO and enzymatic-oxidative) and three different procedures for transferring the contents of the filters to the reflective slides (manual, total evaporation, partial aliquots). A simplified enzymatic-oxidative digestion combined with a Syncore® automatic evaporation system is finally proposed as a reliable method. Fortified *Scomber scombrus* samples were studied, with recoveries ca. 100 % for MP >500 µm, ca. 90 % for MP > 200–300 µm and around 75 % for 10 µm thin microfibrils. **Acknowledgements:** Thanks are given to the European Union Funding for Research&Innovation (H2020-LABPLAS project, Grant Agreement No. 101003954 H2020-SC5-2020-2), JPI-Oceans and the Spanish Ministry of Science and Innovation (MicroplastiX project, PCI2020-112145). The Galician government is also acknowledged (Xunta de Galicia, Grant ED431C 2021/56).

3.09.P-Mo163 Effect of Weathering in the Leaching of Alternative and Conventional Additives From Microplastics to Seawater

Estefanía Concha-Graña¹, Alicia López-Viqueira², María Fernández-Amado², Eva Verdejo³, Purificación López-Mahía¹ and Prof. Soledad Muniategui-Lorenzo², (1)Universidade da Coruña, Spain, (2)Universidade da Coruña (UDC), Spain, (3)AIMPLAS, Spain

In the last years there was an increasing concern about the presence of plastic additives in the marine environment. Many of the functional plastic additives are classified as toxic substances and included in REACH¹. In this work, the migration of conventional (BHT, Chimassorb2020, TCPP, triclosan and diisodecyl phthalate) and less toxic alternative additives (?-tocopherol, quercetin dehydrate, lawsone, and Grinsted® Soft–N–Safe) from microplastics to seawater was studied using an accelerated migration method by pressurized liquid extraction. 3 petroleum derived plastics (PA, PVC, LDPE) and a bioplastic (PHB) were considered, both pristine and weathered, to study the effect of the weathering on the lixiviation of additives. Pristine polymers, LDPE and PHB showed in general higher migration than PA and PVC. The additives with a highest migration rate (about 10%) were TCPP and lawsone. In general, the plastic weathering decreased the additive migration and in some cases caused their degradation. Some degradation products of lawsone, triclosan and BHT were detected, which demonstrate that also the additives can be affected by the plastic weathering in the marine environment. This is quite relevant and further studies should be carried out, since some of these degradation products can be more toxic than the original additive. Considering the migration capacity and the toxicity of the additives, the conventional additives triclosan and BHT are the main contributors to the potential toxicity of plastics among the studied and the alternative additives tested seem to be a good choice to replace them. Finally, the substitution of conventional polymers by the biodegradable biopolymers could not be always a good alternative, since additives leachates easily from PHB (higher additive migration than PA and PVC), unless innocuous additives are used in the formulation. ¹EU, 2011. Commission Regulation (EU) No 10/2011 on plastic materials and articles intended to come into contact with food. Support: The Spanish Inter-Ministerial Science and Technology Commission and ERDF through ARPA-ACUA (CTM2016-77945-C3-3-R) project; the Spanish Ministry of Science and Innovation through JPI_Oceans 2019 MicroplastiX (PCI2020-112145) and CHEMPLAS (PID2019-108857RB-C3/AEI/10.13039/501100011033) projects. 3.09.P-Mo164 Different Software for Different Samples? Comparison of Two Automated Approaches for the Fast Analysis of Microplastics With Raman Microspectroscopy

Kristina Enders¹, Robin Lenz¹, Franziska Fischer¹, Lucie Marx², Dirk Holz², Elisavet Kanaki¹ and Dieter Fischer¹, (1)Leibniz Institute of Polymer Research Dresden, Germany, (2)University of Applied Sciences Dresden, Germany

Raman microspectroscopy in combination with optical particle detection is a commonly used approach to identify and quantify microplastic (MP) particles in a wide range of samples. This particle-based approach often comprises of the steps optical image acquisition, particle detection, Raman scan, spectra analysis and result evaluation. To speed up analyses, software packages have been developed that provide all these steps in one application. While these packages include the same basic functionality, they differ in speed, accuracy and other functionalities that favor, for example, their application in certain MP size ranges over others. Here we present example analyses of MP particles in environmental and bottled water samples. We compare the results in the size ranges > 50 µm, >10 µm and > 4 µm obtained in parallel with the commercially available software WITec ParticleScout and the python-based GNU GPL-licensed GEPARD, which was developed at the IPF Dresden. ParticleScout as the proprietary software of the Raman microscope manufacturer WITec fully utilizes their instrument's capabilities, which results in optimized analysis speed, precision and ease of use. As an open source software GEPARD can be adapted to a broader range of instruments. In contrast to ParticleScout, it provides a unique annotation module for correcting inaccuracies in the particle detection with regards to, e.g., particle shapes, sizes, or over-fragmentation. For the two software packages, we discuss performance trade-offs between speed and accuracy for samples with varying particle size ranges and shapes. We also present how we combine GEPARD and Particle Scout to optimize the workflow and result accuracy.

3.09.P-Mo165 Advanced Image Recognition As Requirement for a Valid Analysis of Very Small (1--10 Mm) Microplastic Particles

Oliver Jacob, Alejandro Ramírez Piñeiro, Martin Elsner and Natalia Ivleva, Technische Universität München, Germany

Microplastic (MP) particles (polymer fragments, 1µm—1mm) are found in a multitude of environmental samples. Reliable high throughput methods for quantification of the lowest size fraction within representative particle numbers, however, are still needed. In principle, Raman microspectroscopy (RM) is suitable for identifying particles down to 1 µm when deposited on a filter. *TUM-ParticleTyper*, an open source software, has been developed for detection of particles down to 10 µm *via* recognition in darkfield

images [10.1371/journal.pone.0234766], where measurement points (one per particle) are initialized for subsequent automated quantitative RM analysis. Here, we report on image processing methods that aim at improving the recognition performance further, thus enabling reproducible results down to 1 μm (maximum Feret diameter) under varying conditions. When advancing the methodology towards lower particle sizes, suitable methods of image processing are required to enable a correct detection despite influences of the instrumental framework. Specifically, construction-related contrast differences in sample illumination are problematic when using different objectives even if each of them may provide suitable magnification (50x or 100x). Here, filtering in the Fourier domain provides a solution, as it not only reduces the contrast of the filter pores that otherwise might interfere, but also preserves the sharpness of particles. Also, refined methods are needed to reduce false positive (e.g. morphological opening, median blur) or false negative results (e.g. top-hat transform). To separate agglomerates, watershed transformation is normally used, which is, however not reasonable when it needs to be applied to the whole sample involving too many small particles. Instead, an algorithm is applied here that considers only those objects whose convexity surpasses a threshold, which is derived beforehand by applying Otsu's algorithm to the convexity distributions of single particles and agglomerations after manual classification. Preliminary results show an increase in particle numbers to a value similar to the total number of particles obtained from manual subdivision. In combination, these advances provide the foundation for an improved image recognition in terms of useful and representative lateral positions for successive automated RM measurements. Ongoing developments aim to extend the applicability of the *TUM-ParticleType* approach for particles smaller than 10 μm .

3.09.P-Mo166 Micro Raman Analysis of Micro- and NanoPlastics in Drinking Water: From Number to Mass

Luca Maurizi¹, Lucian Lucian Iordachescu², Inga Kirstein³, Jes Vollertsen² and Asbjørn Nielsen², (1)The Built Environment, Aalborg University, Denmark, (2)Aalborg University, Denmark, (3)Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Germany

Lack of standardization still affects the microplastics science as a whole, and this is especially true for Raman microscopy applications in the field. In particular, calculating the particles' masses from Raman data remains challenging, though necessary in order to provide more significant evidences. The current work aims to exploit Raman microscopy in order to analyze micro- and nanoplastics in drinking water samples from a local facility, and to propose an assumption capable of allowing the calculation of particles' masses. In addition, a novel analytical protocol for micro- and nanoplastics analysis with Raman microscopy is presented. The main points of the research are the following: A sample preparation protocol for drinking water is presented. Large volumes (ca. 1 cubic meter) can be sampled through low-mesh size filters, and the retained particles can be concentrated in small volumes; Samples are deposited through a custom-made device on a proper Raman substrate; Relevant size parameters (major and minor axes) are obtained from visible image analysis of the deposited sample, and from them the volume of each particle is calculated assuming them as ellipsoids; According to the Raman spectrum of each particle, the pristine polymer's density is associated. The authors stress the novelty of the work, which is, at the best of their knowledge, the first of its kind.

3.09.P-Mo167 Chemical Mapping of Environmental Tyre Wear Microplastics by Py-Gc-Ms

Verónica Fernández-González, Carmen Moscoso-Pérez, Estefanía Concha-Graña, Purificación López-Mahía and Prof. Soledad Muniategui-Lorenzo, Universidade da Coruña, Spain

Tyre wear particles (TWPs) not only are assumed to be the most dominant source of environmental microplastics but also act as a source of various organic micropollutants, many of which are likely still unknown [1,2]. Most commonly, polymer identification in environmental samples is performed by non-destructive spectroscopic techniques, like Fourier transform infrared (FTIR) or Raman spectroscopy, but thermoanalytical methods such as pyrolysis coupled to gas chromatography and mass spectrometry (Py-GC-MS) is the most promising technique for microplastics quantification [3]. A successful thermal desorption (TD-GC-MS) and pyrolysis (Py-GC-MS) method for the simultaneous characterization of organic additives/pollutants and main tyre composition was applied to used tyres. Knowledge of the chemical composition of TWPs, and the transformations that these compounds undergo with weathering, will help to better identify and quantify these particles in environmental studies. A weathering study of tyres in the marine environment has been carried out to monitor changes in additive composition and chemical structure. Besides styrene butadiene rubber (SBR), main component of TRWs which is used to Py-GC-MS quantification, hundreds of compounds as benzene, alkyl-benzenes, toluene or polycyclic aromatic hydrocarbons (PAHs) were identified. [1]Goßmann I. et al, Car and truck tire wear particles in complex environmental samples – A quantitative comparison with traditional microplastic polymer mass loads, *Sci. Total Environ.* 773 (2021) 145667. [2]Müller K. et al, Probing the chemical complexity of tires: Identification of potential tire-borne water contaminants with high-resolution mass spectrometry, *Sci. Total Environ.* 802 (2022) 149799. [3]Lauschke I. et al., Evaluation of poly(styrene-d5) and poly(4-fluorostyrene) as internal standards for microplastics quantification by thermoanalytical methods, *J. Anal. Appl. Pyrolysis.* 159 (2021) 105310. This work was supported by the European Union Funding for Research&Innovation H2020-LABPLAS project (Grant Agreement No. 101003954 H2020-SC5-2020-2), JPI-Oceans Program 2019 and the Spanish Ministry of Science and Innovation MicroplastiX project (PCI2020-112145) and by the Spanish Ministry of Science and Innovation 'ChemPlas' project (PID2019-108857RB-C31). The Program 'Consolidación e Estructuración de Unidades de Investigación Competitivas' of the Galician Government (Xunta de Galicia) is also acknowledged (ED431C 2021/56).

3.09.P-Mo168 Microplastics Analysis Throughout a Large Water Supply Network in Barcelona Urban Area by Py-Gc-Ms

Joan Dalmau-Soler¹, M Rosa Boleda Vall-Ilovera² and Silvia Lacorte³, (1)Aigües de Barcelona, Barcelona, Spain, (2)Aigües de Barcelona, Empresa Metropolitana de Gestio del Cicle Integral de l'Aigua, Spain, (3)Institute of Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain

The consumption of plastics in Europe was 57.9 million tonnes in 2019 and has increased progressively over the years. Today, the

contamination derived from plastic represents a global threat and a matter of political, social and health concern. Many studies have shown that microplastics are widely distributed in the environment. Since most surface waters may be used as drinking water, the possible presence of microplastics in drinking water despite the treatments applied in DWTPs, is a matter of concern. However, the lack of standardized analytical methods leads to a discrepancy of the results between different studies. In the field of water policy, microplastics will be included in the watch list of the future European drinking water directive 2020/2184, once a harmonised methodology has been adopted. Thermoanalytical methods as pyrolysis-gas chromatography coupled to mass spectrometry (Py-GC-MS) provides the identification and the mass quantification (in terms of μg) about the concentration of the microplastics. The objective of the present study is to develop a fast, quantitative and suitable for routine analytical method based in Py-GC-MS, to determine the microplastics concentration in drinking water samples. The developed analytical methodology was applied to determine the concentrations and the distribution of microplastics throughout the drinking water supply network of Barcelona urban area, that provide drinking water to 3.000.000 inhabitants.”

3.09.P-Mo169 Quantitation of Tire Rubber Particles by Pressurized Liquid Extraction Coupled With Pyrolysis Gas Chromatography-Mass Spectrometry

Lorenzo Scibetta¹, Marthinus Brits², Feride Öykü Sefiloglu³, Martin van Velzen⁴, Quinn Groenewoud⁴, Juan Garcia-Vallejo⁵, Heather Leslie⁶ and Marja Lamoree⁷, (1)A-life, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (2)Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (3)Environment and Health, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (4)Vrije Universiteit Amsterdam, Netherlands, (5)Amsterdam UMC, Netherlands, (6)VU Amsterdam, Netherlands, (7)VU University, Department Environment & Health, Netherlands

Tire and road wear particles (TRWP) pollution is an important problem because might generate health issues in humans and cause ecological damage. Furthermore, it is one of the largest sources for the distribution of microplastic particles in the environment. The complexity of this type of pollution is clear from the large variation in materials content: typically, 6 different rubber polymers are used for tire production. Moreover, the total mass of a tire generally consists of only 40-60% of natural and synthetic rubber. The remaining mass is composed of black carbon, vulcanization agents(1-2%), salts, heavy metals (5%), fillers (20-35%), process oils (12-15%), and other additives. Due to the complex mixture of these components, the characterization and quantification, of the rubber polymers, especially in environmental matrices, is challenging. There are many techniques to analyze rubber particles and pyrolysis gas chromatography-mass spectrometry (py-GC-MS) is a powerful tool for this purpose and probably one of the best for the quantitation in human and environmental matrices. The pyrolysis of tire particles generates different products (pyrolysates) that can be used as markers in the identification and quantitation of rubbers. In particular, the two main compounds that are generally utilized are vinyl cyclohexane (for styrene-butadiene rubber and butadiene rubber), and dipentene (also known as D-limonene for natural and isoprene rubber). However, recent studies show that the uncertainties of the results using only these two products can be remarkably high, especially when considering the high variability in the composition of different tires. We have developed a selective analytical method for the extraction and analysis of tire particles in environmental matrices. Quality control (QA/QC) parameters which include extraction efficiency (recovery), method specificity (pyrolysis temperature optimization and unique pyrolysate selection), and sensitivity (LOD/LOQ). The method has been characterized using different calibration curves produced by extracting tire samples using accelerated solvent extraction (ASE) and using an internal standard to balance the responses of the different pyrolysis products. This method will be used as a base for further investigations, in particular, for the characterization and quantitation of TRWP polymers in human matrices like blood and environmental samples such as air and soil.

3.09.P-Mo170 Quantification of Microplastics by Pyrolysis Coupled With Gas Chromatography and Mass Spectrometry in Sediments: Challenges and Implications

Nadia Bouzid¹, Rachid Dris², Bruno Tassin² and johnny gasperi³, (1)Laboratoire Eau Environnement Systèmes Urbains (LEESU), France, (2)Univ Paris Est Creteil, France, (3)LEESU, France

Over the last few years, there has been a growing interest in studying microplastic (MP) contamination in freshwater systems. However, the knowledge on MP contamination is still insufficient and the developed analytical methods do not allow to establish a precise mass balance between the different environmental compartments. Generally, MP are analyzed by Fourier transform infrared microscopy (FT-IR) or Raman. These spectroscopic techniques provide information on the morphology of MP and an estimate of their number above a minimum size (25 μm), but do not provide a mass quantification of MP. Pyrolysis coupled to gas chromatography and mass spectrometry (Pyr-CG-MS), which was mainly used until now to identify the nature of MP in environmental samples, has recently been proposed to quantify them. This method allows both the simultaneous identification of polymers, without size limit, and their mass quantification. To date, this quantification of MP by Pyr-CG-MS is generally done by external calibration, without considering potential matrix effects. The matrix effect related to the analysis of MP in river sediments, for which it is difficult to totally isolate MP from the residual mineral and organic fractions, has been studied in floodplain sediments. This presentation aims to demonstrate and quantify this matrix effect through various experiments, and its implication on the study of MP in sediments.

3.09.P-Mo171 A Thermodynamic Method to Improve Microplastic Analysis of Common Plastics Using DSC

Sven Schirmeister¹, Xhoen Gjashta², Martin Socher² and Kathrin Harre², (1)HTW Dresden, Germany, (2)Dresden University of Applied Sciences, Germany

The occurrence of microplastics in environmental compartments is a topic of upcoming risk assesment. The understanding of fate and pathways of microplastics in the environment is based on the environment compartment, enrichment processes and the analytical methods. An environmental monitoring is needed, which is provided by a reliable, cost-efficient and fast analytical

process. Therefore, the microplastic analysis by Differential Scanning Calorimetry (DSC) in combination with an electrostatic separation and density separation is a promising method to fulfil these requirements. The quantification and identification of microplastics by DSC depends on their thermodynamic properties. The polymer specific signals of melting, crystallisation and glass transition can be obtained by define heating and cooling regime in DSC measurements. The six common plastics named PE, PP, PET, PS, PVC and PA are subject of our study. The analytical properties of the method, e.g. the limit of quantification is discussed elsewhere. So here we want to show some limiting conditions for overlapping signals and furthermore present thermodynamic methods to overcome limitations of the applied method. Here, three different overlaps of signals are investigated. First, an overlap of two glass transition temperatures (PET, PVC). Second, an overlap of a glass transition and a melting peak (LD-PE, PS) and third, an overlap of different melting and crystallisation peaks (PET, PA). The glass transition is a kinetic process. This allows the signals of glass transitions in the thermogram to be specifically influenced by different heating and cooling rates. Thus, relaxation peaks can be obtained, which allow the identification or quantification despite overlapping signals. The signals from overlapping melt and crystallization regions of semi-crystalline polymers behave additively. Consequently, a clear assignment to a specific polymer can be generated from the information of the thermograms. These properties of semi-crystalline polymers thus correspond to a thermodynamic fingerprint. The results shown in this study improve the cost efficient analytical method for the determination of microplastics by DSC. The reliability of the method is increased. The adjustment of heating and cooling rates influences the time required for an analysis.

3.09.P-Mo172 Application of Electrostatic Separation and Differential Scanning Calorimetry for Microplastic Analysis in Particulate Matrices

Lucas Kurzweg¹, Jann Schneider², Maurice Hauße², Sven Schirrmeister³, Martin Socher² and Kathrin Harre², (1)Chemical Engineering, Dresden University of Applied Sciences, Dresden, Germany, (2)Dresden University of Applied Sciences, Germany, (3)HTW Dresden, Germany

Microplastics in environmental compartments are a topic of growing concern. Time-consuming processes and analytical methods hamper the understanding of occurrence and fate of microplastics in the environment. Therefore, a fast, reliable and cost-efficient method for environmental monitoring is required. Most of the commonly used methods do not meet all requirements. They are highly time-consuming or may not give immediately confirmation of the polymer. Here we want to present an approach for microplastic analysis in particulate matrices combining electrostatic separation (corona drum separator, Hamos, Germany), density separation (potassium iodide solution, $\rho = 1.55 \text{ g/cm}^3$) and differential scanning calorimetry (DSC, Netzsch, Germany). Sand and river sediment samples were spiked with microplastic particles of ultra-high molecular weight PE (PE-UHMW), PET and PCL in the size range of 100 to 200 μm . Microplastic concentrations from 1 to 150 mg/kg were investigated. Subsequently, DSC data with phase transition temperatures and enthalpies allow identification and quantification of the polymer type. The recovery of microplastic was compared for different particulate matrices and polymer types. The electrostatic separation removed above 99 percent of the initial matrix from sand samples. In river sediments, above 90 percent of the initial matrix was removed, depending on the particle size distribution, bulk density and total organic carbon. Density separation increased the sediment removal to above 99 percent for all investigated matrices. The recovery of PE-UHMW was determined as 91 ± 5 percent in sand for concentrations between 40 to 100 mg/kg. The recovery was lower for river sediments than for sand. The recovery of PET and PCL were both above 80 percent. The recovery after density separation showed higher precision than the values after electrostatic separation. Additionally the presented combination of separation methods reduces to volume of necessary density solution. The first electrostatic separation step removes the majority of the matrix, hence the amount of density solution was reduced by 80 percent. Moreover, one sample can be analysed in 8 hours (waiting periods not included). This shows the economic advantages of this method for a comprehensive environmental monitoring of microplastic in river sediments. Our approach has the potential as a reliable, fast and cost-efficient alternative to methods commonly used like pyrolysis GCMS.

3.09.P-Mo173 Improvement of Retention in a Solid Phase for Thermoextraction-Desorption/Gas Chromatography/Mass Spectrometry (TED-GC-MS) in the Analysis of Microplastics

Debora Sorolla¹, Julio LLORCA², Agustin Bueno³, Dolores Lozano³ and Monica Perez⁴, (1)Labagua, Alicante, Spain, (2)Labagua, Spain, (3)UNIVERSITY OF ALICANTE, Spain, (4)Interlab, S.A., Spain

To trap thermodecomposition products during pyrolysis in Thermoextraction-Desorption/Gas chromatography-mass spectrometry (TED-GC-MS), Gerstel twister stir bar coating with PDMS is usually used, being mainly suitable for non-polar compounds. Thermodecomposition products from microplastics are mostly non-polar, but some products may have polarity and are not properly retained in a PDMS sorbent, so to improve adsorption of thermodecomposition products of microplastics with a certain polarity a carbon adsorbent is used in this study being suitable for both polar and non-polar compounds. Furthermore, carbon materials usually have slit-type pores that are optimal for the adsorption of aromatic compounds, the nature of which is most of the decomposition products of microplastic.

3.09.P-Mo174 New Insights From Td-Gc-Ms Data on Microplastics in Salt Samples

Jan Peter Mayer¹, Laura Miles², Caroline Widdowson³ and Carlos Gil⁴, (1)Markes International Ltd, Germany, (2)Markes International, UK, (3)Markes International, United Kingdom, (4)Markes International GmbH, Germany

Detecting and analysing microplastics in the environment is challenging. The method must be able to detect and distinguish between a large variety of polymers. Additives, such as hardeners, flame retardants and preservatives, used during the manufacturing process and other compounds, that can adhere to the surfaces of microplastics from their environment, can affect their toxicity assessment. These additives could be used to link the microplastics found in the environment to their original use or potentially even back to the manufacturer. In this study, various salts were sampled and filtered and analyzed for their

microplastic content. TD–GC–MS was used to identify and measure which concentration of the plastic PS, PET, PVC and Nylon 6 had been incorporated into the crystalline structure of the salt during evaporation. By using direct desorption and backflushing technology, a large sample size could be easily isolated from the lab environment during analysis while ensuring a large range of volatile organic compounds (VOCs) including the marker compounds for four polymers could be trapped and analyzed. The VOC-profile of the microplastics not only gave information about the polymer and its concentration within the sample, but further information about the toxicity could be extracted. This enabled the determination and tentative identification of additional compounds in the samples, such as dimethyl ether, acrolein and cyclopentane. These are used in the process of manufacturing plastics, so could assist with identifying the source of the plastics. They also tentatively identified bisphenol A. Research suggests that BPA may be an endocrine disruptor in humans, making it a compound of interest when assessing toxicity. For the four analysed polymers distinct marker compounds could be identified and calibration curves determined for each polymer. In all of the real-world salt samples microplastics were identified, highlighting the ubiquitous nature of the microplastic contamination. Especially low-density polymers, which can be found in the surface of the ocean, can easily make it into natural-origin sea-salt, but potentially into surface feeding sea life as well. This further information about the origin of the polymer, as well as the origin of the microplastic particles can be gathered by investigating the full VOC-profile obtained by TD-GC-MS. This allows both polymer and particle source characterization simultaneously.

3.09.P-Mo175 Quantification of Polyvinyl Chloride Microplastics Via Solvent Extraction and Combustion Ion Chromatography

Jan Kamp¹, Georg Dierkes², Arne Wick² and Thomas Ternes³, (1)Federal Institute of Hydrology - BfG, Germany, (2)German Federal Institute of Hydrology, Germany, (3)Bundesanstalt für Gewässerkunde, Germany

Thermal methods have largely become established in the environmental analysis of polymers. They offer good opportunities for both identification and quantification of a wide variety of polymer types in aqueous and solid environmental samples. For example, methods for analyzing different plastics such as polyethylene, polypropylene or polystyrene in different environmental matrices by means of pyrolysis gas chromatography / mass spectrometry have been developed. However, one challenge with quantification *via* pyrolysis products is to identify specific marker substances for each plastic that are not produced by naturally occurring substances. The thermal decomposition usually results in relatively unspecific substances, which makes it difficult to quantify several polymers in one sample at the same time. State-of-the-art pyrolysis methods for polyvinyl chloride (PVC) analysis are using benzene as quantifier. However, benzene can also be formed during the pyrolysis of polyethylene terephthalate or organic substances such as cellulose. A promising alternative is the indirect quantification *via* hydrogen chloride (HCl), which is released during thermal decomposition of PVC. In this study the applicability of combustion ion chromatography (C²IC) for determination of PVC in environmental was evaluated and showed a good linearity and sensitivity. A fundamental problem, however, is that HCl can also be generated during thermal decomposition of the environmental matrix and chlorine-containing substances that may be present in it. To ensure selectivity an extraction method for PVC *via* solvent extraction has been developed. In the first step methanol is used to eliminate chlorine-containing substances such as PCBs. In a second step using tetrahydrofuran (THF) PVC is extracted and separated from inorganic compounds such as sodium chloride. The THF extract is sorbed onto silica gel and transferred into the combustion system. Validation of the influence of chlorine-containing substances and organic components revealed no disturbance of PVC determination by these compounds. So the presented method is suitable for a sensitive and selective determination of PVC in complex environmental samples.

3.09.P-Mo177 Separation and Purification Method for Microplastic Analysis of Glacimarine Sediment (Disko Bay, Greenland)

Karla B. Parga Martinez¹, Vitor Hugo da Silva², Thorbjørn Andersen³, Nicole Posth⁴ and Jakob Strand², (1)Geosciences and Natural Resource Management, University of Copenhagen, Copenhagen, Denmark, (2)Ecoscience, Aarhus Universitet, Denmark, (3)University of Copenhagen, Denmark, (4)NordCEE-Biology, Denmark

Separation and purification methods for microplastic (MP) analysis are greatly dependent on the type of matrix and size fraction of target MP particles. In general, MP extraction methods for sediments commonly include in-between steps such as sample transferring and intermediate filtrations for the removal of biogenic and inorganic matter. However, all those intermediary steps increase the sample processing time and pose a risk of MP loss, especially for the small size fraction (< 100 µm). This work proposes a four-step separation and purification method for MPs in glacimarine sediments (Disko Bay, Greenland), where all purification steps are carried out in one single glass flask, transferring the sample only once for the density separation to minimize particle loss. The sample was initially dried and treated with 10% acetic acid to remove foraminifera shells. The digestion procedure was performed with 5% KOH and 7% NaOCl, which was neutralized prior to density separation (ZnCl₂ 1.6 g.cm⁻³) to avoid precipitation. Each step required a 24h resting and settling time. All reagents have demonstrated not to damage the MPs. The method efficiency and recovery were evaluated spiking PE fluorescent microspheres (63-75 µm, 125-150 µm and 300-500 µm) in the sediments. All analyses were carried in triplicate and the density separation was performed twice per sample for efficiency evaluation. The floating fraction was filtered with a customized metal filtration system using steel filters with mesh size 10 µm and 100 µm. This system allows backflushing the MPs directly onto a membrane for further chemical characterization. The average recovery was higher than 90% for particles >100 µm and 82% for particles >10 µm. The majority of the large particles were collected in the first density separation, whereas 50% of the collected particles >63 µm were extracted in the second separation. The method was also compared to performing intermediate filtrations and sample transferrings showing 90% recovery particles >100 µm and 72% for particles >63 µm. This demonstrates that the separation and purification processes that minimize intermediate steps in this method, improve MP recovery and assessment accuracy. Furthermore, this method can be applied to

different type of sediment samples where the expected amount of MP is low, such as glaciamarine sediment and samples from more pristine areas.

3.09.P-Mo178 Assessment of Oxidative Digestion Protocols Effects on the Integrity of Virgin and Aged Microplastics Through Scanning Electron Microscopy Analysis

Ilaria Savino¹, Pasquale Trotti², Vito Felice Uricchio¹ and Claudia Campanale¹, (1)Italian National Research Council, Italy, (2)University of Bari, Italy

Microplastics (MPs) presence in the environment is a certainty by now; therefore its monitoring is fundamental to assess their potential risk for human health and ecosystems. Despite these assumptions, there are still huge gaps and uncertainties in the validation of analytical methodologies. Preliminary purification of samples is required before MPs quantification to isolate them from the environmental matrix. Usually, chemical digestion treatments based on oxidizing reagents (acids, bases, enzymes) are used to remove the organic substance facilitating particles extraction. However, some of these are aggressive with a risk of damaging particles and underestimating data. Moreover, most of the methods assess digestion treatments on virgin MPs ignoring that their impact on environmental MPs could be higher due to the fragility of these particles already exposed to environmental conditions. In this context, our study aims to evaluate the impact of the most common oxidative treatment (Fenton's reaction) on virgin and aged MPs of different shapes and sizes. Six polymers (polyethylene, polypropylene, polyamide, polystyrene, polyvinylchloride, and polyethylene terephthalate), were selected among the most used plastic items. MPs standards were artificially aged in a climate room and changes in chemical bond structures were measured by Fourier Transform Infrared spectroscopy analysis. Different digestion treatment conditions were evaluated changing temperature (75, 50, 30°C) and reagents volume (100, 60mL H₂O₂) on virgin and aged MPs. Particles integrity was observed by *Scanning Electron Microscopy*, before and after treatments. The overall results showed morphological and dimensional alteration of all particles of different entities. On the one hand, virgin MPs exhibited evident cracks, holes, corrosion in polyamide, polyvinyl chloride, polypropylene, and polystyrene caused by the treatment at 75 °C. The protocol at 50 °C impacted just polyvinyl chloride and polystyrene particles, while at 30 °C generated a dimensional reduction and corrosion of the margins of polyethylene and polypropylene. On the other hand, the stronger treatment caused the loss of material and the damage of all aged particles and pellets abrasions. In contrast to virgin MPs, the milder and intermediate treatment did not produce strong changes. In conclusion, the temperature may influence the integrity of the particles and this may alter the quality of the final data.

3.09.P-Mo179 Comprehensive Analysis of Plastics in Vulture Regurgitates: From Mega to Micro Size

Sarah Smebakk Nilsen¹, Gaëtan Tucoo², Andrea Faltynkova³, Javier De la Puente⁴, Veerle Jaspers⁵ and Laura Monclus⁶, (1)Norwegian University of Science & Technology (NTNU), Norway, (2)University of Pau and Pays de l'Adour, France, (3)Biology, Norwegian university of science and technology, Trondheim, Norway, (4)SEO BirdLife, Spain, (5)Norwegian University of Science & Technology, Norway, (6)NTNU, Norway

Landfills are important sources of plastic pollution in the terrestrial environment, and this is of special concern for opportunistic species foraging in these sites. Vultures are obligate scavengers and frequently use landfills as important alternate food resources. Previous studies have reported plastic consumption in vultures, but they have focused on large plastic particles disregarding small microplastics (sMP, < 1 mm size). In this study, we evaluated occurrence of large plastic particles, MP and sMP in a Cinereous vulture (*Aegypius monachus*) population in Sierra de Guadarrama, Madrid, Spain, using regurgitates as a proxy of ingestion. Eighty-eight nests were visited during the breeding season in 2020 from a population breeding close to a landfill. The regurgitates and plastic material present in regurgitations were collected from each nest (n = 88) and the surrounding area (15 m radius from nest tree) and stored in paper envelopes. Once at the lab, the regurgitates material were weighted and visible plastic particles were separated. These plastic particles were sorted in two different groups for further qualitative and quantitative analyses: mega-plastic (> 100 mm) and macro-plastic (> 20 – 100 mm). The color, area, size, and number of particles were evaluated, and the polymer type identified by attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FT-IR). The remaining regurgitate material for 55 samples was digested for 48h using KOH treatment and sieved into meso-plastic (> 5 – 20 mm), MP (> 1 – 5 mm) and sMP (< 1 mm). A novel framework based on infrared hyperspectral imaging (IR-HIS) was then used to detect and quantify meso-plastic, MP and sMP by polymer type and size down to 150 μm. Our study is the first to provide such specific data on plastic regurgitates, down to micrometer size, in a terrestrial raptor species.

3.09.P-Mo180 Can Microplastics in Molluscs to Have a Potential Risks for Human Health of Catalonia Coast Habitants?

Nora Exposito Lorenzo¹, Joaquim Rovira¹, Jordi Sierra², Gemma Gimenez³, José Luis Domingo⁴ and Marta Schuhmacher⁵, (1)University Rovira i Virgili, Spain, (2)Universitat Rovira i Virgili, Spain, (3)Sorbonne Universités, France, (4)TecnATox / Universitat Rovira i Virgili, Spain, (5)Rovira i Virgili University, Spain

The determination of an ingestion rate is essential to assess potential human health risks of microplastic ingestion but due the consumption rates varies widely by country, culture, lifestyle options, and geography, the ingestion rate must be estimated according specific zones conditions and features. Because Catalonia is a great producer and consumer of molluscs, this study focused on microplastics (MPs) concentrations estimations of commercially relevant molluscs from Catalan coast (northwest Mediterranean Sea) and MPs exposure assessment in Catalan people as a first step for an estimate of high confidence on microplastics exposures by seafood quantity intakes in Spain. An accurate and practical methodology for MPs extraction and identification was applied to high quantity of seafood samples (50-70 g), improving existent previous methodologies as a contribution for standardized protocols for analysis of MPs in biota. Seafood samples depurated or not were collected along Catalonia Coast (NE Spain) in October-November 2017. Seafood samples included wedge clams (*Donax trunculus*), marine snail (*Bolinus brandaris*), razor clams (*Ensis silicua*), fine clams (*Tapes decussatus*), big oyster (*Crassostrea gigas*) and musells

(*Mytilus galloprovincialis*) from north, middle, and south zone at depurate and not depurated conditions. The dietary intake of MPs from depurated mussels, oysters and clams of Catalan population was estimated by applying the following equation: $E_t = C_f * X_{t,f}$, where E_t is the dietary exposure to the MPs (MPs/day), C_f is the mean consumption of that molluscs (f) (g/day) by population and $X_{t,f}$ is the concentration of the MPs in each samples group f (MPs/g wet weight fresh and soft tissue). The mean consumption of each age group was after normalized by dividing the dietary intake by the mean body weight of each age group. An optimized method for analysing MPs in molluscs samples has been developed successfully for reliable MPs quantification. The average MPs concentration values in molluscs found in this study were higher than reported for previous studies, vulnerable population as adults 40-65 years (higher incidence of chronic diseases) and pregnant woman have high MPs diary intakes compared with the intakes of entire population from other countries. A systematic and comprehensive analysis of MPs concentration in molluscs from Catalan coast and local consumption seafood surveys are needed to clarify the status of human exposure of Catalan people

3.09.P-Mo181 Plastic and Non-Plastic Microparticles Show Surface-Related Effects on the Reproduction of the Nematode *Caenorhabditis elegans*

Sebastian Hoss¹, Marie-Theres RauchsSchwalbe², Hendrik Fueser² and Walter Traunspurger², (1)Ecosa, Starnberg, Germany, (2)Bielefeld University, Germany

Microplastic particles can disturb the food availability of nematodes and, by this indirect effect mechanism, also inhibit their reproductive output. Thus, microplastic might pose a risk to aquatic organisms under realistic conditions, where food availability is not always guaranteed. Benthic invertebrates, such as nematodes, live and feed in sediments, consisting of organic and inorganic particles of all sizes and shapes. Therefore, any observed effects of synthetic plastic particles on benthic invertebrates must be put in perspective to the abundance of natural particles in their habitat, for evaluating the ecological risk of microplastic. We tested a variety of microplastic particles of various sizes (0.1 to >100 µm), shapes (beads, fibers, fragments) and polymers (PS, PFTE, PET, PA) in terms of their effects on the reproduction of *C. elegans* using a standardized test protocol (ISO 10872) and compared the effects to those of naturally occurring microparticles, such as clay minerals (dolomite, kaolin), silica beads and plant spores. We could show that, independent of the material or polymer, the particle size determined the quantity of the nematode's response (i.e. EC50). However, if relating the effect to the total surface area of the particles, a size-independent EC50 (expressed as cm²/ml) could be identified for beads and fragments. These results bring up several questions that should be discussed in context of the effect and risk assessment of microplastics in the environment: (1) Do microplastics add an additional risk to organisms that live in particle-rich environments, such as soils and sediments? (2) Can naturally occurring particles, such as minerals or spores can serve as reference particles in routine toxicity testing of microplastics? (3) Is the total surface area of particles a suitable parameter to predict adverse effects of microparticles?

3.09.P-Mo182 In-Vitro Assessment of the Sensitivity of Bivalve Hemocytes to Nanoplastic Exposure

Jenevieve Hara¹, Maaïke Vercauteren², Colin Janssen³, Ronny Blust⁴, Prof. Jana Asselman⁵ and Raewyn Town¹, (1)Systemic Physiological and Ecotoxicological Research (SPHERE), University of Antwerp, Belgium, (2)Ghent University, Ghent, Belgium, (3)University of Ghent, Belgium, (4)University of Antwerp, Belgium, (5)Ghent University, Belgium

Plastic particles are prevalent in the environment, and the risks they pose especially to aquatic organisms are of growing concern. A range of responses attributed to plastic particle exposure have been documented across various levels of biological organization, extending from cellular to population-level endpoints. However, systematic analyses of sub-lethal endpoints at the cellular level, which are considered as a sensitive response variable to plastic particle exposure, are still lacking. It has been established that plastic particles can be internally distributed in organisms through various ways, such as translocation and penetration of biological barriers. In particular, particles with dimensions in the order of nanometers (i.e. nanoplastics, NPs, < 1000 nm) are able to enter cells via endocytotic pathways (i.e. phagocytosis). These cellular processes have been highlighted as integral factors that influence key physiological functions including cellular immunity. Hemocytes are responsible for cell-mediated immunity in bivalve mollusks such as the mussel *Mytilus edulis*, which is highly susceptible to NP exposure due to its sedentary and filter-feeding life style. The hemocytes circulate within the hemolymph and can cross all epithelial boundaries, acting as phagocytes against foreign particles, including plastic particles. Assessing the different physicochemical properties of NPs, such as polymer type, size, shape, and surface charge, is crucial as these parameters may directly affect the cellular uptake mechanisms as well as cytotoxicity. Hence, this study aims to mechanistically evaluate whether NPs induce cytotoxicity in the different hemocyte subpopulations of mussels *M. edulis*. The timescale and extent of cellular responses will be assessed, particularly those related to apoptosis and the production of reactive oxygen species (ROS) as a biomarker for oxidative stress. An in-vitro approach will be applied to characterize and interpret the response profiles under environmentally relevant exposure conditions and in assessing differential effects linked to characteristics of the plastic particles (type, size, shape). The assessment of the cellular responses to plastic exposure will be carried out through the complementary use of flow cytometry and fluorescence microscopy. The results will provide insights into the underlying mechanisms associated with different physicochemical characteristics of NPs at a cellular level which is crucial for assessing their fate and toxicity in aquatic organisms.

3.09.P-Mo183 Ingestion and Toxicity of Polystyrene Nanoparticles (PS-NPs) on Artemia larvae (*Artemia urmiana*)

Abolfazl Naji¹ and Farhan R. Khan², (1)University of Hormozgan, Germany, (2)NORCE (Norwegian Research Center), Norway
Currently little knowledge is available on the impact of nanoplastics (defined as being < 1 or < 0.1 micron depending on the definition used) on marine organisms. Although the amount of nanoplastics in the aquatic environment is not yet known, it is expected that nanoplastics will have a different impact on aquatic organisms than larger microplastics due to their small size, high surface curvature, and large surface area. The current study aimed to evaluate the effects of 40 nm anionic carboxylated (PS-

COOH⁻) and 50 nm cationic amino (PS-NH⁺₂) polystyrene nanoplastics (PS-NPs) on brine shrimp *Artemia urmiana* larvae. Larvae were exposed for 14 days with a concentration of 0.5, 1, 1.5, 2.5 and 5 ppm and then depurated for 24 h in clean medium. Measured endpoints included mortality, growth, total fatty acid and protein content. For both PS-NPs (5–100 ppm), nanoplastics were found in the gut lumen of larvae (24 and 48 h) and adsorbed at the surface of sensorial antennules and appendages. Some of PS-NPs were excreted as fecal pellets following 24h depuration in clean seawater, but a complete emptying of the gut was not observed. Larvae exposed to PS-NH⁺₂ underwent multiple molting events during 24 and 48 h of exposure compared to controls and PS-COOH⁻. No significant *Artemia nauplii* mortality was found following 48 h of exposure for both PS-NPs in the tested concentration range (5-100 ppm). Significant mortality was observed after 14 days of exposure for both PS-NPs of different concentrations (0.5-5 ppm) at nauplius stage. The results also showed that exposure of *Artemia urmiana* larvae to anionic carboxylated (PS-COOH⁻) after 14 days reduced total fatty acid and protein concentrations by 15.4% and 9.4%, respectively. Nano-sized PS was shown to impair feeding and motility, and cause multiple molts of brine shrimp larvae indicating that the sub-lethal effects of nanoplastics should be further investigated

3.09.P-Mo184 Effect-Directed Analysis (EDA) of Beach Plastic (PlastEDA) From Baltic Sea

*Arslan Hashmi*¹, *Anna Kärrman*¹, *Maria Larsson*², *Anna Rotander*³, *Marina Albentosa*⁴ and *Steffen Keiter*¹, (1)Orebro University, Sweden, (2)School of Science and Technology, Orebro university, Örebro, Sweden, (3)Örebro University, Sweden, (4)Instituto Español de Oceanografía, Spain

The rising presence of plastic debris along with chemical pollution in aquatic environments caused increasing concern regarding potential impacts on human and environmental health. Apart from physical effects, plastic particles contain toxic additives, and these particles adsorb various chemicals present in the surrounding environment. Upon reaching in the living organisms' gut these chemicals may desorb which lead to adverse effects. Beach plastic was collected from Gotska Sandön, an island in the Baltic Sea, south-east of the Swedish mainland. The samples were cleaned, and polymer type characterization was conducted using a fourier transform infrared (FTIR) spectroscopy. Each polymer was grinded separately and sieved into various sizes by using steel sieves. For size characterization a Multisizer Coulter counter III (MSIII) was used. Each particle size group was extracted separately with a mixture of organic solvents. For the measurement of the mechanism-specific hazard potential, the plastic extracts were screened with different Chemical Activated Luciferase gene eXpression (CALUX) bioassays for agonistic and antagonistic activities for various nuclear hormone receptors (estrogenic, androgenic, and thyroid), aryl hydrocarbon receptor (AhR) and for mutagenic response i.e., P53. Complexity of samples is reduced by using gas chromatographic- (GC-) fractionation with parallel mass spectrometric (MS) detection system and obtained fractions are biologically analyzed. Bioactive fractions are chemically screened by using quadrupole-time of flight mass spectrometry linked to gas chromatography (GC-QTOFMS). Preliminary results indicate high estrogenic and AhR potencies in various extracts, which were selected for effect-directed analysis (EDA) to identify chemicals that are causing these effects.

3.09.P-Mo185 Sea Urchin Interaction With Nano-And Microplastics Particles: Size and Morphology Influence on Ingestion-Egestion

*Nora Exposito Lorenzo*¹, *Joaquim Rovira*², *Jordi Sierra*¹, *Vikas Kumar*¹, *Maria I Arnone*³, *Salvatore D'Aniello*³ and *Marta Schuhmacher*⁴, (1)Universitat Rovira i Virgili, Spain, (2)University Rovira i Virgili, Spain, (3)Stazione Zoologica Anton Dohrn Naples, Italy, (4)Rovira i Virgili University, Spain

Microplastics on sea bottom have potential to be ingested by benthic organisms with adverse effects as disrupting feeding and digestion, energy reserves and fecundity decrease. In addition, hazardous substances released from microplastics might impact these organisms; this implies that microplastics accumulation and interaction time in organisms could be directly related to their toxic effects. In this study, adult and larvae sea urchins (*Paracentrotus lividus*), a common Mediterranean benthic organism, were used to study ingestion, egestion and body interactions with micro and nanoplastics. Several types of plastics were used: polyethylene (PE) spheres of 53-63, 125-150, 250-300 and 425-500 µm of diameter, polyamide (PA) fibres and polystyrene (PS) nanoplastics (80 nm of diameter). For adults, six experiments were designed with microplastics at same weight ratio (1:1): ingestion 48 h, ingestion-egestion 48 h, ingestion 96 h, all of them at two concentrations 50 and 250 mg/L. For larvae (pluteus-4 arms), were tested four concentration of 53-63 µm PE spheres and fibres (1.4 mg/L, 2.5 mg/L, 12 mg/L, 26 mg/L) and 80 nm PS nanoplastics (0.05 mg/L, 0.26 mg/L, 2.6 mg/L, 26 mg/L) in 24 h. Results showed that adult sea urchins actively ingested PE spheres of 53-63µm and 125-150 µm, conversely, 450-500 µm the biggest PE spheres and fibres were the less ingested, although the fibers showed signs of chewing. For 53-63 µm, adults sea urchin ingested 1285 ± 1056 per individual (0.2 % of particles added) and egested up to 84 % of the quantity ingested. Regarding 125-150 µm PE spheres, 267 ± 244 were ingested per individual (0.5 % of particles added) and egested up to 82 % of the quantity ingested. The total body interaction (plastic particles present in intestine, plates, spines, tube feet and water vascular system) with these both particles was 0.6 % of the total particles added. The ingestion-96 h rate was similar to ingestion-48 h for 250 mg/L test and for all sizes and morphology with r²= 0.82. The adults does not select the particles, they feed depending on particles concentration and distribution, the spheres were more easily ingested, the microplastics were not fully excreted within 48 hours, the ingestion rate 48 h was similar to ingestion 96 h. Regarding larvae, microplastics concentration 26 mg/L and nanoplastics concentration 2.6 mg/L decreased the 24 h-survival rate to 74 % and 78%, respectively

3.09.P-Mo186 Toxic Effects of Micro- and Nanoplastic (MNP) Across Different Taxonomic Groups and Their Key Mechanisms

*Elvis Genbo Xu*¹, *Sara Matthews*², *Lei Mai*³, *Chang-Bum Jeong*⁴, *Jae-Seong Lee*⁵ and *Eddy Zeng*³, (1)University of Southern Denmark, Odense, Denmark, (2)McGill University, Canada, (3)Jinan University, China, (4)Incheon National University, Korea,

South, (5)Sungkyunkwan University, Korea, South

Detrimental biological effects of micro- and nanoplastics (MNPs) have been observed on a variety of organisms. A fast-growing number of toxicological studies report diverse responses and wide species-dependent sensitivity upon MNP exposure. While studies are dominated by *in vivo* animal tests, our understanding of cellular toxicity and the corresponding toxicity mechanisms is still limited. This challenges the proper assessment of environmental hazards and health risks of MNPs. In this presentation, we gathered and analyzed recent studies including our own laboratory data on human cells, animals, plants, alga, and bacteria, and identified the similarities and differences in toxic effects and key mechanisms of MNPs across different taxonomic groups. In general, toxicities are often observed at high doses (~mg/L) and the effects and mechanisms of MNPs depend on their sizes, surface characteristics, polymer types, as well as cell types. Plausible toxicity mechanisms mainly include membrane disruption, extracellular polymeric substance disruption, reactive oxygen species generation, DNA damage, cell pore blockage, lysosome destabilization, and mitochondrial depolarization. The identified plausible toxicity mechanisms are useful to prioritize and improve future *in vivo* and *in vitro* toxicological and risk assessment studies of MNPs.

3.09.P-Mo187 The Toxicity of Microplastic Degradation Products to PLANTS Following Composting

Emma Danby¹ and Sian Mitchell², (1)Covance, United Kingdom, (2)Labcorp Early Development Laboratories Limited, United Kingdom

Microplastics are small pieces of plastic that pollute the environment. Microplastics are not a specific type of plastic, but rather any plastic fragment that is less than 5 mm in size. They enter the environment via many sources, including cosmetics, clothing, and industrial processes. Once in the oceans, microplastics can either float or sink. Plastics degrade slowly, over hundreds or thousands of years. This increases the likelihood of microplastics being ingested and incorporated into, and accumulated in, the bodies and tissues of many organisms. This may have toxic effect on the organisms. Or the microplastics may enter the food chain, especially via fish and shellfish. This could have consequences for the health of human consumers. Variations to existing standardised biodegradation methods or potentially entirely new standardised testing methods are likely to be necessary to appropriately assess the (bio)degradability of microplastics in the environment. However, application of existing standardised methods can provide valuable information on the (bio)degradability potential of some microplastics. Unfortunately, unlike standard biodegradable chemicals, very little is understood about the environmental impacts of degraded microplastic material. These are either disintegrated into smaller micro or nano plastics or into their composite monomers. The toxicity profiles of these degradation products might not be known. Here we present our early results from a successive composting test on a series of micro plastic materials culminating in a plant toxicity tests to determine the toxicity of the degradation products.

3.09.P-Mo188 Plastic Contamination of Edible Parts of Marine Organism in the North Atlantic French Coast

Bettie Cormier¹, Florane Le Bihanic¹, Charlotte Lefebvre², Sophie Lecomte³, Jérôme Cachot¹ and Bénédicte Morin¹, (1)University of Bordeaux, France, (2)Environnements et Paléoenvironnements Océaniques et Continentaux, F-33600 Pessac, France, (3)Centre National de la Recherche Scientifique, France

For the last decades, scientific community agreed on the widespread of microplastics (MPs, < 5 mm) in aquatic environments. MPs are ingested by most of marine organisms, including the ones consumed by humans. In this study, we evaluated the MPs contamination of the aquatic biota and determined the exposure via seafood consumption, both for French consumers as well as world average eater (Arplastic project). The present study aimed at describing the MPs contamination in the aquatic foodweb of Arcachon Bay (France) along the year 2019 by selecting four edible species as pacific oyster (*Crassostrea gigas*), sea spider crab (*Maja squinado*) and two fish, a benthic one (common sole, *Solea solea*) and a pelagic one (sea bass, *Dicentrarchus labrax* or *punctatus*). All sorted particles detected in organisms were chemically characterized by ATR-FTIR. Among all particles, fibers was the predominant shape for all species (75-100%) and color depended on species and were mainly blue, white or black. Cellulosic particles ($1836 \pm 1321 \mu\text{m}$) represented 69 to 84%, equivalent to 1.60 ± 1.74 items/individual for *M.squinado*, while other species contained in average 0.62 ± 1.15 items/ind. Besides, MPs contamination ($2022 \pm 1923 \mu\text{m}$) represented less than 1 particle/individual in average, corresponding to 0.0083 ± 0.023 MPs/g (ww). However, particles contamination did not vary over time, and no seasonal trend was observed. Particle's contamination in organisms collected in Arcachon Bay participated to assess the potential seafood contamination of humans. According to the results of this study, we can estimate that a medium French seafood eater would ingest in average 4 to 5 cellulosic particles per week depending if it is a men, a women or an elderly, while they would consume 1 MPs per week. More globally, a world average eater would ingest 6 cellulosic particles and 2 MPs per week. This work contributes to a better consideration of MPs in environmental and health risk assessment.

3.09.P-Mo189 Embryotoxic and Neurobehavioral Effects of Different NanoPlastics on the Early LIFE Stage in Zebrafish (*Danio rerio*)

Xiaoyu Duan¹ and Elvis Genbo Xu², (1)Department of Biology, University of Southern Denmark, Odense, Denmark, (2)University of Southern Denmark, Odense, Denmark

Abstract: Nanoplastic has attracted global attention due to its potential ecological and health impacts. Current ecotoxicological studies on animals are dominated by using plain polystyrene nanobeads, however, our understanding of the toxic effects of other types of nanoplastics is left far behind. In this study, we compared the embryonic and neurobehavioral effects of different nanoplastic types, including polystyrene (PS), polypropylene (PP), polyethylene terephthalate (PET), and polyethylene (PE), polyester-polyurethane (PUR), polycaprolactone (PCL), and polyamide (PA). Early-life stage zebrafish embryos and larvae (2 to 120 h postfertilization) were used as the model. The impacts of nanoplastic exposure on hatchability, embryonic development rate, mortality, and deformity rate, and brain histology were measured. Furthermore, the larval locomotor activity, as a highly sensitive and rapid neurobehavioral indicator, was quantified and compared between different nanoplastic treatment and control

groups. These comprehensive results provide new insights into the similarity and difference in toxicity of different types of nanoplastics and highlight the challenge of assessing the ecological risks of nanoplastics due to the great complexity of nanoplastic mixtures in the environment.

3.09.P-Mo190 Maternal Exposure to Plastics Impacts Fetal Development in a MOUSE Model of Pregnancy

Zahra Aghaei¹, Grace Victoria Mercer², Nikita Harvey³, Xiaolei Li¹, Karl Jobst¹ and Lindsay Cahill⁴, (1)Memorial University of Newfoundland, Canada, (2)Chemistry, Memorial University of Newfoundland, St. John's, NF, Canada, (3)Chemistry, Memorial University of Newfoundland, Bay Bulls, NF, Canada, (4)Memorial University of Newfoundland, St John's, NF, Canada

Plastics are ubiquitous in modern society and when released into the environment, they break down into smaller particles termed microplastics (plastic particles with diameters < 5mm) and nanoplastics (diameter < 1 um). These micro- and nanoplastics can be ingested by organisms and potentially accumulate in tissues and organs. Humans are primarily exposed to plastic particles by inhalation of dust, ingestion of food contaminated by dust fall, and through drinking water. Recently, 5-10 um plastics were found in the placentas of healthy women, raising the concern that plastics exposure may have an impact on pregnancy and fetal development. In this study, we investigated the effect of maternal exposure to plastics on fetal growth and brain development using experimental mice. The mouse reproduces many of the physiological and molecular features of pregnancy, making it a commonly used model to study pregnancy. Throughout gestation (gestational day 0.5 to 17.5; full-term is 18.5), pregnant CD-1 dams were exposed to 5 um polystyrene plastics in filtered drinking water at concentrations ranging from 0-1000 ug/L (n=11-12 dams/group). The pregnant dams were sacrificed at E17.5 and fetal and placental weights were recorded. The umbilical cord length was also measured. In a separate cohort, dams were sacrificed at gestational day 15.5 and fixed for scanning by X-ray micro-computed tomography. 3D datasets were acquired and compared between groups to assess differences in embryo morphology. While there was no significant difference in placental weights between groups, the fetal weights were significantly decreased with plastics exposure in a dose-dependent manner (p=0.002). There was also a significant decrease in the umbilical cord length (p< 0.0001), suggesting decreased fetal growth and decreased fetal movement. We will also present the results of the micro-computed tomography study to detect anatomical differences between groups. This study demonstrates that maternal exposure to plastics at a high concentration have a deleterious effect on placental and fetal development.

3.09.P-Mo191 Does Exposure to NanoPlastics Impact Pregnancy Outcome and Fetal Development?

Nikita Harvey¹, Grace Victoria Mercer², Zahra Aghaei³, Xiaolei Li³, Karl Jobst³ and Lindsay Cahill⁴, (1)Chemistry, Memorial University of Newfoundland, Bay Bulls, NF, Canada, (2)Chemistry, Memorial University of Newfoundland, St. John's, NF, Canada, (3)Memorial University of Newfoundland, Canada, (4)Memorial University of Newfoundland, St John's, NF, Canada

There is growing concern about the potential human health impacts of exposure to nanoplastics (diameter < 1um). Humans are primarily exposed to nanoplastics by inhalation of indoor dust and ingestion of food contaminated by dust fall. Following exposure, nanoplastics are small enough to translocate from the lungs into the blood stream and accumulate in other organs. A recent study reported plastics (diameter 5-10 um) in the placentas of health women, raising the concern that exposure to plastics may have an impact on pregnancy and fetal development. In this study, we investigated the effect of maternal exposure to nanoplastics on fetal growth and postnatal brain development using experimental mice. The mouse is a well-accepted model of human pregnancy, reproducing many of the physiological and molecular features of pregnancy. There is also considerable cross-species alignment between mouse and human fetal neurodevelopment, making the mouse a good model for studying brain maturation. Throughout gestation (18.5 days) and during lactation (23 days), pregnant CD-1 dams were exposed to 50 nm polystyrene nanoplastics in filtered drinking water (1000 ug/L, n=5 dams). A control group drinking filtered water without plastics was also included (n=5 dams). During the neonatal period, the pups were weighed weekly and underwent a series of behavioural tests to determine the timing of developmental milestones including righting reflex (from postnatal day 2-6) and eye opening (from postnatal day 9-17). At weaning (postnatal day 23, equivalent to adolescence in a human), a subset of the pups (2 females and 2 males/litter) were sacrificed by perfusion fixation for ex vivo high-resolution 3D magnetic resonance imaging (MRI) to investigate neuroanatomical differences between the groups. A second subset of pups (2 females and 2 males/litter) were sacrificed for metabolomics studies of the brain tissue using high-resolution magic angle spinning magnetic resonance spectroscopy. The MRI and metabolomics data will be correlated with the outcomes from the behavioural tests. This study demonstrates the impact of maternal exposure to nanoplastics on pregnancy outcome and fetal development.

3.09.P-Mo192 Endocrine Disruptive Effects of Disposable Face Mask Leachates on the Androgen Receptor Within an Aqueous Environment

Rialet Pieters¹, Suné Claassen² and Suranie Horn³, (1)North West University, Potchefstroom, South Africa, (2)North West University, South Africa, (3)North West University Potchefstroom, South Africa

To fight the spread of Covid-19, the use of disposable face masks increased drastically as most countries made it compulsory to wear a mask in public. The face masks are made up of polymeric materials, mainly polypropylene. Some well-known leachates from plastics are phthalates, bisphenol A (BPA) and nonylphenols, which are known to cause endocrine disruption. Since masks are not being discharged as medical waste only they end up in landfills, and due to weather conditions end up in water bodies. This study aimed to determine whether leachates from face masks have (ant)agonistic effects towards the androgen receptor (AR) using the MDA-kb2 reporter gene assay. Face masks were leached in ethanol for 24 and 48 h at 4°C and 30°C to allow the leaching of water-soluble compounds. The MDA-kb2 cells were exposed to the leachates and because these cells are genetically modified with a transcribed luciferase enzyme, (ant)agonistic AR effects could be determined by measuring the luminescence produced. The glucocorticoid receptor (GR) is also under the control of the same reporter gene construct in the same cell line. The amount of light emitted by the cells is expressed in terms of the known reference compound: testosterone (T) for the AR and

dexamethasone for the GR. For antagonism, the cells received T during seeding and the known antagonist, flutamide, was used as reference compound. The MTT viability assay was also performed to determine the cytotoxicity of the leachates but no cytotoxicity was recorded. Neither dose-related agonistic effect of the AR or GR was observed, nor quantifiable antagonism of the AR at the concentrations tested. Since the face mask leachates did not show any effect on the AR and are considered non-cytotoxic, it is possible that the leaching of toxic compounds did not occur or that the concentrations of the leachates used are not sufficient for quantification of endocrine disruptive activities. Many variables from the study can further be experimented with for example extended leaching periods, adjustments to leaching temperatures, use of different leaching solvents and exposing the cells to different leachates concentrations. Further research on mask leachates is crucial to protect human and environmental health from this emerging pollutant.

3.09.P-Mo284 Paint Particles in the Weddell Sea (Antarctica): A Forensic Investigation

Clara Leistenschneider¹, Patricia Burkhardt-Holm², Sebastian Primpke³, Thomas Mani⁴, Heidi Taubner⁵ and Gunnar Gerds⁶, (1)Alfred-Wegener-Institut, Switzerland, (2)University of Basel, Switzerland, (3)Alfred Wegener Institute, Germany, (4)The Ocean Cleanup, Netherlands, (5)University of Bremen, Germany, (6)Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Germany

Microplastics (MP; < 5mm) are ubiquitous in the marine environment and considered as an emerging threat to marine biota what raised extensive scientific attention over the recent decades. Paint particles, which have similar compositions to microplastics, however, received little attention, even though antifouling-paints can have more severe impacts on marine biota than other synthetic particles. In this study, we evaluate MP (>300 µm) concentration and composition in surface (n=34) and subsurface water samples (n=79, 11.2 m depth) of the Weddell Sea. All putative MP were analyzed by attenuated total reflection Fourier transform infrared (ATR-FTIR) spectroscopy. MP was found in 65% of surface and 11.4% of subsurface samples, with mean concentrations of 0.01 (±0.01 SD) MP m⁻³ and 0.04 (±0.1 SD) MP m⁻³, respectively, being within the range of previously reported values for regions south of the Polar Front. Of all recovered MP, 47% are possibly associated to ship paints due to their polymer composition, visual characteristics and brittleness. This indicates that paint particles might be an important microplastic source in the southern ocean. Additionally, particles with same colors as paints from RV *Polarstern* were found (n=394) but could mostly not be assigned to a polymer by means of FTIR due to low quality matches with the spectral library. Particles of that type (n=101) with similar FTIR spectra to reference paints from the research vessel and fresh paint references generated in the laboratory, were further subjected to micro-X-ray fluorescence spectroscopy (µXRF), a method also used in forensic science to discriminate paint particles left on traffic accident sites based on the composition of inorganic pigments and additives. Besides Ti, Ca and Fe, which were found in nearly all particles, heavy metals such as Cu, Pb and Zn were detected. Further µXRF measurements revealed that 45.5% of all recovered synthetic particles derived from vessel-induced contamination, while 11% of the measured paint fragments could be distinguished from the reference paints via their elemental composition and might derive from other sources. This study demonstrates that low-quality matches for FTIR spectra of ship paints might lead to underestimation of paint particles in the marine environment if not analyzed further. The additional evaluation of inorganic pigments and additives is needed, to evaluate and understand the full contribution of paint particles to the marine MP load.

3.10 Microplastics in the environment: Behaviour, transport, fate, risks, and alternatives to conventional plastics (Part I)

3.10.T-01 Biodegradation of Engineering Plastics: Influence of the Polymer Backbone on TPU Microplastic Degradation and Fragmentation

Patrizia Pfohl¹, Daniel Bahl¹, Markus Rückel¹, Marion Wagner¹, Lars Meyer¹, Patrick Bolduan¹, Thorsten Huffer², Michael Zumstein³, Thilo Hofmann³ and Wendel Wohlleben, Dr.⁴, (1)BASF SE, Germany, (2)University of Vienna, Vienna, Austria, (3)University of Vienna, Austria, (4)Material Physics & Analytics AND Experimental Toxicology & Ecology, BASF SE, Germany

Since plastic pollution increased over the last decades, authorities had to take actions: Bans, reporting and labelling requirements for intentionally added primary microplastics serve to avoid their release into the environment during or after product application. Biodegradable polymers are derogated from the restriction proposed by the European Chemicals Agency, thus putting a lot of focus on the development of biodegradable alternatives. Biodegradation is based on microbial oxidation and hydrolysis processes in environmental matrices that result in the complete transformation of polymer carbon into biomass and CO₂. Polymers based on polylactic acid and polybutylene adipate terephthalate are commonly used biodegradable plastic products, which is why its biodegradation processes have been intensively investigated. In contrast, little is known about biodegradation of engineering plastics like thermoplastic polyurethanes (TPU). TPUs based on polyester polyols provide the possibility for hydrolysis, which might make them susceptible to microbial attack. Here we studied biodegradation of TPU esters in compost, and systematically varied the polymer backbone to provide guidance to future polymer development. We investigated the influence of a hydrolysis stabilizer, low and high hard segment contents and crosslinking on the fragmentation and degradation of TPU microplastics. During biodegradation (ISO 14855, part of EN13432) CO₂ evolution was monitored. To gain insights into the fragmentation, we developed and validated a non-destructive and efficient extraction protocol for the partially biodegraded TPUs from compost. We assessed the particle number and the particle size distribution via fluorescence microscopy (staining with Nile Red) and FT-IR microscopy. In addition, we confirmed the reduction of molar masses by GPC and the hypothesized increase of crystallinity by WAXS. We successfully developed methods to extract TPUs from compost and to monitor biodegradation of TPUs in compost. Our research revealed that hydrolysis stabilizers change the rate and pathway of fragmentation, that a low hard phase content increases biodegradability and that crosslinking reduces biodegradability. These are safer-by-design principles for the development of alternatives or improved versions of conventional plastics.

3.10.T-02 Impacts of Polyethylene Microspheres on the Freshwater Duckweed *Lemna minor*

Mariana Rodrigues¹, Nelson Abrantes², Fernando J. M. Gonçalves², Andreia Filipa Mesquita², Carolina Rocha³ and Ana Marta Gonçalves⁴, (1)University of Aveiro, CESAM - Centre for Environmental and Marine Studies, Portugal, (2)CESAM & University of Aveiro, Portugal, (3)University of Coimbra, MARE - Marine and Environmental Sciences Centre, Portugal, (4)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Coimbra, Portugal

There is great concern regarding the abundance and impacts of plastics, namely microplastics (particles < 5 mm), in aquatic ecosystems. Microplastics can derive from a variety of sources, reach high densities, adsorb chemical compounds from water/sediment compartments and cause negative impacts on the environment and in human health. This issue has been well documented for marine environment; however, freshwater systems are still overlooked leading to a gap in knowledge, especially about the impacts of these micro-sized particles on primary producers. Hence, this is a pioneering study aiming to evaluate the impacts of polyethylene microspheres on the freshwater duckweed *Lemna minor* by assessing the ecotoxicological effects on the growth, root length, and nutritional profile (i.e., fatty acids and carbohydrates composition and abundance). Results pointed out that growth (based on fronds number and dry weight), root length and the nutritional profile were not affected by polyethylene microspheres. In fact, when exposed to the highest concentration the growth rate and yield of *L. minor* were significantly stimulated. Regarding the root length, it was observed an inhibition trend that does not follow a dose-response relationship. The composition and abundance on fatty acids and carbohydrates were not significantly affected by polyethylene microspheres guaranteeing the important input of non-synthesized fatty acids (e.g., essential fatty acids – omega-6 and omega-3) and carbohydrates into higher trophic levels. Moreover, polyunsaturated fatty acids and rhamnose increased their abundance over the range of polyethylene concentrations suggesting that they were the main contributors to *L. minor* resisted polyethylene exposure. Thus, polyethylene microspheres at environmentally relevant and higher concentrations do not present a hazard to freshwater macrophytes.

3.10.T-03 From Rivers to the Tap: Investigation of Micro- and NanoPlastics in Drinking WATER by Pyrolysis-Gc-Ms

Feride Öykü Sefiloglu¹, Marthinus Brits², Lorenzo Scibetta³, Martin van Velzen⁴, Quinn Groenewoud⁴, Dick Vethaak⁵, Heather Leslie⁶ and Marja Lamoree⁷, (1)Environment and Health, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (2)Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (3)A-life, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (4)Vrije Universiteit Amsterdam, Netherlands, (5)DELTA RES, Netherlands, (6)VU Amsterdam, Netherlands, (7)VU University, Department Environment & Health, Netherlands

The occurrence of micro- and nanoplastics (MNPs) in freshwater has been globally recognized. This raised the question of possible human exposure to MNPs through drinking water from freshwater sources. Recent studies have shown that potable water may contain MNPs, but a high degree of variation in concentrations has been reported. These variations are attributed to the differences between raw water and the treatment and distribution processes. However, the analytical techniques employed for the identification and quantification of MNPs also have a significant role at the level of reported. To be able to estimate the MNP associated risks via drinking water consumption, reliable exposure concentrations with lower size limits of polymers are urgently needed. In the present study, a sensitive method was developed to detect and quantify MNPs in water samples based on the protein corona mediated aggregation of particles followed by filtration and analysis with pyrolysis-gas chromatograph-mass spectrometry (Py-GC-MS). The method was validated using different types of water and acceptable recoveries were obtained for PE, PP, PVC and PS ranging from 97 to 118%. Given the ubiquity of microplastics in freshwater systems and increased particle numbers with decreasing polymer sizes, this method is a promising tool to quantify MNPs in water samples and to evaluate the risks for human health.

3.10.T-04 A Sequential Extraction Scheme to Selectively Analyze Adsorbed (Trace) Elements on Plastic Particles

Gilberto Binda¹, Stefano Carnati², Davide Spanu², Damiano Monticelli², Andrea Pozzi², Arianna Bellasi², Roberta Bettinetti³ and Luca Nizzetto⁴, (1)NIVA - Norwegian Institute for Water Research, Oslo, Norway, (2)University of Insubria, Italy, (3)University of Insubria, DISUIT, Italy, (4)Norwegian Institute for Water Research NIVA, Norway

Plastic pollution is an environmental issue of concern, as the mismanagement of plastic wastes strongly impacts water environments. Plastic particles were recently observed to adsorb dissolved (trace) elements in water environments, and this issue has attracted interest of researchers in order to understand their interaction mechanisms. Accordingly, the analysis of plastic environmental samples plays a crucial role in understanding the likelihood of such interactions. Recent approaches focused on the total extraction of metals from plastic samples through acid digestion, which dissolve the polymer matrix and overestimate the elemental load of plastics. In addition, this procedure does not provide any information on the speciation of the adsorbed elements: the implementation of a detailed speciation scheme is therefore strongly advised. In this study, we propose a three-step extraction protocol that was tested on different plastic particles sampled from a freshwater environment. Plastic samples were obtained grinding macroscopic plastic materials collected on the shores of an oligotrophic lake (Lake Como, Italy). Non degraded plastic was also investigated to assess the effect of degradation on the metal adsorption capacity. Sequential extraction was performed using empty solid phase extraction cartridges with the following reagents: i) ammonium nitrate 1M, to extract physisorbed metals; ii) acetic acid 0.1M to extract metals in slightly acid condition; iii) hydrogen peroxide 30% to extract metals bound to organic matter and biofilms. Solutions were then analyzed by inductively coupled plasma – mass spectrometry. Kinetics test in the 1-72h range suggested that equilibrium in the extraction was achieved after 24h under shaking. The comparison of environmental and unaged samples showed that the former generally enrich in different micronutrients (Fe, Sr and Mn) and other trace elements (Sn, Pb, Ba and partly Ti), which show concentration at least ten-fold higher than in the unweathered material. Moreover, most of the microelements were prevalently present in the H₂O₂ extraction step, indicating organic species as the prevalent form of the elements onto plastic surfaces and pointing to biofouling as the major mechanism for (trace) elements

accumulation onto plastics from lake water. These results will be then compared with different single-extraction protocols present in the literature and applied to microplastic samples in different water environments.

3.10 Microplastics in the environment: Behaviour, transport, fate, risks, and alternatives to conventional plastics (Part II)

3.10.T-06 Microplastic in Sediment and Macroinvertebrates From a Norwegian Stream in Connection to a Plastic Recycling Plant

Emilie Maria Falk Kallenbach¹, Nikolai Friberg², Rachel Hurley³, Dean Jacobsen⁴, Cecilie Singdahl-Larsen² and Tor Erik Eriksen², (1)NIVA Denmark, København s, Denmark, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Nowegian Institute for water research, Norway, (4)University of Copenhagen, Denmark

Freshwater systems are close to sources of microplastics from e.g. sewage treatment plants, runoff from urban and agricultural areas and industry. e.g. plastic recycling plants. Freshwater systems have been found to not only act as a vector for transport of microplastics to the marine environment but also to accumulate microplastics in the sediment. Benthic macroinvertebrates are important component of freshwater ecosystems and expected to be exposed to microplastic as they live in close association with the sediment. Macroinvertebrates has been widely used to assess the status of a freshwater system, as the very diverse groups shows tolerance/sensitivity towards different stressors, and some of them have long life cycles which enables accumulation of contaminants. Apart from monitoring, macroinvertebrates also make up an essential link to the higher trophic levels in the freshwater food web and might thus constitute an essential pathway for microplastic into the food web and if ingested, microplastic might act as a potential stressor in these organisms. Despite the obvious exposure risk, it is still unknown how and if this macroinvertebrates can be used as a sentinel for microplastic pollution as there is a lack of studies on freshwater macroinvertebrates, and little is known about the occurrence of microplastic, the correlation with microplastic in the sediment and the effect from feeding trait and lifestyle. This study focusses on plastic in three macroinvertebrates species living in a natural environment, however heavily polluted by microplastic due discharge from a plastic recycling plant into the stream. We investigate differences between organisms living upstream and downstream the recycling plant, differences between species and correlation to sediment concentrations.

3.10.T-07 Where Does the Marine Plastic Go? Abundance and Distribution of MPs in the Kattegat Sea

Gunaalan Kuddithamby¹, RODRIGO ALMEDA², Torkel Gissel Nielsen³, Claudia Lorenz⁴, Alvise Vianello⁴, Rocío Rodríguez-Torres³, Lucian Lucian Iordachescu⁴, Konstantinos Papacharalampos⁴ and Jes Vollertsen⁴, (1)National Institute of Aquatic Resources, DTU Aqua, Lyngby, Denmark, (2)Danish Technical University, Spain, (3)Technical University of Denmark DTU, Denmark, (4)Aalborg University, Denmark

Microplastics are ubiquitous pollutants in the ocean and their persistence and potential effects on marine ecosystems is a major global environmental concern. However, we still know little about the distribution and fate of MPs in the marine environment, particularly for the smaller size fraction of MPs ("small MPs"). These "small MPs" (>10 µm) could fatefully overlap in size with the phytoplankton and can possibly be ingested by zooplankton. This study aims to estimate the concentration and distribution of MPs down to 10 µm in the Kattegat Sea. The sampling of fourteen stations in the Kattegat Sea was carried out from the research vessel DANA (DTU Aqua) in October 2020. MP samples were collected in surface waters using plastic-free pump-filter devices ("UFO" sampler). Zooplankton samples (> 200 µm) were collected using multi nets. All the samples were analyzed using µFTIR and the scanned data was processed with the siMPle software. MP concentration in the surface waters ranged between 2 and 77 particles m⁻³. The most abundant polymer particles were Polyester, Polypropylene, and Polyethylene. The concentration of MPs in the zooplankton samples varied from 0 to 3 particles m⁻³, indicating non-bioaccumulation of MPs in the mesozooplankton communities. Our results show a relatively low abundance of MPs in marine waters of the Kattegat Sea and a low ecological risk of physical impacts of MPs on marine planktonic food webs.

3.10.T-08 Extraction and Analysis of 14c-Radiolabelled Polymers From Soil - Results of a Two Years Outdoor Lysimeter Study

Boris Meisterjahn¹, Dieter Hennecke¹, Eva-Maria Teggers², Nicola Schröder², Karlheinz Weinfurter², Christoph Eggenstein-Deime², Joana Bräutigam² and Adisa Hasanbasic², (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmalleberg, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Germany

Due to the production volumes of plastics and their application i.a. consumer products, plastics in the environment are becoming increasingly relevant. Worldwide, researchers developed concepts for the determination of microplastics in almost all environmental compartments. In most cases, the focus is on aquatic ecosystems and research on microplastics in soils is still uncommon. One direct application of plastics to agricultural soils is the use of plastic mulch films. In order to fill knowledge gaps, the objective of the presented project "iMulch" was thus to study the fate and the effect of polymers used in agricultural mulch films on organisms and soil ecosystems. Two ¹⁴C-radiolabelled synthesized polymers (polyethylene copolymer (PE) and polybutylenadipat-terephthalat (PBAT)) were tested under realistic conditions in outdoor lysimeters. Soil samples from the lysimeters taken throughout the study as well after cutting the lysimeters in 9 horizontal layers at end of the study were analysed in a first step for their radioactivity content by combustion followed by LSC. For further characterisation different extraction procedures were applied to soil samples depending on the polymer applied. Soil samples from PBAT-lysimeters were subjected to harsh extraction (ASE or soxhlet) with a mixture of CHCl₃ and MeOH in order to dissolve the polymer. PE-containing samples were subjected to both a density separation procedure as well as dissolution at high temperatures with TCB. Quantification of the total extracted radioactivity was performed after filtration of aliquots followed by combustion of the filters. The obtained extracts were analysed by GPC coupled to radiodetection, either at ambient temperature (PBAT) and high temperature GPC (PE). The

recoveries of radioactivity in soil samples taken from the top 5 cm of the lysimeter surface of both the PE and PBAT-lysimeters decreased over the whole incubation period. Analysis of the different soil layers at end of the study showed some translocation of radioactivity. However, nearly no radioactivity was found below 30 cm. Extraction of soil samples from the PBAT-lysimeter with $\text{CHCl}_3/\text{MeOH}$ resulted in good recoveries in the range of 75-90% of the applied radioactivity. The separation of radioactive material from the soil matrix applying a density separation protocol was successfully performed for soil samples containing PE. The extraction of soil samples with TCB is part of ongoing work results will be available on short notice.

3.10.T-09 Microplastic Fiber Emissions From Wastewater Effluents: Abundance, Transport Behaviour and Exposure Risk for Biota in an Arctic Fjord

Dorte Herzke¹, Peygham Ghaffari², Jan Sundet³ and Claudia Halsband², (1)Environmental Chemistry, NILU - Norwegian Institute for Air Research, Tromsø, Norway, (2)Akvaplan-niva, Norway, (3)IMR, Norway, Norway

Microfibers have been identified as one of the major classes of microplastic found in the environment on a global scale. Very little is known about how they move and distribute from point sources as wastewater effluents into the ocean. We chose the settlement of Longyearbyen on Svalbard as a case study to investigate how microfibers emitted by untreated wastewater will get distributed in the fjord both on a spatial and temporal scale in the remote Arctic. We sampled waste water during two sampling campaigns covering each time the period of one week. We combined the acquired field data with several modelling approaches to include plastic particles into their frame, developed a versatile tool to forecast the fate of the fiber plume leaving the effluent in comparison to abundance of local biomass and their probability to encounter microplastic. The results of this study will add to the knowledge base for future evaluation of a variety of point sources in the Arctic as well as the impact of increasing urbanization and tourism. We used several modelling approaches (FVCOM and OpenDrift) and parameterized plastic fibers into their frameworks, to develop a versatile tool that simulates and forecasts the fate of i) a single fiber plume leaving the pipe and b) continuous emissions from the pipe over one week. We used different densities representing a variety of synthetic fiber materials in our modelling of discharge distribution. The results show that the northern part of the fjord will receive most fibers within 5 days of discharge. Neutrally buoyant fibers will be distributed throughout the water column and also deposit on the seafloor due to hydrodynamic water movement. The tidal cycle will return part of the fibers back into the fjord from the fjord mouth. The implications for pelagic and benthic marine habitats in the fjord are discussed. This pilot study is instrumental in developing tools suitable for future evaluation of a variety of microplastic point sources, as well as the influence of increasing urbanization and tourism on the microplastic distribution in the Arctic.

3.10.T-10 Occurrence and Characteristics of Microplastics in a Small Community Wastewater Stabilization Pond and a University Oxidation Ditch Wastewater Treatment Plant

Zhiqiang Gao¹, James Cizdziel¹ and Alvis Vianello², (1)University of Mississippi, United States, (2)Aalborg University, Denmark

Given the high loads of microplastics (MPs) in wastewater, effluent from wastewater treatment plants (WWTPs) can increase the MP burden to recipient waters, even when MP removal efficiencies are >95%. Waste sludge, abundant in microfibers, can also lead to the release of MPs to the environment. Whereas studies investigating MPs in WWTPs have increased, few have examined wastewater stabilization ponds (WSPs), which serve rural and small communities worldwide, and WWTPs that serve universities where sudden and drastic population changes occur. Here, we assessed the distribution and characteristics of MPs in a WSP serving ~500 houses and in a modern oxidation ditch WWTP at the University of Mississippi. Triplicate water samples were collected by rapidly transferring water to fill a 50 L polypropylene container and subsequently passing it through 1 mm, 125 μm and 45 μm sieves. Particles on each sieve were rinsed into 1L glass Mason jars and subjected to Fenton's reagent, followed by density separation, and final filtration. MPs were quantified by stereomicroscopy with a subset of samples identified by focal plane array μFTIR imaging followed by automatic analysis via siMPle software. For the WSP, the predominant polymers detected were polyester and polyethylene. Duckweed and sludge had the highest concentration of MPs, and likely harbor the bulk of the MPs in the system. The concentration of MPs in the treated effluent was lower than in the pond water. There was no seasonal difference in MP abundances. Potential sources of the MPs in the WSP include laundering of clothes, plastics pieces from consumer products washed down the drain, storm water runoff, shedding of paint, and atmospheric fallout. We estimate that the WSP discharges ~786,000 MPs per day in the treated effluent. We conclude that WSPs should not be overlooked as a source of MPs to the environment. For the university WWTP, >90% of the MPs were removed through settling and surface skimming in the primary treatment. Concentrations of MPs in secondary clarifier and final effluent were lower during the higher-flow periods than lower flow periods, likely due to a higher return percentage of sludge to the oxidation ditch and longer process times. MPs were mainly composed of polyester, acrylic paint, polyvinyl chloride, polyethylene, polypropylene and polyurethane. We show that flow rates can have a profound influence on MPs concentrations in the effluent and MP removal efficiencies.

3.10 Microplastics in the environment: Behaviour, transport, fate, risks, and alternatives to conventional plastics (Part III)

3.10.T-11 Investigating Microplastic > 25 μm in the Seine River

Cleo Stratmann¹, Rachid Dris², Johnny Gasperi³, Sarina Guerin⁴, Sam Azimi⁴, Vincent Rocher⁴ and Bruno Tassin², (1)Ecole Nationale des Ponts et Chaussées, France, (2)Univ Paris Est Creteil, France, (3)LEESU, France, (4)SIAAP, France

The extensive use and mismanagement of plastic causes environmental pollution in air, soil, and water and threatens ecosystem health and functioning. A large part of plastic in the environment is microplastic (MP), small particles ≥ 5 mm. To advance the understanding of MP pollution in river and anthropogenic environments and to provide new insights into the fate of small (25-300 μm) and large (300-5'000 μm) MPs, we investigate MPs in Greater Paris and the Seine river catchment in France. To compare MP concentrations upstream and downstream of Paris we carried out two of four samplings at seven sites along the Seine river in

different flow seasons using a novel in-situ pump and cascade filtration system to increase representativity by sampling larger water volumes up to one m³. In addition we monitored a flood event at an urban site of the Seine river in 2021 over the course of four weeks during the increase, peak, and decrease of the flood. Preliminary data analysis of samples collected upstream and downstream of Paris indicate increased MP concentrations and higher polymer type variation downstream compared to upstream. Among others we detected PP (polypropylene), PE (polyethylene), PS (polystyrene), PVC (polyvinyl chloride), Polyester (including PET), SBR (styrene butadiene rubber), PA (polyamide), PU (polyurethane), Acrylic and ABS (acrylonitrile butadiene styrene). These findings confirm the hypotheses that urban agglomerations contribute to MP concentration in surface water. This trend needs to be confirmed by final data analysis including all samples and size fractions. Final results are foreseen to be complete in early 2022. These studies can help to identify sources and pathways of microplastics in rivers in urban agglomerations and help policy and decision makers to address environmental pollution and mitigation actions.

3.10.T-12 Microplastic Fate in Marine Sedimentary Records of the Ebro Prodelta (NW Mediterranean)

Laura Simon-Sanchez¹, Michaël Grelaud², Claudia Lorenz³, Jordi Garcia-Orellana², Alvisé Vianello³, Fan Liu⁴, Jes Vollertsen³ and Patrizia Ziveri², (1)ICTA-UAB, Spain, (2)Autonomous University of Barcelona (UAB), Spain, (3)Aalborg University, Denmark, (4)Department of Build, Aalborg University, Denmark

The accumulation of microplastics in the sedimentary record has developed into the definition of “Plasticene” as a new geological era starting in the 1950s. The current knowledge on the occurrence of microplastics in the ocean points to marine sediments as a major reservoir of microplastic pollutants. However, still little is known on their pathways, fluxes, and accumulation trends in deeper- environments. In the present study, we analyzed one high-resolution sediment core retrieved offshore of the Ebro Delta, NW Mediterranean Sea, for historical microplastic records. To establish the chronology of the last hundred years, radiometric analyses (based on ²¹⁰Pb, and ¹³⁷Cs) were applied. To quantify microplastics and polymer characterization, samples were treated to FPA-μFTIR-Imaging spectroscopy with automatized microplastic recognition analysis, targeting particles down to 10 μm in size. Preliminary results show microplastic contamination in sediments spanning the last 70 years, with an increase in the accumulation rate and polymer diversity over time. New results based on the determination of the carbonyl index for the polyolefins, polyethylene and polypropylene, aim to provide new insights into the degradation status of these pollutants once buried in the sediments.

3.10.T-13 Commercial Plastic Degradation Under Seawater Conditions

Sara López Ibáñez¹, Angelika Włodarczyk², Jakob Quade³, Olalla Alonso López⁴, Alejandro Vilas⁴, María José Abad López⁵, Cynthia Gómez⁴ and Ricardo Beiras⁶, (1)University of Vigo, Vigo, Spain, (2)University of Vienna, Austria, (3)RWTH Aachen University, Germany, (4)University of Vigo, Spain, (5)University of A Coruña, Spain, (6)University of Vigo, Afghanistan

Since the use of plastic materials entails certain risks, due to their wide presence in natural environments, new alternatives (bioplastics) are emerging claiming to be more environmentally friendly. However, their behaviour, degradation and potential risks are scarcely described, especially in marine environments. For this purpose, there is a need of standard methods for biodegradability and toxicity assessment under marine conditions. In this study, we tested plastic mineralization in closed bottles and mechanical degradation (weathering) in both small aquariums and large tanks (mesocosms). In the latter, we included pelagic, benthic and littoral exposures. We also assessed toxicity along weathering in *Paracentrotus lividus* larvae, a sensitive marine model organism. Furthermore, two key endpoints for mechanical degradation were measured: weight loss and deformation at break point. The latter is especially useful and it was clearly reduced over time for the compostable bags, while it did not vary for the PE bag. Mineralization, however, was low. Regarding toxicity, it was found that the compostable bags were more toxic than the PE one (2.65 and 2.37 toxic units vs. < 1) and this toxicity disappeared over exposure time, except for littoral treatment, where UV radiation plays a key role. This work helps further understanding biopolymer-based products behaviour in the ocean, contributing to the development of new assessment methods for marine environments.
