Rechargeable batteries are increasingly used in a number of applications, such as consumer electronics, electric vehicles, and stationary energy storage. An increased use in the latter two applications is envisioned to reduce greenhouse gas emissions. However, the dominant rechargeable battery technology – the lithium-ion battery (LIB) – impacts the environment in several ways throughout its life cycle. In addition, LIBs require critical and/or geochemically scarce materials, such as lithium, natural graphite, and sometimes nickel and cobalt. One promising next generation battery (NGB) is the sodium-ion battery (SIB). While other NGBs can provide higher energy densities, the SIB technology holds great promise from a resource point of view, since it can be made to contain mostly low-cost, abundant and readily available elements, such as sodium and iron. In addition, the manufacturing processes and equipment developed for LIBs can in principle be re-used, enabling convenient scale-up of production. We here assess the life-cycle impacts of a specific SIB with a low content of scarce metals using prospective life cycle

assessment (LCA). The SIB is assumed to be a mature technology produced at large scale and this we accomplish by using data from a small-scale producer and scale these up using available large-scale factory data for LIB production. We use a functional unit of 1 kWh of installed battery cell storage capacity and focus on climate and mineral resource impacts, since those have been highlighted in several publications and guidance documents as particularly important to address in LCAs of batteries. Different shares of renewables are considered in energy supply scenarios, along with scenarios for specific energy density developments. The impacts are compared to those of large-scale produced LIBs and to another NGB – the lithium-sulfur battery. To investigate mineral resource impacts of the different technologies in depth, we include two resource impact assessment methods, the crustal scarcity indicator and the surplus ore potential. The aims of the study are (i) to assess the prospective life cycle impacts of the SIB technology in order to reveal whether it is preferable to other battery technologies from an environmental and resource point of view, and (ii) to understand the environmental profile of the SIB in order to identify hotspots.

5.05.P-Th171 Prospective Life Cycle Assessment of the Electricity-Based Primary Steel Production Technology of Electrowinning

Carina Harpprecht¹, Tobias Naegler², Bernhard Steubing³ and Romain Sacchi⁴, (1)Leiden University, Germany, (2)German Aerospace Center, United States, (3)CML Leiden University, Netherlands, (4)Paul Scherrer Institute (PSI), Switzerland

It is crucial to decarbonize steel production systems to achieve the climate targets of the Paris Agreement, as steel production is currently responsible for 7 to 9% of global greenhouse gas emissions. Most of these emissions are caused by primary steel production, specifically the most commonly used route using a blast furnace (BF) and basic oxygen furnace (BOF). The BF-BOF route is strongly dependent on coal, as it allows to achieve the very high temperatures required and also serves as a reducing agent. Low-emission, cost-competitive and ready-to-implement alternatives are currently lacking, which makes the steel sector hard to decarbonize. A key strategy for decarbonization is electrification. In the case of steel, electricity-based technologies for primary production, i.e., electrolysis of iron ore, are still under development. Electrolysis of iron ore at low temperatures (~110°C) can be realized through electrowinning (EW), an emerging technology with a technology readiness level of 4 to 6. First, this study aims to determine the future environmental impacts of primary steel production via electrowinning (EW) using prospective life cycle assessment (LCA). Second, we compare the environmental performance of EW with the incumbent production route of BF-BOF. We developed a life cycle inventory for primary steel production via EW using data from literature and the background database ofecoinvent. Data gaps have been filled using assumptions, e.g., based on stoichiometric relations or expert judgement. Impacts are calculated for 1 kg of steel produced in Europe for the time period of 2020 to 2050. To account for transitions in the background system, we integrated background scenarios for electricity supply of global coverage from integrated assessment models. Lastly, the future environmental impacts of EW are compared to the conventional route of BF-BOF, which is modelled with datasets from ecoinvent. The results show that EW reduces direct emissions from steel production compared to the BF-BOF. Yet, considerable impacts still occur upstream of steel production processes, specifically during electricity production. Thus, the environmental benefit of EW strongly depends on the environmental performance of electricity supply. This stresses the relevance of taking a systems perspective and of background scenarios which allow to consider scenarios also in sectors other than the foreground system.

5.05.P-Th172 LCA for Sustainable Innovation: A Prospective View on Printed Circuit Boards vs. Printed Electronics

Akshat Sudheshwar¹, Bernd Nowack², Roland Hischer¹ and Claudia Som³, (1)Empa – Swiss Federal Laboratories for Material Science and Technology, Technology and Society Laboratory, Lerchenfeldstrasse 5, 9014 St. Gallen, Switzerland, (2)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (3)EMPA Technology & Society Lab, Switzerland

Novel Printed Electronics are manufactured through additive methods and are proposed as sustainable alternatives to conventional Printed Circuit Boards (PCBs), especially in novel and niche Internet-of-Things (IoT) applications. Thus, this study aims to verify the environmental advantage of paper-based printed electronics through a comparative LCA with PCBs. The LCA considers the flow of conductor and substrate materials through the various phases of an optimistic lifecycle (including recycling) of PCBs and printed electronics. All the relevant processes throughout the lifecycle of printed electronics and PCBs have been modelled in a life cycle inventory (LCI) using Ecoinvent v3.7.1 and the environmental impacts were calculated as per ILCD's 2018 total climate change method. The results highlight that the Silver (Ag) ink-based conductor used in printed electronics has a higher net environmental impact over the entire lifecycle than the Copper (Cu) conductive tracks of the PCBs; this is attributable to the higher environmental impact of Ag and chemicals required to manufacture the conductive ink. Furthermore, from a substrate perspective, the PCBs glass-fibre and epoxy resin-based FR4 boards have a much higher net impact over the entire life cycle than the CNC-coated paper substrate required for the printed electronics. Combining the impacts of the conductor and substrate for a conclusive comparison between PCBs and printed electronics underscores that the substrate material is crucial: the lower impacts from the CNC-coated paper give printed electronics an environmental advantage over PCBs. Thus, further exploration of replacement possibilities for PCBs with printed electronics is viable from a sustainability perspective. This study also exemplifies how LCAs are critical in identifying and solving environmental challenges associated with innovations. As a decision-making tool, an early stage LCA can verify the sustainability prospects of a project, and assist in targeting and remedying sustainability hotspots early on while the material and product development process is still flexible and open to adaptations.

5.05.P-Th173 Development of a Radiative Cooling Material Database to Benchmark the Environmental Impact of a Newly Developed Photonic Meta-Concrete

Nick Adams¹ and Karen Allacker², (1)Architecture, KU Leuven, Heverlee, Belgium, (2)KU Leuven, Belgium

Global warming and the heat-island-effect in cities led to an increased use of conventional air-conditioners. This increased usage is responsible for 10% of the total energy consumption and 7% of global greenhouse gas emissions. In the overall aim to reduce

these greenhouse gas emissions and to mitigate climate change and the heat-island-effect, a new radiative cooling material is under development. Although radiative cooling materials already exist, this material stands out because, for the first time, it is based on conventional concrete. This paper describes the first step of the environmental life cycle assessment (LCA) study that is performed along the development of the photonic meta-concrete (PMC). In this step we generate a database with environmental data of existing radiative cooling materials in order to create a comparative base for the PMC. Information about the various materials is collected through a literature review and consultation of experts. The environmental impact of the materials are assessed with the Belgian LCA method for buildings, i.e. the MMG method. The MMG method is in line with the EN15804:A2 and hence covers 16 environmental impact categories, such as global warming potential, acidification, eutrophication, water scarcity, toxicity. Furthermore, the environmental impact will be compared with the first composition of the photonic meta-concrete. The first results show that a lot of product-specific information regarding radiative cooling materials is lacking to date to assess their environmental impact and this makes it challenging to create a reference database. However, the environmental impact of the radiative cooling materials assessed in this paper is in line with the expectations. The first mixture of the photonic meta-concrete is promising as this shows great potential from an environmental point of view compared to the existing daytime radiative cooling materials.

5.05.P-Th174 Prospective Life Cycle Assessment of Road Infrastructure in the Context of Circular Economy: Advances, Challenges, and Opportunities

Zhaoxing Wang¹, Morten Birkved² and Zhi Cao³, (1)EMIB, University of Antwerp, Antwerpen, Belgium, (2)University of Southern Denmark, Denmark, (3)University of Antwerp, Belgium

Road infrastructure is an integral building block of our society by provisioning essential services (e.g., movement of resources and commuting) and stimulating the socio-economic development of local communities. The deterioration of road infrastructure is a dynamic process that affects such essential services through degrading the pavement durability and increasing the rolling resistance, which further influences the material and energy consumption for pavement maintenance, rehabilitation, and reconstruction. Existing life cycle assessment (LCA) studies of pavements have established a foundational framework to estimate environmental impacts but fail to include the dynamics of pavement in the system. In response to calls for a transition toward a circular economy, utilization of secondary materials through various recycling technologies (e.g., hot, warm, or cold recycling) has been increasingly considered in the LCA of road infrastructure. However, it remains unclear under what conditions one recycling technology is superior to other options. In order to understand the key methodological advances and challenges and identify opportunities for improving the utility of LCA tools of pavement, we provide a critical review of recent pavement LCA literature by conducting a semi-quantitative analysis on geographic coverage, temporal trend, time horizon, functional unit, life cycle stages, and consideration of reclaimed/secondary materials. In this review, we reflect on a variety of methodological and data issues, including inconsistencies in the functional unit, ambiguity of system boundary, incompleteness of certain life cycle stages, and omission of certain important impact categories, but also highlights that due attention to the use phase of pavement can improve the utility of pavement LCA significantly. Our review finds that using more secondary materials (e.g., reclaimed asphalt pavement, recycled tire, waste glass, construction & demolish waste, etc.) in pavements can reduce environmental impacts notably. For future research, it is recommended that knowledge gaps in the use phase of pavement, such as albedo effect, rolling resistance, and lighting, should be addressed in pavement LCAs, and more sophisticated models (e.g., mechanistic-empirical models) should be used to predict the deterioration of pavement performance to have accurate LCA results and close-to-reality estimation of location-specific effects.

5.05.P-Th175 Life Cycle Assessment of Commercial Scale Ozonation Plant for Advance Oxidation of Micropollutats in Wastewater Treatment. Case of Study in Netherlands

Gema Amaya Santos¹, Nadine Boelee² and Paola Lettieri³, (1)Chemical Engineering, University College London, London, United Kingdom, (2)Nijhuis Industries, Netherlands, (3)University College London, United Kingdom

The improvement of water quality and ecosystems are important UN goals towards sustainable development. In Europe, effluent discharges from wastewater treatment plants are the main cause of degradation of ecosystems, due to the presence of micropollutants. These compounds, which cover a wide range of chemical species of organic nature, are poorly degraded in conventional wastewater treatment, and their presence in water bodies remains at low concentrations ($\mu\text{g/l}$) causing negative effects due to chronic exposure. Thus, an improvement in conventional wastewater treatment plants is becoming urgent to ensure the efficient removal and safeguard the protection of water resources. Ozonation has amply proven its effectiveness in disinfection of drinking water, due to the high oxidative power of the ozone molecule, able to react with a large number of organic compounds. For this reason, this advance oxidation technology can also be applied to the degradation of recalcitrant micropollutants in wastewater streams, whose large-scale implementation as a tertiary treatment of wastewater effluents is becoming more and more attractive. Hence, it is crucial to take into account the environmental burdens involved in the deployment and implementation of commercial scale of ozonation as tertiary treatment. In this study, Life Cycle Assessment is used to analyse the environmental performance of ozonation as an emerging technology for the advance oxidation of micropollutants from wastewater effluents in tertiary treatment of municipal wastewater. A commercial scale Ozonation facility developed in the Netherlands has been chosen as a case of study. The functional unit is the treatment of an average effluent flow of 580m³/h, with a dosage of ozone of 0.7gO₃/gDOC, for the removal of 70% of the micropollutant load from the wastewater effluent. The system boundaries comprise a gate-to-gate study, focusing on the use phase of the ozonation system, which entails in situ ozone generation and effluent treatment in the ozone reactor. Results show that the main environmental burdens are attained to energy consumption, mainly associated to the in situ ozone generation, followed by the pumping of the effluent from the treatment plant to the reactor. This study demonstrates the relevance of LCA as a powerful tool to determine the sustainability of

early stage implementation technologies in wastewater treatment. Allowing to refine the decision making-process for its large-scale consolidation.

5.05.P-Th176 Comparing Prospective Methods for Life Cycle Assessment of Emerging Energy Technologies

Stefany Villacis¹, Veatriki Papantoni², Urte Brand² and Thomas Vogt², (1)German Aerospace Center (DLR), Institute of Networked Energy Systems, Ecuador, (2)German Aerospace Center (DLR), Institute of Networked Energy Systems, Germany

The introduction of new energy technologies that intend to produce lower environmental impacts is one option to tackle climate change. However, it is still unclear to what extent these technologies can actually contribute to reach the sustainability goals. To answer this question, the amount of resources needed and the potential environmental impacts throughout the whole lifecycle of emerging technologies should be determined. One approach to accomplish this is to follow the well-known life cycle assessment (LCA) methodology. Nevertheless, this scheme is generally intended for assessing mature technologies that have been already introduced into the market. Therefore, a proper framework that considers the inherent challenges of future-oriented assessments including limited data, scalability and uncertainty is still lacking. Consequently, the outcome of our research consists in providing a guideline on choosing methods for conducting a prospective LCA of emerging energy technologies, as well as their link with uncertainty characterization and quantification. For instance, these methods can include: extrapolation, technological learning, technological diffusion, own assumptions, participatory approaches and scenario analysis. To the best of our knowledge, these methods have not yet been extensively explored in the literature. Thus, at this conference, we would like to present the following first steps to this approach: · The identification, comparison, selection and categorization of methods for generating life cycle inventory (LCI) data of emerging technologies at early development stages. · The criteria for the selection of methods in order to be applicable to energy technologies and compatible with uncertainty management. · How these findings can contribute to explore new modeling approaches and to better understand uncertainty in the LCA of technologies under development.

5.05.P-Th177 Environmental Assessment of New Technologies for Mixed Plastic Waste Treatment Using LCA

Methodology

Tatiana Trečakova¹ and Vladimír Kocí², (1)University of Chemistry and Technology Prague, Prague, Czech Republic, (2)Prague Inst. of Chemical Technology, Czech Republic

The poster presents a project in which the concepts of integrated systems for the management of mixed plastics are proposed. These concepts will respond to new trends and principles of waste policy of the European Union, i.e. landfill reduction and, to the maximum extent, material and energy recovery of waste and overall environmental acceptability. The subject of the Life Cycle Assessment are two new technologies for the treatment of mixed plastic waste, which are promising and will enable the further development of the circular economy. These are technologies for thermal decomposition of plastic waste and Polybet. Thermal depolymerisation is a method of energy recovery of carbon-based materials. It is a physicochemical endothermic process that occurs in an anaerobic environment at various stages at temperatures ranging from 300 to 2 000 °C. These temperatures exceed the limits of thermal and chemical stability of organic and synthetic compounds, they decompose and form low molecular weight products and solid residue. The input materials will be mixed plastic waste produced as residual fractions in production processes. Thermal depolymerisation cleaves hydrocarbon chains and releases relatively low molecular weight process products. These process products (process oil and process gas) will be used as fuel in the production process (gas) and as a raw material for further processing (oil). The inorganic inert material (carbon) will remain relatively unchanged as a solid residue after depolymerisation and will be further recycled for further practical use. Polybet technology recovers mixed thermoplastics and internal fillers. The resulting composite has widely usable technical properties, especially minimal water absorption. It is a technology for a preparation of polymer concrete mixture with high variability of inputs and a wide range of applicable recipes. The final shape of the final product is designed individually according to the specific requirements of the customer. It is expected to produce a universally usable construction product of medium dimensions, such as road curbs, blocks, footings or tiles, or variants of partition walls. The project also proposes a detailed methodology for assessing these types of technologies using the LCA method in order to ensure an independent and realistic environmental impact assessment.

5.05.P-Th178 Conceptualizing Prospective LCA Approaches to Assess Novel Perovskite Photovoltaic Technology at Lower TRLs - the CASE of the H2020 APOLO Project

David Wilde¹ and Marta Escamilla², (1)R&D, ACONDICIONAMIENTO TARRASENSE (LEITAT TECHNOLOGICAL CENTER), TERRASSA, Spain, (2)LEITAT Technological Centre, Spain

Prospective assessment approaches to LCA on emerging technologies, such as perovskite solar cells (PSC), have been argued to offer more informative and relevant impact results, especially when attempting comparisons with mature technologies. However, few if any European Commission-funded research projects evolving around perovskite technology seem to apply a prospective assessment approach to their LCA that considers the potential impacts of full-scale implementation at a future point in time. The H2020 APOLO is developing fully printable perovskite solar cells on flexible substrates, which are to be integrated in varying formats into different demonstrators for architectural uses in building and structures, combining functionality with aesthetics. With the purpose of supporting the R&D stage from an environmental and eco-design perspective, the project contains a LCA that, in so far as possible, considers likely industrial production means, and makes projections about potential use, re-use, and end-of-life scenarios, thereby attempting to step beyond the limitations of actual lab-scale and demo-focused production taking place under the umbrella of the project. Building on existing literature and frameworks, as well as actual impact results, the example of the APOLO project serves to discuss which life cycle stages and underlying aspects may be most susceptible to future changes and uncertainty compared to the status quo, and where major opportunities and necessities may lie for the application of a more comprehensive and effective prospective assessment in future PSC or other PV technology LCA research.

5.05.P-Th179 Life Cycle Assessment of Highly Emissive CsPbBr₃ Perovskite Nanocrystals

Olivera Vukovic¹, Rene Janssen², Laurent Billon³ and José Jorge Espí Gallart⁴, (1)TU Eindhoven, Eindhoven, Netherlands, (2)TU Eindhoven, Netherlands, (3)Univesrité of Pau (UPPA), France, (4)Eurecat, Spain

Despite being a small contributor to the current global electricity production, interest in solar cells has rapidly increased over the past decade, and photovoltaic (PV) industry is expected to have major role in the electricity market in the long term. High power conversion efficiency, low costs of materials and simple and eco-friendly manufacturing are main requirements for solar cells. Promising candidate in such search are perovskite solar cells. Perovskite is a term used for the whole group of organic-inorganic materials with generic formula ABX₃ and crystallographic structure based on a structure of calcium titanium oxide. Perovskite nanocrystals are able to act as semiconductor nanocrystals with an exceptional photophysical (photoluminescence quantum yield and easily tunable photoluminescence emission) and primary optoelectronic properties (direct bandgap, tunability of bandgap, low recombination rates, long carrier diffusion length and high carrier mobility). In addition, its easy processability with the use of wide available chemical components makes them very attractive for mass production. Many synthesis processes for CsPbX₃ were reported among many groups, but CsPbBr₃ NCs in this research were prepared using so called ligand assisted room temperature precipitation (LARP) and more common hot- injection (HI). Environmental impact of perovskite solar cells is very important to determinate, since they are still in a process of development and it is important to estimate its impact for the possible mass production; to that end, a cradle-to-gate LCA study has been performed. Our recent results showed that, for lead halides salts the most contribution in all impact categories is coming from lead. But, for CsPbBr₃ nanocrystals, prepared via LARP, Isopropanol has the most impact and in hot- injection method, Oleylamine. It was of a high interest to compare contributions to emission, for the same type and amount of nanocrystals (1 kg of CsPbBr₃), but produced with already mentioned two different synthetic ways. Perovskite nanocrystals, as itself, do not contribute significantly to the global emission comparing to the other layers in perovskite solar cells, which is positive result for the massive production. From the point of view of the Ecodesign, these LCAs are important to choose and/or redefine the processes to be up-scaled to the industry level.

5.05.P-Th180 Life Cycle Assessment of 3D Printed Furniture Using Fine Recycled Aggregates - Cirmap Project

Sylvie Gros Lambert¹, Gaspard Chantrain² and Angelique Leonard², (1)University of Liège - Chemical Engineering, Belgium, (2)University of Liege, Belgium

In North West Europe, about 65 Mt of Recycled Fine Aggregates (RFA) are generated yearly from the crushing of Concrete Construction and Demolition Wastes and are disposed in landfills or in banks. In the meantime, 54 Mt of marine sands are extracted in zones where natural aggregate resources are missing, threatening fragile marine spaces. Reusing RFA in concrete would save natural resources. However, no market exists for RFA owing to rigorous construction standards. RFA is a local resource, with large variability, which is not suited to mass production needing regular materials. But it could be used at a smaller scale, for the manufacture of products needing neither to comply with rigorous construction standards nor to possess high performances. About 5 Mt of RFA could be recycled into concrete for the manufacture of Urban, Memorial or Garden (UMG) furniture, being the starting point of a circular economy loop. Traditional precast concrete cannot be used for small scale production because of the high share of moulds in the global cost (50 to 80%). However, concrete 3D Printing (3DP) allows manufacturing customized pieces that could be shown by customers as a banner of their identity. UMG furniture are always located in difficult to access zones, reducing their weight by shape optimization and printing them onsite would be easier. Moreover, online control of 3D Printing could be used to compensate materials variability, providing an efficient tool for the valorisation of these resources. Cirmap will provide a new Mixture Proportioning Method (MPM) for the design of 3DP mortars with RFA and a new Design Methodology for Customized Shapes (DMCS). A new Master Control Command (MCC) for concrete 3DP will be implemented for the equipment of 3DP machines, and an integrated mobile 3D printing unit will be developed for onsite 3D printing of UMG furniture. A Cirmap-network will also be created for lobby and dissemination, leading to a new market for the reuse of RFA. The Chemical Engineering research team is in charge of the environmental aspects of the project and applies Life Cycle Assessment (LCA) in an eco-design approach. Acknowledgements - The authors would like to thank the Cirmap project (INTERREG NWE, n° NWE1062), partly financed by the European Regional Development Funds, and the Walloon Region.

5.05.P-Th181 Handling Multifunctionality Within a Prospective LCA of a Biobased Emerging Process: A CASE Study of PHA Production

Mateo Saavedra del Oso¹, Miguel Mauricio-Iglesias², Almudena Hospido² and Bernhard Steubing³, (1)Department of Chemical Engineering, Universidade de Santiago de Compostela, Santiago de Compostela, Spain, (2)CRETUS (Cross-Research in Environmental Technologies), Universidade de Santiago de Compostela, Spain, (3)CML Leiden University, Netherlands

PHA production from carbon-rich waste streams by mixed microbial cultures (MMC) can diminish both environmental impacts and production costs, specially when it is integrated into a biorefinery approach. However, these processes are still at low technology readiness level (TRL 5-6). At this level there are still opportunities for major adjustments. Prospective life cycle assessment (pLCA) can be a useful tool to ensure that environmental guidance is included in the development of PHA production by MMC. Under this research, different approaches on how to handle multifunctionality within a prospective LCA of PHA production are discussed. PHA production is 3-step process comprised by anaerobic fermentation, biomass selection and PHA accumulation. After that, PHA is recovered from the biomass in the downstream process. Waste streams produced in anaerobic fermentation and downstream processing are sent to anaerobic digestion, where biogas and digestate are produced. Biogas produced in both anaerobic fermentation and digestion are transformed into electricity and heat in a CHP unit. Two different approaches can be applied to solve the multifunctionality: partitioning or substitution. When applying partitioning, system was splitted into 5 different subsystems: (1) anaerobic fermentation, (2) biomass selection and PHA accumulation, (3) PHA

downstream, (4) anaerobic digestion and, (5) cogeneration. Subsystems (1), (3) and (4) functional flows ((1) VFA, biogas and solid-rich waste stream, (3) PHA and waste stream and (4) biogas and digestate) were allocated based on COD, while subsystem (5) functional flows (electricity and heat) were allocated based on exergy. PHA production involves subsystems (1), (2) and (3), while consumed heat and electricity comes from subsystem (5). Regarding the substitution approach, PHA production system is expanded including the waste treatment, anaerobic digestion and cogeneration. Digestate, heat and electricity avoided products are related avoided products are fertilizers, steam production and EU electricity mix. Substitution entails more challenges than partitioning, since requires more data (e.g., digestate composition) and non-identical functional flows will have to be considered equivalent (e.g., electricity mix based on renewables). Furthermore, when applying a systematic scenario methodology, given credits by an avoided product may differ depending on the background parameter (e.g., electricity mix based on carbon source vs renewables).

5.05.P-Th182 From Lab to Plate: Life Cycle Assessment of Valorization of Herring and Lingonberry Co-Products

Carla Coelho and Gregory Peters, Chalmers University of Technology, Sweden

With the aim of conserving resources, several methods have been developed to recover protein from fish filleting co-products. These products can be destined for human consumption such as pate, fish burgers, fish sausages, or used as soup thickeners. A recently developed technique has been demonstrated at laboratory scale for the extraction of protein-based on cross-processing of coproducts from herring (*Clupea harengus*) filleting with lingonberry (*Vaccinium vitis-idea*) pressing coproducts. The outputs of the cross-processing are three products: oil, protein, and other solids. We carried out a life cycle assessment of this cross-processing by up-scaling it to an industrial scale using literature data and expert information, considering the volume of the herring and lingonberry co-products available in Sweden. The protein product was modeled as being used in a fish ball with the addition of other agricultural ingredients, and it was compared with a commercially available fish ball. Calculations were run in OpenLCA v3.01 software, using ecoinvent, and Agribalyse data for background process as well as literature and industry data. Environmental impacts were assessed in terms of climate change, energy consumption, land occupation, and marine biotic resources depletion. The results showed that fishery operations and the transportation of both berries and of the berry-picking workforce dominated the impact of the protein product for climate change. The protein product dominated the impact of the fishball in all categories. For land occupation, an improvement potential was associated with using oil derived from the cross-processing itself instead of vegetable oil in the product formulation. Beyond the production of the recovered protein and raw materials, the building infrastructure and production of electricity for chilled storage and processing played significant roles. When assessed as a consumable product, the fishball made with recovered protein represented less environmental impact than the benchmark fish ball in all categories investigated. Overall, the results support the utilization of herring and lingonberry co-product as a source of protein for human consumption, with LCA helping identify an environmental opportunity that can also improve the nutritional profile of the product.

5.06 Safe and Sustainable by Design for chemicals, materials and products

5.06.T-01 Safe and Sustainable by Design: A Computer-Based Approach to Redesign Chemicals for Reduced Environmental Hazards

Joanke van Dijk¹, Hannah Flerlage², Steven Beijer², Chris Slootweg² and Annemarie van Wezel³, (1)Environmental Sciences, Copernicus Institute of Sustainable Development - Utrecht University, Utrecht, Netherlands, (2)University of Amsterdam, Netherlands, (3)University of Amsterdam/IBED Institute, Amsterdam, Netherlands

Persistency of chemicals in the environment is seen as a pressing issue as it inevitably results in the accumulation of these chemicals over time and the possibility of long-term exposure resulting in adverse effects. Persistent chemicals can on the other hand be an asset in a well-functioning circular economy where products are more durable and can be reused or recycled. However, this objective cannot always be fulfilled as the release of chemicals from products into the environment can be inherently coupled to their use. In these situations, the chemical should be designed for degradation to avoid adverse effects. In this study, an approach was developed to select chemicals for redesign and to facilitate the systematic design of Safe and Sustainable chemicals based on in silico structure generation. The resulting approach includes elements of Green and Circular Chemistry, Essential Use, and Alternatives Assessment and ties into goals recently formulated in the context of the EU Green Deal. We used the organophosphate compound tri-isobutyl phosphate (TiBP) as a case study for exploration of the approach, as the emission of TiBP to the environment was expected to be inevitable for some of its uses as a flame retardant. Over 6.3 million suggested alternative structures for TiBP were created in silico, and then filtered based on outputs from quantitative structure-activity relationships (QSARs) for potentially non-readily biodegradable structures. The remaining structures were further analyzed based on QSAR predicted hazard properties for persistency, bioaccumulation, mobility and toxicity (PBMT) and synthesizability. With a multi-criteria analysis, a top 100 of the most desirable structures was identified from which a target structure (di-n-butyl (2-hydroxyethyl) phosphate) was selected and subsequently synthesized. The first experimental results indicate an enhanced functionality of the alternative compound which would subsequently reduce its environmental impacts. The approach provides a new, systematic and computer-aided workflow for the chemical redesign for reduced persistency and can help take Green and Circular Chemistry principles for the design of Safe and Sustainable chemicals into practice. The approach can be expanded and further verified to reach its full potential in the mitigation of chemical pollution and to help enable a safe circular economy.

5.06.T-02 Can Cable Plastics Be Safe and Sustainable by Design at the End-Of-Life

Mari Engvig Løseth¹, Heidi Knutsen², Gabriela Varela³, Alexandros Asimakopoulos⁴, Sarah Hale⁵ and Hans Peter Arp⁵,

(1)Environmental Chemistry, Norwegian Geotechnical Institute, Oslo, Norway, (2)Norwegian Geotechnical Institute, Norway, (3)Norwegian University of Science and Technology (NTNU), Spain, (4)Norwegian University of Science and Technology (NTNU), Norway, (5)Norwegian Geotechnical Institute (NGI), Norway

Waste of electrical and electronic equipment (WEEE) is one of the fastest growing waste streams in the EU and its toxic components pose a substantial threat to environmental and human health. Cables are one of most plastic rich WEEE items, typically containing 50 % polyvinylchloride (PVC). PVC from electrical cables often contain bisphenols (BPs) as antioxidants to prolong the lifespan of the cables, a group of high volume produced, hazardous compounds with well-known potentials for endocrine disruption in humans and wildlife. Currently, the metals and plastic are separated by granulation, however recycling of cable granulates is only on a business-to-business level. Consequently, most PVC cables and cable granulates are landfilled or incinerated with energy recovery. Yet, energy recovery of PVC is challenging due to the formation and emissions of dioxins, furans, hydrochlorid compounds, and heavy metals during incineration. Consequently, an increasing fraction of cables and PVC cable granulates are being landfilled in Norway, despite that landfilling is the least preferred option of waste management in a circular economy. To evaluate the potential for end-of-life recovery for reuse and/or recycling of cables, the present study aims to investigate the mass flow of BPs in cable plastic in Norway between 2018-2020. To provide information essential for designing safe and sustainable cables, the potential transfer of BPs to plastic recycles and emissions and impacts on the environment was investigated. Our mass flow analyses shows that on average, 38% of the collected cables were deposited onto landfills between 2018 - 2020, of which was 4 900 tonnes cable plastic (incl. fly and bottom ash) containing over 300 kg of BPs which accumulated on the landfill each year. Landfilling was also the major contributor to the environmental emissions with a total of 50 kg BPs emitted as lechate or particles to sludge, water and air each year. Incineration with energy recovery and thermal destruction efficiently removed 130 kg of BPs from the mass flow, however almost 100 kg of BPs was sent to material recycling to produce new products. As such, the present study emphasize a need for designing safe and sustainable plastics where end-of-life waste management is considered, such as by phasing out PVC and BPs and other hazardous substances. Further, it shows the need to improve the current waste management of cables to reduce environmental emissions of BPs.

5.06.T-03 Implementing Safe by Design in Product Development Through Combining Risk Assessment and Life Cycle Assessment

Vrishali Subramanian¹, Tiny van der Werff², Colet te Grotenhuis³ and Jeroen Guinee⁴, (1)CML Leiden University, Netherlands, (2)Ministry of Infrastructure and Water Management, Nederland, (3)Ministry of Infrastructure and Water Management, Netherlands, (4)University of Leiden, Netherlands

The Safe by Design (SbD) concept aims to ensure safe, sustainable and circular materials and products from early stages of product development. While there is growing interest in the potential of SbD to help meet the goals EU Green Deal and Circular economy, methodological approaches and practical guidelines on SbD for product design are however largely missing. The combined use of Life Cycle Thinking (LCT) or Life Cycle Assessment (LCA) and Risk Assessment (RA) is considered suitable to operationalize SbD. We explored the potential of the combined use of LCT/LCA and RA by product design teams at Technological Readiness Level (TRL) 1-6 through a literature review combining LCT/LCA and RA at early stages of product design, to identify and understand the approaches that have been used to combine the methods, and the potential of these approaches for product design teams to implement SbD. We found that product design teams can already perform themselves basic early-on-evaluations of safety and sustainability (e.g., apply lifecycle thinking to assess risk hotspots, avoid use of hazardous chemicals, minimize environmental impacts) while collaborating with experts or coordinating across the value chain will be necessary for more complex assessments (ex-ante LCA, control banding, predictive toxicology, etc). The application of these simplified approaches and guidelines cannot substitute a full-fledged RA or LCA at higher TRLs but they may help avoid some obvious sources of risks and impacts early on. However, the full potential of combining these methods has not been exploited in most of the literature. Critical gaps need to be addressed before SbD can be operational in product design practice, including more studies in product design context, developing tools and databases from the product designer's perspective, greater collaboration between RA/LCA researchers and companies, and policy discussion on the expansion from SbD to Safe and Sustainable by Design (SSbD).

5.06.T-04 Deriving Non-Cancer Human Toxicity Effect Factors With Quantified Uncertainty for More Than 10,000 Chemicals

Nicolo Aurisano¹, Lei Huang², Olivier Jolliet² and Peter Fantke³, (1)DTU (Technical University of Denmark), Denmark, (2)University of Michigan, United States, (3)Technical University of Denmark, Denmark

Life cycle impact assessment (LCIA) characterizes toxicological impacts on human health from chemical exposures via effect factors based on chemical-specific points of departure (PODs) from regulatory sources. However, such data are available only for a few hundred substances, and consequently, effect factors are lacking for the broader range of currently marketed chemicals. To address this gap, recent updates of the globally recommended approach for deriving human dose-response factors for non-cancer endpoints in LCIA propose using experimental animal data to estimate PODs for substances lacking regulatory data. The aim of this study is thus to broaden the coverage of chemicals by using available *in vivo* data to estimate suitable PODs and derive non-cancer health effect factors for application in LCIA. As a starting point, we curated and selected experimental animal toxicity data from the U.S. EPA's Toxicity Value Database following a semi-automated approach and built two distinct datasets covering reproductive/developmental and other non-cancer effects. Next, we fitted the curated data to a lognormal distribution for each chemical in the datasets and derived PODs as the 25th percentile of the fitted distributions to best mimic regulatory data ($R^2 > 0.78$). In addition, we quantified for each POD uncertainty, considering both intra-study and inter-study variability. We then derived human-equivalent lifetime dose-response factors from the identified PODs. Finally, dose-response factors were combined with

severity factors to derive effect factors expressed in disability-adjusted life years lost associated with incremental exposure (DALY/kg_{intake}), differentiating between the two disease categories considered. Based on this approach, we estimated non-cancer health effect factors with quantified uncertainties for 6,703 substances covering reproductive/developmental effects and for 8,032 substances covering other non-cancer effects. The estimated effect factors range across chemicals over several orders of magnitude from 4.4×10^{-5} to 2×10^8 DALY/kg_{intake} with effect factors covering reproductive/developmental effects being on average higher per chemical. These results significantly broaden the coverage of chemicals by estimating effect factors also for substances without regulatory data. Next steps include extending this approach to cover additional exposure routes, such as inhalation and dermal exposure, and increasing the differentiation in non-cancer effects.

5.06 Safe and Sustainable by Design for chemicals, materials and products (Virtual Only)

5.06.V-01 ALBINA: Developing Sustainable, Environmentally Friendly Lubricant Additives for Technical Applications From Algae

Moira McKee¹, **Yvonne Sakka**², **Nina Nentwig**², **Antonio Gavalás-Olea**³, **Antje Siol**², **Jan Köser**², **Imke Lang**³, **Jorg Thöming**², **Juliane Filser**², **Sonja Faetsch**⁴, **Stefan Stolte**⁵ and **Ya-Qi Zhang**⁶, (1)Center for Environmental Research and Sustainable Technology, University of Bremen, Bremen, Germany, (2)University of Bremen, Germany, (3)Bremerhaven University of Applied Sciences, Germany, (4)Hamburg University of Applied Sciences (HAW), Germany, (5)Technical University of Dresden, Germany, (6)Institute of Water Chemistry, Technical University Dresden

The interdisciplinary project ALBINA aims at formulating new lubricant additives based on biological and renewable algae products for use in technical applications. The project is funded by the German Ministry of Nutrition and Agriculture's Agency for Renewable Resources. Conventional mineral oil based lubricant additives are often highly toxic to humans and the environment. The goal of this project is to find alternatives with algae based sugar and protein mixtures. The development chain starts with the selection and cultivation of the algae, their extraction, their chemical structure analysis and their ecotoxicological characteristics. The technical application in cutting and reshaping metals are tested as well. A wide range of algae species have been cultivated under varying conditions to optimize the output. Extensive methodological research was necessary to develop extraction protocols with different solvents for extracellular polymeric substances and biomass of various algae species. Especially creating oil-based solutions with algae products for technical testing posed a major challenge. Ecotoxicological screening with acute tests at 1 g L^{-1} *Daphnia magna*, *Arthrobacter globiformis*, *Enchtraeus crypticus* and *Folsomia candida* so far have indicated low toxicity of most extracts. So far, five algae species render the most favorable results; therefore chronic daphnia, algae and Collembola tests are currently being conducted to assess potential long-term toxicity. Biodegradation experiments will run with the technically promising candidates that have been identified so far. We would like to present the aim and structure of ALBINA as well as the processes and results of developing sustainable and environmentally friendly lubricant additives.

5.06.V-02 Review of Frameworks for Safe and Sustainable-By-Design Criteria Definition for Chemicals and Materials

Carla Caldeira¹, **Lucian Farcal**², **Christian Moretti**³, **Lucia Mancini**², **Hubert Rauscher**², **Kirsten Rasmussen**², **Juan Riego Sintet**² and **Serenella Sala**¹, (1)European Commission - Joint Research Centre, Italy, (2)European Commission Joint Research Centre, Italy, (3)Utrecht University, Netherlands

In the context of the EU Green Deal, the Chemicals Strategy for Sustainability (CSS) aims at improving safeguard of human health and the environment as part of an ambitious approach to tackle pollution from all sources and move towards zero-pollution for air, water and soil. A key action defined in the CSS is the development of safe- and sustainable-by-design (SSbD) criteria for chemicals. The SSbD concept promotes a holistic approach that integrates safety, circularity and functionality of chemicals, materials, products and processes throughout their entire lifecycle and minimises their environmental footprint. As a first step for the development of such a framework, we conducted a review of existing safety and sustainability frameworks and the underpinning concepts, methods, models, tools and indicators used to address sustainability dimensions. The starting point of this review was the mapping study and the results of a targeted stakeholders' survey conducted by European Commission's Directorate General Research and Innovation. There are multiple challenges related to the integration of safety and sustainability dimensions (as well as the related concepts) and the review has covered approaches proposed by different stakeholders, being in research, business, government or civil society (e.g. NGOs). A few frameworks encompass safety and the three dimensions of sustainability (environmental, economic and social) and many frameworks are purely conceptual, listing elements to be included but without reporting the operational methods or approaches to address qualitatively or quantitatively the issues at stake. In most of the frameworks safety considerations refers to legislative requirements. Regarding life cycle considerations, these are often mentioned and integrated in the frameworks, with different level of details in terms of models and indicators to be adopted. In some of the framework, criteria are already derived and illustrated, and are complemented by operational tools that allow ranking chemicals based on specific criteria.

5.06 Safe and Sustainable by Design for chemicals, materials and products (Poster)

5.06.P-Tu296 Machine Learning Models Based on MOLECULAR Descriptors to Predict Toxicological and EcoToxicological Characterization Factors

Remi Servien¹, **Eric Latrille**², **Dominique Patureau**¹ and **Arnaud Helias**³, (1)INRAE, France, (2)Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France, Metropolitan, (3)INRAE - ITAP, Montpellier, France

It is a real challenge for life cycle assessment practitioners to identify all relevant substances contributing to the ecotoxicity. Once

this identification has been made, the lack of corresponding ecotoxicity factors can make the results partial and difficult to interpret. So, it is a real and important challenge to provide ecotoxicity factors for a wide range of compounds. Nevertheless, obtaining such factors using experiments is tedious, time-consuming, and made at a high cost. A modelling method that could predict these factors from easy-to-obtain information on each chemical would be of great value. Here, we present such a method, based on machine learning algorithms, that used molecular descriptors to predict two specific endpoints in continental freshwater for ecotoxicological and human impacts. The different tested machine learning algorithms show good performances on a learning database and the non-linear methods tend to outperform the linear ones. The cluster-then-predict approaches usually show the best performances which suggests that these predicted models must be derived for somewhat similar compounds. The median values of the absolute errors were below one log, which is the commonly assumed margin of error for experimental characterization factors. This promising results show that this methodology could be a quick alternative to provide characterization factors when they are lacking. It could be noticed that this machine learning predictive strategy could be applied to any other compartment and/or characterization factors, provided that a sufficiently large learning database already exists.

5.06.P-Tu297 New Life Cycle Inventories of Chemicals Used in the Production of Airframe Parts

Ana Nioac de Salles¹, Corinna Lätsch¹, Gabriela Gromer² and Ute Pohsner², (1)Fraunhofer-Institut für Chemische Technologie ICT, Germany, (2)Fraunhofer Institute for Chemical Technology ICT, Germany

New Life Cycle Inventories (LCI) of chemicals used in the production of airframe parts has been developed by Fraunhofer in the Eco-Design Transversal Activity (ECO-TA) Platform of Clean Sky. Clean Sky, a Public Private Partnership between the European Commission and the Aeronautical Industry and the largest European aeronautics research programme, funds research activities to deliver significant reduction of the environmental footprint of aviation. In order to ensure the environmental improvement of the new materials and technologies, Fraunhofer performs the Life Cycle Assessment (LCA) of some airframe demonstrators, such as thermoset wing, thermoplastic and metallic fuselage, and cabin interior parts. However, one of the main challenges is the missing LCI data. Since the database is the core of an LCA, Fraunhofer itself has developed life cycle inventories of various chemical products used in the manufacturing of metal and polymer parts and in recycling processes related to airplane applications. Moreover, in Clean Sky the new technologies have to be developed in accordance with REACH - Regulation on Registration, Evaluation, Authorization and Restriction of Chemicals. These technologies make use of chemicals such as corrosion inhibiting primer based on leaching inhibitor technology (Strontium chloride, Zinc phosphate); chemical solvent stripping (paint removal non-phenolic) and preparation of sol-gel solutions (3-(Trimethoxysilyl)propyl glycidyl ether, Trichlorsilan), which are not available in the current LCA databases (open source data, OpenLCA, ecoinvent, GaBi, etc). As one of Fraunhofer's institutes specialised in chemistry, Fraunhofer ICT (Institute for Chemical Technology) has the necessary know-how and infrastructure to gather more accurate data and develop new and more reliable LCIs for chemical products. At the moment, more than 60 new LCIs are being modelled by Fraunhofer ICT, with the development of a new classification system that aims at creating different clusters of chemical traits, processes and uses that will improve usability and accessibility of said data. With the development of these LCIs and database, the classification and the environmental impact – especially the toxicity – of these chemicals can be better assessed and compared.

5.06.P-Tu298 Filling ProScale Hazard Factor Data Gaps for Unclassified Substances

Tomas Rydberg, Hanna Holmquist, Therese Kärnman and Veronika Slabanja Lantz, IVL Swedish Environmental Research Institute, Sweden

The ProScale method is one of the tools in the Mistra SafeChem SSbD toolbox and calculates the toxicological potential for substances and mixtures with an exposure/dose factor and a hazard factor (HF) to be used for characterization of chemicals in life cycle assessments and chemical footprints. ProScale Hazard Factors (HF) are based on data from classification of chemicals in GHS and CLP. For small volume chemicals and new chemicals, data are scarce. By obtaining data typically used for classification purposes, a relevant interim HF could be derived. Relatively much data is needed so as a first step for an initial ProScale screening a simplified approach is suggested, making use of the precautionary principle. In ProScale, the highest possible HF has a value of 100 000. So this value could be assigned by the practitioner to all unknown substances in the first iteration of assessment of a system. Only if these substances are contributing significantly to the overall impact, there will be a need to look for more data and refine the HF.

5.06.P-Tu299 Gaps in Chemical Sector Life Cycle Inventories of Main Inventory Databases and How to Fill Them

Christopher Oberschelp¹, Stephan Pfister² and Stefanie Hellweg², (1)ETH Zurich, Zurich, Switzerland, (2)ETH Zurich, Switzerland

The life cycle inventories (LCIs) of chemicals are central to life cycle assessment (LCA) studies for a broad range of products, for example in the agriculture, healthcare, food, plastics or construction sector. Thus, maintaining high data quality is vital, while the complexity of chemical supply chains and the high diversity of products and processes makes this challenging. From a review of the main unit-process LCI databases (ecoinvent, IDEA, USLCI), we identify the gaps in chemical sector LCI data. The two most critical gaps are in the energy inputs, both for heat and electricity, and in the coverage of new process routes deployed in recent years. In terms of energy inputs, we observe that energy supply is frequently modeled with generic datasets such as national or regional electricity supply mixes, as well as generic steam supply. In contrast, we find about 7'000 power plants owned and operated by chemical companies, of which most are fossil fuel-based. We calculate the emission intensities of these power plants with a detailed unit-level model and utilize them to quantify environmental impacts of electricity and heat supply specifically for chemicals production. In addition, we model several key technologies for chemical production, that have gained major market shares in recent years and have not been covered by the main LCI databases, yet. With the results, we are then able to show at

high spatial resolution how the environmental impacts of chemicals production differ due to specific energy inputs, and which new technologies perform environmentally very differently from established technologies covered by the main life cycle inventories. Central roles for portraying the environmental impacts of today's chemicals production have the disproportionately large share of fossil fuel use in heat supply, and the massive expansion of coal-based chemicals production in Asia. In consequence, the results can be used to prioritize chemical sector updates and data improvements for main LCI databases.

5.06.P-Tu300 Development of a Site-Specific LCA Model to Assess Pathways Towards a Net-Zero Chemical Industry

Ronja Hermanns, Laura Stellner, Arne Kätelhön and Raoul Meys, Carbon Minds GmbH, Germany

The chemical industry is responsible for 18% of the global industrial greenhouse gas emissions. To reduce this impact, various alternative technologies for reducing greenhouse gas emissions are being discussed for the chemical industry. However, environmental assessments to a net-zero chemical and plastic industry are available only on a global scale. Thus, the required changes in the chemical production sites on a more regional level to achieve net-zero emission chemicals are currently unknown. Precisely regional data as the demand for future raw materials are important for policy decisions in a country to plan infrastructure development, investment in new plants, and import strategies. To fill this gap, we will present a new chemical production site-specific, life cycle assessment (LCA) based model that can be used to determine technology choices in chemical production sites while systematically considering the site-specific utility supply, the site-specific feedstock availability, and the trade between the technologies in a chemical production site and regions of the world. In a subsequent case study, the bottom-up LCA model is used to assess pathways towards a net-zero German chemical industry. The case study includes 592 chemical production plants in 54 production sites to produce 85 chemical products. The alternative technologies, electrification, water electrolysis, Carbon Capture and Utilization, and biomass utilization, are investigated for Germany. The assessment of the pathways shows that greenhouse gas emissions of chemical production can reach zero if a combination of different alternative technologies and electricity with a carbon footprint below 50g CO₂-eq per kWh is available. Furthermore, the pathways' assessment reveals site-level demand shifts of intermediate chemicals, resulting in a mass increase by a factor of 2.6. This case study shows that the developed chemical production site-specific LCA model can map complex production systems and provide regional results of a holistic life cycle assessment with a high level of detail. The results can be used to guide policy strategies towards a sustainable chemical and plastic industry.

5.07 Standardization and harmonization of life cycle assessment

5.07.T-01 Inconsistencies Regarding Product System Definition and Multifunctionality Solutions in ISO 14040-14044 & Proposed Amendments

Thomas Schaubroeck¹, Dieuwertje Schrijvers², Simon Schaubroeck³, Christian Moretti⁴, Alessandra Zamagni⁵, Nathan Pelletier⁶, Gjalt Huppes⁷ and Miguel Brandão⁸, (1)Luxembourg Institute of Science and Technology, Esch-sur-Alzette, Luxembourg, (2)WeLOOP, France, (3)KU Leuven, Belgium, (4)Utrecht University, Netherlands, (5)Ecoinnovazione, Italy, (6)University of British Columbia, Canada, (7)CML Leiden University, Netherlands, (8)KTH - Royal Institute of Technology, Sweden

We focus on two aspects of the ISO 14040-14044 standards where inconsistencies are unfortunately persistent. We explain and argue these inconsistencies and propose possible amendments. The first issue relates with the specification of a product system. In LCA, the environmental impact of a product system is assessed. In the main text of the ISO 14040 standard, a product system is a "collection of unit processes with elementary and product flows, performing one or more defined functions, and which models the life cycle of a product". However, in the annex A of ISO 14040 is written that: "the products and processes studied in an LCA are those affected by the decision that the LCA intends to support". These statements are contradictory, as a product system cannot be both a consequence of a decision and a product life cycle. The first definition, i.e. considering a product life cycle, from the main text, is at the core of attributional LCA (ALCA). The other approach, concerning consequences of a decision as stated in annex A, aligns with the concept of consequential LCA (CLCA). The second issue deals about the solutions for multifunctionality. The multifunctionality issue concerns processes/systems providing multiple products that have different functions, and the assignment of impact among them. The ISO standards present a fixed hierarchy of a limited set of solutions. This procedure is contradictory with other text in the standard which states that the first step of the LCA method allows to specify a goal and scope, on which to base further methodological choices. For example, for ALCA and CLCA, only certain solutions for multifunctionality should be applied. To address the inconsistencies, we present two adapted overarching aims for the standards, for which amendments can be specified. The first is to consider a more open & general LCA standard, with the addition of a novel product system definition and a general approach for multifunctionality solutions. The second is to limit the standard to a certain LCA type, e.g. ALCA, and develop new standards for others. Finally, these inconsistencies are persistent, should not be ignored and addressed swiftly. It is up to the standard committee to select a certain proposed amendment or perhaps conceive others. In the meantime, we recommend for now to consider a more open & general LCA framework, which may be the best option in the long run.

5.07.T-02 System Expansion in ISO Documents

Tomas Ekvall, Chalmers University of Technology, Sweden

The international standard on life cycle assessment (LCA) stipulates that, wherever possible, allocation should be avoided by subdividing the unit process or by expanding the product system to include the additional functions related to the coproducts. System expansion has been interpreted in different ways: to assess the full multifunctional system, or too create a monofunctional model by giving the system a credit for the avoided production of products substituted by the coproducts. Standardisation is a consensus process, and the outcome will depend on who is attending the meetings of the International Standardisation

organisation (ISO). The content of a standard can shift simply because the composition of the group developing the standard has changed. Thus, the annex explaining system expansion as substitution in ISO 14041 was removed when this standard was revised and integrated into ISO 14044, but a similar annex was added 14 years later in the most recent amendment of this standard. Meanwhile, the same subcommittee produced a technical report (ISO/TR 14049) that interprets system expansion as expansion into a multifunctional system. Perhaps more importantly, and more difficult to amend, various LCA-related standards are developed within different ISO committees, creates inconsistencies between the documents. For example, the standard on life cycle inventory analysis of steel products stipulates system expansion and interprets it to imply substitution. The standard for Environmental Product Declarations (EPDs) in the construction sector states that system expansion with substitution fits in consequential LCA but should not be used in attributional EPDs. The draft standard on LCA of biobased plastics explicitly excludes substitution from the interpretation of system expansion. The original version of ISO 14044 allowed for different interpretations of system expansion. The new annex makes it more difficult to reconcile this standard with other LCA-related documents from ISO. The annex also misleadingly indicates that the two interpretations of system expansion are mathematically the same. A consolation can be found in the fact that the annex is informative and not normative. This seems to allow for other interpretations of system expansion in ISO than the one presented in the annex.

5.07.T-03 Investigating the Link Between LIFE Cycle Assessment and Circularity Indicators: A SETAC/ACLCA Working Group

Christine Minke¹, Guillermo Babilonia², Pahola Benavides³, Nick Blume⁴, Seth Jackson⁵, Christoph Koffler⁶, Ashley Kreuder⁷, Manish Kumar⁸, Jennifer Richkus⁹, Cheryl Smith¹⁰, Michele Wallace¹¹ and Michael Saidani¹², (1)Leibniz Universität Hannover, Germany, (2)Little Venice Manufacturing, LLC., United States, (3)Argonne National Laboratory, United States, (4)Research Center Energy Storage Technologies, Clausthal University of Technology, Goslar, Germany, (5)Sherwin Williams, United States, (6)Sphera Solutions, Inc., United States, (7)Ramboll, United States, (8)INDIAN INSTITUTE OF SCIENCE, India, (9)MITRE, United States, (10)Owens Corning, Granville, Ohio, United States, (11)Cotton Incorporated, United States, (12)University of Illinois, Urbana-Champaign, United States

Current research has indicated that circularity practices and circular economy (CE) methods do not always reduce environmental impacts. The aim of this research is to investigate the adoption of life cycle assessment (LCA) methods to improve the environmental impacts of circularity practices. As part of the SETAC forum, an interest group (IG) on Circularity & LCA was formed in partnership with the American Center for Life Cycle Assessment (ACLCA) to tackle related methodological and technical issues. The membership structure is intended to be a good balance between academia, industry and government/environmental agencies. The IG's research approach is summarized in four key steps: Defining Goals & Objectives, Literature Review & Gap Analysis, Ideation, and Experimentation. To meet the mission of the SETAC/ACLCA IG Circularity & LCA, we have organized into four sub-working groups (Sub-WGs) so that complementary tasks can be completed concurrently in an effective manner. In Sub-WG 1 a literature review is developed in order to clarify the existing circularity and LCA end-of-life indicators. In addition the current status of the implementation of CE indicators by companies is assessed. Sub-WG 2 investigates the existing approaches to evaluate the environmental impact of circularity through LCA. In a survey and expert discussion a list of "pain-points" and methodological gaps is collected and analyzed. Sub-WG 3 delivers a mapping of the trade-offs between environmental benefits and circularity performance throughout the product life cycle and its resource loops. In Sub-WG 4 use cases based on the outcomes of the other Sub-WGs are developed. The main goal is to identify successes, challenges and opportunities when applying CE models and standards. In conclusion, LCA methods and software do not provide clear guidance and approaches to including CE pathways, measuring impacts, and defining system boundaries. There are an increasing number of circularity indicators and lack of clear guidance on how to assess the CE. The indicators do not always provide insight on the environmental savings or benefits of implementing CE principles. In this context, an ISO Technical Committee (ISO/TC 323) on CE has been established to develop standards on general implementation approaches and metrics for CE. A standardized CE evaluation method should support strategic decisions and monitor the progress towards sustainable development. In future work, a guiding flowchart or logigram could help users to navigate between these indicators, as well as to aggregate existing approaches into an integrated solution.

5.07.T-04 Where Are All the Additives? Identifying Trends in Plastic Additive Inclusion in LCAs of Mechanical Recycling

Heather Margaret Logan¹ and Anders Damgaard², (1)Technical University of Denmark (DTU), Denmark, (2)DTU, Denmark

Pathways for circular plastics are key topics in today's Life Cycle Assessment (LCA) community. To ensure the accuracy and reliability of these studies, LCAs on circular plastic materials and circular plastic recycling scenarios must consider the impacts of the entire chemical composition of the plastic assessed. Plastic additives are essential to the production and reprocessing of all plastics (Hahladakis et al., 2018). Added throughout all stages of production and recycling, plastic additives make up between .01-70% of the net weight of plastic materials (Aurisano, et al., 2021; ECHA, 2020). However, recent studies into the flows and reporting of additives throughout the EU found between 6,000-10,000+ additives were underreported despite their common use in plastic materials (Aurisano et al., 2021; Wiesinger et al., 2021). When considering scenarios for circular plastic pathways in LCA, it is vital that the flows and impacts of plastic additives are accounted for in the discussion and life cycle inventory (LCI) of the study. Previous literature reviews of LCAs of plastics have speculated that additive exclusion is due to knowledge gaps or cutoff approaches but have not explored these suspicions in detail (Bishop et al., 2021; van Oers et al., 2012). This systematic literature review separates author talk about additives from additive data presence in the LCI to identify if additive exclusion, or inclusion, occurs due to knowledge gaps or data quality. Focusing on LCAs that assessed plastic circularity in mechanical recycling pathways, we identified 103 LCAs published in peer-reviewed journals from 2010-2020. Despite one-third of the authors discussing additives in the text and one fifth mentioning the importance of additives, we could not classify additive inclusion in

the data for one-half of all articles despite thorough reviews of the article text and all accompanying supplemental materials. This review highlights the importance of data transparency in published LCAs and underscores the difficulty in informing decision making due to the state of standardization and harmonization in LCA today.

5.07 Standardization and harmonization of life cycle assessment (Virtual Only)

5.07.V-01 A Streamlined Methodology to Integrate Life Cycle Thinking With Existing Environmental Sustainability Assessment Tools in Construction Sector

Daniela Camana¹, Sara Toniolo² and Alessandro Manzardo², (1)Department of Industrial Engineering, University of Padova, Padova, Italy, (2)University of Padova, Italy

The use of the multi-dimensional life cycle thinking approach can support quantitative and qualitative analysis of policies and help to assess the environmental sustainability of strategies, revealing gaps, challenges, and interactions. However, LCT studies seem too expensive for an extensive implementation. Moreover, findings are always complex and a more transparent communication to non expert stakeholders is needed. In contrast, other environmental assessment tools are less robust, but more easily applicable, comprehensible, and communicable. As emerged from existing research, different assessment tools of policies give different environmental results, both in literature and in case studies. Therefore, the use of a single indicator seems not appropriate to define clearly if a policy is more sustainable than another and to avoid the risk of greenwashing. The present research suggests a step-by-step methodology to verify advantages when the quantitative results of a comprehensive LCT approach are combined with qualitative outcomes of other tools. Phases considered in the method are anticipation and problem definition, impact assessment based on quantitative research, policy implementation, and strategies evaluation. The step-by-step methodology is revealed helpful to plan analysis and to conduct data collection and interpretation. As a case study, the Environmental Product Declaration of an “eco-concrete” is performed and compared to qualitative analysis based on Italian legislation on constructions works and other existing environmental labels. Results show that environmental product declaration highlights some areas of interest (efficiency, comprehensiveness, space boundaries) but non hugely consider other aspects (i.e. trade off, and social or economic issues). Moreover, existing approaches seem focus mainly on some stages of the life cycle of concrete, disregarding others (end of life, product use, facility buildings, transport conditions). Rebound effects and degrowth patterns are also investigated. The step-by-step method proposed appears useful to include in local policies for the construction sector both environmental impacts and economic and social aspects of sustainability. The approach is revealed flexible and usable for products, services, strategies at various territorial level. Therefore, future uses of the method for other policies are wished.

5.07.V-02 Environmental Assessment of an Offshore Wind Farm With Concrete-Based Floating Substructures to Support 15MW Turbines

Gabriela Benveniste¹, Jose Ignacio Rapa², Victor Ferreira³, Jos Luís Dominguez² and Cristina Corchero², (1)IREC, SANT ADRIA DE BESOS, Spain, (2)IREC, Spain, (3)IREC, Sant Adria de Besos, Spain

Ever since the onset of transition from onshore to offshore wind power, there has been a constant effort to move the turbines further from the coast to the deep-water areas, which requires floating substructures. One innovative alternative for offshore wind floating substructures is based on concrete materials. The environmental impact of this new concept needs to be assessed through the resources demand along as its life cycle. COREWIND is a European project that aims to the reduce costs of floating substructures designed to carry wind turbines of 15MW in deep offshore marine environments. In this work, a prospective fully comprehensive life cycle assessment (LCA) of monolithic concrete spar platform for 15MW offshore turbines located in Gran Canaria Coast-Spain, has been performed through the production, installation, operation and maintenance, decommissioning and End-of-Life (EoL) recycling stages. The production stage, including the transportation of raw materials to the manufacturing facilities, shows the highest contribution in all environmental impact categories studied, while the impacts associated with the EoL stage bring benefits due to the material recycling considered in the model, whose contribution ranges from -11% to -42% through all impact categories. When focusing on the global warming impact category, the overall result is 7.23 gCO₂ eq/kWh, being below average from studies found in the literature (19 gCO₂ eq/kWh), which entails carbon payback times between 0.5 and 0.9 years considering future emission factors of the electricity grid mix in the European Union. The floating structure manufacturing entails 1.45 gCO₂ eq/kWh (24% of contribution in the manufacturing stage), which positions the use of concrete support structures for offshore wind to power the renewable energy transition.

5.07.V-03 Towards the Operationalisation of Life Cycle Sustainability Assessment: Integrating User Needs in LCSA Methodology Development

Hanna Pihkola¹, Mauro Cordella² and Alessandra Zamagni³, (1)VTT Technical Research Centre of Finland, Espoo, Finland, (2)JRC-IPTS, Spain, (3)Ecoinnovazione, Italy

The assessment of sustainability impacts of products is more and more requested by EU customers, investors, and regulators. Principles and requirements for a comprehensive sustainability assessment of products are described in the life cycle sustainability assessment (LCSA) framework proposed by UNEP/SETAC in 2011, according to which LCSA is the combination of environmental life cycle assessment (LCA), social life cycle assessment (SLCA) and life cycle costing (LCC) approaches. However, conducting an LCSA requires interdisciplinary knowledge and access to modelling tools and information that may not always be directly available and accessible. This means the existence of some entry-level barriers, which hamper the operationalisation of LCSA. It is thus necessary to understand the main needs and requirements from potential users of LCSA, i.e., which characteristics LCSA should have for being applicable, useful and affordable. Users' needs and wishes on LCSA have been investigated in the framework of ORIENTING (Operational Life Cycle Sustainability Assessment Methodology Supporting

Decisions Towards a Circular Economy), a EU H2020 project aimed at developing a robust and operational methodology for the LCSA of products (goods and services). A workshop was organised in April 2021 to discuss needs and wishes of users together with around 150 stakeholders, including academia and research representatives, policy makers, civil society, financial institutions, and industry representatives (both SMEs and large corporations). Flexibility of scope, transparency of results and support for interpretation of the results were among the key aspects highlighted during the workshop. The reflection of these needs into the LCSA methodology is currently under development, further strengthened by i) the connection with the standardisation activities, and ii) the testing and validation of the methodology in practical case studies. Environmental assessment will be conducted according to the PEF method, applying the category rules documents (when available for the case products). One of the aims of the project is to consider, how the PEF could be extended towards a comprehensive Product Sustainability Footprint in future. Additional consultation processes will take place in 2022 to further refine the LCSA methodology, which will be delivered in its final status by the end of 2023.

5.07 Standardization and harmonization of life cycle assessment (Poster)

5.07.P-Th183 Recycling Approaches in Lca-Related International Standards

Tomas Ekvall, Chalmers University of Technology, Sweden

Recycling of materials from one life cycle into another introduces an allocation problem in life cycle assessment (LCA). The problem can be defined as the task of partitioning the impacts of common processes between the life cycles where the material is used. Alternatively, it can be defined as the task to partition the environmental impacts and environmental benefits between the life cycle that generates material for recycling and the life cycle where the recycled material is used. Existing scientific literature and LCA guidelines recommend very different approaches on how to deal with this allocation problem. Even standards developed within the International Organization for Standardization (ISO) diverge in the methods suggested, particularly in cases when the recycled material has a lower quality compared to primary material. The international standard on LCA (ISO 14044) states that quality losses can be accounted for, but without stipulating a method. A technical report guiding the application of ISO 14044 (ISO/TR 14049) suggests that, in the case of quality losses, the impacts of primary-material production can be equally divided between all products in which the material is used. The standard for carbon footprint (ISO 14067) includes a method that partitions the impacts of primary-material production between the first and the last product where this material is lost. The standard for Environmental Product Declarations in the construction sector (ISO 21930) assigns the full impact of primary-material production to the product where the primary material is used, although the environmental benefit of recycling can be included as additional, in a voluntary Module D. When there is no loss of quality in the material, most LCA-related international standards suggest or stipulate that the net environmental benefit of recycling can or should be assigned to the product that generates material for recycling, when there is no loss of quality in the material. An exception is ISO 21930, which does not give any credit for recycling in the calculations, but only as additional information in Module D.

5.07.P-Th184 Sensitivity Analysis of the Use of Allocation Methods on Slaughterhouse Level: A Case Study on Danish Pork Production

Selma Alzohairi, Marie Knudsen and Lisbeth Mogensen, Aarhus Universitet, Denmark

Life Cycle Assessment (LCA) is a method used to assess the environmental impacts of products throughout their entire life cycle. When applied in livestock systems, it faces the problem of multiple outputs. The meat supply chain, particularly from slaughterhouse gate, produces many products and byproducts with multiple usages, values and actors involved. Current literature suggests that the allocation method chosen to divide impacts among products and byproducts is an important issue, since it may change the conclusions about a product's environmental impact. Four different allocation methods emerged from a literature review: system expansion, biophysical, economic, and mass allocation. The allocation methods in the guidelines and scientific articles showed that several of them follow the ISO standards closely (avoid allocation if possible, if not, follow hierarchy of allocation rules). Thus, their precedences are no clearer than those of the ISO standards. The Product Category Rules for red meat recommends using economic allocation on slaughterhouse level. However, economic allocation is often criticized by meat processors for its sensitivity to prices fluctuations in the market. In the present study, an LCA on Danish pork production was performed in which the potential impacts resulting from use of different allocation methods on slaughterhouse level was compared, followed by a sensitivity analysis of price fluctuations within the economic allocation. The results from the study suggests that economic allocation is stable despite price fluctuations in the market because the shares in the total proceeds remain stable over time. Economic allocation reacts to changes within the production when increasing the relative yields for human consumption and let the economically main product bear the main environmental burden. Mass allocation, assesses the same impacts to the product and byproduct and thereby does not stimulate to increased utilization of the live animal. Biophysical allocation reflects the underlying mechanisms of building tissues upstream while disregarding their fates downstream. System expansion is reflecting the utilization of the byproducts from the slaughterhouse. The different allocation methods gave very different results for the pork product. Hence, to achieve comparability and reduce the possibility of masking and manipulating results by selecting more convenient allocation methods, the same method should be applied in comparable studies.

5.07.P-Th185 Recovering Treated Sewage Sludge Nutrients for Agricultural Use: Life Cycle Assessment for a Circular Economy

Esra Eisa Aleisa, Abdalrahman Alsulaili and Yasmeeen Almuzaini, Kuwait University, Kuwait

Utilizing treated sewage sludge (SS) has been perceived as means to close the product-life-cycle loop in agriculture by embracing the cradle-to-cradle philosophy of circular economy transition (CE). Within CE context, management of wastewater treatment

sludge has undergone a paradigm shift of being considered as waste to burden societies to a value-added material that could use to produced energy or a source to recover essential elements. The aim in this study is to assess the lost opportunity associated with disposing treated SS as opposed to recirculating its valuable constituents to support CE. The SS nutrients are modeled as CE consumables to an 'open-loop' system that is also subject to end of life (EoL) allocation in LCA as indicated by JRC (2010) guidelines. Consequential modeling system paradigm is applied, to avoid coproduct allocation by system expansion. The functional unit is defined in terms of the amounts of nitrogen (N), phosphorus (P) and potassium (K) recirculated from the treated sewage sludge produced annually in Kuwait. The results indicate a reduction in environmental burden with respect to fossil fuel depletion, metal depletion and climate change. A total of 95% of the reduction is realized by avoiding virgin nitrogen production and instead using its recirculated counterpart. Considerable amounts of natural gas, coal, dinitrogen monoxide (nitrous oxide, N₂O) and copper are consumed during virgin N fertilizer production. Because P is an essential nutrient, that underpins global food security, we use LCA to assess using SS as secondary sources of P compared to that recovered using sewage sludge ash (SSA). The results indicated that P from phosphatic rock had almost three times the burden borne by the current treatment of sludge and 1.6 the burden of SSA. The current system had a slightly smaller environmental impact compared SSA, except for climate change due to extensive Methane and CO₂ production in the current system. SSA approach could be particularly relevant for countries, such as Kuwait where agricultural reuse of SS is not generally accepted by the general public. Treated SS needs to be tested for microbiological agents (viruses, bacteria, parasites and helminths), chemical substances and heavy metals to avoid risks to public and occupational health via direct or indirect exposure.

5.07.P-Th186 The Overlooked Nutrient Substitution Issue in LCA

Zoe Chunyu Miao¹, Vanessa Zeller² and Liselotte Schebek³, (1)TU Darmstadt, Darmstadt, Germany, (2)Institute IWAR, Technische Universität Darmstadt, Darmstadt, Germany, (3)Technische Universität Darmstadt, Germany

Limitation on natural resources and the pursuit of sustainable development have promoted material recycling from waste streams. One good example is to use municipal biowaste or agricultural residuals in biological treatment and to reuse the digestate or compost as soil conditioners and fertilizers. Life cycle assessment has been widely applied in the nutrient recycling field to identify potential environmental consequences and trade-offs. Due to the nature of the recycling process, dealing with multifunctionality is then an inevitable and crucial question. Substitution is one of the common approaches to solve multifunctionality. It keeps mass balances intact and is in line with LCA that supports decision support. Previous studies have highlighted the inconsistency in substitution and the possibility of over-/underestimation due to different substitution approaches that are applied. However, the specialty of soil nutrient substitution has hardly been captured and discussed as a separate methodological topic. Furthermore, no guidelines and frameworks address nutrient substitution specifically. The LCA community has acknowledged the importance of the substitution approach but overlooked the specific demand from explicit sectors. This blind spot has obstructed the comparability, accuracy, and comprehensiveness of LCA. My proposed presentation will offer insights into the inconsistency and the potential methodological shortcomings of soil nutrient substitution. With the result of an undergoing systematic literature review, limitations and further directions regarding this issue will be shared. The results shall contribute to the development of a structured nutrient substitution methodology and promote sector-specific guidelines.

5.07.P-Th187 Review of LCAs Based on Chemical Processes

Sergi Arfelis, Pere Fullana and Alba Bala, UNESCO Chair in Life Cycle and Climate Change (ESCI-UPF), Spain

Chemical production is essential for helping society to achieve sustainable progress. Green chemistry innovative reactions can contribute to achieving some Sustainable Development Goals (SDGs), as reported by the Global Chemicals Outlook-II (GCO-II). In particular: Zero hunger (SDG 2), Human health and well-being (SDG 3), Clean water and sanitation (SDG 6), Affordable and clean energy (SDG 7), Responsible consumption (SDG 12) and Climate change (SDG 13). The chemical sector is currently a \$4 trillion global business, employing more than 20 million people directly and indirectly and affecting more than 95% of manufactured products. The holistic approach of Life Cycle Analysis (LCA) applied to the design and evaluation of chemical products and processes has aided scientists in looking into the environmental impacts of their life cycle, comprising the raw material procurement, synthesis, use and end-of-life. The proposed presentation aims to review and compare publications of 47 industrial-scale chemical processes LCAs from 2012 to 2021 indexed in three of the most common scientific databases: Science Direct, Scopus, and Web of Science.

5.07.P-Th189 Environmental Footprint of Seafood Products Based on the Nexus Water-Energy-Food Approach

Pedro Villanueva-Rey¹, Samuel Domegan², Lucia Poceiro², Diego Quiñoy² and Eduardo Rodríguez², (1)Industry & Sustainable Buildings, EnergyLab, Vigo, Spain, (2)EnergyLab, Spain

During the last decades, the stakeholders within the seafood supply chain are raising the awareness of the environmental impacts related to fishing, aquaculture, processing, transportation, packaging and to all steps from farm to fork, increasing the demand of sustainable seafood products. Hence, there is a growing interest in calculating the environmental footprint of these products. However, there is not yet any standard methodology for calculating it. In the framework of the Interreg Atlantic area Neptunus project, it was developed a standardized framework to perform environmental footprint of seafood products based on life cycle assessment (LCA) perspective. The proposed framework delves into the typical issues when performing LCA such as the functional unit selection, system boundaries definition, inventory data modelling and identification of proper life cycle impact assessment methods. In addition, the Neptunus framework aims at the integration of environmental and nutritional indicators based on the NEXUS Energy-Food-Environment approach, allowing a better communication to the public. As a result of the integration, it was developed a single indicator to report not only the environmental performance of seafood products, but also nutritional issues related to the product on scope: the Nexus Water-Energy-Food. The methodology for the Nexus Water-Energy-

Food calculation comprises several stages: i) selection of environmental footprints, which include water, carbon, and energy footprints; ii) calculation; iii) normalization; iv) weighting; and v) communication, which includes the results communication throughout the designed NEXUS ecolabel. The application of the proposed framework to seafood products showed interested results in terms of impact based on fishing species, fishing ground, fishing gear, manufacturing processes, or ingredients added.

5.07.P-Th190 An Innovative Methodological Framework to Perform Life Cycle Assessment of Tourist Activities

Pedro Villanueva-Rey¹, Eduardo Rodríguez², Lucia Poceiro², María Gallego², Diego Quiñoy² and Samuel Domegan², (1)Industry & Sustainable Buildings, EnergyLab, Vigo, Spain, (2)EnergyLab, Spain

As whatever human activity, tourism is not exempt from environmental impacts related to the stay in destination. Hence, tourism implies travelling (road, air, and sea), accommodation, catering, and activities (social events, cultural visits, adventure, etc.). Traditionally, sustainability issues in tourism sector were addressed in terms of greenhouse gas (GHG) emissions, focusing on transportation from origin up to destination, disregarding accommodation, catering, and activities. Furthermore, up to now, life cycle assessment (LCA) of tourism activity has not been properly addressed due to the following issues: i) poor and limited life cycle inventory data; ii) reluctance of the sector; and iii) lack of a sectorial methodological framework. The Interreg SUDOE project Greentour — Circular economy and sustainable tourism in destinations of the SUDOE space, delves into the abovementioned issues developing and innovative methodology based on life cycle perspective. In this sense, the proposed approach includes the tourism activity as whole —i.e., from travelling, accommodation, drinking and eating, to the activities carried out in destination. In addition, the project proposes a methodological framework to deal with matters such as life cycle inventory modelling, allocation, system limits and exclusions, end of life, and life cycle impact assessment (LCIA) reporting. The framework developed is based on the requirements and provisions of other life cycle methodological frameworks such as ISO 14040, ISO 14046, PEF, ILCD, and PAS 2050 among others. Although the project is focused in SUDOE area and the pilot destinations Rías Baixas, Camino Lebaniego and Lloret de Mar (Spain), Guimaraes (Portugal), Ordino (Andorra), and Auvergne (France); the methodology can be used in other destinations, intending to become the reference framework for LCA in the field of tourism. As the LCIA results shall be reported to citizens, working groups in the field of sustainable tourism and public authorities, the environmental reporting (i.e., in terms of life cycle impact categories) was adapted to break the communication barriers when target audience is not familiar with LCA indicators. To do so, the impact pathways were evaluated from a life cycle impact results and the Sustainable Development Goals (SDGs) of the United Nations. As a result, the LCIA results were linked to the SDGs indicators related to tourism activities.

5.07.P-Th191 Towards a Sustainable Religious Tourism Under a Life Cycle Thinking: The CASE of Study of the Camino Lebaniego in Cantabria

Cristina Campos¹, Jara Laso², Israel Ruiz-Salmón¹, Jaume Albert³, Pere Fullana⁴, Maria Margallo¹ and Rubén Aldaco⁵, (1)Universidad de Cantabria, Spain, (2)Ingeniería Química y Biomolecular, Universidad de Cantabria, Santander, Spain, (3)Escola Superior de Comerç Internacional. Universitat Pompeu Fabra UPF, Spain, (4)UNESCO Chair in Life Cycle and Climate Change (ESCI-UPF), Spain, (5)University of Cantabria, Spain

Tourism is one of the most important economic sectors in the world, contributing significantly to global gross domestic product (GDP). This contribution was forecast, before COVID-19, to grow at an annual 4%, increasing as consequence the greenhouse gas (GHG) emissions related to this activity. There many types of tourism activities based on the geographical and tourist demand, destination of travel, mode of transportation or means of accommodation. In particular, religious tourism is gaining special attention in many countries, such as the pilgrimage in Spain. In this sense, the main objective of this research is to develop an integrated sustainable model of the pilgrimage to the *Camino Lebaniego* in the region of Cantabria (Spain), which is one of the most popular routes in northern Spain. This study applies the methodology of Life Cycle Assessment (LCA) to evaluate the environmental impact and hotspots of the pilgrimage in this region. For this purpose, the selected functional unit (FU) is “*a pilgrim walking the route in three days*” and the sub-sectors of accommodation, food and beverage and waste management are included in the system boundaries. The results show that the pilgrimage of the *Camino Lebaniego* generates a total global warming impact of 12.30 kg CO₂ eq./FU, where accommodation contributes almost 66%, food and drink 26%, and waste management is almost negligible, with 8%. Electricity consumption in the hostel and the dinner contribute almost 85% of the total impact. In order to reduce the high impact of electricity consumption, alternatives are proposed such as the use of other types of heating such as natural gas or pellet boilers instead of electric heating. Likewise, if a meat-based diet is considered (13.65 kg CO₂ eq./FU) the impact is significantly higher than if a vegetarian diet is consumed (2.63 kg CO₂ eq./FU). Finally, origin of the pilgrim and the type of transportation were analysed, finding a higher impact as the distance increased. For instance, the impact of a pilgrim from Cantabria going by car is 6.55 kg CO₂ eq./pilgrim, compared to 171.46 kg CO₂ eq./pilgrim of German pilgrim coming by plane. Finally, these aspects are discussed and improvement measures are proposed to reduce GHG emissions through the introduction of good practices and environmental commitments with the pilgrims themselves.

5.07.P-Th192 Towards Harmonized Methodology to Indicate Neutralization Potential of Carbon Sequestered in Perennial Crop Systems

Alexi Ernststoff¹, Paula Sangines de Carcer¹, Alicia Ledo², Patrick Lawrence³, Richard Heathcote⁴ and Daniella Malin⁵, (1)Quantis, Switzerland, (2)Independent Consultant, France, (3)Independent Consultant, United States, (4)Cool Farm Alliance, UK, (5)Cool Farm Alliance, United States

To achieve climate targets, **long-standing removal of atmospheric CO₂ through land management** is essential in addition to **deep reductions in greenhouse gas (GHG) emissions** from agriculture and other sectors. Most current methods and tools for product and corporate GHG accounting, however, exclude the influence of land-based GHG emissions and CO₂ removals in

relation to land management. In order to address this methodological gap and to avoid non-science based claims, **harmonized methods are needed**. This project aims to fill the gap in current GHG accounting related to carbon sequestration and emissions associated with perennial biomass by **developing a common public methodology**. A generic model has been parameterized for apple, citrus, cocoa and coffee, based on empirical data. The model evaluates crop biomass compartments (i.e. branches, roots, stem and leaves), which is key to estimating carbon sequestration and emissions. This methodology describes the underlying procedure to parameterize a generic model to estimate biomass for selected commercially relevant typologies, and the framework to use these estimations in GHG accounting. Specifically, for GHG accounting only additional carbon sequestration following a land management or practice change (i.e. the difference between the average stock of a new state and a reference state) can be accounted for, and future reversibility of carbon sequestration in perennial systems (e.g. due to planting cycles or unexpected events such as fires) also must be considered. The final outcome of this work is to provide the groundwork for a harmonized methodology to indicate the neutralization potential (-CO₂e) of the carbon sequestered in perennial cropping systems.

5.07.P-Th193 The PEFCR on Batteries: Applicable to Smartphone Batteries?

Maeva Philippot¹, Daniele Costa², Joeri Van Mierlo³ and Maarten Messagie⁴, (1)Vrije Universiteit Brussel (VUB) - ETEC, Brussels, Belgium, (2)Evergi/MOBI, Vrije Universiteit Brussel (VUB), Brussels, Belgium, (3)Vrije universiteit Brussel, Belgium, (4)Vrije Universiteit Brussel (VUB), Belgium

Smartphones have a high market penetration raising the awareness of the environmental impacts of these products. Life Cycle Assessment (LCA) studies of smartphone batteries are scarce in the scientific literature. The environmental impacts of smartphones have already been studied, highlighting the impact of the manufacturing stage. However, only one study focused on its battery [1]. To ensure the comparability of LCA results, harmonization of methods is needed. In that sense, the Product Environmental Footprint Category Rules (PEFCR) for High Specific Energy Rechargeable Batteries for Mobile Applications provide a methodological framework for LCA of batteries, even though not intended for research purposes. These PEFCR are applicable for batteries for electric vehicles and Information & Communication Technologies such as smartphones [2]. However, these PEFCR are often not used in scientific literature, partly due to their recent publication. Besides this issue, the PEFCR are not related to the various goals LCA studies can have. This study questions the relevance of these PEFCR to a self-healing smartphone battery developed in the context of the BAT4EVER project. Thanks to the increased battery performance, the possible second life of the battery will also be studied. Issues regarding the goal and scope of the PEFCR will be discussed, such as the choice of the Functional Unit (FU). The FU is defined as “1 kWh of the total energy provided over the service life by the battery system” which represents the function of a battery but is not widely used in literature. This total energy is based on battery industry standards that have been withdrawn and are not representative of the use of a smartphone. The inventory and the data need matrix will be compared to the data LCA experts frequently have. Most LCA experts usually do not have access to test results for the battery lifetime, or cannot calculate the energy efficiency as described in the PEFCR. The PEFCR recycling process is a pyrometallurgical treatment, followed by hydrometallurgical treatment, but other processes exist (such as hydrometallurgy and direct recycling) and are not described. In addition, the second life of batteries will be discussed as it is still not present in the current version of the PEFCR. Besides these issues, the PEFCR do not mention interpretation or sensitivity analysis of the results, calling for harmonization in this stage. **Acknowledgements:** This project has received funding from the European Union’s Horizon 2020 research and innovation programme under the grant agreement No. 957225. **References**[1] Mejame PPM, Jung DY, Lee H, Lee DS, Lim SR. 5.07.P-Th194 Life Cycle Assessments (LCA) of a Heterogenized Ruthenium Catalyst Molecular Anode for Water Oxidation Catalysis

Andrew Howe¹, José Jorge Espí Gallart² and Frederic Clarens², (1)SMC, Uppsala University, Uppsala, Sweden, (2)Eurecat, Spain

An artificial leaf is a concept which is an experimental design, to be coupled with a renewable energy source. There are very few impact studies on a water electrolysis system for hydrogen production, with an impact study on a ruthenium-based molecular anode not being in existence at the time of writing. Therefore, Life Cycle Assessment (LCA) was used to generate a compilation and evaluation of the inputs, outputs and potential environmental impacts of a ruthenium-based molecular anode. A preliminary cradle-to-gate study is carried out to understand the net primary energy requirement of each stage of manufacture and net energy gain as a function of efficiency and the longevity of the molecular anode. Due to the complexity of the synthesis for the molecular anode, which included all the steps for the synthesis of the complex, the polymer and the attachment onto the polymer, many steps for manufacture required modelling. Reported inventory data was often unavailable due to the molecules not being in widespread use or modelled previously in any previous study. It was often necessary to resort to patents and even real-world laboratory data from experiments. Through this methodology, we were able to identify different points in the manufacturing process where the environmental impact was most acute. This enabled quantification of how much impact the use of ruthenium had on the overall LCA. It also enabled identification of problematic steps in the synthesis of the equatorial ligand, particularly the use of a common reagent used as an electrophilic cyanide source and the accumulative energy demand required for heating at different points of manufacture. This modelling was a useful process further down the line, since it is novel due to it being the first preliminary modelling of a molecular anode for water oxidation, it also provided data which will be useful when coupling this molecular anode with all the other components parts of an artificial leaf.

Track 6: Environmental policy, risk management, and science communication

6.01 Advances in the Regulation and Life Cycle Assessment of Metals in the Environment

6.01.T-01 Assessing Potential Environmental Risks From the Use of Zinc-Based Medicines in Piglets

Adam Peters¹, Graham Merrington² and Ken Stapleton³, (1)wca, United Kingdom, (2)WCA Environment Limited, United Kingdom, (3)Veterinary Medicines Directorate, United Kingdom

Zinc oxide has been used as a medicine to prevent diarrhoea in piglets during weaning but concerns regarding potential risk to the environment from the resulting zinc in manures spread on agricultural land have led to restrictions on its use in Europe. Concerns about the scientific robustness of the evaluation that led to the restrictions in Europe, and its relevance to important pig farming regions in the UK, led the Veterinary Medicines Directorate to evaluate the potential risks to the environment from this specific use of zinc for several UK soil scenarios. The evaluation of potential risks to the environment used the Intermediate Dynamic Model for Metals to calculate the loadings of zinc in agricultural soils receiving manures, and the resulting levels of zinc in local surface waters and their sediments over several decades of use. The evaluation of the potential risks due to zinc took account of zinc bioavailability in the soils, surface waters, and sediments. This presentation outlines the approach followed to perform the risk evaluation for the environment.

6.01.T-02 Assessment of the Potential for the Use of Lead Ammunition at Shooting Ranges to Contaminate Groundwater and Drinking Water

Edward Stutt¹, Graham Merrington² and Michael John Whelan³, (1)WCA Environment Limited, Faringdon, United Kingdom, (2)WCA Environment Limited, United Kingdom, (3)University of Leicester, United Kingdom

Extremely high concentrations of lead have been measured in near surface soils at shooting ranges in Europe, for example up to 30-40% Pb has been recorded in the drop zone of clay target shooting ranges. Certain soil conditions enhance the solubilisation and mobilisation of lead through the soil profile, and the toxicity of this metal has led to concerns about the potential contamination of groundwater that may be abstracted as drinking water. This assessment has been undertaken during the development of ECHA's proposed restriction on the use of lead in ammunition and has sought to determine which soil and hydrogeological conditions are likely to present the greatest risk of lead migration from shooting ranges to groundwater and the extent to which these conditions are prevalent across the EU. A review of lead soil chemistry indicated that there will be greatest solubilisation and migration in acidic and organic rich soils with coarse soil texture, low Fe, Mn and ortho P. The hydrogeological assessment found that the connectivity between near surface soil, the vadose zone and underlying groundwaters is dependent on a combination of local factors, such as soil texture, soil chemistry and organic matter content, soil structure (particularly the existence of preferential flow pathways), local geology, topography, climate, and the depth to the saturated zone. It is difficult to estimate the prevalence and extent of groundwater vulnerability to lead contamination at shooting ranges at European, national or even regional levels because many of the contributing factors are local and difficult to predict at wider geographical scales. Local factors will always influence potential risks more than generic considerations, but areas with high intrinsic vulnerability (especially macropores and fracture flow) are likely to occur in all EU member states, although to differing extents. Lead in soil waters in the mg.L⁻¹ range have been measured in near surface soils but concentrations have been observed to rapidly decrease with depth and to date only a few studies have measured elevated lead in groundwater, with these being in near surface groundwaters under acidic soils (in areas that would generally be considered as wetlands).

6.01.T-03 Updating the Chronic Biotic Ligand Model for Nickel in Europe

Christian E. Schlekot¹, Elizabeth Middleton¹, Emily Garman¹, Adam Peters², Graham Merrington³ and Iain A Wilson³, (1)NiPERA Inc, United States, (2)wca, United Kingdom, (3)WCA Environment Limited, United Kingdom

Nickel was identified as a Priority Substance under the Water Framework Directive and an Environmental Quality Standard was set in 2013 that applies throughout Europe. The EQS was set as a "bioavailable nickel" concentration, and the assessment of compliance against it should take account of bioavailability. The EQS was based on a Species Sensitivity Distribution for nickel that is normalised to the local site-specific water chemistry conditions using the Biotic Ligand Model. The ecotoxicity database that is used as the basis for the SSD, and the underlying models that define the bioavailability normalisation within the BLM, is based on information that was available in 2010. Several developments in the scientific basis of the Ni EQS have occurred since 2010, including additional ecotoxicity data that provide increased diversity in represented species, and the applicability of the underlying bioavailability normalisation models to broader ranges of water chemistry conditions. This presentation covers the inclusion of these data into an updated version of the chronic BLM for nickel. The chronic nickel BLM has been revised to update the ecotoxicity dataset and to enable bioavailability normalisation models to be applied over a wider range of water chemistry conditions than was possible previously. The most sensitive region for nickel toxicity was identified as Austria, due to the predominance of alpine stream waters, which have moderately high pH, low DOC concentrations and low or moderate calcium concentrations.

6.01.T-04 An Eu-Wide Assessment of Potential Nickel Risks Under the Water Framework Directive

Iain A Wilson¹, Adam Peters², Graham Merrington¹, Elizabeth Middleton³ and Christian E. Schlekot³, (1)WCA Environment Limited, United Kingdom, (2)wca, United Kingdom, (3)NiPERA Inc, United States

Nickel is a priority substance under the Water Framework Directive (WFD) and has a bioavailable environmental quality standard (EQS_{bioavailable}) of 4 µg L⁻¹. A procedure for deselection of current priority substances has been proposed by the European Commission. A substance that is deselected does not present an EU-wide risk, and is not required to be monitored by all Member

State countries. Unfortunately this procedure undertakes a comparison of the measured dissolved concentrations of nickel to the EQS, without accounting for bioavailability. We have performed a similar assessment, with the exception of using a comprehensive dataset covering as much of the EU-27 as possible. In addition, the data were processed to account for samples with concentrations that were less than the limit of detection. Site average concentrations were calculated in accordance with European Commission procedure and a tiered assessment was performed to assess site and sample exceedances. After data processing, the Spatial, Temporal and Extent of the EQS exceedances (STE) score was calculated, again in accordance with the European Commission procedure for three temporal subsets of the obtained data; all data from 2006 onwards (the European Commission procedure), data from 2013 onwards (the date the current EQS was set) and data from 2018 onwards (an assessment of data available from the last three years). The processed data were also evaluated against the further European Commission deselection criteria, including temporal trends. This platform presentation provides the outcomes of the European Commissions deselection procedure including the calculation of the STE score, when conducted using appropriate datasets and accounting for bioavailability. Implications of the outcomes of this work will be discussed in relation to European-wide nickel risks.

6.01.T-05 Calculating Comparative Toxicity Potentials With Metal-Specific Approaches: Does It Make a Difference?

Charlotte Nys¹, Koen Ooris¹, Kevin Rader² and Kevin Farley³, (1)ARCHE Consulting, Belgium, (2)Mutch Associates, LLC, United States, (3)Manhattan College, United States

Within the life-cycle assessment (LCA) arena, the UNEP-SETAC life-cycle initiative has proposed to compare the impact of elementary flows on freshwater ecotoxicity using characterization factors (CF) derived by the USEtox model. However, several short-comings in the USEtox approach regarding specific metal issues have been identified, such as the lack of consideration of metal bioavailability and metal cycling within the environmental compartment. To overcome these issues, the life-cycle assessment arena has proposed to use the Free Ion Activity Model (FIAM) for incorporating metal bioavailability. However, this proposed approach still represents a simplification of real-life exposure situations as it does not account for all possible processes that influence metal transport in the aquatic environment and metal bioavailability effects to aquatic organisms. More complex approaches to model metal bioavailability and metal partitioning (Biotic Ligand Model [BLM] and Tableau Input Coupled Kinetic Equilibrium Transport-Unit World Model [TICKET-UWM], respectively) are available. The purpose of the current study is to compare the methods currently proposed for the derivation of characterization factors for metals in LCA and to evaluate these against the scientifically accepted metal-specific methodologies using Cu and Ni as case-metals. In that perspective, the CF values were calculated for Cu, and Ni for 7 freshwater Archetypes. More specifically, FF values were calculated based on fate modelling with the TICKET-UWM, the BF was calculated with speciation modelling in WHAM VII and the EF was calculated with the BLM approaches currently integrated in European risk assessment frameworks under REACH for Cu and Ni, as well as using the FIAM approach (using WHAM VII-speciation calculations). The use of the FIAM approach clearly increased variation in the Cu EF between Archetypes compared to the BLM-approach. This can be attributed to the omission of the competition effects of cations at the sites of toxicological action for metals for the FIAM approach. Relatively large differences in Cu FF, EF and to a lesser degree for BF were observed with values for the same Archetypes reported in literature, which can be explained based on the use of a simplified fate model in the USEtox framework, differences in toxicity databases and in speciation modelling assumptions. However, the discrepancies in FF, BF and/or EF are largely negated at the level of CF. Therefore, the range of the CFs calculated in the present study (partly) overlaps with those reported in literature. For Ni, the calculated FF, BF and EF_{FIAM} in the present study were comparable with those reported in literature, while larger differences were observed for EF_{BLM}. Hence, CF_{FIAM} were relatively comparable with those reported in literature, while CF_{BLM} tended to deviate more from reported values. In conclusion, differences in FF, EF and BF were observed when calculated using more complex, but more realistic metal approaches compared with values reported in literature. However, the discrepancies in FF, BF and/or EF are largely negated at the level of CF.

6.01 Advances in the Regulation and Life Cycle Assessment of Metals in the Environment (Virtual Only)

6.01.V-01 A Regulatory Application of a 30-year Soil and Sediment Background Metals Dataset

Frannie Nilsen¹, Paul Goodwin², Matthew Nichols³, Alexis van Venrooy⁴ and James Bateson³, (1)NC DEQ, United States, (2)North Carolina State University, United States, (3)North Carolina Department of Environmental Quality, United States, (4)Rice University, United States

The remediation of Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) or Superfund sites is limited to clean-up to levels no lower than background conditions. Naturally occurring background metals in soil and sediments often complicate this process. In effort to support cleanup decisions and policy development regarding metals in soil the North Carolina Department of Environmental Quality Division of Waste Management (DWM) compiled a statewide set of naturally occurring metals background data from publicly available reports of United States Environmental Protection Agency (EPA) Superfund site investigations. The dataset represents background conditions at 326 Superfund sites in the state of North Carolina, USA. It includes site location data and analytical measurements of 18 metals (Al, As, Ba, Cd, Ca, Cr, Co, Cu, Fe, Pb, Mg, Mn, Na, Ni, K, V, Zn, Hg) in 624 soil and 228 sediment samples representing site evaluations from 1985 to 2015. This 30-year dataset combines metals measurements acquired using the EPA Methods appropriate at the time of their analysis. To combine this diverse dataset, the presence of extreme outliers for all metals, and the need to perform a common analysis on all metals were both used to determine the nonparametric methods were used to describe the data. The data are presented in an interactive dashboard that presents summary statistics and graphical representations of the data. The dashboard includes user options for selecting and viewing the data in various ways so the presented information can be tailored to support specific types of decisions. The data and dashboard serve two main goals: 1) to support cleanup decisions and policy development regarding soil metals, such as

remediating parties' design of site-specific studies to define cleanup goals at contaminated sites, or North Carolina DWM's development of policies for managing off-site transfer of soils; and 2) to support public awareness of the levels of naturally occurring background metals in soil and sediments by providing communities the ability to investigate their own backyard and better understand background environmental conditions and understand anthropogenic contamination in a greater context.

6.01.V-02 Development and Validation of Multiple Linear Regression Models for Predicting Chronic Zinc Toxicity to Freshwater Algae in Australian Natural Waters

Gwilym Price¹, Jennifer Stauber², Aleicia Holland³, Darren Koppel⁴, Eric J. Van Genderen⁵, Adam C Ryan⁵ and Dianne Jolley², (1)University of Technology Sydney, Sydney, NSW, Australia, (2)CSIRO, Australia, (3)La Trobe University, Australia, (4)Australian Institute of Marine Science, Australia, (5)International Zinc Association, United States

Zinc is mined and refined extensively across Australia, so robust water quality guidelines are required to protect Australian freshwater ecosystems. To better manage and protect aquatic ecosystems, an improved understanding of how water chemistry influences zinc toxicity is required. Water chemistry parameters, such as dissolved organic carbon (DOC), pH and hardness are known to influence metal toxicity by modifying metal bioavailability. This study developed multiple linear regression (MLR) models to predict chronic zinc toxicity to a tropical freshwater alga *Chlorella sp.* based on EC10, EC20 and EC50 values from zinc-spiked laboratory waters. Developed models were validated using toxicity data from chronic toxicity tests using six natural waters covering a range of water chemistry parameters and geographies across Australia. Models were developed at the EC10, EC20 and EC50 level, both with and without interaction terms. In general, models performed better during auto-validation when interaction terms were included. At all effect levels, models with interaction terms predicted >80% of the observed data within a factor of 2 and >90% within a factor of 3. The MLRs consistently overpredicted zinc toxicity in all natural waters at all effect levels. Interestingly, the relationship between toxicity and the model parameters were generally consistent, with similar slopes in the data compared to the perfect agreement 1:1 line. This suggests that there may be a consistent factor not captured by pH, hardness, or DOC, causing this overprediction across the waters. Additionally, other MLRs developed using *Raphidocelis subcapitata* also provided poor and inconsistent predictions in the natural waters. The results of this study suggest that more toxicity modifying factors (other than pH, hardness, and DOC) may need to be considered when applying chronic algal bioavailability models to natural Australian waters. Further work is needed to better understand the effect of water chemistry on the mechanisms of zinc toxicity to *Chlorella sp.* which would allow for more appropriately developed algal bioavailability-based models and the subsequent use of these models in water quality guideline derivation for the Australian environment.

6.01.V-03 Regionalized Life Cycle Assessment of Global Sulfidic Copper Tailings: Dynamic, Site-Specific Approach

Lugas Raka Adrianto¹, Stephan Pfister² and Stefanie Hellweg², (1)ETH Zurich, Zurich, Switzerland, (2)ETH Zurich, Switzerland
Copper mining operations around the world have been dumping tailings as wastes on a massive scale. These residues, when poorly managed, carry environmental risks through metals leaching and long-term acid mine drainage. At present, the life cycle assessment of copper tailings is limited by data availability and model limitations. We provide a set of calculation approaches in our analysis to integrate state-of-the-art ore processing and geochemical models, evaluating the environmental impacts of tailings of 75% of the world's copper production (~400 individual sites). The methods comprise production data from market research and mineral processing handbook to construct site-specific life cycle inventories for tailings effluent. The leaching model involving geochemistry is employed to estimate releases of heavy metals from tailings at different time steps. Together with the ore composition and local hydrology, the change in pH value controls the leachability of tailings over time. Our results suggest that copper tailings from the large (i.e., porphyry) and medium-size copper deposits (i.e., volcanogenic massive sulfide and sediment-hosted) contribute to more than three-quarters of the total global freshwater ecotoxicity impacts of copper tailings. The former copper deposits are mined in the Americas (Chile, Peru, USA) and Asia (Indonesia, Papua New Guinea), while the latter are located in DR Congo, Zambia, Russia, and Poland. The hydrological condition strongly enhances metal leaching, especially over long-term horizons. The generated tailings inventories vary locally, even within single countries, indicating the importance of site-specific models and bottom-up data aggregation for country or global averages. Compared to averaged data in the previous database, our inventories show generally smaller impacts, but the estimated site-specific impacts can be higher for certain mine sites and countries. Our study provides regionalized inventories of copper tailings through the inclusion of a dynamic model, thus improving emission data precision for copper in life cycle assessments.

6.01.V-04 Towards Bioavailability-Based Guideline Values for Zinc in Australian and New Zealand Natural Waters

Jennifer Stauber¹, Gwilym Price², Anthony Evans³, Jennifer Gadd⁴, Aleicia Holland³, Anthea Albert⁵, Graeme Batley¹, Monique Binet¹, Lisa Golding¹, Chris Hickey⁶, Andrew J Harford⁷, Dianne Jolley¹, Darren Koppel⁸, Kitty McKnight¹, Mashanta Mosin⁴, Lucas Morais³, Adam C Ryan⁹, Karen Thompson¹⁰, Eric J. Van Genderen⁹, Rick van Dam¹¹ and Michael Warne¹², (1)CSIRO, Australia, (2)University of Technology Sydney, Sydney, NSW, Australia, (3)La Trobe University, Australia, (4)NIWA, New Zealand, (5)NIWA, Australia, (6)rmascience, New Zealand, (7)Dept. of Agriculture, Water and the Environment, Eaton, NT, Australia, (8)Australian Institute of Marine Science, Australia, (9)International Zinc Association, United States, (10)National Institute of Water and Atmospheric Research, New Zealand, (11)WQadvice, Australia, (12)University of Queensland, Australia
Bioavailability models developed in the northern hemisphere cannot be adopted in Australia and New Zealand without validation due to (i) the high level of endemism found in local freshwaters, and (ii) distinct water chemistry characteristics, such as higher magnesium and lower dissolved organic carbon, which can influence metal bioavailability and toxicity. Toxicity modifying factors (TMFs) such as DOC and pH are only beginning to be incorporated into metal freshwater guidelines in Australia and New Zealand. This study investigated the applicability of existing chronic zinc bioavailability models to predict zinc toxicity in 12 uncontaminated natural waters (spiked with zinc) with varying pH, hardness and natural DOC. Model predicted toxicity was

compared to observed toxicity in chronic tests with sensitive local isolates of an alga *Chlorella* sp 12., the cladocerans *Ceriodaphnia cf dubia* and *Daphnia thomsoni*, as well as the green alga *Raphidocelis subcapitata*. A new chronic multiple linear regression model (MLR) was also developed for *Chlorella* sp. by varying pH, DOC and hardness in a laboratory water. Total and dissolved metals were determined in all toxicity tests, while ultrafiltered and DGT-labile zinc were also determined in all *Chlorella* toxicity tests. Existing Northern Hemisphere and NZ MLRs for *D. magna* based on EC50 values gave reasonable predictions of toxicity of zinc to *D. thomsoni* for a range of NZ waters. These EC50 MLR models could generally predict toxicity within a factor of two of the measured concentrations when the sensitivity coefficient was updated for *D. thomsoni*, which is more sensitive than the model species *D. magna*. Predictions were less accurate at the EC10 and EC20 level. TMFs had little influence on zinc toxicity to the Australian isolate of *C. dubia*, with a null model predicting EC20 values within a factor of two. The new MLR for *Chlorella* sp. consistently overpredicted zinc toxicity in the natural waters. Similarly, existing MLRs for *R. subcapitata* were also poor predictors of zinc toxicity to *Chlorella* sp., but were better for *R. subcapitata* in NZ waters. Further work is required to understand the effect of TMFs on mechanisms of zinc toxicity to microalgae before these bioavailability models can confidently be applied across algal species and to guideline value derivation in local waters.

6.01 Advances in the Regulation and Life Cycle Assessment of Metals in the Environment (Poster)

6.01.P-We243 Bio-Met a Simple Tool for Ni EQS Compliance Assessment

Adam Peters¹, Graham Merrington², Iain A Wilson², Elizabeth Middleton³, Christian E. Schlekert³ and Emily Garman³, (1)wca, United Kingdom, (2)WCA Environment Limited, United Kingdom, (3)NiPERA Inc, United States

Nickel is a Priority Substance under the Water Framework Directive and the EQS is therefore applied throughout the whole of Europe. Although the EQS was set in 2013 there are still some limitations in the way that Member States implement it. Whilst this issue is likely to be reduced somewhat by the recent publication of guidance on the implementation of bioavailability for metals it may also be limited to some extent by the usability of the simplified tools that are available to practitioners to apply bioavailability corrections. In many cases nickel is the only substance that Member States need to apply a bioavailability correction to that is based on a Biotic Ligand Model. The existing user-friendly tool bio-met has been modified to simplify its use for nickel bioavailability calculations and improve its usability whilst retaining the high level of accuracy provided by the model. This presentation outlines what changes have been made and how they help users in the regulatory community to properly perform the assessment of bioavailability for nickel in freshwaters.

6.01.P-We244 Nickel EQS in Europe: Implementation or Update

Adam Peters¹, Graham Merrington², Christian E. Schlekert³, Elizabeth Middleton³ and Emily Garman³, (1)wca, United Kingdom, (2)WCA Environment Limited, United Kingdom, (3)NiPERA Inc, United States

Nickel is a Priority Substance under the Water Framework Directive and the Environmental Quality Standard (EQS) is therefore applied throughout the whole of Europe. The EQS is set as a bioavailable nickel concentration, and therefore requires bioavailability to be taken into account to properly assess compliance against it. Technical guidance on the implementation of bioavailability-based standards for metals has recently been published by the European Commission. Implementation of the EQS for nickel has been very variable between different member states, and it is likely that this reflects the limited guidance that was available until recently. The EQS for nickel has been identified by the European Commission as potentially requiring an update, despite the limitations surrounding the proper implementation of the existing EQS. An update of the science that is used for the assessment of nickel bioavailability in European freshwaters suggests that the proportion of monitoring sites that would be likely to fail an updated EQS is very similar to the proportion of sites that would fail the existing EQS. This suggests that focusing on improving the implementation of the existing EQS for nickel may be a more appropriate use of the limited time and resources available, especially given the very recent publication of guidance on the implementation of bioavailability based EQS for metals.

6.01 Advances in the Regulation and Life Cycle Assessment of Metals in the Environment (Poster Corner)

6.01.PC-We07 Review of Metal Toxicity Testing With *Lymnaea stagnalis*

Adam Peters¹, Dean Leverett², Kate Roylance³, Graham Merrington⁴, Charlotte Nys⁵, Mohammed J. Chowdhury⁶, Adam C Ryan⁷, Stijn Baken⁸, William Stubblefield⁹, Christian E. Schlekert¹⁰, Elizabeth Middleton¹⁰, Emily Garman¹⁰, David Boyle¹¹, Christopher Cooper¹², Carrie Claytor¹³, Marie-Christine Simard¹⁴, Amiel Boullemant¹⁵ and Eric J. Van Genderen⁷, (1)wca, United Kingdom, (2)WCA-Environment Ltd, Faringdon, United Kingdom, (3)wca consulting, United Kingdom, (4)WCA Environment Limited, United Kingdom, (5)ARCHE Consulting, Belgium, (6)International Lead Association, United States, (7)International Zinc Association, United States, (8)European Copper Institute, Brussels, Belgium, (9)Oregon State University, United States, (10)NiPERA Inc, United States, (11)Cobalt Institute, Afghanistan, (12)International Zinc Association, Belgium, (13)Copper Development Association Inc., United States, (14)Rio Tinto, Afghanistan, (15)Rio Tinto Aluminium Pechiney, France

Although there is a standard OECD test guideline for chronic toxicity testing with adult *Lymnaea stagnalis* based on reproduction, most academic studies on this species have used juvenile growth tests. There is considerable variation in the methods and endpoints used in the studies, and very few follow the standard OECD reproduction test guideline. Several different food sources (e.g., lettuce, sweet potato, carrot, fish flakes) have been used for both maintaining the cultures and for the tests themselves that have been reviewed. Food source can have a considerable influence on the outcome of the tests, and this appears to be greatest for low effect levels on growth endpoints for juveniles. The nutritional quality of the food source used can have a considerable influence on the sensitivity of the test subjects to metal toxicity. There is considerable variation in both the methods and endpoints used for juvenile growth tests on *L. stagnalis*, and this severely limits any comparisons that can be made between the results of

different studies. For example, a significant number of tests have been conducted in waters with hardness levels considerably lower than those recommended by the OECD test guideline (140-250 mg/L as CaCO₃). Overall, relatively high levels of variability between replicates are not uncommon, and poor control performance including high mortality in controls has been observed in several cases. Control performance criteria based on the endpoints measured (i.e. growth) should be established for the juvenile growth test to enable the performance of different tests to be compared. The OECD test guideline should be adapted to include a standardised method for a juvenile growth test. A ring-test of any revised methods should be conducted to assess the variability of results between different testing laboratories.

6.01.PC-We09 Effects of Water Hardness on Zinc Toxicity in *Daphnia magna*

Berkay Paylar¹, Solomon Asnake², Viktor Sjöberg², Daniel Ragnvaldsson³, Jana Jass⁴ and Per-Erik Olsson⁴, (1)Biology, Örebro University, Sweden, (2)Örebro University, Sweden, (3)Envix nord AB, Sweden, (4)School of Science and Technology, Örebro University, Örebro, Sweden

Aquatic organisms are often exposed to a wide array of different heavy metals. Proper risk assessments are required to ensure safe environments. At present, most environmental risk assessments derive acceptable exposure levels based on measured levels of chemical pollutants with the addition of safety factors. Bioavailability models have been developed to predict metal toxicity as a result of variation in the local physicochemical conditions. However, due to the complexity of biological systems, the theoretically calculated set limit values represent non-optimal concentrations for essential trace metals such as zinc, due to having both a lower and upper limit for tolerance. While all living organisms require a minimum level of zinc for proper cell function, high concentrations can result in toxic effects. There is a growing need to connect water characteristics and bioavailability with biological endpoints such as mortality, reproduction, and gene expression. In this study, we analyzed the effects of different water hardness on zinc toxicity using the cladoceran *Daphnia magna*, a freshwater species widely used in ecological risk assessments. Exposure for 96 hours to increasing zinc concentrations in different water hardness significantly altered survival rates. Optimal zinc concentration for survival was observed to be inversely proportional for soft and medium water. However, increased hardness combined with low zinc concentrations led to higher mortality caused by zinc deficiency. Mortality rates were observed to be correlated with the ratio of the sum of the calcium and magnesium over zinc concentrations. Therefore, a competition-based model to describe the effects of hardness on zinc toxicity is proposed. The qPCR analysis was conducted to study different biological pathways involved in the metal response, stress response, oxidative response, and reproduction. Changing hardness resulted in distinct gene expression profiles at the same zinc concentrations. 21 days exposure was conducted to analyze reproduction success and development. Reproduction and development were altered by hardness and zinc. Our data indicate that hardness plays an important role in zinc toxicity by effectively changing the bioavailability at both physiological endpoints and gene expression. Thus, water characteristics and toxicogenomic analysis should be considered to improve environmental risk assessment.

6.01.PC-We10 Updating the Chronic BLM for Nickel in Europe

Adam Peters¹, Graham Merrington², Iain A Wilson², Elizabeth Middleton³, Christian E. Schlekat³ and Emily Garman³, (1)wca, United Kingdom, (2)WCA Environment Limited, United Kingdom, (3)NiPERA Inc, United States

Nickel is a Priority Substance under the Water Framework Directive and the Environmental Quality Standard (EQS) is therefore applied throughout the whole of Europe. The dataset upon which the EQS was based included research up to, and including, 2010. Since that time there have been developments in terms of both the ecotoxicity data that is available, and the bioavailability normalisation models that are used to calculate the site-specific nickel sensitivity of the ecosystem. The additional ecotoxicity data includes both additional data for species that were already represented in the database as well as information on additional species that are not represented in the database that is used for the existing EQS. The updated BLM includes 47 different species, 15 of which were not previously represented in the ecotoxicity database and can be applied over a broader range of water chemistry conditions than the model that is used for the existing Ni EQS. The predictions of the species-specific nickel bioavailability models have been validated laboratory tests on other species in natural waters that cover a wide range of the surface water conditions encountered in Europe and Australia, and the whole community predictions of the nickel BLM are protective of several mesocosm studies. An indicative compliance assessment shows that levels of compliance based on the updated Ni BLM would be very similar to those based on the existing EQS. The most sensitive region for nickel toxicity was identified as Austria, due to the predominance of alpine stream waters, which have moderately high pH, low DOC concentrations and low or moderate calcium concentrations.

6.01.PC-We11 Evaluation of the Priority Substance Deselection Assessment for Nickel

Adam Peters¹, Iain A Wilson², Graham Merrington², Christian E. Schlekat³, Elizabeth Middleton³ and Emily Garman³, (1)wca, United Kingdom, (2)WCA Environment Limited, United Kingdom, (3)NiPERA Inc, United States

Nickel is a Priority Substance under the Water Framework Directive, and the Environmental Quality Standard (EQS) is therefore applied throughout the whole of Europe. An approach for identifying substances that no longer pose a sufficiently widespread risk to surface waters has been developed by the European Commission and nickel has been included in their evaluation. There are several limitations to the analysis conducted by the European Commission, including assessing whether or not nickel exposures complied with the existing EQS several years before the EQS was actually derived or set, and failing to take account of bioavailability even though the EQS for nickel is a set as a “bioavailable nickel” concentration. This presentation summarises how the assessment of the appropriateness of deselecting nickel as a priority substance should be performed so that it is consistent with the existing EQS for nickel under the WFD. The presentation also draws conclusions based on a comprehensive evaluation that includes a proper consideration of nickel bioavailability in accordance with the nickel EQS.

6.02 Developments for regulatory risk assessment for birds and mammals under pesticide legislation

6.02.T-01 Revision of EFSA 'Risk Assessment for Birds and Mammals' Guidance Document

*Rachel Sharp*¹, *Maria Arena*², *Gabriella Fait*², *Alberto Linguadoca*², *Theo Brock*³, *Emily McVey*⁴, *Pierre-François Chaton*³, *Philippe Berny*⁵, *Alf Aagaard*⁶ and *Ana Lopez-Antia*⁷, (1)EFSA - European Food Safety Authority, Parma, Italy, (2)EFSA - European Food Safety Authority, Italy, (3)EFSA Working Group on the revision of the EFSA bird and mammal guidance document, Italy, (4)Ctgb, Italy, (5)VETAGRO-SUP, Italy, (6)Pesticides and Biocide Division, Italy, (7)EFSA Working Group on the revision of the EFSA bird and mammal guidance document, Belgium

In order to gain EU Level approval of a pesticide active substance or plant protection product under Regulation (EC) 1107/2009, it is necessary to demonstrate that there are no unacceptable risks to bird and wild mammals. In 2009, the European Food Safety Authority (EFSA) issued a guidance document ('Risk Assessment for Birds and Mammals', EFSA (2009)). EFSA was requested to update the guidance document clarifying certain aspects and accounting for the latest regulatory and scientific developments. A follow-up project has also been initiated to design an on-line calculator tool to implement the risk assessment methodology. In September of 2020 EFSA published a draft of the updated guidance and sought feedback from stakeholders and the public. This presentation will provide an overview of the tiered risk assessment approach for birds and mammals, an analysis of the comments received as part of the public consultation and discuss areas of the guidance which will be improved. The feedback and ideas for the calculator tool, which is being developed to facilitate the implementation of the revised risk assessment methodology, will be discussed. The current timelines for the revision will be given.

6.02.T-02 Revision of the EFSA Guidance Document on Birds and Mammals: Industry View

*Manousos Foudoulakis*¹, *Markus Ebeling*², *Steven Kragten*³, *Alex Blakey*⁴, *Joerg Hahne*⁵, *Arnd Weyers*⁵, *Thomas Bean*⁶, *Joachim Nopper*⁷, *Dennis Sprenger*⁸, *Sonja Haaf*⁹, *Paula Garcia*¹⁰ and *Judith Neuwohner*¹¹, (1)RAS, Corteva Agriscience, Peristeri, Greece, (2)Environmental Safety, Bayer Crop Science, Germany, (3)Syngenta Agro GmbH, Germany, (4)Syngenta Ltd., United Kingdom, (5)Bayer Crop Science, Germany, (6)FMC Agricultural Solutions, United States, (7)BASF SE, Germany, (8)Ecotoxicology, BASF SE, Germany, (9)ADAMA Deutschland GmbH, Germany, (10)Corteva Agriscience, Abingdon, United Kingdom, (11)Nufarm Europe GmbH, Afghanistan

The EFSA Guidance Document on the Risk Assessment for Birds and Mammals [EFSA, 2009] (EFSA GD) has been used for more than 12 years in the EU for the evaluation of Active Substances and Plant Protection Products. Recently, EFSA has launched the public consultation on the draft updated guidance document on Risk Assessment for Birds and Mammals. Industry will contribute by sharing the experience from risk assessors who have been using the EFSA GD on a daily basis, highlighting those areas where the update should put more emphasis on or requires further guidance. Contributing with specific expertise as for this occasion, industry have mobilized not only the Crop Life Europe Expert Group on Terrestrial Vertebrates but also the CLE Expert Groups on Statistics, Effect Modelling, Residue Definition, Toxicology and E fate. The risk assessment scheme of the current EFSA GD has proven generally adequate to evaluate the acute risks to birds and mammals while major issues have occurred with the refined risk assessments, particularly for the reproductive risk. Numerous changes have been proposed in the new draft EFSA GD while its impact cannot be evaluated as protection goals are still pending and a calculator tool has not been provided. In the opinion of risk assessors from industry, the main refinement parameters that require more discussion before their implementation in routine risk assessment in the future are the following: the Benchmark Dose approach and the selection of the ecotox relevant reproductive endpoint, the use of the f_{TWA} and agreed Tier 1 risk assessment, the selection of focal species of birds and mammals and further clarity or discussions on the higher tier options and modelling. These parameters will be described in more detail in the platform presentation. Targeted actions will contribute to minimize contradictory interpretations by risk assessors, increase the acceptance of, provide clarity and a path forward to a successful guidance.

6.02.T-03 The New Draft Guidance for Birds and Mammals From the Perspective of Practitioners

*Anja Russ*¹, *Benedikt Gießing*², *Olaf Fuelling*¹, *Andrea Rossbach*¹ and *Christian Wolf*², (1)Tier3 Solutions GmbH, Leverkusen, Germany, (2)Tier3 Solutions GmbH, Germany

The risk to wild birds and mammals from applications of Plant Protection Products (PPPs) is assessed in a tiered approach which is regulated in the EFSA Guidance Document (GD). Several refinement options are available. The highest tier and most realistic refinement option is to conduct generic field studies and field effect studies. However, the GD gives hardly any guidance for this kind of studies besides that they have to be adjusted to the focal species, the crop, the season, and the concerns raised by lower tier results. Despite the valuable contribution of field studies to the risk assessment of PPPs, results and their interpretation have been repeatedly questioned as well as their general value for the risk assessment procedure. The recently published draft of the updated EFSA GD for the risk assessment of birds and mammals aims to make a considerable improvement to strengthen the higher tier studies. The main challenge of higher tier studies remains to persuasively demonstrate their suitability and representability. Therefore, the draft GD requests additional information for higher tier studies, such as landscape characteristics, recent and previous-year use of PPPs and agricultural activities at the study sites and neighbouring fields of similar crop, and the food availability at the studied crop and off-crop areas. Here, we aim to pick up some points of the new GD on higher tier field studies and discuss them from the practitioner's point of view. Hence, if conducted appropriately, generic field studies and field effect studies offer the most realistic approach to study the risk from PPPs.

6.02.T-04 Revision of EFSA Birds and Mammal Guidance: Some Academic Reflections

Nico van den Brink, *Toxicology, Wageningen University, Wageningen, Netherlands*

Recently, the EFSA Birds and Mammal guidance has been revisited, not a complete overhaul, but an update. I'd like to

acknowledge the constraints of regulatory testing, especially with vertebrates. In some respects, the current guidance can be a balancing act, but given this, it is of high value. Here, I will highlight some scientific aspects that may need attention. The use of surrogate Protection Goals, especially with respect to the aspect of ‘no visible mortality’ may apply differently to species, according to their size and visibility, which should not be the base of their protection. Indirect effects on e.g. prey availability are currently not addressed, demanding for a clear harmonisation with other guidance’s on potential prey invertebrates or plants. Within the tiered approach of exposure assessment, impacts of some assumptions underlying the definitions of PT and PD on the uncertainty in the RA are not completely clear. These need further attention, as well as those underlying more complex landscape level monitoring. This is of importance with respect to the general approach of less conservative criteria at higher tiers where realism is deemed to be higher and uncertainty lower. The current guidance addresses oral exposures, it is recommendable to include dermal exposures of e.g. egg, chicks and juvenile wildlife that run the risk being over sprayed when in-crop. Finally, future revisions of both the guidance and the regulatory framework should include the operationalisation of new *in vitro-in vivo* tools and assays to minimise the use of test animals.

6.02 Developments for regulatory risk assessment for birds and mammals under pesticide legislation (Virtual Only)

6.02.V-01 Calibrating the EFSA Tier 1 Protection Level for Voles in the Long-Term Risk Assessment

Markus Ebeling¹, Thomas Bean², Manousos Foudoulakis³, Joerg Hahne⁴, Joachim Nopper⁵ and Magnus Wang⁶, (1)Environmental Safety, Bayer Crop Science, Germany, (2)FMC Agricultural Solutions, United States, (3)RAS, Corteva Agriscience, Peristeri, Greece, (4)Bayer Crop Science, Germany, (5)BASF SE, Germany, (6)WSC Scientific GmbH, Germany

According to the draft update of the EFSA bird and mammal GD shared in autumn 2021 for public commenting, calibration of the protection level from the current and future Tier 1 scenarios with field data is recognized as a key research need. Under the current (2009) EFSA GD, common vole scenarios systematically fail the TER_{LT} of 5, but it has been questioned for a long time if this very resilient species requires the same level of protection as other mammalian species. In recognition of that high resilience, TER_{LT} thresholds for voles have already been lowered in a few EU countries. In years of mass occurrence, common voles become an agricultural pest and are the target of direct vole control methods such as rodenticide applications. However, most of the EU countries (and EFSA) still expect the standard TER_{LT} of 5 to be demonstrated in order to accept low risk. The TER_{LT} for voles can be refined to some extent by conducting plant residue decline studies, typically demonstrating foliage DT50 below the 10d default value. However, often there is the need to additionally employ population models (not yet well accepted) and/or field effect studies (technically challenging). Regulatory interpretation of such a field effect study is inevitably complex and difficult to predict. Thus, conducting and evaluating field studies to demonstrate safe use for each case on its own is lengthy and resource-demanding. Therefore, a project has been initiated to evaluate available field effect studies on common voles in order to determine whether the vole scenario requires the standard TER_{LT}, or whether a lower TER_{LT} could still provide a sufficient level of protection. This activity can be related to similar activities by EFSA and member states, e.g., the calibration of the bird TER in EFSA (2008) with field effect studies, the request from the Joint Working Group of Member State Risk Managers (2009) to “re-consider the need for the vole scenario, given the resilience of their populations”, or the concept of the “reference tier” in the Aquatic GD (2013). Over a decade has passed since the implementation of the EFSA Bird and Mammal GD 2009, subsequently a number of vole field effect studies has been conducted which would now allow such calibration exercise. This poster will present an overview on the status of the calibration project for the vole scenario, the analyses, the opportunities and difficulties encountered and the envisaged path forward.

6.02.V-02 Dissipation of Plant Protection Products on Freshly Drilled Seeds

Joerg Hahne¹, Manousos Foudoulakis², Steven Kragten³, Dennis Sprenger⁴, Kai Ristau⁵ and Magnus Wang⁶, (1)Bayer Crop Science, Germany, (2)RAS, Corteva Agriscience, Peristeri, Greece, (3)Syngenta Agro GmbH, Germany, (4)Ecotoxicology, BASF SE, Germany, (5)BASF SE, Germany, (6)WSC Scientific GmbH, Germany

For seed treatments, the current long-term Tier 1 risk assessment for birds and mammals applies an Ftwa value of 1, assuming no dissipation of the active substance on the treated seeds. Partially due to this assumption, for most active substances applied as seed treatment the long-term Tier 1 risk assessment does not demonstrate an acceptable risk and further higher tier refinements are required. One possible refinement is to calculate a Ftwa value using active substance specific DT50 data based on seed residue trials, demonstrating an actual dissipation of the active substance on the treated seeds. This poster will present results from an evaluation of dissipation data from several industry-owned residue dissipation trials on treated seeds. Based on an appropriate kinetic evaluation a default Ftwa for the use in Tier 1 seed treatment risk assessments will be proposed.

6.02.V-03 Field Data Support Combining Refinements on Diet Composition (PD) and Proportion of Diet (PT) Obtained From Fields Newly Drilled With Treated Seeds: Results From an In-Field Enclosure Study With Wood Mice

Susanne Hein¹, Joachim Nopper¹, Olaf Fuelling², Dennis Sprenger³ and Juan Pascual¹, (1)BASF SE, Germany, (2)Tier3 Solutions GmbH, Leverkusen, Germany, (3)Ecotoxicology, BASF SE, Germany

The EFSA Guidance Document for Risk Assessment to Birds and Mammals requires to calculate the chronic risk for birds and mammals exposed to seeds treated with plant protection products. Recently, a draft of an update of this guidance document was published. The updated document states without any scientific justification that a combined refinement of the diet composition obtained from the treated area (PD) and proportion of diet obtained from a treated area (PT) is not acceptable. By using the example of wood mice foraging in newly drilled cereal fields, it is shown that combining both PD and PT is valid and both factors should be regarded as independent refinements. When the recommendation in the updated GD is followed, wood mice are assumed to enter newly drilled fields and exclusively feed on contaminated seeds before emergence of the crop. However, wood

mice are known to be omnivorous, feeding on a mix of dietary items if present. To collect empirical evidence on in-field exposure, a field study was conducted. It was determined which food items are present in a newly drilled cereal field and which of these are consumed by wood mice. A 1 ha in-field enclosure was set up on a conventionally prepared newly drilled wheat field in central Germany. Wood mice were captured in the surrounding landscape and released into the enclosure directly after drilling. Seed density was artificially increased to mirror worst-case exposure conditions. Available dietary items and their abundance were determined. After two nights of foraging, the individual wood mice were re-captured, and their stomach contents examined to determine diet composition. Different dietary items were present inside the newly drilled cereal field. Also, as expected from an omnivorous species, wood mice fed on a mix of dietary items when confined to the in-field enclosure. In conclusion, a combined refinement of the diet compositions (PD) as well as the proportion of diet (PT) obtained in a treated area is justified since both parameters describe different behaviors of wood mice. Our findings thus contradict the recommendation laid out in the draft of the updated guidance document.

6.02.V-04 Laying Hen Studies and Time-To-Effect in Reproductive Risk Assessments for Birds

Markus Ebeling¹, Andre Gergs² and David Heckmann², (1)Environmental Safety, Bayer Crop Science, Germany, (2)Bayer Crop Science, Germany

For pesticides in the EU, the reproductive risk assessment for birds is usually based on 21-d TWA concentrations in feed items (EFSA GD 2009), at Tier 1 estimated with a default DT50 of 10 days. The draft revision of this guidance (2021) contains the view that no TWA be used for “effects on chick development” unless “significant evidence is provided to indicate that these effects are definitively linked to a long-term exposure”. There is no reasoning provided for this exceptionally strong wording, setting high hurdles for evidence in a situation where extra investigations with vertebrates are discouraged. There is also no reasoning why the standard assumption for effects on chick development would be “due to short-term exposure”, but it may be assumed that the concern is based on the short time frame of egg development before it is laid. The regulatory avian reproduction study cannot inform on the time course of exposure and effect because the birds in this study are already under exposure for 10 weeks before the first egg is developed. So the question is where this “significant evidence” may be found or generated. A possible starting point may be to ask how an observed effect on chick development (like impaired embryo growth in the egg) is actually induced. Recent method developments with egg injection of toxicants show that in-ovo exposure of embryos can generate such effects on chick development. Thus, the time course of residue transfer from the exposed hen into the egg may present the evidence for assessing the suitability of TWA concentrations. We present a case study for a fungicide inducing effects on chick weight in Bobwhite quails. Laying hen studies show that the residue in the eggs consists mainly of its metabolite. We conducted a study where the metabolite was injected into fertilised eggs, and assessed the growth of the embryos in the treated eggs one day prior to hatch. Results confirmed that in-ovo exposure to the metabolite reflects the effects on chick development seen in the reproduction study with the parent. The time course of residue concentrations in the laying hen egg residue study showed that an exposure of about 3 weeks is needed to reach plateau concentrations, suggesting that the 21-d TWA window may be a realistic setting for effects on chick development. This case study suggest that laying hen studies should be examined for possible evidence on the length of TWA-windows for effects on chick development in avian reproduction studies.

6.02 Developments for regulatory risk assessment for birds and mammals under pesticide legislation (Poster)

6.02.P-We245 Weed Seed Availability on Crop Fields - How to Make an Unknown Visible

Joerg Staffel¹, Oliver Körner², Sonja Haaf², Katrin Gräf¹, Nadja Schnetzer¹ and Tina Grimm³, (1)Rifcon GmbH, Germany, (2)ADAMA Deutschland GmbH, Germany, (3)RIFCON GmbH, Hirschberg, Germany

Food availability is a key factor for the attractiveness of bare soil fields as potential foraging habitat for birds and mammals. In accordance with the EFSA 2009 Guidance Document on pesticide risk assessment for birds and mammals and the 2021 draft and revised version the availability of weed seeds as wildlife food source on fields over-sprayed with pesticides has to be considered as exposure route. The study aimed to quantitatively identify the reduction of available weed seeds on the soil surface due to agricultural practice: harrowing and sowing in sugar beet fields. For this purpose, four types of weed seed surrogates (*Silybum marianum*, *Phacelia tanacetifolia*, *Trifolium repens*, *Sorghum bicolor*), dyed with fluorescent orange have been distributed on bare soil fields in Germany typically used for sugar beet cropping. Within study fields, four comparable study plots were established. The harrowing process, and the drilling of sugar beet seeds were conducted by local farmers shortly after the distribution of the weed seed surrogates. A black light box was used to determine the number of weed seeds visible after distribution on soil surface. The same procedure was conducted after harrowing and drilling of the sugar beet seeds to determine the impact of these agricultural processes on the number of weed seeds on soil surface before agricultural processes start in the spring drilling period. Results will be presented and discussed regarding the importance of this exposure route on bare soil fields after drilling and their potential use in the context of dietary risk assessment for granivorous and omnivorous birds and mammals.

6.02.P-We246 Deriving Ecorelevant Endpoints for Wild Mammals Under the Draft New Bird and Mammal Guidance (EFSA 2021)

Amy C. Brooks¹ and Sarah Bull², (1)Cambridge Environmental Assessments, United Kingdom, (2)TARA consulting, United Kingdom

Under the EU regulation for authorising plant protection products (Regulation (EC) 1107/2009), the potential risks to wild mammals must be assessed. The current default approach for wild mammal risk assessments is to use the worst-case no observed adverse effect level (NOAEL) that was concluded from the toxicology package for the human health risk assessment. However, there are many parameters that are measured in toxicology studies that are relevant for individual humans but not for wild

mammal populations. The current bird and mammal guidance (EFSA 2009) theoretically allows the derivation of an ‘ecologically relevant’ wild mammal toxicity endpoint that only takes into account those effects relevant for wild mammal populations. It was later recommended by EFSA in 2015 that the assessment of ecological relevance should be made at the active substance level. In September 2021, EFSA released the draft new bird and mammal guidance, which includes recommendations for the derivation of ecorelevant endpoints for wild mammals. The aim of this presentation is to review the proposals under the draft new guidance (EFSA 2021) for deriving ecorelevant endpoints for wild mammals, including issues such as which studies to use, species sensitivity, types of effect, and magnitude of effect.

6.02.P-We247 Experimental Design and Statistical Analysis of Avian Reproductive Studies

John Green¹, Manousos Foudoulakis², Timothy Fredricks³, Thomas Bean⁴, Jonathan Maul⁵, Stephanie Plautz⁶, Pablo Valverde⁷, Adam Schapaugh³, Xiaoyi Sopko⁸ and Zhenglei Gao⁹, (1)JohnWGreen-ecostats.com, United States, (2)RAS, Corteva Agriscience, Peristeri, Greece, (3)Bayer Crop Science, United States, (4)FMC Agricultural Solutions, United States, (5)Syngenta Crop Protection Inc., United States, (6)BASF, United States, (7)Dow AgroSciences LLC, United States, (8)Corteva Agriscience™ The Agriculture Division of DowDuPont™, United States, (9)Bayer Crop Science, Germany

The draft update of the EFSA bird and mammal (B&M) GD shared in autumn 2021 for public commenting recommended the BMDL10 as the default relevant reproductive endpoint for both B&M. In addition, Historical Control Data (HCD) is currently not recommended for risk or hazard assessment without further guidance from toxicology experts. The Terrestrial Vertebrates ad hoc Team (TVahT) of the Crop Life Europe (CLE) Association discusses further the use of the BMD and has developed a statistical protocol for avian reproduction studies. This protocol includes guidelines for the use HCD in risk assessment and detailed statistical tools for estimating BMD10 with confidence bounds and determining a NOAEL when the data do not support BMD methodology, as well as guidance on which of these two approaches is justified. The judicious use of HCD improves risk assessment both by revealing treatment effects that are notably inside or outside the historical control range, and by identifying unusual concurrent controls that may obscure or exaggerate treatment effects. We recommend model averaging to incorporate model uncertainty more completely in risk and hazard assessment. In addition, improved model fit assessment reveals the effect of unusual observations and assures that model averaging is based on stable models not unduly influenced by outliers or poor fits. When BMD10 estimates are not supported by the data, we present methods to determine NOAELs that improve risk assessment that are also backed by case studies and computer simulations. Among the statistical tools are recommendations on the use of generalized linear and non-linear mixed models (GLMM and GNLMM) with extensive computer simulations and case studies that support these recommendations and contrast them to older methods. These methods are more consistent with the actual data collected than methods that require data transformations or force the data to fit a normal distribution. GLMM and GNLMM methods provide a consistent framework for the variety of response types encountered in avian reproduction studies. Also addressed is the experimental design for this type of study. It is shown to be possible to maintain the same total number of birds but allocate them differently to treatment groups and pens so as to increase the likelihood of quality BMD10 estimation without sacrificing the power of NOAEL determinations when that approach is needed.

6.02.P-We248 Focus Matters - Bird Focal Species for HIGHER Tier Risk Assessment

Arnd Weyers¹, Dennis Sprenger² and Steven Kragten³, (1)Bayer Crop Science, Germany, (2)Ecotoxicology, BASF SE, Germany, (3)Syngenta Agro GmbH, Germany

Focal species (FS) are intended to be protective for other species based on their exposure (e.g. food intake rate, diet composition, etc.) and are therefore used for higher tier field studies to refine other factors of the risk assessment (e.g. PT and PD). In the updated draft Birds & Mammals Guidance Document from 2021, FS are defined as “a representative subset of real species that actually occur in the crop when the plant protection product is being used”. FS are usually selected based on their ecological relevance and their likely exposure (and thus risk) to the potential stressor under field conditions. Focal species for higher tier risk assessment are usually determined in field studies in which bird surveys are conducted in the relevant crop and at the relevant BBCH stage for the risk assessment. According to the currently valid EFSA Guidance Document for Birds and Mammals Risk Assessment (2009), species observed with a frequency of occurrence (FO, ie. the percentage of study fields in which the species was observed) of more than 20% would be of high priority especially if they also have high dominance (ie. the species makes up a relatively large proportion of the overall avian population present in the crop). Other factors to be considered in the focal species selection are feeding strata, food intake rate, body weight and diet composition. The draft guidance mentions that for FS selection the frequency of occurrence is not as important as feeding guild, body weight and diet composition and species with a low frequency of occurrence (< 20%) should not be automatically eliminated from focal species selection. Instead, a species with high potential dietary exposure which less frequently observed, may be considered more appropriate for the risk assessment. It may also be more protective and better cover similar species, than other species with higher occurrence. Clear guidance on how this process should look like is missing. Consequently, there is a high risk that future FS selection will lack a harmonized approach and moreover might result in selection of less exposed species for the higher tier risk assessment. We propose a harmonized method for focal species selection. For this purpose, some existing industry owned focal species studies will be selected and the FS will be re-assessed following the recommendations given in the draft guidance. Based on these examples a harmonized approach will be proposed for future FS selection.

6.02.P-We249 Improved ECx/BMDx Estimation for Avian Studies

John Green¹, Manousos Foudoulakis², Timothy Fredricks³, Thomas Bean⁴, Jonathan Maul⁵, Stephanie Plautz⁶, Pablo Valverde⁷, Adam Schapaugh³, Xiaoyi Sopko⁸ and Zhenglei Gao⁹, (1)JohnWGreen-ecostats.com, United States, (2)RAS, Corteva Agriscience, Peristeri, Greece, (3)Bayer Crop Science, United States, (4)FMC Agricultural Solutions, United States, (5)Syngenta Crop

Protection Inc., United States, (6)BASF, United States, (7)Dow AgroSciences LLC, United States, (8)Corteva Agriscience™ The Agriculture Division of DowDuPont™, United States, (9)Bayer Crop Science, Germany

To inform regulatory authorities, to better understand the capabilities and limitations of benchmark dose (BMD) methodology, and to make a recommendation on improved experimental design for the BMD approach, a computer simulation study was conducted to explore the BMD methodology using model averaging applied to generalized non-linear mixed models (GNLMMs) for conditionally binomial and Poisson endpoints that are required in avian reproduction studies. Among the advantages of GNLMM over traditional normality-based approximate methods is the elimination of negative lower confidence bounds. More importantly, these models more accurately reflect the nature of the observations. The work explored alternative experimental designs with different spacing (e.g., common ratio of test concentrations 4 or 6 as well as concentrations equally spaced on an arithmetic scale (rather than geometrically spaced) and different replication with the goal of finding practical experimental design better suited for regression/BMD methodology without unduly affected NOAEL calculation when needed. Power simulations were also done to determine the impact of the alternative experimental designs on NOEC determination. The work also addresses the different models and model selection criteria used by existing software packages to implement BMD methodology and their impact on BMDx and BMDxLB estimation. These packages include both R and Excel-based software and both Bayesian and non-Bayesian methodology. A summary of the benefits of the work follows. • Fully addresses the statistical protocol proposed in Green *et al* (2021) • Eliminate the potential for mis-applying normality-based methods on non-normal data • Inform the most useful experimental design for BMD estimation • Compare NOAEL to EC10 & EC20 to help risk assessment when no BMDx can be estimated

6.02.P-We250 Development of a Bioenergetic Model for Improved Analysis of Avian Reproduction Studies

Marie Trijau¹, Benoit Goussen¹, Richard Brain², Jonathan Maul² and Nika Galic³, (1)IBACON GmbH, Germany, (2)Syngenta Crop Protection Inc., United States, (3)Syngenta Crop Protection LLC, United States

Current environmental risk assessments addressing chronic exposure of chemicals to birds are based on complex and controlled laboratory reproduction experiments. These experiments produce many response variables that are usually separately analysed which can hamper understanding of the physiological mechanisms underlying the effects of the tested chemical as well as extrapolation to field conditions. In addition, behavioural responses are rarely considered. Here we posit that a better way to evaluate avian reproduction study data is to use mechanistic modelling, such as Toxicokinetic – Toxicodynamic (TKTD) modelling. Specifically, Dynamic Energy Budget (DEB) models coupled with TKTD modules (DEB-TKTD) are the leading approach to assess sublethal effects of chemicals on individuals by more comprehensively using data available through integration in a unique framework. Existing DEB models do not include the necessary flexibility to accurately capture the variety and specificity of data from avian reproduction studies. Here we present a tailored DEB-TKTD model able to overcome this challenge. We tested our model on 10 avian reproduction studies conducted on 5 different pesticides. The new implementation accurately captured the growth and reproduction observed in these studies. In addition, with this implementation, it is possible to disentangle and to quantify possible behavioural effects from direct toxic action of the pesticides. This approach has the potential to make better use of existing and future data sets and provides means for a more accurate extrapolation of effects to birds from pesticide exposures in the field.

6.02.P-We251 How to Derive Realistic Foraging and Food Consumption Pattern for Use in TKTD Models for Wildlife Risk Assessments?

Dirk Nickisch, Imme Katzschner, Felix von Blanckenhagen, Jens Schabacker and Ludwigs Ludwigs, Rifcon GmbH, Germany

Following the EFSA Wildlife draft guidance published end of 2021, toxicodynamic-toxicokinetic (TKTD) models have been suggested as Tier 2 refinement for bird and mammal risk assessments of pesticides. In recent years, TKTD models supported the aquatic risk assessment, and first experience were made in soil risk assessments. An important TKTD application in the aquatic risk assessment is the prediction of toxic effects under realistic, time-varying exposure. So far, in Wildlife risk assessments the TK related and species-specific body burden modelling was applied for higher tier weight of evidence assessments particularly for certain mammalian scenarios and based on previous negotiations with member state authorities. Realistic exposure profiles using version-controlled EU modelling tools for aquatic or soil exposure profiles are established in these areas in ecotoxicology. However, the application of TKTD models in Wildlife risk assessments seems practically limited due to the lack of realistic food intake patterns. Wild animals need to feed during large parts of the day (and/or night) to cover energetic requirements within 24h hours. Therefore, toxins are not ingested in a single dose but in multiple small doses in complex feeding patterns. No accepted tools are available, and more realistic foraging pattern of individuals in farmland like the PT (portion of diet from treated area) refinement is part of step 3 of the tiered effect assessment proposed by EFSA in 2021. Here, we present and compare different approaches to estimate foraging and food intake patterns, using the example of the rabbit. We derived patterns from a) literature data, b) GPS satellite tracking data and c) VHF-technology related radio-tracking fieldwork. We tested the different patterns in TKTD models with substances, which are metabolized at different rates in the animal's body. Furthermore we discuss what is needed to improve the possibility to apply TKTD models also in Wildlife risk assessments, and ask to establish a joint way forward implementing this approach as part of the higher tier risk assessment for terrestrial vertebrates.

6.02.P-We252 How to Use Mechanistic Effect Models in Bird and Mammal Risk Assessment Without Additional Vertebrate Testing

Thomas Preuss¹, Roman Ashauer², Andre Gergs¹, Nika Galic³, Mattia Meli⁴, Stephan Partsch⁵ and Pernille Thorbek⁶, (1)Bayer Crop Science, Germany, (2)Syngenta Crop Protection AG, Switzerland, (3)Syngenta Crop Protection LLC, United States, (4)ADAMA Agricultural Solutions, Suresnes Cedex, France, (5)FMC Agricultural Solutions, Germany, (6)BASF SE, Germany

Recently the draft of the EFSA bird and mammals guidance document was published for public commenting. The criteria of the EFSA scientific opinion (SO) on TKTD models for model calibration and validation are cited. According to this EFSA SO (EFSA PPR Panel, 2018) TKTD models must be calibrated based upon experimental data for the specific species-pesticide combination, and subsequently validated on an independent dataset with a different exposure situation to prove that the model is able to extrapolate across different exposure conditions. Unfortunately, this calibration and validation exercise would increase the number of animals tests. One of the aims of the Regulation (EC) No 7441107/2009 is to reduce vertebrate testing. Therefore other ways for model calibration and validation should be used. An option would be to use a combination of *in vitro* assays and toxicokinetic modeling to predict the responses from the standard tests. In that case the species-pesticide specific calibration is conducted with *in vitro* assays for the toxicodynamics and ADME studies for the toxicokinetics and the standard animal studies are used for model validation. Examples of such an approach for lethal and sublethal effects are available in literature. By use of physiological based toxicokinetic models, with the addition of *in vitro* studies it might also be possible in future to conduct the calibration on one species (e.g. rat) and the validation on an independent one (e.g. mouse or quail). This is currently not established and needs further research. We will present an overview of this alternative approach and examples for the different steps.

6.02.P-We253 Comparison of Four Methods of Sampling Nocturnal Flying Insects and Their RESIDUE Results

Ralf Dittrich¹ and Fabian Daza², (1)Eurofins MITOX Group, Germany, (2)Birds and mammals, Eurofins MITOX Group, Dresden, Netherlands

The official update process of the Guidance Document (GD) on the risk assessment (RA) for birds and mammals provides a great opportunity to present developments regarding the collection of data linked to the exposure components of the risk assessment. Crucial for the exposure estimation are the residue decline field studies. The exact methods used to sample the test material, whether arthropods or plants, and their practical application, can differ due to various reasons. Therefore, a systematic comparison among methods should improve our understanding of how these can impact the outcome of such studies. The arthropod group of flying insects represents the link to the potential oral exposure for insectivorous birds and mammals (for the later, especially those with nocturnal behaviour). So far there is no consensus about the best sampling methodology for obtaining data to perform residue analyses on that group. Additionally, information on the comparison of methodologies for trapping flying insects is scarce with respect to the measured residues after pesticide application in agricultural areas. The study aimed to determine a reliable and representative sampling method for performing analyses of residue values of food items (nocturnal flying insects) in common agricultural habitats. Four different methods (light trap, Malaise trap, aspirator and quad-netting) to capture nocturnal aerial insects were tested in two different crops (vineyards and orchards), following the application of two fungicides with Tetraconazole as active ingredient, in the southwest of France during summer 2020. The samples were analysed for residue values RUD (Residue unit per dose). The results allowed the comparison, for each method and habitat, of the sample composition and of the observed residue values and provide the basis for the discussion about the influence of insect community composition in the residue results. This study provides a good example of method comparison, which could be usefully extended to other cases of arthropod sampling for residue studies (pitfall sampling, beating, inventory spraying, sweep netting, etc.).

6.02.P-We254 Industry Data Contribution to EFSA for the Update of the Guidance on Risk Assessment for Birds and Mammals

Paula Garcia¹, Manousos Foudoulakis², Markus Ebeling³, Steven Kragten⁴, Alex Blakey⁵, Joerg Hahne⁶, Thomas Bean⁷, Kai Ristau⁸, Katharina Ott⁹, Sonja Haaf¹⁰ and Judith Neuwohner¹¹, (1)Corteva Agriscience, Abingdon, United Kingdom, (2)RAS, Corteva Agriscience, Peristeri, Greece, (3)Environmental Safety, Bayer Crop Science, Germany, (4)Syngenta Agro GmbH, Germany, (5)Syngenta Ltd., United Kingdom, (6)Bayer Crop Science, Germany, (7)FMC Agricultural Solutions, United States, (8)APD/EE, BASF SE, Germany, (9)BASF SE, Germany, (10)ADAMA Deutschland GmbH, Germany, (11)Nufarm Euroope GmbH, Afghanistan

We present examples of Industry data contributions for the update of the EFSA Guidance on Risk Assessment for Birds & Mammals, and how they were evaluated by the EFSA Working Group: Residue levels of pesticides on fruits for use in wildlife risk assessment. The fruit RUD values in the 2009 EFSA GD were based on a published compilation of various trials of unclear regulatory relevance. Therefore, Industry offered EFSA a dataset of field study data on fruit residue levels from applications of pesticides in fruiting crops. The revised RUD values adopted by EFSA in the 2021 draft GD were derived by merging this Industry dataset with data from the 2018 Lahr et al report. Dissipation of plant protection products from foliage. The 10d default foliar dissipation DT₅₀ value in the 2009 EFSA GD was based on a compilation of residue trials no longer relevant for current pesticide use in the EU. Therefore, Industry proposed to consider the Ebeling & Wang evaluation on regulatory residue trials, from which DT₅₀ values of 3.2d (geometric mean) and 7.9d (90th percentile) were derived. Based on this and other available publications, the 2021 draft GD acknowledged the need to evaluate the adequacy of the 10d value, but this was not conducted due to time limitations and the conservative 10d default DT₅₀ value was maintained. Extrapolation factors for LD₅₀ values from acute mammal studies conducted at the limit dose. The 2009 EFSA GD provided guidance on how to extrapolate a surrogate LD₅₀ for birds, but not for mammals. Industry provided EFSA with an evaluation and a dataset of mammalian acute toxicity studies to derive suitable extrapolation factors. From a broader dataset, EFSA conducted a parallel evaluation which resulted in extrapolation factors for mammals being established and included in the 2021 draft GD. Time-Weighted Average (TWA) In mammalian toxicological studies used for wildlife ecological risk assessment, the duration of exposure is fixed and not adjusted to the expected exposure duration in the field. However, time dependency is a typical feature of toxicity: the longer the exposure, the greater are the effects. In the 2009 EFSA GD a default 21d TWA window to calculate exposure is used. Industry provided an analysis demonstrating this is an overly conservative approach when bodyweight effects after much longer exposures are used for wildlife risk assessment. In the 2021 draft GD, EFSA acknowledged uncertainties that must be considered for those cases

6.02.P-We255 Reducing Exposure: Comparison of Two Application Techniques of a Granular Pesticide in Potato Fields

Anja Cervenc1, Manousos Foudoulakis2, Benedikt Gießing1, Christian Wolf1 and Andrea Rossbach3, (1)Tier3 Solutions GmbH, Germany, (2)RAS, Corteva Agriscience, Peristeri, Greece, (3)Tier3 Solutions GmbH, Leverkusen, Germany

Granular plant protection products (PPP) are widely used and have potential to cause adverse effects to birds and mammals if ingested in sufficient quantities by individual animals. By minimising the availability of granules on the soil surface, the risk of exposure can be reduced to levels that pose a low risk to birds and mammals foraging within treated fields. This study was performed to compare two common application methods - in-furrow application and broadcast - for a granular PPP used in potato cultivation, to assess the number of granules remaining on the soil surface following application. Exposure assessments were carried out on potato fields in four European countries by counting the number of granules on the soil surface for a defined number of plots on each of the study fields directly after application. The number of exposed granules was generally lower on fields with in-furrow applications than on fields where broadcast application was used. Thus, in-furrow application of granular PPP can mitigate the risk of exposure to wildlife potentially ingesting granules left on the soil surface.

6.02.P-We256 EMBARC: To Elucidate the Risks to Bats From Exposure to Agrochemicals

Charles Hazlerigg1, Amy C. Brooks2, Mark Whittingham3 and James Standen3, (1)Enviresearch Ltd, Newcastle-upon-Tyne, United Kingdom, (2)Cambridge Environmental Assessments, United Kingdom, (3)Newcastle University, United Kingdom

Intensification of agriculture has been identified as a key driver for bat population declines, with the associated exposure to legacy agrochemicals being directly linked to mass mortality events in bat populations (e.g. organochlorines). This has led to a general assumption in the scientific community that bats are exposed to agrochemicals and that these could lead to adverse effects on individuals and populations. This is reflected in the recent European Food Safety Authority (EFSA) Scientific Opinion that concluded that in some instances, the risks to bats were not adequately covered by current risk assessment requirements in the authorisation of Plant Protection Products under EC 1107/2009. However, significant data gaps have been identified when trying to quantify routes of exposure, sensitivity to agrochemicals and relevance of effects on bat populations (e.g. Brooks *et al.* 2021). A newly funded project entitled “*Exploring Mayflies and Bats: Assessing Risks from Chemicals (EMBARC)*” will fill some of these data-gaps incorporating fieldwork and effects modelling approaches. Three seasons of bat fieldwork will be undertaken at two Newcastle University Farms monitoring species richness and activity to identify suitable focal species for a range of crops across different growth stages that may be used as a basis for a quantitative risk assessment methodology similar to that currently used for birds and mammals (EFSA 2009). Further field studies will be performed to identify whether different types of disturbance associated with agrochemical application (e.g. noise, artificial light, spray) affect bat activity and ultimately exposure. In conjunction with fieldwork, population models will be developed to explore whether sub-lethal effects of agrochemicals may have more subtle effects on long-term population stability. This project will provide a greater level of understanding of the routes of exposure to bats and how to incorporate this information in a regulatory risk assessment. Furthermore, we will have a better understanding of population responses to agrochemical exposure and how different strategies or agronomic practices may be implemented to mitigate any adverse effects.

6.02.P-We257 Possibilities and Limitations for the Bridging of Focal Species Between Different Countries

Carlos Gutiérrez-Expósito1, Anja Cervenc1, Manousos Foudoulakis2, Olaf Fuelling3, Benedikt Gießing1, Anja Russ3, Paula Garcia4, Raquel Sainz Elipe5 and Christian Wolf1, (1)Tier3 Solutions GmbH, Germany, (2)RAS, Corteva Agriscience, Peristeri, Greece, (3)Tier3 Solutions GmbH, Leverkusen, Germany, (4)Corteva Agriscience, Abingdon, United Kingdom, (5)Tier3 Solutions GmbH, Spain

Plant protection products (PPPs) are applied to specific crops at defined growth stages and during predetermined periods of the year. In order to assess the risk of exposure of birds and mammals to these PPPs, so called ‘focal species’ can be identified. It is the aim of the ‘focal species’ concept, that one (or a few) species cover all other species of the same feeding guild, in the risk assessment that forage on PPP treated fields. A common approach to identify focal species is the implementation of bird and mammal surveys on several fields of the respective crop during the period of potential exposure to the PPP. These surveys are commonly conducted in one region in a single country only, while the PPPs can be applied to the same crop in many different countries. In order to assess the risk to birds and mammals by the PPP in these other countries, a common approach is the so called ‘bridging’. That means that the focal species identified for one country are used to refine the risk for birds and mammals in other countries, too. However, there might be factors that restrict the applicability of this approach. For example, the conditions where and when crops are cultivated or the habitat preferences of the selected focal species might differ between countries. In addition, the geographical distribution of birds and mammals may limit the occurrence of species to certain regions. Hence, the bird and mammal community present on fields of the same crop and at the same growth stage might differ between countries, even within the same regulatory zone. In order to illuminate the possibilities and limits of the ‘bridging’-approach, data on the bird and mammal community in a certain cultivation stage of a field (i.e. ‘bare soil’) obtained in four different countries (two countries in two regulatory zones, respectively) were examined for similarities and differences. This poster will present the results and recommendations of this analysis.

6.02.P-We258 The 'Portion of Diet From Treated Area' As Robust Refinement in Pesticide Risk Assessments for Birds and Mammals in Europe - History and Update

Ludwigs Ludwigs1, Steven Kragten2, Markus Ebeling3 and Sonja Haaf4, (1)Rifcon GmbH, Germany, (2)Syngenta Agro GmbH, Germany, (3)Environmental Safety, Bayer Crop Science, Germany, (4)ADAMA Deutschland GmbH, Germany

The risk quotient based long-term exposure assessment to pesticides for birds and mammals in Europe can be refined by including more realistic exposure field data on the relevant focal species in the relevant crop. One of the most frequently used refinement

factors in the long-term risk assessment is the PT factor, intending to reflect the proportion of the diet taken from the pesticide treated area. PT field data are obtained by tracking individual animals for a single or few daily activity periods. An overall PT factor to be used in the risk assessment is then determined based on a number of individual PT values. In 2017 Ludwigs et al. proposed determining overall PT factors by including inter- and intra-individual variability in PT within the given long-term period in order to obtain a more realistic long-term PT value. The basic principle of this approach is to calculate 21-day mean PT values of individuals followed by a 90th %ile PT factor for a virtual population based on solid PT field data sets using Monte Carlo simulations. The approach by Ludwigs et al. was critically reviewed by Crocker & Langton (2019). Concerns have been raised that the method proposed is unsuited to most radio-tracking datasets, statistically not valid and could lead to misleading and possibly not protective risk assessments. As a follow-up on this discussion, datasets of yellow wagtails (*Motacilla flava*) in strawberries and skylarks (*Alauda arvensis*) in spring cereals were analysed to demonstrate applicability and limitations of the proposed method. With this exercise, we aim to further contribute to the discussion on how to derive protective PT factors for higher tier and long-term risk assessments.

6.02.P-We259 Automated Radio-Tracking in the Risk Assessment for Birds and Mammals Under Pesticide Legislation

Ralf Ditttrich¹ and Paula Machin², (1)Eurofins MITOX Group, Germany, (2)Eurofins MITOX Group, Spain

The official update process of the Guidance Document (GD) on the risk assessment (RA) for birds and mammals provides a great opportunity to present developments aimed to improve the collection and interpretation of data related to the exposure components of the risk assessment. Radio-tracking is a well-known, highly accurate methodology for the monitoring of a number of individuals. In the context of risk assessment, data obtained with this method is primarily used to estimate the Proportion of an animal's daily diet obtained in a Treated habitat (PT) and therefore as a refinement option for higher tier assessments. However, manual radio-tracking as currently prevailing method implies a high manpower need, relatively high costs and a relatively reduced number of monitored individuals in the end. The alternative use of GPS technology is restricted to larger animals, and therefore not operative with, for instance, small songbirds. Within this scenario, the technology of automated radio-tracking as a new, automatic system for recording movement and position of small animals, could be used to generate extensive and valuable information for the higher tier assessment step. This open-source project has developed a system for the monitoring of movement profiles of small wild animals, with emphasis on the ease of system use. The system characteristics include, in theory, a significantly increased precision and the unique possibility to monitor several animals at the same time and during long periods (as long as the transmitters work and birds stay within the monitoring grid) with manageable effort. Originally, the method was developed for bat monitoring. We started trials to test the feasibility of this approach for avian species (and, in the future, for small mammal species). The aim was to learn more about the system itself, the quality of the data collected and the possible technical setbacks or modifications required for birds. Several individuals of three small songbird species were equipped with a radio transmitter, in an area where a number of automated stations were installed. The respective radio signals were recorded by the system, and in parallel the crop development in the study area was monitored. The joint analysis of these data shows the potential for future use of this novel approach in the context of higher tier assessment, and offers a first insight on its advantages and disadvantages with respect to the manual radio-tracking.

6.02.P-We260 Validation and Application of a Non-Invasive Method to Monitor Farmland Bird Exposure to Triazole Fungicides

Elena Fernández Fernández Vizcaíno¹, Francois Mougeot², Rafael Mateo Soria³, Pablo R. Camarero² and Manuel Ortiz Santaliestra⁴, (1)Toxicology, IREC-Instituto de Investigación en Recursos Cinegéticos, Ciudad Real, Spain, (2)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (3)IREC (CSIC- UCLM), Spain, (4)Spanish Institute for Game and Wildlife Research (IREC) UCLM-CSIC-JCCM, Spain

The treatment of seeds with pesticides is an extended practice in current agriculture. In particular, triazole fungicides are the most widely used products to treat rainfed cereal seeds, so there is a high risk of exposure of granivorous bird species, such as the red-legged partridge (*Alectoris rufa*), that can consume those seeds remaining on the field surface during sowing. Triazole fungicides can cause endocrine disruption and reduce the reproductive capacity of partridges, which in the long run could result in population declines. This work aims to (i) develop and validate a non-invasive method to detect the presence of triazole fungicide residues in farmland birds by analyzing fecal samples of experimentally exposed red-legged partridges, and (ii) use the method in a field scenario to assess exposure of wild farmland birds. To this end, we exposed adult partridges to seeds treated with two formulations containing three triazoles as active ingredients (flutriafol, prothioconazole, tebuconazole). We determined the concentrations of the three triazole fungicides and their main metabolite (1,2,4-triazole) in two types of feces (cecum and rectum stool samples) at three different times: immediately after exposure, and on days 7 and 14 post-exposure. To validate the method in a real scenario, we collected a total of 118 fecal samples from wild farmland birds. The results show that the three active ingredients and 1,2,4-triazole were only detected in samples collected at the end of the exposure, not afterwards, indicating that fungicides were rapidly excreted in feces. The presence of triazole fungicides was detected in 43% of rectal stool samples and in 37% of cecum samples from exposed partridges. The metabolite 1,2,4-triazole was detected in 53% of the rectal samples of exposed partridges. The analysis of feces from wild farmland birds found detectable levels of triazole fungicides in 20% of samples. The results of the experimental exposure study indicate that this is a minimum, probably underestimated, exposure level for wild birds. Our results reinforce the need to develop effective and apply non-invasive methods to monitor the real exposure of farmland birds to pesticides in the field.

6.02.P-We261 Higher Tier Field Effect Studies in Practice and the Benefits and Drawbacks of MDDs to Evaluate Them

Olaf Fuelling¹, Ines Hotopp², Benedikt Gießing², Andrea Roszbach¹ and Christian Wolf², (1)Tier3 Solutions GmbH, Leverkusen,

Germany, (2)Tier3 Solutions GmbH, Germany

The proposed new EFSA Guidance Document on risk assessment for birds and mammals strengthens the use of higher tier field effect studies. The draft document describes furthermore the use of Minimum Detectable Differences (MDD) as a viable option for a statistical assessment of a study. We provide MDDs from two different field effect study designs on mammals and discuss a way to evaluate them. Other than a statistical power analysis, MDDs apply only to the one study they are calculated for. Due to different focal species, seasons, years or locations the MDDs of different studies vary a great deal. We calculated the variation of untreated controls within each study to find a benchmark MDD, assuming that any detection level within the natural variation between untreated controls is sufficient to detect any adverse effect of biological importance. We are fully aware that the derivation of an evaluating benchmark from data within a study needs further consideration. Furthermore, the assumption that any effect smaller than the natural (from control sites) variation of a parameter is of no or little biological importance for the population as such will and should not be accepted without further discussion. However, a meta-analysis of control field data instead of the data from just one study may help to strengthen MDD benchmarks. The definition of a set of MDD categories instead of a single benchmark value will help to specify the protective level of the study results.

6.02.P-We262 How to Jump Pitfalls in the Statistical Analysis of Field Effect Studies

Anja Russ¹, Ines Hotopp² and Olaf Fuelling¹, (1)Tier3 Solutions GmbH, Leverkusen, Germany, (2)Tier3 Solutions GmbH, Germany

Field effect study data holds certain pitfalls that have to be taken into account in the analysis as they affect the choice of the statistical method. We draw attention to some of these pitfalls and show possible approaches on how to jump them. Especially, as the draft guidance on birds and mammals risk assessment using higher tier studies does not include approved methods for the analysis of field effect studies. However, there are several appropriate ways to analyse this kind of data statistically. We use the concept of Generalized Linear Mixed Models (GLMMs) to give one option that is able to cope with many of the peculiarities of field effect study data. A first step is to know what kind of data one is dealing with. The numbers itself characterize the underlying data type and distribution. Most data in ecology are Poisson-distributed count data. However, there are other data types such as proportions or ratios. Most statistical methods make assumptions about the data type they are used on and therefore, method and data type should fit together. When applying GLMMs, the distribution can be specified according to the data type. In field effect studies, the data is usually replicated. If a replicate is observed or measured more than once, the data is dependent. Some statistical methods assume independence of the data and are thus not suitable in these cases. GLMMs are made to cope with independence using the concept of 'random effects'. Data exploration is a crucial step in analysing any kind of data. It intends to familiarize oneself with the data and get to know its limitations. It includes the investigation of outliers, zero observations, and correlation between covariates. GLMMs provide options to handle such cases as overdispersion and zero-inflation. They also provide the opportunity to include more than one explanatory variable. This can improve the fit of the model to the data, make other effects easier to detect, and allows to look at effects over time by including interactions between variables. However, explanatory variables should not be correlated and overfitting should be avoided. Validation of fitted models is important to verify that assumptions, such as independence and absence of residual patterns, are not violated, and should accompany the statistical results. If applied correctly, GLMMs are a powerful tool that provide a way to analyse field effect study data and that can handle many of the obstacles that come with ecological data.

6.02.P-We263 Methods for tier3 Bird Mammal Field Studies Beyond the Existing and Upcoming EFSA Guidance Document

Christian Wolf¹, Andrea Rossbach², Benedikt Gießing¹ and Olaf Fuelling², (1)Tier3 Solutions GmbH, Germany, (2)Tier3 Solutions GmbH, Leverkusen, Germany

Within the existing and the proposed new EFSA Guidance Document on risk assessment for birds and mammals a variety of different methods for the conduct of field studies with birds and mammals are mentioned. In the first draft of the 'new' guidance document many aspects of field study methods are further specified and are summarised as tier 3 in the stepwise approach of the risk evaluation. The draft also gives applicants better guidance how methods should be used (and which limitations specific methods may have). Nevertheless, more methodological approaches for field studies were developed within recent years and can broaden and enrich the toolbox for tier 3 studies (field exposure studies and field effect studies). Examples will be given for a set of different methods like the 'giving-up-density' (GUD) approach, use of cameras in field studies and automated systems to verify the survival and activity of individually marked animals by 'passive-integrated-transponders' (PIT's) - without re-trapping the animals. Those approaches can be used as stand-alone methods in specific studies, as combined methods or as additional methods in studies as already defined in the guidance document.

6.02.P-We264 Taming the Wild - Reducing Uncertainties of Field Effect Studies in a Semi-Field Set-Up

Tina Grimm¹, Felix von Blanckenhagen², Steven Kragten³, Alex Blakey⁴, Daniel Pickford⁵, Gianpaolo Montinaro², Christian Classen² and Ludwigs Ludwigs², (1)RIFCON GmbH, Hirschberg, Germany, (2)Rifcon GmbH, Germany, (3)Syngenta Agro GmbH, Germany, (4)Syngenta Ltd., United Kingdom, (5)Syngenta, United Kingdom

Under the current EFSA Guidance Document on Birds & Mammals Risk Assessment the long-term risk assessment of pesticides for small herbivorous mammals (voles) fails on many occasions. The commonly accepted higher tier focal species is the common vole (*Microtus arvalis*). Higher tier approaches refining ecological and species-specific data generally do not significantly improve the Tier I risk assessment due to the general ecology of this species. Therefore, a more common higher tier refinement for small herbivorous mammals are field effect studies, designed to monitor population effects for populations exposed to a certain pesticide and to compare the recorded data to populations not exposed. However, such guidance-recommended field effect studies

conducted to investigate assumed effects of pesticides on small mammal communities are regularly challenged by the evaluating authorities, because these studies are conducted in open systems (i.e. including immigration, emigration, predation etc.). These factors are believed to increase the uncertainty of the outcome of such a field effect study. Consequently, authorities partly question these field study designs and consider them inadequate, even if untreated control communities, investigated at the same time, do not show any statistical differences to the treated subpopulations. In order to address these concerns, Rifcon GmbH established an experimental set-up for semi-field studies in enclosures to address long-term effects on small herbivorous mammals after exposure to a pesticide. The general set-up of these enclosures was presented at the SETAC Europe conference 2017 in Brussels/Belgium. Here, we present individual-based data from recently run enclosure studies demonstrating the functionality of this system in relation to the risk assessment.

6.02.P-We265 Grassland Fields As Surrogate Crop for Field Effect Studies on the Common Vole

Olaf Fuelling and Anja Russ, Tier3 Solutions GmbH, Leverkusen, Germany

The common vole occurs in all countries of the central regulatory zone (except Ireland) and in some countries of the northern and the southern zones too. The species can be found in many crops and during its population outbreaks it even becomes a pest. Yet, the common vole does usually have no permanent populations on arable fields due to farming practices like ploughing, harrowing or harvest. Permanent grassland fields used e.g. for hay production, provide a far more stable habitat that sustains vole populations for a long time. For long-term studies to investigate chronic risks from PPPs, it is essential to examine at least one entire reproductive season. Grassland fields provide another advantage, as they are not treated with PPPs. Consequently, a field effect study in grassland can be conducted with 'clean' control fields and with treatment fields that are only treated with the test item but no additional PPPs. Spray applications on short grass with the same equipment that is used on arable fields provide a realistic worst-case exposure. As common voles have quite small home ranges and feed almost exclusively on the grass- and broad-leaved vegetation, their exposure by food intake is close to 100%. Voles are easy to capture and frequently recaptured after marking and, thus, providing an ideal species for capture-mark-recapture (CMR) study designs. The design features stable small mammal populations that are restricted to a full sized field by habitat preferences and behaviour, and of sufficient population density to obtain statistically robust results. It allows the use of a single test item to be compared to a 'clean' control. The concept of surrogate crop as a valid study design might even be extended to other habitat-focal species combinations.

6.02.P-We266 Review of Approaches Taken for "Vole" Risk Assessment for Plant Protection Products Amongst European Regulatory Authorities

Jennifer Duncan, TSG Consulting, United Kingdom

There is a clear lack of harmonisation in the approaches to higher-tier bird and mammal risk assessments taken by European Regulatory Authorities for Plant Protection Products (PPP). Here we focus on the different approaches taken for the small herbivorous mammal (represented by the "vole"). We have reviewed national approaches, either from published national guidance or contacting the Regulatory Authorities directly. We present a summary of our findings, including the scale of the different approaches taken. The common vole (*Microtus arvalis*) is defined in EFSA's Bird and Mammal Guidance Document (2009), as the representative species for the small herbivorous mammal. The first-tier risk assessment for the small herbivorous mammal is highly conservative and often fails. EFSA's Guidance allows for a number of different refinement options for use in a higher-tier risk assessment. This includes defining the focal species, i.e. a real species that occurs in the crop when the pesticide is being used. Following an EU level assessment/review of a pesticide active substance (under Regulation (EC) No. 1107/2009), refinements including determination of a focal species are often left as an open point to be defined at Member State (MS) level during product authorisation. Some MSs (e.g. Greece and France) simply consider the small herbivorous mammal ("vole") irrelevant, due to its pest status and high fecundity. As such, the risk is covered by assessments for other mammalian generic focal species. Other MSs (e.g. Germany and Czech Republic) allow the reduction of the trigger value, where the toxicity endpoint used for the assessment has been determined for phylogenically related species. The field vole (*Microtus agrestis*) is considered more relevant than the common vole by some MSs (e.g. Northern Zone MSs and UK). Whereas some MSs (e.g. Belgium) require field studies in the crop of interest if the Applicant wishes to refine the focal species. Overall, there is a wide range of approaches taken by different MSs in assessing the risk to the small herbivorous mammal "vole". This ranges from perceiving the vole as a pest species, to considering the vole as a species to be protected, and the need for higher-tier data to support the risk assessment. One of the aims of the revision of EFSA's Bird and Mammal Guidance was to further harmonise higher-tier assessments with regulatory zones, however, the draft revision (2021) does not address these MS approaches.

6.02.P-We267 Secondary Poisoning of Birds and Mammals Via Benthic Invertebrates: Initial Evaluation of This Pesticide Risk Assessment As Found in the Draft EFSA Birds and Mammals Guidance (September 2021)

Gabriel Weyman¹, Amy C. Brooks², Kevin Brown³, Helena Crosland² and Alan Lawrence², (1)Gabe Weyman Consulting Ltd, United Kingdom, (2)Cambridge Environmental Assessments, United Kingdom, (3)Independent Consultant, Sweden

The EFSA (European Food Safety Authority) guidance document for assessment of risk from pesticides to wild birds and mammals (2009) is currently undergoing revision. A draft revised document for public consultation was issued in September 2021. This draft includes revisions to existing risk assessments, as well as some new risk assessments. Risk of secondary poisoning of wild birds and mammals via consumption of earthworms and fish has been included since the original version of the EFSA guidance (2009); and was included in the pre-EFSA guidance too (SANCO/4145/2000, September 2002). In the 2021 draft, a new route of secondary poisoning has been proposed: via consumption of benthic sediment-dwelling invertebrates. We will evaluate this proposed new risk assessment, consider the types of compounds likely to trigger it, the calculations required, the results, and the consequences. We will illustrate our findings using example data sets.

6.03 Environmental Risk Assessment for nanomaterials – challenges and solutions for knowledge transfer and active dialogue between research and regulation

6.03.T-01 Updating the OECD 211 *Daphnia magna* Reproduction Test for Use With Engineered and Anthropogenic Particles

*Iseult Lynch*¹, *Katie Reilly*², *Zhiling Guo*³, *Laura-Jayne Ellis*⁴, *Tommaso Serchi*⁵ and *Maria Dusinska*⁶, (1)School of Geography, Earth and Environmental Sciences, University of Birmingham, Birmingham, United Kingdom, (2)University of Birmingham, Birmingham, United Kingdom, (3)School of Geography, Earth & Environmental Science, University of Birmingham, Birmingham, United Kingdom, (4)The University of Birmingham, United Kingdom, (5)Luxembourg Institute of Science and Technology (LIST), Luxembourg, (6)NILU Norwegian Institute for Air Research, Norway

The goal of standard hazard testing is to facilitate comparison of chemicals under identical conditions for ranking of toxicity to the test organisms, and as such environmental realism is not typically of concern. However, the highly reactive surfaces of nanoscale materials means that they acquire a corona of biomolecules from their surroundings which reduces their toxicity; in the absence of suitable biomolecules in the exposure medium the nanomaterials strip biomolecules from organismal membranes, leading to excessive damage and overestimation of toxicity. Exposure of the indicator species *Daphnia magna* to nanomaterials may lead to reduced growth, delayed maturation and delayed reproduction, induction of males and epigenetic changes passed from exposed mothers to their offspring. The current OECD test guideline looks at only a single generation, thus ignoring the possibility of impacts in subsequent generations, through adaption to continued exposure or sensitisation resulting from parental exposures with consequences for population dynamics. Recommendations for adaption of the OECD 211 for testing of nanoscale particles are presented, grouped into three broad categories: 1 Adjustments to exposure conditions and duration, to allow for delays in maturation and brood timings, use of daphnia-conditioned media to disperse the particles and passivate the particle surfaces prior to exposure to the organisms, monitoring of the induction of males and the presence of fertilised eggs, and testing both freshly dispersed and medium-aged particles. 2 Addition of particle-specific analyses to support determination of mode of action, including quantification of uptake dose before and after depuration, imaging of phenotypical changes and sub-cellular localisation of nanomaterials in the daphnia gut. 3. Extension to additional generations and inclusion of additional stressors (e.g., temperature) to explore epigenetic effects of environmental exposures, including the potential for adaption to nanomaterials exposure and/or increased sensitization to nanomaterials of organisms whose parent or grandparent generations had been exposed to nanomaterials. This would require multi-generational assessment, over at least 2-3 generations. As part of the EU Horizon 2020 project RiskGONE, these recommendations are being submitted to the Working Party on manufactured nanomaterials (WPMN) for consideration as a standard project proposal to update the OECD 211 Test Guideline.

6.03.T-02 Similarity Assessment of Metallic Nanoparticles

*Willie Peijnenburg*¹, *Eric Bleeker*², *Willie Peijnenburg*³ and *Martina Vijver*³, (1)VSP, RIVM, Bilthoven, Netherlands, (2)RIVM, Netherlands, (3)CML Leiden University, Netherlands

Similarity assessment is one of the means of optimally using scarcely available experimental data on the fate and hazards of nanoforms (NFs) for regulatory purposes. For a group of NFs that are shown to be similar it is allowed in a regulatory context to apply the information available on any of the NFs within the group to the whole group of NFs. Obviously, a proper justification for such a similarity assessment is to be provided. Within the context of exemplifying such a justification, a case study was performed aimed at assessing the similarity of a group of spherical metallic NFs that differ with regard to chemical composition (three metals) and particle size (three different sizes). The endpoints of assessment were root elongation and biomass increase of lettuce (*Lactuca sativa* L.) seedlings and exposure assessment was performed in order to express the actual exposure concentration in terms of time-weighted average particle concentrations. The results of the study show that for the specific endpoints assessed, chemical composition is driving NF toxicity, and this is mostly due to impacts on the fate of the NFs. On the other hand, particle size of Cu NFs had a negligible impact on the dose-response relationships for any of the endpoints assessed. It is thus concluded that hazard data available on any spherical Cu NF can be used to inform on the hazards of any spherical Cu NF within the size range of 25 – 100 nm. Also, toxicity data for the Cu²⁺-ion are suited for such a similarity assessment.

6.03.T-03 Assessing the Similarity of Nanoforms Based on the Biodegradation of Organic Surface Treatments

*Richard Cross*¹, *Marianne Matzke*², *David Spurgeon*³, *Maria Diez-Ortiz*⁴, *Veronica Gonzalez-Andres*⁵, *Elena Cerro Galvez*⁵, *Nina Jeliaskova*⁶ and *Claus Svendsen*⁷, (1)Centre for Ecology and Hydrology, United Kingdom, (2)UK Centre for Ecology & Hydrology (UKCEH), UK, (3)Centre for Ecology & Hydrology, United Kingdom, (4)Leitat Technological Center, Spain, (5)LEITAT Technological Centre, Spain, (6)IdeaConsult Ltd, Bulgaria, (7)CEH, Wallingford, United Kingdom

Understanding how modulation of key intrinsic properties of nanoforms, such as different surface treatments, affects exposure and hazard is a priority to address for developing grouping approaches. One hypothesis to group nanoforms with different organic surface modifications is to use parameters linked to the biodegradation of the surface treatment, where demonstrating loss of the organic surface treatment indicates it will no longer drive the fate and toxicity of the nanoform and so the nanoform may be grouped with other non-coated analogous forms. To this end, a tiered testing strategy consisting of a 48 hour colorimetric based screening assessment and a higher tier OECD ready biodegradability test (OECD TG 301F), is used to assess the similarity in biodegradation of 6 commonly used organic surface treatments for nanoforms. The pairwise similarity in biodegradation between substances using the data from the two tiers of testing is evaluated by Euclidean distance and maximal fold difference. The presentation will demonstrate a tiered testing strategy for biodegradability of organic surface treatments for nanoforms that may be employed within integrated approaches to testing and assessment (IATA), to group nanoforms according to their environmental fate and toxicity. Lessons learnt from pairwise similarity assessment inform thresholds for groups within each tier of testing, and

define the applicability range, wherein similarity assessment of biodegradability between nanoforms would be appropriate as part of a justification for grouping nanoforms with different surface treatments. Acceptable limits of similarity are yet to be determined, however approaches to validate limits of similarity will be discussed in the context of the six case study substances tested. This study has relevance for grouping and read-across approaches of nanoforms for both regulatory and safer by design purposes.

6.03.T-04 How Can We Justify Grouping of Nanoforms for Hazard Assessment? Concepts and Tools to Quantify Similarity at Relevant and Measurable Ranges

Wendel Wohlleben, Dr.¹, Nina Jeliazkova², Eric Bleeker³, Richard Cross⁴, Andrea Haase⁵, Gemma Janer⁶, Willie Peijnenburg⁷, Andrea Haase⁵, Hubert Rauscher⁸, Claus Svendsen⁹, Georgia Tsiliki¹⁰, Alex Zabeo¹¹, Danail Hristozov¹² and Vicki Stone¹³, (1)Material Physics & Analytics AND Experimental Toxicology & Ecology, BASF SE, Germany, (2)IdeaConsult Ltd, Bulgaria, (3)RIVM, Netherlands, (4)UK Centre for Ecology & Hydrology, United Kingdom, (5)BfR Federal Institute for Risk Assessment, Germany, (6)Acondicionamiento Tarrasense, Spain, (7)VSP, RIVM, Bilthoven, Netherlands, (8)European Commission Joint Research Centre, Italy, (9)CEH, Wallingford, United Kingdom, (10)Athena Institute, Greece, (11)University Cà Foscari Venice, Italy, (12)Ca' Foscari University of Venice, Italy, (13)Heriot-Watt University, United Kingdom

To reduce the animal testing of *each* nanoform (NF), regulatory information requirements may be fulfilled by grouping approaches. The GRACIOUS Framework supports the user to identify a hypothesis, gather the data matrix by targeted testing, and to assess the similarity of the NFs within the proposed group. Algorithms quantify similarity, and thus compare the candidate group of NFs against each other and against representative test materials that represent the biologically relevant range of selected descriptors. Several approaches are accessible via a browser-based tool and are embedded in the blueprint of the e-tool implementation of the full framework. For the pairwise comparison of NFs we included: A Bayesian model assessment which compares two sets of values using nested sampling. A Arsinh-Ordered Weighted Average model (Arsinh-OWA) which applies the arsinh transformation to the distance between two NFs, and then rescales to biologically relevant threshold An x-fold comparison as used in the ECETOC NanoApp. Euclidean distance, which is a highly established distance metric. GRACIOUS Tier 1 methods typically are physical-chemical screenings or in-vitro assays, as suggested by ECHA guidance for a grouping justification. Similarity assessment is possible and required only within the overlap of measurable and biologically (environmentally) relevant ranges. The values of the data matrix can then be cropped to the relevant range before applying similarity algorithms. By a pilot interlaboratory comparison on all descriptors *defining* a nanoform (size, composition/impurities, shape, surface area, surface treatment), we found e.g. that differences in size percentile D10 up to 34% should not be interpreted; differences in the main constituent elements up to 8% should not be interpreted, etc. The robustness of methods lags behind for descriptors of *interaction* (such as in-vitro, dosimetry, dissolution), and depends on current and future OECD guideline projects.

6.03.T-05 Marine Risk Assessment of a Reference Anti-Corrosion Nanomaterial: Contributions From the NANOGREEN Project

Joana Figueiredo¹, Tânia Oliveira², João Tedim³, Susana Loureiro⁴ and Roberto Martins⁵, (1)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (2)Smallmatek, Small Materials and Technologies Lda., Portugal, (3)University of Aveiro, Portugal, (4)Universidade de Aveiro, Portugal, (5)CESAM & Department of Biology, Department of Biology, University of Aveiro, Aveiro, Portugal

Metallic corrosion is an unsolved problem that represents 3.5% of the worldwide Gross Domestic Product. It has been minimized through toxic corrosion inhibitors, such as 2-mercaptobenzothiazole (MBT), that are added into maritime protective coatings. Some of those compounds have been successfully immobilized in stimuli-responsive engineered nanomaterials, namely Zn-Al layered double hydroxides (LDH) that can release the entrapped active ingredient under specific conditions coinciding with the degradation phenomena. In particular, the innovative nanomaterial LDH-MBT has been submitted to industrial validation by a Portuguese manufacturer of nano-based additives and thus, the soluble and nanostructured forms of the corrosion inhibitor can end up in the marine environment during the lifetime of the coating. However, their toxic effects on marine organisms remain scarcely studied. Thus, the present study comprehends a marine hazard and risk assessment of MBT in both soluble and nanostructured forms, which will be critical for benchmarking purposes with the upcoming nanoproducts developed under the NANOGREEN project that aims at developing a new generation of sustainable anti-corrosion nanoadditives. For that purpose, ecotoxicological short-term tests were carried out on 15 marine species for which NOEC and L/E/IC₅₀ values were calculated. Then, hazard endpoints (predicted no-effect concentration) were derived, and the risk quotient (RQ) was calculated between the maximum measured environmental concentration (MEC) of MBT in worldwide oceans (0.0017 mg/L) and the estimated marine PNEC (based on the NOEC values) for both forms of MBT. In terms of results, MBT was toxic, very toxic or extremely toxic for 66% of the tested species (lowest NOEC_{MBT}=0.001 mg MBT/L). LDH-MBT was at least 2-fold less toxic than the soluble form for all tested species (lowest NOEC_{LDH-MBT}=0.02 mg MBT/L), being not toxic for 40% of the tested species. The immobilization of MBT into the engineered nanoclay can protect the marine ecosystem by decreasing 15-fold the MBT hazard. It was also demonstrated that MBT poses environmental risks for the marine compartment (RQ=15.5), while its nanostructured form seems to be a promising nanoadditive featuring low environmental risk (RQ=1.0).

6.03 Environmental Risk Assessment for nanomaterials - challenges and solutions for knowledge transfer and active dialogue between research and regulation (Virtual Only)

6.03.V-01 Effects of Exposure Route and Surface Coating on the Bioaccumulation of CdTe Quantum Dots in Fish

Judit Kalman¹, Mona Connolly², Rocío Fernández-Saavedra³, Ana I. Cardona-García³, Isabel Rucandio³ and Maria Luisa

Fernandez-Cruz⁴, (1)National Distance Education University (UNED), Spain, (2)INIA National Institute for Agricultural and Food Research and Technology, Spain, (3)CIEMAT, Spain, (4)Environment and Agronomy, INIA - National Institute for Agricultural and Food Research and Technology, Madrid, Spain

Fish can be exposed to nanomaterials (NMs) in several ways, however, little is known about their bioaccumulation potential. Although OECD Test Guidance 305 describes the methods for bioaccumulation testing in fish via water and diet, testing using an aqueous exposure of NMs may not be feasible. Dietary route testing is especially useful to overcome stability issues. Moreover, dietary ingestion of NMs has been shown to be an important route for aquatic organisms, yet knowledge is limited. Bioaccumulation potential of NMs is likely influenced by several physico-chemical properties and the distinct exposure pathway, and thus it is important to take into account all these factors when evaluating the bioaccumulation of these materials. CdTe quantum dots (QDs) were selected for our studies, because limited information exists regarding their bioaccumulation potential in fish. To address specifically the influences of exposure route and surface coating on bioaccumulation, the uptake and depuration kinetics of two differently coated QDs in rainbow trout (*Oncorhynchus mykiss*) were assessed following exposure via water and diet. In the minimised aqueous bioaccumulation tests, fish were exposed for 28 days to 4 or 40 µg/L QDs followed by 14 days of depuration. Fish were sampled at days 0, 14, 28, 35 and 42 for Cd and Te accumulation in the whole body to derive bioconcentration factors (BCFs). In the complete dietary bioaccumulation assays, fish were exposed for 28 days to 10 or 100 mg/kg QDs followed by 28 days of depuration. Fish were sampled at days 0, 7, 15, 21, 28, 29, 31, 35, 42 and 56 for analysis of concentrations of both Cd and Te in the whole body to derive biomagnification factors (BMFs). Additionally, fish were sampled for tissue analysis at days 28, 29 and 56. Cd and Te concentrations in whole fish and tissues following exposure to CdTe QDs showed uptake, distribution to tissues as well as a slow and incomplete elimination following a 14 day (aqueous study) or 28 day (dietary study) depuration period. Higher levels of Te were measured in fish exposed using the dietary route, however it is eliminated from fish bodies to the same extent as Cd. Dietary Cd appears to have a slower elimination from the liver, gill and intestine compared to Te. The PEG and COOH coatings did not appear to have an influence on bioaccumulation potential, however a higher bioavailability of Cd was observed after the water exposure. BCF/BMF values indicate a low bioaccumulation potential of Cd and Te following CdTe QD exposure in fish. *Acknowledgement* - The authors thank H2020 project GOV4NANO 814401 for its funding.

6.03.V-02 James Bond and the DaNa4 Knowledge Base: Why Reliable Risk Communication of Nanomaterials and Advanced Materials Are Crucial

Andreas Mattern¹, Dana Kühnel², Christoph Steinbach³, Sara Espinoza³, Harald Krug⁴, Clarissa Marquardt⁵ and Katja Nau⁵, (1)Helmholtz Center for Environmental Research - UFZ GmbH, Germany, (2)Helmholtz-Centre for Environmental Research, Leipzig, Germany, (3)Society for Chemical Engineering and Biotechnology e.V. (DECHEMA), Germany, (4)NanoCASE GmbH, Switzerland, (5)Karlsruhe Institute of Technology KIT, Germany

In the recent Bond movie “No Time to Die” James Bond is fighting a supervillain who wants to kill millions of people with nanobots. To answer the questions whether or not this scenario is a threat for humans or the environment, the DaNa project is providing information about the safety of advanced materials including nanomaterials and related technological developments. For more than ten years, the DaNa webpage (www.nanoobjects.info) provides safety-relevant information on 28 advanced materials including nanomaterials with respect to human and the environmental health. Even though many publications of the toxicology of nanomaterial or advanced material have been published, misinterpretations and fake news are a constant challenge. Such misrepresentations have multiple causes, both on the scientist’s side as well as on the side of multipliers. Therefore, the DaNa knowledge base offers a library of novel materials which are carefully and critically examined. A team of ecotoxicologists, human toxicologists and materials scientist is selecting proper publications by using a literature criteria checklist. The scientific knowledge of the quality assured studies is then transformed into an easy-to-understand material text. Furthermore, the DaNa knowledge base providing FAQ to socially relevant topics like nanomaterials in corona vaccines. With respect to the proper risk communication the project is transparent in how information and methodology are selected. Last but not least nanomaterial news are shared on social media and request from citizens as well as journalists are answered to fight fake news. This poster gives an overview on our activities of science communication in the field of materials safety. We describe our strategy and methodology to deal with risk communication issues and highlight the lessons learned over ten years of science communication on nanomaterials by outlining key principles that can be applied to communication on advanced materials. And if you are now wondering about nanobots, just check out our recent article “Nanobots – Science or fiction?” *Acknowledgement: The funding for the DaNa4.0 project is provided by the German Federal Ministry for Education and Research (BMBF) under grant no. 03XP0282.*

6.03.V-03 Static and Dynamic Testing for Determining Dissolution Rates of Metal Nanoparticles

Thorsten Klawonn¹, Julien Dennerle², Rolf-Alexander Düring³ and Heinz Ruedel⁴, (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Justus-Liebig-University Giessen, Germany, (3)Justus Liebig University Giessen, Germany, (4)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany

Potential adverse effects of metal nanomaterial towards the environment are attributed to their release of dissolved ions. The dissolution rate is therefore important regarding the assessment of potential ecotoxicological effects of metal nanoparticles and often requested by the European Chemicals Agency (ECHA). OECD Guidance Document (GD) 318 was issued in 2020 and describes the static and dynamic testing of metal nanomaterials to assess their dissolution rates. The OECD GD 318 offers diverse possibilities for testing concerning, e.g., test item loading, sampling times and testing media composition. First, the OECD GD 318 static batch test was realized on basis of OECD GD 29 (Transformation/Dissolution of Metals and Metal Compounds in Aqueous Media) and nano-forms of Zn, ZnO and TiO₂ were investigated. For metal analyses of samples taken at different times, separation of solid or particulate material from dissolved species was conducted by centrifugal ultra-filtration. While static batch

testing of nano-Zn and nano-ZnO yielded sound results, tests with nano-Ag exhibited a fast formation of dissolved species as well as a reaction with constituents of the OECD 29 test medium. Therefore, the dissolution rate could not be determined using the static batch test. According to OECD GD 318, a dynamic test should be performed as an alternative. Thus, an appropriate dynamic test setup was developed and successfully applied to determine the dissolution rate for nano-Ag.

6.03 Environmental Risk Assessment for nanomaterials – challenges and solutions for knowledge transfer and active dialogue between research and regulation (Poster)

6.03.P-Th195 Comparison of Dispersion Stability of Organic Pigments: In Environmental Media of TG-318 and in Media for Guidelines TG-210 (Fish), TG-211 (Daphnia) and TG-221 (Lemna)

Denis Botin¹, Wendel Wohlleben, Dr.², Simon Lüderwald¹, Heidi Stratmann³, Bjoern Hidding¹ and Nicole End³, (1)BASF SE, Germany, (2)Material Physics & Analytics AND Experimental Toxicology & Ecology, BASF SE, Germany, (3)Colors & Effects Switzerland AG, Switzerland

The TG 318 on “Dispersion stability of nanomaterials in simulated environmental media” was the first nano-specific test guideline, published 2017 [1] and it has been previously applied to test the dispersion stability of organic pigments. Here we explored a suggestion by GD-318 [2] and tested the dispersion stability of 10 organic pigments in dispersion media that are used for eco-toxicological tests described in the OECD 210, 211 and 221 guidelines. The observed dispersion stability was compared to the prediction from the TG-318 matrix of media. In the present study was shown, that: · Testing the dispersion stability in the actual ecotoxicity medium could be an option. The main factor influencing the stability seems to be the ionic strength of the media. All three media have pH = 7 to 8, but differ in ionic strengths ($I_{210} < I_{211} < I_{221}$). Almost all tested pigments had low stability in OECD 211 and 221 media, while the stability in OECD 210 medium varied between pigments. · The stability results in the eco-toxicological testing media correlate to the ones obtained with the media in TG-318 at similar pH and I , with NOM. However, testing the original 3x3 media matrix (0, 1, and 10 mM Ca, pH = 4, 7 and 9) could be unnecessary. When direct testing in the ecotoxicity medium is not preferable, one can consider a testing in the media from TG-318 at the relevant for the ecotoxicological test pH value, but with more discrete levels of calcium. · In addition to the UV/Vis spectroscopy, recommended by TG-318 for organic materials, the particle size distribution directly in the environmental medium was checked with the analytical ultracentrifugation (AUC) [3]. The observed size distributions allow to exclude the pigment dissolution in the tested media. Moreover, the distributions of all 10 pigments confirm the presence of agglomeration, especially in the OECD 211 and OECD 221 media. Thus, the analytical alternatives to the TG-318 method of settling at 1 g can be considered: the measurement of time-resolved mass settling at 10 g to 10,000 g by the AUC method provided consistent results.

6.03.P-Th196 Reproducibility of Methods Required to Identify and Characterize Nanoforms of Substances - What Is the Achievable Accuracy for Similarity Assessments?

Richard Cross¹, David Spurgeon², Claus Svendsen³ and Wendel Wohlleben, Dr.⁴, (1)UK Centre for Ecology & Hydrology, United Kingdom, (2)Centre for Ecology & Hydrology, United Kingdom, (3)CEH, Wallingford, United Kingdom, (4)Material Physics & Analytics AND Experimental Toxicology & Ecology, BASF SE, Germany

Nanoforms of a substance are distinguished from one another through differences in their physicochemical properties. When registering nanoforms of a substance under the EU REACH framework, five basic descriptors are required for their identification: composition, surface chemistry, size, specific surface area and shape. To reduce the burden of testing of multitudes of nanoforms with only slight differences in these basic properties, similarity assessment can be employed to justify structural similarity of nanoforms on individual physicochemical properties. However, similarity assessment requires an understanding of the achievable accuracy of available methods, to have confidence in whether measured or reported differences are indeed, real. To estimate the achievable accuracy of common methods to characterise nanoforms, we assess the reproducibility of six analytical techniques routinely used to measure these five basic descriptors of nanoforms. Assessment was performed on representative test materials to evaluate the reproducibility of methods on single nanoforms of substances. The achievable accuracy is defined as the relative standard deviation of reproducibility (RSD_R) for each method. Well established, routine methods such as inductively coupled plasma mass spectrometry for main constituent analysis (ICP-MS), BET (Brunauer–Emmett–Teller) measurements of specific surface area, transmission and scanning electron microscopy for size and shape and Electrophoretic Light Scattering for surface potential and isoelectric point, all performed well with low RSD_R , generally between 5 and 20%. Maximal fold differences were usually < 1.5 fold between laboratories. Applications of technologies such as thermo-gravimetric analysis (TGA) for measuring water content and putative organic impurities, additives or surface treatments (through loss on ignition), demonstrated poorer reproducibility, but still within 5 fold differences. This poster will outline the research need for estimations of achievable accuracy under realistic conditions, present the results from this study for each of the techniques assessed and provide a discussion on the implications of this research for current approaches to similarity assessment and grouping of nanoforms based on intrinsic physicochemical properties.

6.03.P-Th197 Standardizing Methodologies in Ecotoxicology: Adapting Technical Guidelines to Assess Engineered Nanoclays (LDHs) Toxicity to *Daphnia magna*

Fábio Campos¹, Patricia Silva², Roberto Martins³ and Susana Loureiro², (1)CESAM & Department of Biology, Universidade de Aveiro, Aveiro, Portugal, (2)Universidade de Aveiro, Portugal, (3)CESAM & Department of Biology, Department of Biology, University of Aveiro, Aveiro, Portugal

The expansion of the nanotechnology market may lead to the release of nanomaterials (NMs) into the environment. Consequently, there is an increasing need to evaluate their potential risk to the environment and humans. However, the wide variety and distinct

physico-chemical properties of NMs make their environmental risk assessment very challenging. The standard guidelines currently available do not account for all the nano-specificities, leading to uncertainties regarding NM's hazard assessment. Zn-Al layered double hydroxides (LDHs) are anionic nanoclays with 20 to 40 nm in height, standing as an innovative NM-based solution for a wide range of medical, environmental, or industrial applications, such as corrosion and/or biofouling prevention, or eutrophication mitigation. Such NM properties lead to several challenges when developing strategies to assess their hazard. Considering this, the present study aimed to i) assess the influence of two different OECD-recommended exposure methodologies (serial dilutions of the stock dispersion vs. direct addition of NM powder to each concentration) in the ecotoxicological profile of Zn-Al LDH (bulk powder) to the freshwater species *Daphnia magna*; ii) use the preferred methodology to evaluate the toxicity of different Zn-Al LDH grain size powders (bulk powder, < 25, 25-63, 63-125, 125-250 and >250 µm) to *D. magna*. In the direct addition of NM powder methodology, Zn-Al LDH was weighted individually for all tested concentrations. For the serial dilutions methodology, a stock dispersion was made and used for the highest tested concentration, with the remaining concentrations being achieved by a serial dilutions method. The direct addition of NM to each concentration was deemed as the preferred exposure methodology as the results revealed less variability. For the second aim, the ecotoxicological tests involving the different Zn-Al LDH grain size powders were performed using this methodology. The results showed that different grain sizes caused different toxic effects in *D. magna*. Some of the used Zn-Al LDH grain size powders were less toxic compared to the bulk Zn-Al LDH (with high variability in grain size distribution), helping to advise the producer company on the more eco-friendlier granulometry for several applications. Moreover, our findings support Zn-Al LDHs as a less toxic option compared to other Zn nanoforms (e.g. ZnO). To conclude, this study provides important data to help harmonizing methodologies for standardized protocols for testing NMs hazard. In the future, interlaboratory testing should be performed to establish standardized guidelines for ecotoxicological testing with Zn-Al LDHs.

6.03.P-Th198 Reliable Algal Testing of Nanomaterials - Results From an Inter-Laboratory Study

Lars Skjolding¹, Sara Sørensen², Jane Bergstrøm³, Anastasia Georgantzopoulou⁴, Lindsey St Mary⁵, Anna Bradshaw⁵, Miguel Sanchez-Lopez⁵, Emily Didaskalou⁶, Villem Aruoja⁷, Teresa Fernandes⁵, Martina Vijver⁸ and **Anders Baun**², (1)DTU, Denmark, (2)DTU Environment, Denmark, (3)DHI group, Denmark, (4)NIVA - Norwegian Institute for Water Research, Norway, (5)Heriot-Watt University, United Kingdom, (6)Leiden University, Netherlands, (7)Laboratory of Environmental Toxicology, National Institute of Chemical Physics and Biophysics, Tallinn, Estonia, (8)CML Leiden University, Netherlands

The algal toxicity test is one of three mandatory tests required for classification, labelling, and safety assessment purposes in European and international chemical and nanomaterial regulations. Algal testing of nanomaterials has traditionally faced a number of challenges affecting the reproducibility of test results and hence their regulatory adequacy. To address these challenges, we have previously developed a testing platform, LEVITATT (LED Vertical Illumination Table for Algal Toxicity Tests) within the EU project PATROLS. In the current study, the LEVITATT and a standard operating procedure (PATROLS SOP) compliant with OECD TG201 was tested for repeatability (intra-laboratory variability) and reproducibility (inter-laboratory variability). The latter was done in a round-robin test with five European laboratories as participants. The validity of results obtained in the round-robin testing was addressed by the inclusion of a reference toxicant (3,5 dichlorophenol) as one of the two test compounds. In terms of variability, the round-robin testing of 3,5 dichlorophenol was comparable to the ISO 8692 round-robin test (coefficients of variation 0.41 and 0.38 for the PATROLS and ISO testing, respectively). This, as well as comparisons of EC_{50,72h,-} values confirmed the validity of the PATROLS round-robin test. For the tested nanomaterial, CeO₂ (NM-212), a somewhat larger variability was found. While this was to be expected when nanomaterials are tested, the variability could largely be traced back to the method for biomass determination. When comparing test results using the method recommended in the PATROLS SOP, the variability of test results in the round-robin test obtained with NM-212 was in the same range as seen for the reference toxicant. Based on the above, it is concluded that the PATROLS SOP and the LEVITATT testing setup increases the reliability of algal toxicity testing of nanomaterials by introducing practically feasible methods and testing principles that have been documented to be in compliance with regulatory requirements.

6.03.P-Th199 Nanoclays (LDHs) As Eco-Friendly Nanomaterials: Testing Their Safety Towards Freshwater Species

Patricia Silva¹, Fabio Chen¹, Fábio Campos², Evila Pinheiro Damasceno³, João Tedim² and Susana Loureiro¹, (1)Universidade de Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)Department of Biology & CESAM - University of Aveiro, Aveiro, Portugal

Layered double hydroxides (LDHs) are emerging engineered nanomaterials, having recently received a lot of attention from both industry and academia. LDHs are anionic nanoclays, composed of positively-charged layers with di- and trivalent metal cations, and stabilized by anions and water molecules in the interlayers. Their excellent anion exchange ability and memory effect are some of the outstanding properties that make these nanomaterials attractive for a vast field of applications, such as medicine, pharmaceutical, biotechnology, among others. Even though LDHs have been regarded as promising eco-friendly nanomaterials, their ecotoxicological effects towards organisms need to be tested to ensure their safety and regulation. In particular, there is a lack of studies on the ecotoxicity of LDHs to freshwater species, which is critical for regulatory purposes due to their applications for remediation of water bodies and antifouling paints. Considering this, the aim of this study was to assess the ecotoxicity of Zn-Al LDHs and Mg-Al LDHs (calcined and non-calcined), in several test model freshwater species: the microalgae *Raphidocelis subcapitata* (algal growth inhibition test), the zebrafish *Danio rerio* (fish embryo toxicity test), the water flea *Daphnia magna* (acute immobilization test) and the macrophyte *Lemna minor* (growth inhibition test). Overall, results showed that LDHs have very low toxicity to the species tested, with EC₅₀ > 100 mg/L to *R. subcapitata*, *D. magna*, *D. rerio* and *L. minor*. This study provides data that supports the environmentally safe application of LDHs and can be used for nanoregulations, contributing for their environmental risk assessment.

6.03.P-Th200 Evaluation of the Toxicity of Corrosion Sensing Coatings Lixiviates to Marine Microalgae and Crustaceans

*Ines Pimparel*¹, *Caroline Nelson*¹, *Severine Larroze*¹, *Alesia Sushkova*², *Manon Wilhelm*², *Juan Yang*³, *Monika Pilz*³ and *João Tedim*², (1)AquaBioTech Group, Malta, (2)University of Aveiro, Portugal, (3)SINTEF Industry, Norway

The project “SMARTAQUA” (MarTera ERA-NET cofund scheme of H2020) is developing an eco-friendly low-cost early corrosion detection tool which can be applied directly on maritime steel structures. Hexacyanoferrate ions $[\text{Fe}(\text{CN})_6]^{3-}$, which can coordinate with Fe^{2+} ions resulting from the corrosion of steel, giving a blue colour associated with the formation of Prussian Blue, were incorporated in layered double hydroxides (Mg-Al LDH). Entrapment of active compounds in LDH nanocarriers were found to render controlled release of $[\text{Fe}(\text{CN})_6]^{3-}$ ions under conditions relevant for corrosion processes. Fe_3O_4 magnetic nanoparticles were also developed for magnetic detection of corrosion. Then, materials were incorporated to two types of polyhedral oligomeric silsesquioxanes based formulations: LAPOSS 1 and LAPOSS 3. A total of 3 coatings per formulation were produced: a blank coating, a coating with 5wt% Fe_3O_4 , and a coating with 5 wt% Mg-Al/ $[\text{Fe}(\text{CN})_6]^{3-}$. The coatings were applied to glass slides, cured, and submerged in Sea water at $20 \pm 2^\circ\text{C}$ at 30 rpm in brown Duran bottles. Samples of the lixiviates were taken after 1, 3, 7, 10 and 30 days and tested on the marine microalgae *Tetraselmis chuii* and the crustacean *Artemia salina*. Cultures of *T. chuii* were maintained at $20 \pm 1^\circ\text{C}$ and a photoperiod of 12 h light: 12h dark in medium (F/2+ Si Guillard). Growth inhibition following exposure tests was evaluated following the ISO 10253:2016 adapted to 24 wells microplates using raw lixiviates or after filtration at $0.45\ \mu\text{m}$. *A. salina* nauplii were transferred to lixiviates and incubated at $25 \pm 2^\circ\text{C}$ for 24 hours when their mobility was assessed. For microalgae assays, filtration had no impact on the toxicity of coatings with LDH but increased the toxicity of coatings with Fe_3O_4 . Lixiviates of all coatings LAPOSS 1 induced around 50% microalgae growth inhibition regardless of the day of sampling. Lixiviates of LAPOSS 1 with Fe_3O_4 or LDH at 5 wt% induced similar growth inhibition levels compared to the blank coating, indicating the toxic effects observed originated from compounds lixiviated from the coating matrix of LAPOSS 1, and these components were already lixiviated 24 hours after immersion. Lixiviates from the coating LAPOSS 3 did not induce marine microalgae growth inhibition. Immobility tests with *A. salina* results indicated the lixiviates of LAPOSS 1 and 3 with or without additives had no toxic effects to the crustacean even after 30 days of lixiviation.

6.03.P-Th201 Bioaccumulation of Non-Dissolvable Engineered Nanomaterials in Freshwater Aquatic Organisms: A Meta-Analysis of the Available Data

*Yuanfang Zheng*¹ and *Bernd Nowack*², (1)EMPA Technology & Society Lab, Switzerland, (2)Empa – Swiss Federal Laboratories for Material Science and Technology, Technology and Society Laboratory, Lerchenfeldstrasse 5, 9014 St. Gallen, Switzerland

Understanding the bioaccumulation of engineered nanomaterials (ENMs) is essential for regulatory decisions on potential environmental risks. Research in the field of ENMs bioaccumulation has increased in recent years but the compilation and statistical analysis of the available experimental data has not been updated. We therefore performed a meta-analysis of the existing laboratory and field data on the bioaccumulation of eight types of non-dissolvable ENMs (TiO_2 , Al_2O_3 , Au, C_{60} , fullerenes, carbon nanotubes, FeO_x , graphene, polystyrene) in non-mammalian freshwater aquatic organisms across three trophic levels including phytoplankton, zooplankton and fish. Three typical endpoints were used to assess the bioaccumulation potential: the bioconcentration factor (BCF), the bioaccumulation factor (BAF) and the biomagnification factor (BMF). Our results suggest that zooplankton has greater mean logarithmic BCF and BAF values than phytoplankton (3.31 vs. 1.42) and fish (2.04). ENMs are biomagnified in zooplankton with a mean BMF of 17.4 whereas trophic transfer from primary consumers (zooplankton) to secondary consumers (fish) is not observed (mean BMF of 0.13). No clear dependency was identified between the physico-chemical characteristics of ENMs (e.g. primary particle size, hydrodynamic diameter or zeta potential) and bioaccumulation, except for coated vs. uncoated particles in phytoplankton. Carbonaceous ENMs were found to be more bioaccumulated than the other ENMs, except TiO_2 . The meta-analysis of bioaccumulation data can i) deepen the understanding of bioconcentration, bioaccumulation and biomagnification of ENMs, ii) be used to support grouping strategies as a basis for a safer-by-design approach for ENMs, iii) be integrated into comprehensive hazard and risk assessments, iv) promote the standardization of testing guidelines, and v) enhance the future kinetic bioaccumulation modelling.

6.03.P-Th202 The Bioaccumulation Testing Strategy for Nanomaterials: Physico-Chemical Triggers and Read Across From Earthworms in a Meta-Analysis

*Joanne Vassallo*¹, *Richard Handy*², *Nathaniel Clark*³, *Christopher Green*⁴, *Fatima Nasser*⁵, *Kristi Tatsi*⁶, *Tom Hutchinson*⁷, *David Boyle*⁸, *Marta Baccaro*⁹, *Nico van den Brink*¹⁰ and *Claus Svendsen*¹¹, (1)School of Biological and Marine Sciences, University of Plymouth, Plymouth, United Kingdom, (2)University of Plymouth, United Kingdom, (3)University of Plymouth, Plymouth, United Kingdom, (4)DEFRA, United Kingdom, (5)Department of Environment Food and Rural Affairs, United Kingdom, (6)Corteva Agriscience, United Kingdom, (7)Reckitt Benckiser, United Kingdom, (8)Cobalt Institute, Afghanistan, (9)Wageningen University, Netherlands, (10)Toxicology, Wageningen University, Wageningen, Netherlands, (11)CEH, Wallingford, United Kingdom

Determining the bioaccumulation potential of manufactured nanomaterials (MNs) is a key part of environmental risk assessment for chemicals. For traditional chemicals, the Organisation for Economic Co-operation and Development (OECD) Test Guideline (TG) 305, bioaccumulation in fish is often used. However, for MNs, there are no approved processes to trigger or waive this test, or consider alternatives to vertebrate animals. A meta-analysis of existing data sets on particle properties and bioaccumulation in earthworms was undertaken in order to understand what particle metrics could be used as a trigger for bioaccumulation testing. An apparent steady state tissue concentration of metal from MNs exposure in the earthworm (*Eisenia fetida*) was evident following exposures to Ag nanoparticles (NPs), CuO NPs and CdTe quantum dots (QDs). Nano bioaccumulation factors (*n*BAFs) were calculated using soil and earthworm tissue metal concentrations. A prediction equation using all the particle metrics correlated with BAFs was possible. Similarly, nano biomagnification factors (*n*BMFs) were calculated in the rainbow trout

(*Oncorhynchus mykiss*) tissue, relative to the concentration of total metals in the fish diet. Pearson's correlations were found to be significant, with $p < 0.05$ for n BMFs for the liver, mid intestine, hind intestine and kidney relative to the earthworm tissue n BAFs. The results with silver and copper nanomaterials showed that the earthworm bioaccumulation test is predictive of the fish bioaccumulation test and that there is scope to predict the bioaccumulation potential of MNs with confidence from a few simple particle metrics.

6.03.P-Th203 The Bioaccumulation Testing Strategy for Nanomaterials: Correlations With Particle Properties and a Meta-Analysis of In Vitro Alternatives to In Vivo Fish Tests

Nathaniel Clark¹, Richard Handy², David Boyle³, Joanne Vassallo⁴, Christopher Green⁵, Fatima Nasser⁶, Tarryn Botha⁷, Victor Wepener⁸, Nico van den Brink⁹ and Claus Svendsen¹⁰, (1)University of Plymouth, Plymouth, United Kingdom, (2)University of Plymouth, United Kingdom, (3)Cobalt Institute, Afghanistan, (4)School of Biological and Marine Sciences, University of Plymouth, Plymouth, United Kingdom, (5)DEFRA, United Kingdom, (6)Department of Environment Food and Rural Affairs, United Kingdom, (7)University of South Africa, South Africa, (8)North-West University - School of Biological Sciences, South Africa, (9)Toxicology, Wageningen University, Wageningen, Netherlands, (10)CEH, Wallingford, United Kingdom

In a regulatory context, determining the potential of substances to bioaccumulate is a key part of the chemical safety assessment. For manufactured nanomaterials (MNs), given the breadth of forms produced, it is not ethical or practical to test all materials using vertebrates in line with the 3R's (replacement, reduction, refinement). This study aimed to show how alternative methods could predict the *in vivo* bioaccumulation potential of MNs in fish. This included exploring the physico-chemical properties of MNs as predictors of bioaccumulation, using the *ex vivo* gut sac technique to measure total metal uptake, and an *in chemico* digestibility assay to simulate the bioaccessible metal in the gut lumen of fish. An apparent plateau in net metal accumulation by rainbow trout was evident from data on dietary exposures for 4 weeks to CuO nanoparticles (NPs), Ag NPs or Ag₂S NPs *in vivo*. From the metal concentrations in the tissues compared to the diet, it was possible to derive nano biomagnification factors (n BMFs) from tissue total metal concentrations approaching steady state, which varied between organs and materials from 0.0004 to 1.5162. For instance, the CuSO₄, CuO NPs, AgNO₃, Ag NPs and Ag₂S NP liver BMFs were 0.3782, 0.3942, 1.3186, 1.3372 and 0.1240, respectively. The n BMF for the liver showed the best correlations with the physico-chemical parameters, with a significant correlation to the particle dissolution rate (Spearman's correlation, $p < 0.01$). The mid intestine mucosa of the *ex vivo* gut sac technique also gave good correlations to *in vivo* liver tissue total metal concentrations, with r^2 values between 0.8 and 0.9. For example, the correlation coefficients between the mid intestine mucosa and the liver tissue total metal concentrations of the CuSO₄, CuO NPs, AgNO₃, Ag NPs and Ag₂S NPs were 0.9067, 0.7639, 0.9167, 0.8326 and 0.9142, respectively. Moreover, there was a significant relationship between the total metal released in the stomach compartment of the digestibility assay and the total metal concentration in the liver of trout *in vivo* (Pearson's correlation coefficient, $p = 0.02$), suggesting the *in chemico* digestibility assay can predict the bioaccumulation potential of the ENMs. In conclusion, the meta-analyses supports the development of an integrated and tiered approach to bioaccumulation testing that considers the 3Rs and minimises the use of the fish bioaccumulation test (e.g., OECD TG 305), for manufactured nanomaterials.

6.03.P-Th204 Environmental Fate of CeO₂ Nanoparticles - Critical Evaluation of Available Data and Implications for Exposure Assessment

Nele Deleebeck¹, Francesco Fratepietro¹, Michiel Claessens² and Anne-Lise Mandrillon³, (1)Arcadis Belgium, Belgium, (2)Chemours, Belgium, (3)SOLVAY, France

Cerium dioxide nanoparticles are being used in important applications such as automotive catalysts, industrial polishing, and various niche applications. As of 1 January 2020, REACH dossiers needed to be updated taking into account the various information requirements for nanomaterials as stipulated by the amended REACH Annexes, although for multiple endpoints no harmonised or internationally standardised methodologies dedicated to the testing of nanomaterials were available yet. For cerium dioxide, a huge amount of information has been published or made publicly available over – predominantly – the past two decades. Inevitably, studies were performed according to different methodologies, which complicates their overall assessment. In view of the update of the REACH dossier, this huge amount of information has been critically evaluated, taking into account current recommendations for the environmental fate testing of nanomaterials (where available), to arrive to a selection of sources that – in a weight of evidence approach – best reflects the findings on the different endpoints. In this poster, an overview will be given of the approach followed and the main findings. Additional discussion will be included on the implications for environmental exposure assessment and the assessment of exposure of humans via the environment, the mismatch between input parameters for available exposure models and available data, and the possibilities to assess exposure and risk in a qualitative or semi-quantitative way.

6.03.P-Th205 Marine Hazard Assessment of Soluble and Nanostructured Forms of the Booster Biocide DCOIT in Tropical Waters

Fernando Perina¹, Cristiane Ottoni², Juliana Vitoria Nicolau dos Santos², Vithoria Santos², Mariana Bruni², Bruno Campos², Mayana Karoline Fontes³, Debora Santana², Frederico Maia⁴, Denis Abessa² and Roberto Martins⁵, (1)University of Aveiro, Portugal, (2)Sao Paulo State University - UNESP, Brazil, (3)UNIVERSIDADE ESTADUAL PAULISTA - UNESP, Brazil, (4)Smallmatek - Small Materials and Technologies, Lda., Portugal, (5)CESAM & Department of Biology, Department of Biology, University of Aveiro, Aveiro, Portugal

Recently, the encapsulation of commercial AF biocides, such as DCOIT, in mesoporous silica nanocapsules (SiNC) has demonstrated to be an efficient and eco-friendly alternative to current state-of-the-art booster biocides. However, there is little information on the chronic effects on non-target tropical species, which is critical for a more comprehensive environmental risk

assessment of such innovative nanomaterials. Thus, the present study aimed at assessing the chronic toxicity of both soluble and encapsulated forms of DCOIT (DCOIT and SiNC-DCOIT) on tropical marine species as well as at assessing the chronic hazard of both conventional and nanostructured AF additives in the tropical environment. To accomplish this goal, short and long-term chronic exposure tests were carried out on six ecologically-relevant tropical marine species, including bacteria, fungi, microalgae, and sensitive life stages of crustaceans and echinoderms, for which NOEC values were calculated. For the marine hazard assessment, NOEC values available in the literature for other marine species reported on tropical waters were also considered. The marine tropical hazard assessment of DCOIT and SiNC-DCOIT was based on the determination of the predicted no-effect concentration ($PNEC_{\text{marine}}$) using the probabilistic approach (species sensitivity distribution method). As the main findings, DCOIT was the most toxic compound for all tested tropical species (lowest $NOEC=0.03 \mu\text{g DCOIT/L}$). Apart from the tested bacteria and fungi ($NOEC \geq 100 \mu\text{g/L}$), the nanostructured form of DCOIT was 3 to 10-fold less toxic than its free soluble form. Probabilistic-based $PNEC_{\text{marine}}$ was set on 0.0001 and 0.0097 $\mu\text{g DCOIT/L}$ for the soluble and nanostructured forms of DCOIT, respectively. Accordingly, the immobilization of DCOIT into SiNC led to an 84-fold hazard decrease which is more expressive compared with the most conservative approach to determine the $PNEC$ values for temperate species (2-fold decrease). These findings confirmed that the encapsulation of DCOIT into SiNC is a promising eco-friendly alternative technique, even in a chronic exposure scenario. Finally, the present study brought contributions of paramount importance to better understand and manage the environmental risks of such innovative products in marine tropical areas.

6.03.P-Th206 Form-Specific Environmental Risk Assessment of Three Engineered Nanomaterials (Nano-Ag, Nano-TiO₂, and Nano-ZnO) in Freshwaters

Hyunjoong Hong¹, Veronique Adam¹ and Bernd Nowack², (1)EMPA Technology & Society Lab, Switzerland, (2)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Engineered nanomaterials (ENMs) are widely applied in many commercial products and applications. The fate and toxicity of ENMs vary depending on the forms in which the ENMs are released into the environment (i.e. pristine, dissolved, transformed, and matrix-embedded forms). So far, environmental risk assessments for ENM have not considered the released form. The aim of the current study was to estimate the form-specific environmental risk of nano-Ag, nano-TiO₂ and nano-ZnO for European freshwaters. The form-specific material flow analysis was based on Adam et al., (2018). Probability distributions of predicted environmental concentrations (PEC) for freshwaters were obtained for the different forms. Probabilistic species sensitivity distributions were obtained for the different released forms based on an analysis of the ecotoxicological literature. The risk characterization ratio (RCR) was calculated by dividing the PEC distributions by the $PNEC$ distributions. The total risk of an ENM was determined by summing the RCRs for each ENM form.

All RCR distributions of the different forms of nano-Ag and nano-TiO₂ were lower than 1 and indicated acceptable environmental risks. None of the means of the RCR distributions of different forms of nano-ZnO were greater than 1. However, 20% of the RCR estimations for pristine ZnO and 1.45% of the RCR estimations for transformed ZnO exceeded the value of 1. The overall risk of ENM considering the released forms was compared with the standard approach which computes RCR values regardless of the released form and is based on the hazard assessment of the pristine nanoparticulate form. The overall risk of nano-Ag and nano-ZnO decreased by considering the released form. The RCRs of nano-TiO₂ were estimated to be the same in both methods as transformation or dissolution is not relevant for this material.

The results of this work show that there is now sufficient information available to perform form-specific risk assessments for ENM. The first results indicate that considering the released form changes the risk assessment and thus a further extension of this approach and incorporation into regulatory risk assessment needs to be moved forward.

6.03.P-Th207 Environmental Hazard Assessment of CeO₂ Nanoparticles - How to Evaluate the Huge Amount of Available Ecotoxicological Data in a Transparent Way for Regulatory Purposes

Nele Deleebeek¹, Michiel Claessens², Laura Lefevre¹ and Anne-Lise Mandrillon³, (1)Arcadis Belgium, Belgium, (2)Chemours, Belgium, (3)SOLVAY, France

Cerium dioxide nanoparticles are being used in important applications such as automotive catalysts, industrial polishing, and various niche applications. As of 1 January 2020, REACH dossiers needed to be updated taking into account the various information requirements for nanomaterials as stipulated by the amended REACH Annexes, although for multiple endpoints no harmonised or internationally standardised methodologies dedicated to the testing of nanomaterials were available yet. For cerium dioxide, a huge amount of information has been published or made publicly available over – predominantly – the past two decades. Inevitably, studies were performed according to different methodologies, which consequently resulted in contrasting findings. In view of the update of the REACH dossier, this huge amount of information has been critically evaluated, taking into account current recommendations for the testing of nanomaterials, to arrive to a selection of sources that – in a weight of evidence approach – best reflects the findings on the different ecotoxicological endpoints. In this poster, an overview will be given of the approach followed and the main findings. Where applicable, additional discussion will be dedicated to the impact of methodology on the observations in the different studies, and to the importance of studying sub-apical endpoints to unravel mode of action as well as apical endpoints to retain a view on the potential ecological relevance of observed effects, if any. Also, the attention is drawn to the fact that for risk assessment purposes, there is a clear need to fully understand the environmental fate and behaviour of the nanoparticles – discussed in the poster “Environmental fate of CeO₂ nanoparticles – critical evaluation of available data and implications for exposure assessment” also submitted in this Session – to be able to place any observed effects into perspective.

6.04 Impact assessment of chemical alternatives and beneficial substitution

6.04.T-01 Delphi Study to Identify and Assess Factors Specifying the Concern of Persistent Chemicals to Support Risk Management

Karen Thiele¹, Silke Gabbert² and Hilde Tobi³, (1)Wageningen University & Research, Germany, (2)National Institute for Public Health and the Environment (RIVM), Netherlands, (3)Wageningen University, Netherlands

Due to the lack of information on risks or impacts on the environment and on human health, a fundamental challenge for effective risk management of PBT/vPvB substances is therefore, to prioritise those substances for regulatory action which are of highest concern. So far, there is no comprehensive and systematic approach identifying which information on PBT/vPvB substances is (most) relevant in order to support risk management decisions. This also applies to new hazard categories that are currently under debate such as PMT substances. Obviously, expert knowledge is an important source of information to support prioritisation and decision-making in the risk management of PBT/vPvB substances. To date, a thorough understanding of what experts would consider to be relevant factors characterising the concern of persistent chemicals is lacking. The purpose of this study is to explore experts' opinions on what factors they consider relevant for specifying the concern of PBT/vPvB substances to risk managers. Specifically, the purpose of the study is to contribute to a better understanding of the PBT/vPvB concern by exploring · what factors experts consider to be important to specify the concern about PBT/vPvB substances. · how experts evaluate the importance of these factors. · the level of agreement among experts. · if there are differences in the opinion of experts from different groups (i.e. science, authorities, industry and NGOs) or different global regions. In our talk we will follow up on the presentation during SETAC Europe 2021 by providing insights into the process, the intermediary results as well as the lessons learnt of this Delphi study. The results of this Delphi study can facilitate a better understanding of the PBT/vPvB concern, which contributes to a better-informed risk management of persistent chemicals in different ways: (i) by exploring factors considered to characterise this concern, (ii) by revealing level of agreement among experts and potential patterns between different stakeholder groups and (iii) by providing input to prioritising information to support regulatory strategies and decision-making on phase-out of these chemicals, as envisaged under, for example, the European Chemicals Strategy for Sustainability.

6.04.T-02 Applying the Essential Use Concept Within the REACH Authorisation Process

Flora Borchert¹, Romain Figuière², Christina Rudén³, Ian Cousins³ and Marlene Ågerstrand³, (1)Stockholm University, ACES, Sweden, (2)Department of Environmental science, Stockholm University, Stockholm, Sweden, (3)Stockholm University, Sweden

Since the suggestion to implement the essential use concept (EUC) from the Montreal Protocol to determine when uses of PFAS should be phased out the concept has been discussed in the peer-reviewed literature as well as regulatory settings such as the new EU Chemicals Strategy for Sustainability (CSS). Researchers developed the categories “non-essential”, “substitutable” and “essential” to evaluate necessity of the continued use of a substance of concern. At present, it is not clear if and how this categorisation approach can be integrated into existent chemicals regulation, i.e. the REACH Authorisation process, in order to decide if a continued use is essential or not. Further, if a substance is anticipated to be substituted, there is a risk that the alternative is not safer than its predecessor (known as regrettable substitution). Thus, to reach the goal of a non-toxic environment as stated in the CSS the assessment of alternatives needs to be done in a comprehensive, thorough, and transparent way. The objectives of this study were to (a) investigate if and how the EUC has been (implicitly) referred to in the REACH Authorisation process, (b) analyse how alternatives to substitutable substances are assessed in applications for authorisation at present, and (c) clarify and suggest how the EUC could fit in the REACH Authorisation process. We analyse REACH regulation articles 55 to 66 and the applications for authorisation by industry on which the ECHA's Committee for Socio-Economic Analysis (SEAC) has published its final opinion on. Elements of the EUC are implicitly incorporated in the REACH Authorisation process as companies are required to justify the importance of the function provided by a SVHC in a particular use in order to get an authorisation. They are also supposed to show the socio-economic impacts if they were not able to use the substance anymore. There is still a need for guidance in order to effectively integrate and apply the EUC for REACH Authorisations. This could be a questionnaire that results in a “degree of essentiality”, and includes a statement of values and preferences. Preliminary results further suggest that the hazard screening of alternatives performed by applicants for authorisation lack of thorough evaluation of (eco-) toxicological endpoints, data and transparency which hampers identification of safer alternatives and could result in regrettable substitution.

6.04.T-03 Persistent but Pivotal - Which Uses of Persistent Chemicals DO European Citizens Consider Essential or Non-Essential for Society?

Annika Karinen¹, Silke Gabbert², Jeroen Devilee¹, Arianne de Blaeij³, Hilde Tobi⁴ and Martijn Beekman², (1)Dutch National Institute for Public Health and the Environment (RIVM), Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands, (3)National Institute for Public Health and the Environment RIVM, Netherlands, (4)Wageningen University, Netherlands

One aim of the European Chemicals Strategy for Sustainability (CSS) is to phase out Substances of Very High Concern (SVHC), such as chemicals classified as persistent, toxic, and bioaccumulative (PBT) or very persistent and very bioaccumulative (vPvB), unless their use is considered essential for society. However, clear criteria to distinguish between essential and non-essential uses are yet to be identified. Hence, the aim of this project is threefold. First, we provide an overview of the criteria for essential use that have been suggested in the literature. This literature review illuminates different criteria and frameworks to define essential use, as well as insights into past applications of the essential use criteria as specified in the Montreal Protocol, a multinational environmental agreement to phase out ozone-depleting substances. Second, we present the results of a participatory stakeholder consultation aimed at identifying societal goals that the use of persistent chemicals should contribute to in order to be considered essential for society. In total, 14 societal goals emerged: health, food and water, shelter, energy, safety, security, climate and the environment, mobility, communication, education, culture, recreation, innovation, and economy. These results suggest

considerable diversity in stakeholder views considering essential use of persistent chemicals. Third, we present the first results from an EU citizen's survey examining which uses of persistent chemicals do EU citizens consider essential or non-essential for society. The EU citizen's survey is, to the best of our knowledge, the first to examine citizen's perspectives on essential use of persistent chemicals. The results from this survey will inform us of the uses that EU citizens consider essential or non-essential for society, whether emphasizing the consequences of allowing or not allowing the use of persistent chemicals affects essentiality ratings, and whether nationality, age, gender, socioeconomic status, education, or political orientation affect essentiality ratings. Data collection will take place in early 2022, and the first results from this survey will be presented at the SETAC plenary.

6.04.T-04 Comparative Ranking of the Long-Term Impact Potential of Chemical Substances

Monika Nendza¹, Stefan Hahn², Michael Klein³, Ursula Klaschka⁴ and Silke Gabbert⁵, (1)Analytisches Laboratorium, Germany, (2)Fraunhofer ITEM, Hannover, Germany, (3)Fraunhofer IME, Germany, (4)University of Applied Sciences, Germany, (5)National Institute for Public Health and the Environment (RIVM), Netherlands

Replacing substances of concern by less harmful alternatives is a straightforward strategy for reducing the environmental and health impact of chemicals. A new concern-based scoring scheme allows for flexible and transparent comparative ranking of the impact potential of chemical alternatives (SCoRA). The approach accounts for hazards due to ecotoxicity to organisms in water/sediment and soil, and effects on human health such as CMR properties and endocrine disruption. Exposure-related information, in particular the expected environmental pollution stock levels, is then also taken into account. Both hazard and exposure information are translated into ordinal scores and weighted with factors addressing substance- and scenario-related uncertainties due to (yet unknown) long-term impacts. Aggregation of the individual substance-specific scores yields the overall impact potential, which is used for an ordinal ranking of chemicals. Visualisation of concern components by a heatmap and fingerprints allows for a practical comparison of the potential impact of different substances. The SCoRA approach is illustrated using case study chemicals of very high concern (15 SVHC, mostly PBT, representing different chemical classes with different modes of bioaccumulation and toxicity). Notably, there are substantial differences between the impact profiles of these substances. CMR properties stand out in addition to PBTness. Fingerprinting underlines that, by covering a broad range of concerns, SCoRA goes well beyond binary screening criteria, e.g. for PBTness, and allows for a comprehensive characterisation of concerns especially in cases where a particular metric is just below, close to or just above a threshold. SCoRA, therefore, offers a complement to established chemical assessment tools under REACH and other regulations. In conclusion, SCoRA is an effective tool to compare and to communicate the impact potential of chemicals based on consistent criteria (impact scores) and supports decision-making towards safe and sustainable substitution.

6.04 Impact assessment of chemical alternatives and beneficial substitution (Poster)

6.04.P-Th208 Ecotoxicological Assessment of Two Potential Environmentally Friendly Red Dyes

Natalia de Farias¹, Anjaina Fernandes de Albuquerque², Harold S. Freeman³, Riikka Raisanen⁴ and Gisela Umbuzeiro⁵, (1)UNICAMP, Limeira, Brazil, (2)UNICAMP - University of Campinas, Brazil, (3)North Carolina State University, United States, (4)University of Helsinki, Finland, (5)School of Technology- UNICAMP, Brazil

Research on natural resources has increased and, biocolourants have been investigated as an alternative source of color for textiles to synthetic dyes, which can have harmful effects on the environment and ecological balance. The possibility of using natural dyes to help achieve the production of sustainable materials has not been properly explored. The objective of this work was to evaluate the aquatic toxicity of two highly purified anthraquinone red dyes, dermocybin (>99%) and dermorubin (>98%) obtained from the fungi *Cortinarius sanguineus*. Tests were conducted in concentration-response experiments. Dyes were dissolved in Dimethyl sulfoxide (DMSO) at the limit of solubility and tests were conducted with a maximum of 0.01% DMSO as recommended by OECD 23. A chronic toxicity test was performed with the freshwater *Pseudokirchneriella subcapitata* according to OECD guideline 201. After 72h of exposure to dermocybin (0.1 – 0.7 mg/L) and dermorubin (0.0625 – 1 mg/L), growth inhibition was evaluated and the IC₅₀ was determined. Acute toxicity tests with *Daphnia similis* were performed according to OECD guideline 202. Immobilized organisms were counted after 48h of exposure to dermocybin (0.035 – 0.7 mg/L) and dermorubin (0.03 – 1 mg/L), and EC₅₀ was determined. For lethal and sub-lethal toxicity assessment a fish embryotoxicity test (FET) was performed according to OECD guideline 236 with the extension of time exposure of 96h to 168h at concentrations range 0.01 to 1 mg/L for dermorubin. Mortality and developmental abnormalities were registered daily. FET test with dermocybin is underway. For both dyes, it was not observed significant differences in cell density of microalgae between treatments and the control group, with an IC₅₀ > 0.7 and 1 mg/L for dermocybin and dermorubin, respectively. Dermorubin was not toxic to *D. similis* with an EC₅₀ > 1 mg/L, while dermocybin showed acute toxicity, with an EC₅₀ of 0.99 mg/L. Dermorubin did not affect the survival of embryos/larvae or caused any other sublethal effect, EC₅₀ > 1mg/L. Our findings emphasize that those two dyes seem to be promising and can be part of a family of environmentally friendly natural dyes for traditional and waterless dyeing technologies. For future studies, chronic tests will be performed with *Ceriodaphnia dubia* and also, we will evaluate the genotoxicity of the dyes using the Comet assay with zebrafish.

6.04.P-Th209 Risk Indicators for Pesticides Based on Sales, Exposure, Ecotoxicity and Mitigation

Muris Korkaric¹, Lolita Ammann¹, Irene Hanke¹, Jérôme Schneuwly¹, Mikko Lehto¹, Thomas Poiger¹, Laura De Baan¹, Otto

Daniel¹ and Judith F. Blom², (1)Agroscope, Switzerland, (2)Plant Protection Products - Impact and Assessment, Agroscope, Switzerland

The European Commission's «Sustainable Use of Pesticides» Directive aims to reduce the use of pesticides and the associated risks by promoting alternative approaches or lower-risk techniques. To measure progress towards the main objective of this Directive, the «Harmonized Risk Indicator» (HRI) has been introduced. It shows the change in sales volumes of active ingredients of plant protection products (PPPs) divided in four categories, with each category assigned a weighting that is used when adding up the sales volumes. However, as the HRI does not consider exposure (i.e. the concentration of active ingredients in environmental compartments) or ecotoxicity, risk mitigation measures cannot be accounted for. The aim of this study was to develop suitable risk indicators for PPPs that can show trends in the risks to organisms in surface waters and terrestrial habitats, as well as groundwater pollution. These indicators are based on the sales figures of PPP active ingredients and take into account their exposure and ecotoxicity as well as the effects of risk mitigation measures. To calculate the risk indicators, a *Treated Area* is determined for each active substance and multiplied by a *Risk Score* and a *Risk Reduction* factor. The *Treated Area* is estimated by dividing the annual sales figures of each active ingredient by its average agricultural application rate. The *Risk Score* expresses the exposure of the active ingredients in each environmental compartment based on a standardized application, taking into account the environmental chemical properties of the active ingredients. For the risk indicators «Surface Water» and «Terrestrial Habitats», the exposure is multiplied by the ecotoxicity for aquatic and terrestrial organisms, respectively. The *Risk Reduction* factor considers product-specific mitigation measures as well as general risk-reducing measures (e.g. in relation to drift or run-off) and their rate of implementation. The new approach presented here allows to show both changes in sales of high-risk PPPs and effects of product-specific and general mitigation measures. This is a clear advantage over existing risk indicators such as the HRI and can help to assess the risk-reduction goals of national policies. Moreover, the calculation on a factor-by-factor basis also provides sufficient flexibility to incorporate future mitigation measures as well as new data on implementation rates.

6.04.P-Th210 Bioadditives for Sustainable Energy Production

Ogemdi Chinwendu Anika, MSc and Raffaella Villa, De Montfort University, United Kingdom

Imagine what goes on in the stomach of cows when they feed on grass and what comes out as by-products. Also imagine the possibility of trapping the gaseous components of the by-products in a balloon for use as an energy source. All the activities that occur in the stomach of cows as they feed are termed anaerobic digestion, which is the breakdown of organic matter in the absence of oxygen to release biogas rich in methane and solid deposits that can serve as organic fertiliser. The problem, however, is that agricultural emissions, particularly that from the stomach of cows are major contributors to greenhouse gases in the environment. It is, therefore, necessary to cut down on these emissions, manage agricultural wastes and generate valuable energy by mimicking the activities that occur in the stomach of cows in enclosed systems such as bioreactors. The challenge, still, is that agricultural wastes are composed of materials that are too difficult to degrade and bioreactors are not sophisticated like the stomach of cows that are highly efficient at breaking them down. One way of resolving this challenge is by treatment with bioadditives, which are cheap, naturally sourced and environmentally friendly. Bioadditives are already used in industry with positive results but are still not optimized because there is still a gap in the knowledge of how they work. Consequently, the aim of this research, is to understand their mechanisms of action to optimize the system. So, by manipulating bioadditives in lab scale bioreactors, this research is positioned to discover how bioadditives can be used correctly to improve the anaerobic digestion process, sustainably produce more energy and stable organic fertilizer for the green farmer.

6.04.P-Th211 Importance of Customising Bioadditives Dose for AD Optimisation

Ogemdi Chinwendu Anika, MSc¹, Anna Strzelecka², Yadira Bajón -Fernández³ and Raffaella Villa¹, (1)De Montfort University, United Kingdom, (2)De Montfort University, UK, (3)Cranfield University, United Kingdom

Anaerobic digestion (AD) has been described as the golden technology for alleviating environmental issues associated with waste generation from the agricultural sector as well as representing a sustainable waste biorefinery from cheaply sourced agricultural waste biomass. The major component of agricultural biomass, lignocellulose, is composed of different polymers: cellulose (15–99%), hemicellulose (0–85%) and lignin (0–40%). These polymers have different biodegradability levels in anaerobic conditions and their ratios in the agricultural waste will affect the degradation process in different ways. This study aimed to evaluate the response of two different lignocellulosic waste biomass (ensiled corn and rye) to a commercial yeast-based bioadditive. The results showed that rye was more responsive to the bioadditive than corn as the bioconversion time was shortened by half while improving the biogas and methane yields when compared to the control by 58% and 100% respectively with a 2mg addition. Biogas increase for corn was limited to 21% with the 10 mg dose although the quality of the biogas was higher for all doses and for both substrates: 35% in corn control samples vs 37%, 41% and 38% for 1, 2 and 10 mg bioadditions respectively with corn and 47% in rye control samples vs 58%, 61% and 47% for 1, 2 and 10 mg bioadditions respectively with rye.

6.04.P-Th212 Proactive Environmental Hazard Assessment of Liquid Organic Hydrogen Carriers (LOHCs) As Novel Carriers of Renewable Energies

Yohan Seol¹, Marta Markiewicz² and Stefan Stolte³, (1)TU Dresden, Germany, (2)Institute of Water Chemistry, Technical University of Dresden, Dresden, Germany, (3)Technical University of Dresden, Germany

The development of renewable energy is an indispensable step toward a sustainable society. Liquid Organic Hydrogen Carriers (LOHCs) are very promising vectors for hydrogen storage and transportation. LOHC systems consist of a pair of H₂-lean, typically (poly)cyclic aromatic compounds, and H₂-rich form, (poly)cyclic heteroaromatic compounds. The scale of LOHC implementation can reach that of liquid fossil fuels if full replacement shall occur – in this scenario there is a high likelihood of release of LOHC chemicals into the environment. Until now, the LOHC systems based on dibenzyltoluene and benzyltoluene are

technically mature but there are some technological hurdles. Thus, it is of high interest for LOHC developers to find potential LOHC, which allow similar hydrogen capacity but also similar or better hazard profile. To avoid regrettable substitution (of fossil fuels or one LOHC system by another) a comprehensive hazard profile is crucial before widespread use. This study aims to understand the harmful effects of novel LOHC compounds by conducting ecotoxicity tests with *Raphidocelis subcapitata*, *Daphnia magna* and *Vibrio fischeri*, and biodegradation test to determine their persistence. Additionally, the octanol-water partition coefficient ($\log K_{ow}$) is used to build Quantitative Structure Activity Relationship (QSAR) to determine the mode of toxic action of novel LOHC compounds. The exposure concentration of test solutions in ecotoxicity tests was measured using LC/MS-MS. The comparative hazard assessment was conducted including comparisons between different forms of the same carrier (H₂-lean vs H₂-rich forms) and between LOHCs and conventional energy sources (fossil fuels). All tested LOHC compounds seem to be baseline toxicants (i.e. toxicity is driven by hydrophobicity of compounds). H₂-lean form of novel LOHC is readily biodegradable. On the other hand, H₂-rich and partially hydrogenated forms are rather less biodegradable. Overall, tested LOHC compounds seem to have a similar level of environmental hazard to that of diesel oil based system. The research outcome will be of the highest interest to environmental scientists, LOHC developers (in academia and industry), regulatory agencies, governments, and the general public.

6.04.P-Th308 Toxicity Testing of Technical Mixtures of Liquid Organic Hydrogen Carriers

Felix Irrgang¹, Yohan Seo², Viktor Schmalz³, Stefan Stolte⁴ and Marta Markiewicz⁵, (1)Institute of Water Chemistry, TU Dresden, Dresden, Germany, (2)TU Dresden, Germany, (3)Institute of Water Chemistry, TU Dresden, Germany, (4)Technical University of Dresden, Germany, (5)Institute of Water Chemistry, Technical University of Dresden, Dresden, Germany

Hydrogen has the potential to become a carbon neutral energy source in the upcoming century, especially if it is produced using excess renewable energy. However, currently we lack efficient storage methods, as hydrogen itself suffers from very low volumetric energy density and (cryo)compressing requires specialised infrastructure, is costly and rises issues in terms of handling safety. In recent years a new possibility of hydrogen storage emerged with liquid organic hydrogen carriers (LOHC) whereby hydrogen is chemically bound to an unsaturated, mostly aromatic, compound. Through a catalytic process the hydrogen is then recovered and can then be used (e.g., in fuel cell). Substances like (di)benzyltoluene, carbazoles, benzenes, etc. are currently being investigated or entered the market. However, little is known about the environmental behaviour of these compounds. Their physical-chemical properties (mainly relatively high hydrophobicity) suggest considerable toxicity and bioaccumulation potential. Reliable toxicity tests require a constant exposure concentration to provide solid results. To achieve that and mitigate losses during the tests (e.g., adsorption to organic matter or vessel walls, evaporation) passive dosing via a PDMS reservoir is used during the experiments. By controlling and varying the loading of the PDMS reservoir with the test substance it is furthermore possible to adjust the concentration in the test medium. Thus, it is possible to not only conduct limit tests (at the maximum water concentration) but with this approach a full dose-response tests are possible. We could show that there is a linear relationship between the loading of the polymer (up to 10 % in methanolic solution) with benzyltoluene and the resulting concentration in the medium. We furthermore conducted acute algae and daphnia toxicity tests of technical grade mixtures of LOHC based on benzo- and dibenzotoluene. We showed acute toxicity for a benzyltoluene isomer mixture and furthermore determined an EC₅₀ value for that compound.

6.05 Mixtures matter – from science to regulation and management

6.05.T-01 How to Operationalize the Mixture Assessment Factor (MAF) for Facilitating the Regulatory Risk Assessment of Chemical Mixtures?

Thomas Backhaus, University of Gothenburg, Sweden

The new EU Chemicals Strategy for Sustainability (CSS) states that “The Commission will: assess how to best introduce in REACH (a) mixture assessment factor(s) for the chemical safety assessment of substances;” Furthermore, the corresponding Annex states that the Commission will assess until 2022 how to best introduce such a MAF (mixture assessment factor) into Annex I of REACH. However, details on the operationalization of a MAF are largely missing. This presentation will first provide a brief overview of the recent regulatory developments in European chemical policy, especially exploring the conceptual demands on a MAF in the context of the CSS and the EU’s Zero Pollution Action Plan. It will then present and compare different algorithms on how to estimate an adequate size of the MAF for a given mixture, i.e. a MAF size that is sufficiently protective, but not excessive. All algorithms are based on the assumption that the mixture behaves largely concentration-additive and acknowledge the typical Pareto-distribution of individual toxic units (risk quotients). It determines the maximum tolerable total concentration of the mixture, i.e. the PNEC(mixture) using a level of protection similar to the individual chemicals. The outlined approaches will be applied to a range of published case studies, including chemical monitoring data from various chemical monitoring programs, with a focus on mixtures comprising pesticides, pharmaceuticals and industrial chemicals. Results indicate that a MAF of 5 to 50 is sufficiently protective, dependent on the chemical complexity of the mixture. Between roughly 10% and 30% of the mixture components are affected by the application of a MAF, i.e. their concentrations exceed the critical value of PNEC/MAF.

6.05.T-02 In Depth Characterisation of Chemical Co-Exposure and Cumulative Risks of Environmental Monitoring Data in the EU

Karel Viaene, Frederik Verdonck, Linh-Dan Ngo, Charlotte Nys and Marnix Vangheluwe, ARCHE Consulting, Belgium

Chemicals are typically regulated on a chemical-by-chemical basis in which regulatory frameworks set safe exposure levels. As a result, current environmental risk assessment procedures of chemicals focus on exposure to individual chemicals. However, the

recognition is growing that exposure to a cocktail of chemicals may cause risks not captured by these single chemical evaluations. Monitoring datasets offer a unique perspective on this issue as they can provide information on the co-exposure patterns of chemicals. In the current analysis the focus was on three databases: EU Waterbase, Rhine (ICPR) and EauFrance. To understand which mixtures occur in the environment, principal component analysis (PCA) was used as a data mining technique to identify and characterize observed mixtures. Additionally, cumulative mixture risk was analyzed using different techniques. The majority of the chemicals are not detected (50-80% of chemicals) and a limited set of chemicals is nearly always included in the monitoring strategies (mainly priority pollutants). The PCA revealed that most of the mixtures in the databases consist of a wide range of chemicals and are not determined by specific chemical groups. Cumulative risk analysis showed that the vast majority of the mixtures are not contributing to risk: 84-94% of the samples were predicted as being of no concern, even with a conservative assumption of additivity. The percentage of mixtures with potential concern not identified by single substance assessment is small (

6.05.T-03 MAF Implementation for Inorganic Substances: REACH Impact Assessment and Identification of Inorganic Priority Contributing Substances I-Pcs

Maxime Eliat¹, Karel Viaene¹, Charlotte Nys¹, Hugo Waeterschoot², Violaine Verougstraete³ and Marnix Vangheluwe¹, (1)ARCHE Consulting, Belgium, (2)Chemicals Management, Eurometaux, Hove, Belgium, (3)Eurometaux, Belgium

Policy makers are moving forward with the combination effects assessment of non-intentional mixtures, by proposing a Mixture Assessment Factor (MAF) under REACH. A preliminary analysis of REACH registered chemicals, performed by ECHA, indicated that a blanket MAF of 10 would allow to focus on the most relevant substances. However, inorganic substances were not included in this assessment. For these substances it is expected that such a generic MAF would be problematic for natural occurring substances. Therefore, the objectives of this study were the following: (i) assess the impact of a generic MAF on the risk characterisation ratios (RCRs) in REACH dossiers of inorganic substances; and (ii) identify ten inorganic-priority contributing substances (I-PCS) based on monitoring data for further follow-up research. The first part of the study was based on RCRs taken from the exposure scenarios in the Chemical Safety Reports (CSR) of the REACH dossiers. In total 16 inorganics were included with 846 contributing exposure scenarios out of 51 CSRs. A MAF of 10 would mean that 76% of the contributing exposure scenarios for freshwater and soil would need further refinements. A MAF of 10 applied to reasonable worst-case regional background values for freshwater will already result in RCRs > 1 for 8 out of the 16 inorganics included in this assessment. The issue is thus complicated for many inorganics by the relatively high regional background value compared to the PNEC. Scenarios to improve the reference RCRs seems only feasible for a limited number of data-poor metals. In the second part of the study, three monitoring databases were considered to identify the I-PCS: two freshwater databases (Waterbase, FOREGS) and one soil database (GEMAS). Risk quotients were calculated for all inorganics based on the measured concentrations divided by effect concentrations (both PNEC and HC5 values were evaluated). The inorganic substances most contributing to environmental risk across monitoring databases were (in alphabetic order) Ag, As, Cd, Co, Cr, Cu, Hg, Li, Mn, Ni, Pb and Zn. The choice of the effect value was critical for most inorganics, i.e., the number of samples at risk was lower using the HC5 versus the PNEC. Refinements for individual inorganics are needed to reduce the uncertainty on calculated risks. Further research will be initiated to determine the actual environmental combined risks posed by these metals in a mixture context with other metals and organics.

6.05.T-04 Petroleum Refinery Effluent Contribution to Chemical Mixture Effects in the Environment

Jiaqi Wang, MSc¹, Mathijs Smit², Yves Verhaegen³, Tom Nolte⁴, Prof. Jan A.J. Hendriks⁵ and Markus Hjort⁶, (1)Environmental Science, Radboud University Nijmegen, Nijmegen, Netherlands, (2)Shell Global Solutions International BV, Netherlands, (3)CONCAWE, Belgium, (4)Radboud University Nijmegen, Netherlands, (5)Radboud University Nijmegen, Nijmegen, Netherlands, (6)Concawe, Brussels, Belgium

Petroleum refinery effluents (PRE) are wastewaters mainly from industries associated with oil refining. Within Europe, PREs are regulated through local discharge permits and they receive significant treatment before emission. After treatment, PREs can still contain various hazardous pollutants (e.g. hydrocarbons, ammonia, heavy metals). Earlier work, including whole-effluent toxicity assessments, has shown that toxicity of PREs is often limited. However, the extent to which PREs contribute to mixture pressure in the receiving environment is unknown. Environmental risks of PREs depend on several factors including effluent compositions and receiving water conditions: exact risks may vary from case to case. Therefore, our study aimed to develop a holistic approach to assess the mixture pressure of PREs both before and after discharge, using the multi-substance potentially affected fraction of species (msPAF) as an indicator. Dissolved concentrations of total petroleum hydrocarbons (TPH) in PREs were determined based on TPH concentrations and hydrocarbon block compositions, using the PetroTox model. Species sensitivity distribution data (SSD) were compiled, and the target lipid model (TLM) was applied to compute toxicity values for TPH. Based on concentrations and SSDs, msPAF levels were calculated for more than 80 PREs at discharge points and downstream (diluted in the recipient using standard dilution factors). Computed msPAF levels were compared with msPAF background levels in European waters to assess the PRE contribution. Lastly, computed msPAF levels were compared with bioassays to assess the level of conservatism of the method. The average mixture pressure of PREs at discharge points was estimated to be 73.5% (msPAF-chronic) and 30.2% (msPAF-acute). Mixture pressure was reduced downstream, and the extent depended on the corresponding receiving environment (dilution factor). Hydrocarbons (mainly TPH) and inorganics (mainly ammonia) explained at least 85% of the mixture pressure. PREs were likely to contribute less than other sources to pollution, while the contribution varied between 0.03% to 620% of msPAF background levels across sites. Compared with available bioassays, our msPAF estimates were regarded conservative. With proper chemical characterisation of PREs, our method could be applied for risk assessment of any PRE of interest. Site and substance rankings would help identify hotspots and take effective targeted action to remediate potential risks.

6.05 Mixtures matter - from science to regulation and management (Virtual Only)

6.05.V-01 An Industrial Pollution Investigation Reinforced the One Health Concept

Frannie Nilsen, NC DEQ, United States

Emerging compounds (EC) present unique challenges to environmental scientists and regulators alike, who are both often required to chase the contamination rather than design comprehensive studies. The lack of chemical information and toxicological knowledge about ECs complicates communication between scientists, regulators, and the affected communities. An affected community in North Carolina, USA, inspired regulators to investigate an industrial polluter in new ways and devise a holistic investigation strategy through environmental science. The holistic strategy included sampling air emissions, atmospheric deposition, soil, sediment, groundwater, and drinking water; testing the effectiveness of filtration units to remove the pollutants from drinking water; conducting non-targeted analyses to identify additional unidentified ECs, aquatic and mammalian toxicology studies; and sharing the newly found information with the affected community. To date, this holistic approach as identified contaminated drinking water sources more than 17 miles away from the industrial facility, provided the data needed to enforce emissions control requirements at the facility, identified several previously unidentified ECs, and elucidated the need for cross-pollination between media-specific groups. The investigation is still in progress and has been a continual effort since 2017. This situation and the complex nature of EC investigations have highlighted the One Health concept in a regulatory and enforcement setting as well as demonstrated the importance of diverse skillsets, backgrounds, and experiences in solving complex environmental problems.

6.05.V-02 Can Commercial Formulations of Pesticides Be Optimised Towards Environmentally Safer Alternatives?

Libânia Queirós¹, Patrícia Pereira², Sirine Bouguerra³, Ruth Pereira⁴, Artur Alves², Fernando J. M. Gonçalves² and Joana Luisa Pereira², (1)CESAM & DeBio, University of Aveiro, Portugal, (2)CESAM & University of Aveiro, Portugal, (3)GreenUPorto & Faculty of Sciences, University of Porto, Portugal, (4)Faculdade de Ciências da Universidade do Porto, Portugal

The production of environmentally safe commercial pesticide products is a current concern that has been managed by the development of very specific regulation. While the formulation of new products by the agrochemical industry is restricted to the use of approved substances, namely active ingredients (AIs) and other chemicals used as co-formulants, the approval of new substances requires time, testing and investment. Thus, the reformulation of available commercial products using authorized AIs represents a faster and viable option. In this context, two commercial pesticide products were used as models in this study to assess the feasibility of their reformulation towards safer alternatives concerning effects on non-target organisms (first stage) keeping efficacy against target species (second stage). One was an herbicide formulation combining the AIs bentazone and terbuthylazine, and the other a fungicide combining azoxystrobin and tebuconazole. Terrestrial and aquatic model species were used as non-target organisms in the first stage of testing for safety assessment, and a weed and two fungal species in the second stage as recommended targets of the model herbicide and fungicide products, respectively. Specifically, the AIs were tested at recommended and alternative doses/ratios with sensitive non-target organisms (oilseed rape *Brassica napus*; microalgae *Raphidocelis subcapitata*) to identify options with reduced impacts to the environment. Then both recommended and safer alternatives were tested against the weed (*Portulaca oleracea*) or fungi (*Pyrenophora teres* and *Rhynchosporium secalis*) for efficacy assessment. Results showed that: (i) commercially recommended doses of the herbicide product represent a remarkable potential risk to soil ecosystems; (ii) application doses 10-fold lower than recommended are effective in the control of the target weed; (iii) a one-way formulation including only bentazone seems to represent an environmentally safer alternative to the two-way formulation in the control of *P. oleracea*; (iv) recommended doses of azoxystrobin and tebuconazole were not very effective in preventing the growth of the target fungi; and (v) there was not an apparent gain in the fungal growth control by combining these two fungicide AIs compared to single options. These results suggest that commercial pesticide formulations have room for optimization in order to improve their environmental safety while keeping efficacy against weeds/pests.

6.05.V-03 Ovarian Ultrastructure and Embryonic Development of the Fish *Poecilia reticulata* Exposed to Maghemite Nanoparticles (Y-Fe₂O₃) Associated With Glyphosate

Victoria Costa da Silva¹, João Marcos Faria¹, Lucas Guimarães¹, Ryan Rezende², Gustavo Cardoso³, Thamires Arantes Sardinha², Lucas Camilo Moraes Alves¹ and Simone Sabóia-Morais³, (1)Federal University of Goiás, Brazil, (2)ICB UFG, Brazil, (3)Universidade Federal de Goiás, Brazil

The synthesis of nanomaterials to act in environmental remediation and depollution of the aquatic environment indicated that the use of maghemite nanoparticles (IONP) is promising. But its ability to interact with glyphosate-based pesticides is still underexplored. Thus, to investigate the toxic effects on reproduction and embryogenesis in guppies, experiments were carried out with IONPs and those associated with GBH and GLY. Thus, 7 young and adult females of guppy (*Poecilia reticulata*) were exposed for 7.14 and 21 days in triplicate to the experimental groups with iron ions - IF (0.3mg / L) and IONPs associations (0.3 mg Fe / L) with GLY (0.65 mg / L) and GBH1 GBH2 (0.65-1.30 mg GLY / L, respectively), a control group (GC) was also considered, as well as post-exposure groups in which the same number of fish remained for an equal period in reconstituted water. The fish were euthanized, dissected, and the ovaries were fixed in 2.5% glutaraldehyde and post-fixed in 1% OsO₄, dehydrated in acetone concentrations, critically point dried (Leica EM CPD300), covered with a 20nm layer of gold in the sputtering (Leica EM SCD050) and analyzed under a scanning electron microscope (JEOL JSM IT300LV - CRTI / UFG). The ultrastructural analyzes considered the treatment/time relationship. Multiple embryos were observed at different stages, therefore, development was asynchronous and took place in waves of embryonic maturation. There was an indication of recovery in the groups exposed for the same time to reconstituted water. But the treatments promoted changes in the connective tissue structure that involves the ovary, both externally and internally, being more intense after 14 days for the IF and GLY groups. In IONPs+GBH, the alterations

were smaller, suggesting that they are larger elements and had difficulty in transposing the conjunctival barrier. Exposure to IONPs induced reproductive toxicity in female guppies, it was observed that in embryos at early and intermediate stages of development, the chorion had disorganized microfolds when compared to GC, and the outer layer of oocytes had alterations in the structure of the fibril complex of the inner layer. These analyzes demonstrated the importance of evaluating the development process in order to understand the biological characteristics of the species and indicate the capacity for preservation in vulnerable environments, which may be the target of remediation by maghemite.

6.05 Mixtures matter – from science to regulation and management (Poster)

6.05.P-We268 A Battery of EcoToxicological Tests to Assess Environmental Risk After Utilization of Mineral Fractions From Incineration Bottom Ash Treatment

Silvia Messinetti¹, Erica Tediosi², Giulia Costa³, Francesco Lombardi⁴, Iason Verginelli⁴, Lorenzo Maggi⁵, Claudia Mensi⁶ and Domenico Marchesini⁷, (1)ChemService s.r.l., Italy, (2)ChemService srl (Labanalysis Group), Italy, (3)University of Rome, Italy, (4)University of Rome Tor Vergata, Italy, (5)Labanalysis, Italy, (6)A2A, Italy, (7)ARPA Lombardia, Italy

At EU level, neither End of Waste criteria, nor a harmonized methodology for establishing the requirements for the utilization of the mineral fraction of bottom ash in construction have been issued. To promote the utilization of BA, an evaluation of the potential risks that these materials may pose to the environment and human health is needed. The aim of the project was to use a battery of aquatic and terrestrial ecotoxicological tests to characterize the risk after the use of End of Waste material from incineration BA. Ten different samples provided by four different plants were analyzed. Each sample was divided in three aliquots and the column percolation test according to EN 14405 was carried out on each aliquot. The eluates obtained were employed in the aquatic ecotoxicological tests, performed according to OECD 201 Freshwater Alga and Cyanobacteria Growth Inhibition test, OECD 202 Daphnia sp. Acute Immobilization test, OECD 203 Fish Acute Toxicity test and OECD 211 Daphnia magna Reproduction test. The tests were performed at 5 different concentrations, starting from a 1:5 dilution of the original eluate. Terrestrial ecotoxicity tests were performed on the samples that were ground to obtain a particle size of 1 mm, to grant a better homogenization with the soil. Five different concentrations ranging from 100 to 1000 mg/kg d.w. have been tested. To cover different ecological level, the tests selected were OECD 208 Terrestrial Plant Test: Seedling Emergence and Seedling Growth Test, OECD 216 Soil Microorganisms: Nitrogen Transformation Test, OECD 222 Earthworm Reproduction Test, OECD 207 Earthworm, Acute Toxicity Test, OECD 232 Collembolan Reproduction Test in Soil and OECD 226 Predatory mite reproduction test in soil. The EC₅₀ was derived for all the acute tests and the NOEC and EC₁₀ for all the chronic tests. To perform the aquatic risk assessment, the concentrations expected in the groundwater and in surface water were estimated using standardized fate and transport models that account for the attenuation during the leaching in the unsaturated zone and the dilution occurring in the groundwater and in surface water, considering three different utilization scenarios. These concentrations were compared with the endpoints derived in the aquatic toxicity tests and at least one safe use was defined for each sample. For the terrestrial risk assessment, a weight of evidence approach was used to evaluate the potential risk based on the obtained results.

6.05.P-We269 Analysis of Cumulative Risks of Unintentional Mixtures in Europe

Pim Wassenaar¹, Emiel Rorije², Jaap Slootweg³, Lonneke van Leeuwen², Fleur Van Broekhuizen⁴ and Leo Posthuma³, (1)National Institute for Public Health and the Environment (RIVM), Bilthoven, Netherlands, (2)National Institute for Public Health and the Environment RIVM, Netherlands, (3)RIVM, Netherlands, (4)European Chemicals Agency (ECHA), Finland

Unintentional exposure to chemical mixtures might be a problem, as mixtures are generally insufficiently acknowledged in chemical risk assessment. Therefore, the EU commission suggests a preventive (pro-active) approach in the form of a Mixture Assessment Factor (MAF, also referred to as Mixture Allocation Factor) to account for these risks. To stimulate the debate, this study (1) evaluated the need for addressing unintentional co-exposures to multiple chemicals in chemicals risk assessment by quantifying the fraction of water bodies that is insufficiently protected, and (2) explored the effect of fractional reductions of exposure concentrations on improving the percentage of water bodies that is sufficiently protected. We curated and aggregated EU surface water monitoring data from the NORMAN network (>9.5 million chemical measurements) to derive ambient chemical mixtures. For these mixtures, the total toxic pressure was calculated using several different approaches, including mixture Risk Characterization Ratio's (RCRs) and multi-substance Potentially Affected Fractions of species (msPAF) under several assumptions. In addition, we applied simplified scenarios to obtain insights on the effects of potential fractional exposure reduction on environmental quality. The results indicate (1) that water bodies are insufficiently protected against unintentional mixtures, (2) that a relative small fraction of chemicals (e.g. ~10%) dominate the ambient mixture toxic pressure (e.g. ~85%), and (3) that low fractional reductions in exposure concentration can result in a steep increase of the percentage of water bodies that are sufficiently protected. Although the monitoring data do not represent the full spectrum of real-life ambient mixture exposures, the results appear to be robust under several other assumptions. Accordingly, the results indicate the need for adapting policies to reach European Union goals for a toxic-free environment and underpin the utility and possible magnitude of a Mixture Allocation Factor.

6.05.P-We270 An Assessment of Chemical Risk of Unintentional Mixtures at the EU Continental Scale Based on Aquatic Chemical Monitoring Data

Ismael M Rodea-Palomares¹, Zhenglei Gao², Arnd Weyers² and Markus Ebeling³, (1)Bayer Crop Science, United States, (2)Bayer Crop Science, Germany, (3)Environmental Safety, Bayer Crop Science, Germany

Existing regulatory frameworks in the EU have proven to be effective in identifying and mitigating chemical risk. However, there is growing interest in understanding to what extent mixtures of chemicals from different regulatory domains may result in

additional risk. We analyzed the potential additional chemical risk from unintentional mixtures of chemicals from multiple domains in EU freshwaters by performing a screening level chemical mixtures risk assessment at the continental scale. Our analysis combined the largest publicly available chemical monitoring database in the EU: the Waterbase Waterquality ICM database, with state-of-the-art ecological effects metrics and chemical mixture assessment methods. The investigation included more than 330 chemicals across pesticides, pharmaceuticals, metals, and industrial chemicals. The evaluation included 22 EU countries, more than 4000 monitoring sites in more than 4000 waterbodies. Central elements of our approach were (1) the classification of chemical monitoring observations by the type of chemical risk, and (2) the determination of the number and identity of main chemical risk drivers. We found that most monitoring samples did not pose a chemical risk concern from single substances or mixtures (92.92%). The percentage of samples whose risk was dominated by complex mixtures was very low (less than 3% in all cases). We found that the three first chemical risk drivers per sample contributed on average a 90% of the total risk, and the first risk driver alone contributed on average a 50% of the total risk per sample. The combined contribution of all other chemicals present in the mixtures was on average less than 10% of the total risk per sample. We identified that a very specific set of chemicals (about 2% of all measured chemicals) drove most of the risk in the entire dataset. Our findings provide critical evidence on the prevalence, characteristics, and drivers of the chemical mixtures risk found in “unintentional mixtures” currently in EU freshwaters.

6.05.P-We271 Short-Term Chronic Toxicity Test for Assessing the Adverse Effects of Chemical Mixtures Using Zebrafish Embryos

Chang-Beom Park, Seonggeun Zee and Go-Eun Kim, Korea Institute of Toxicology, Korea, South

With increase of usage and production of household chemical products, there is rising public concerns about the hazards of chemical mixtures in wild lives, including human. Methodological approach for determining the potential effects of chemical mixtures should be assumed that the mixture profile of environmental chemicals and the dissolved levels of the individual constituents are preserved between the toxicity tests. In this study, mixture toxicity test with zebrafish embryos was conducted to investigate the adverse effects profile induced by exposure to different chemical mixture combinations, within short-term period. Toxicity values of chemical mixtures were estimated by the effective concentration (EC_x) focusing biological response index during during the embryonic developmental phase in zebrafish. The adverse effects profile from chemical mixtures was examined by the transcriptional alteration of target genes related to cellular damage and development with phenotypic analysis of embryonic development. The embryonic developmental toxicity of chemical mixtures was relied on the interactive effects between individual constituents due to mixture combinations. Consequently, our results provides toxicological information regarding the impacts of chemical mixtures, such as household chemical products, using the embryonic development of zebrafish. This methodological approach applied transcriptional alteration of target genes with phenotypic analysis can serve a response biomarker for assessing the environmental hazards of chemical mixtures.

6.05.P-We272 Ecotoxicological Drivers in Bio-Hybrid Fuel Development

Karsten Eike Braun, M.Sc.¹, Sebastian Heger², Martina Roß-Nickoll³ and Miaomiao Du³, (1)Institute for Environmental Research, RWTH Aachen University, Germany, (2)Institute for Environmental Research, RWTH, Germany, (3)RWTH Aachen University, Germany

Increasing industrialization, standard of living and population are leading to an increase in global energy and fuel demand, particularly in the transportation sector. While changes in propulsion method challenge the relevance of internal combustion engines, liquid fuels will remain a relevant form of energy carriers in many regions and for many applications in the future. While the use of petroleum-derived diesel and gasoline fuels poses a significant risk for the environment, human health and global climate, the introduction of sustainable, less toxic fuels provides an opportunity to avoid or reduce harmful effects. This is especially important considering the large amount of fuels required by the transportation sector and the consequential contamination of the environment by fuel spills and leakage. Therefore, research on developing alternative and renewable fuels is increasing. Bio-hybrid fuels represent promising alternatives to fossil fuels. They are generally considered to be more environmentally friendly and more sustainable than fossil fuels and contribute less to global climate change, especially when produced with excess renewable energy. The new regulatory focus regarding mixtures based on the EU Chemicals Strategy for Sustainability is highly relevant for the future of Bio-Hybrid fuel blends and needs to be considered accordingly. In this study, toxicity assessment of bio-hybrid fuel candidates and blends thereof is integrated in the fuel development process of a novel ketone-ester-alcohol-alkane blend (KEAA blend) following the previously proposed framework for a “Green Toxicology” approach. The KEAA blend consists of six constituents (methyl isopropyl ketone, ethanol, methyl acetate, ethyl acetate, pentane and methanol) and has recently been identified as a possibly superior fuel for spark ignition engines. Toxic potential towards aquatic organisms of blend constituents and the blend itself is assessed *in silico* and *in vivo*. By modifying the blend to trigger lower toxic effects, collaborators in chemistry and engineering gain insight into environmental optimization potential. By providing this information on potentially hazardous constituents early in the development process, further development can be focused on less toxic blend variants. This work was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany’s Excellence Strategy – Cluster of Excellence 2186 „The Fuel Science Center” – ID: 390919832.

6.05.P-We273 Risk-Based Screening for Prioritisation of Organic Micropollutants in Swedish Freshwater

Romain Figuière¹, Lutz Ahrens², Sylvia Waara³ and Oksana Golovko⁴, (1)Department of Environmental science, Stockholm University, Stockholm, Sweden, (2)Swedish University of Agricultural Sciences, Sweden, (3)Halmstad University, Sweden, (4)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences, Uppsala, Sweden

Concerns related to the contamination of the environment by organic micropollutants (OMP) are raising due to their potential

bioaccumulative and toxic properties. The aim of this study was to evaluate the risk posed by OMPs to the aquatic ecosystem in Swedish freshwaters. The assessment was based on measured environmental concentrations (MEC) of OMPs in surface waters upstream and downstream of Swedish wastewater treatment plants (WWTP). A novel optimized risk quotient (RQf) was used to identify potential high-risk substances in the aquatic environment. Among the 126 substances investigated, this study showed that 10 compounds are likely to pose a risk to the aquatic ecosystem (i.e. $RQf > 1$), and two compounds are posing a moderate risk to the aquatic ecosystem in Swedish surface waters (i.e. $0.1 < RQf < 1$). The data presented here could be used for assessing the effects of OMP mixtures in aquatic ecosystems, and ultimately by local and international authorities to prioritise OMPs and contaminated hotspots, in order to decrease the risk posed by these compounds. This study highlights the importance of the selection and the reliability assessment of ecotoxicological data for the calculation of predicted no-effects concentrations (PNECs), which are the basis to determine the risk quotients (RQs). It also critically evaluates the efficacy of this method globally used in chemical regulations to protect ecosystems.

6.05.P-We274 Suggestion for Mixture Assessment of Pesticide Concentrations Monitored in European Waters

Eberhard Kuester¹, Dana Kühnel² and Rolf Altenburger³, (1)Helmholtz Centre for Environmental Research, Dept. Bioanalytical Ecotoxicology, Germany, (2)Helmholtz-Centre for Environmental Research- UFZ, Germany, (3)UFZ Centre for Environmental Research, Leipzig, Germany

Different pesticides are regularly monitored by different member states for their unintended occurrence in surface and groundwaters of the European Union. The selection of pesticides for monitoring is based on different regulations, expert knowledge and political rationales. Monitoring data are subsequently submitted and collected in the publicly available WISE database (<https://www.eea.europa.eu/data-and-maps/data/wise-wfd-4>). Based on this database summaries are published such as for example yearly concentrations of the nationally selected pesticides for designated monitoring stations in different member states. One goal behind the substantial efforts of monitoring pesticides is to identify and manage those substances which are drivers of toxicity and thus contribute to the bad quality of European surface- and groundwaters. Research in ecotoxicology over the last decades demonstrated that organisms are often exposed and affected by contaminant mixtures rather than by single substances. Even if the different contaminants occur in low concentrations in the environment they may contribute to a joint overall effect ("something from nothing")- which can be predicted using the mixture concept of Concentration Addition (CA). Experimental evidence supporting the use of this mixture prediction approach and its use for chemical risk assessment has been reviewed and discussed by various institutions and authors, e.g. SCHER, SCCS, SCENIHR, Opinion on the Toxicity and Assessment of Chemical Mixtures, 2012 or Kortenkamp et al. (State of the Art Report, 2009). In light of this knowledge on mixture toxicity the current means of assessing monitoring data and deriving subsequent management for individual substances only may lead to an underestimation of existing risks. One goal of the work presented here was to suggest a way of how to make use of the multitude of pesticide concentration data in the WISE database for a mixture toxicity assessment strategy. Based on a toxic unit summation approach different ways of prioritizing are suggested. Ideally, this would be a starting point for enabling member state authorities and other stakeholders to prioritize and target the pesticides and pesticide groups for regulation or management (e.g. phasing out, reduction or replacement).

6.05.P-We275 Rural Emission to Kaldvellfjorden in Norway and Characterization of Cumulative Risk of Metals

Hans-Christian Teien¹, Raoul Wolf², Emil Jarosz³, Lindis Skipperud⁴ and Knut Erik Tollefsen⁵, (1)Norwegian University of Life Sciences NMBU, Norway, (2)Norwegian Geotechnical Institute (NGI), Oslo, Norway, (3)Norwegian University of Life Sciences (NMBU), Norway, (4)Norwegian University of Life Sciences NMBU/Centre for Environmental Radioactivity - CERAD, Norway, (5)NIVA - Norwegian Institute for Water Research, Norway

Kaldvellfjorden is located in the Lillesand area situated near the border of the Skagerrak Rift south in Norway and the fjord are impacted by acid rock drainage (ARD) due to construction work in the nearby sulfide-bearing bedrocks. Exposure of rock surfaces to air and precipitation have occurred over a long time, however the oxidation of the rock increased especially after the E18 road construction in 2006 and 2008, when also three large landfills of waste rock material were constructed. Especially landfill close to Kaldvellfjorden has contributed to high ARD and one treatment plant has been constructed to reduce the metal concentration in the ARD. Trace elements monitored in the fjord was subjected to a component-based Cumulative Risk Assessment (CRA) using the NIVA Risk Assessment database (NIVA RADb, www.niva.no/radb) to predict site-specific impacts. The resulting CRA demonstrated that fish had the highest risk (i.e. risk quotient) for acute effects in Kaldvellfjord, followed by molluscs and algae. For fish several elements were estimated to contribute significantly to the acute risk and in the following order $Fe > Zn > Cu > Cd$. Analyses of gills of caged Atlantic Salmon smolt exposed to the fjordwater showed significant accumulation of several of the elements identified to cause risk, but also accumulation of other elements not identified to cause risk due to lack of toxicity data for marine organisms. The observed data suggest that several of the trace metals including rare earth elements contribute to risk in Kaldvellfjord, and studies combining computational and experimental efforts presented herein may provide complementary information to impact assessments of complex exposure scenarios. Acknowledgement: This project was supported by the Research Council of Norway through project 268294: Cumulative hazard and risk assessment of complex mixtures and multiple stressors (MixRisk), Centre of Excellence funding scheme, project number 223268/F50 and NIVAs Computational Toxicology Program (www.niva.no/nctp).

6.05.P-We276 Addressing Mixture Related Policy and Research Priorities With Data From IPCHEM, the EU Information Platform for Chemical Monitoring

Antonio Franco¹, Stephanie Bopp¹, Alberto Cusinato¹, Stylianos Kephelopoulos¹ and Xenia Trier², (1)European Commission - Joint Research Centre, Italy, (2)HSRI, European Environment Agency (EEA), Copenhagen K, Denmark

The Information Platform for Chemical Monitoring (IPCHEM) is the EU reference access point for finding and retrieving chemical monitoring data. IPCHEM supports a coordinated approach for collecting, storing, sharing and assessing data on the occurrence of chemicals and chemical mixtures in humans and the environment. The data is structured in four thematic modules: environmental monitoring, human biomonitoring, food and feed, products and indoor air. The database currently incorporates over 450 million concentration measurements from over 3000 substances and 170 data collections. Data streams coming from periodic regulatory monitoring and research consortia is continuously integrated following defined quality and harmonisation procedures. By providing monitoring data from data collections covering multiple exposure sources IPCHEM supports the assessment of risks from combined exposure to multiple chemicals. Examples of mixture related policy questions that can be addressed with help of IPCHEM include: - the assessment of risks from combined dietary and non-dietary exposure to pesticides mixtures for human health; - the derivation of chemical mixture profiles and associated risks in the European population using human biomonitoring data representing internal exposure in the general adult population or in specific (sub)populations (e.g. children, pregnant woman); - the derivation of chemical mixture profiles and associated risks in the environmental media including surface water, drinking water, sediments, soil, air, etc.; - the development of exposure risk indicators for use in policy evaluation under specific regulatory instruments (sustainable use of pesticide directive) and the broader Chemical Strategy for sustainability; - Identification and characterisation of sources, routes of exposures, body burdens and associated health effects from real-life scenarios of indoor exposure to chemicals; These examples illustrate the importance of data harmonisation and interoperability as key features necessary to address chemical mixtures problems across regulatory domains. In fact, monitoring data becomes most useful when used in combination with additional exposures (e.g. biologicals) and other health and ecological data. For example, monitoring data combined with human health data (e.g. disease registries) or ecological monitoring (e.g. ecological stressors, biodiversity indicators) can feed into (eco)epidemiological studies linking exposure to effects.

6.05.P-We277 MEEDs: The Multiyear Metals Environmental Exposure Data Collection Program, Anticipating the Challenges of the EU Zero Pollution Ambition Policy and the Chemicals Strategy for Sustainability

Hugo Waeterschoot¹, Lara van de merckt², Violaine Verougstraete² and Marnix Vangheluwe³, (1)Chemicals Management, Eurometaux, Hove, Belgium, (2)Eurometaux, Belgium, (3)ARCHE Consulting, Belgium

As part of the EU Green Deal, the European Union Zero Pollution Ambition aims at reducing exposures of chemicals to levels that are no longer expected to be harmful to health and the Environment. The Chemicals Strategy for Sustainability (CSS) is a pillar of this ambition. It will be implemented through revisions of key chemicals legislations like REACH and CLP bringing in new challenges like the Mixture Assessment Factor (MAF) to demonstrate safe use and lack of impact on ecosystems for the cocktail of chemicals exposures in environmental compartments. The volumes of metals in use are expected to increase in view of the role metals play in reaching the climate and circularity objectives of the Green Deal. Hence, it is crucial to demonstrate that exposure of metals and their mixtures in the receiving environment will meet the challenge of this ambition and the MAF, now and in the future. Therefore, the EU metals sector designed a comprehensive “environmental exposure gathering programme” (MEED), complemented by scientific concepts development to comply with the Zero Pollution Ambition and biodiversity objectives. The programme’s timeline (2022-2024) has been defined to feed the deliverables in due time into regulatory debates (e.g., REACH Revisions, MAF impact assessments and debates, Zero Pollution Action Plan activities, Water Framework Directive etc.). MEED consists of 6 interlinked projects covering a comprehensive update of the Regional and Sewage Treatment Plants (STP) exposure assessments to identify EU relevant time trends and perform source allocation. A specific module of MEED focuses on the ‘MAF’, by assessing metal mixture interactions for priority contributing substances and increasing understanding of metals-organics mixture interactions. Both the regional exposure and the MAF modules feed into an ecorelevance project to check the impact on biota under realistic EU exposure conditions. MEED will deliver a long series of data that can be used in REACH registration updates and other regulatory programmes.

6.05.P-We278 Metal Mixture Risks in European Soils: Support for a Tiered Metal Mixture Risk Assessment Framework

Charlotte Nys¹, Koen Oorts¹, Karel De Schamphelaere² and Erik Smolders³, (1)ARCHE Consulting, Belgium, (2)Ghent University (UGent), Belgium, (3)KULeuven -BE0419.052.173, Belgium

Metal contamination in soils occurs generally as mixtures of metals. However, metal mixture risk assessment is complicated due to the influence of bioavailability on metal toxicity, natural background concentrations of metals, and for some metals also essentiality. The most basic mixture reference model available for assessing risks at the ecosystem level (CA_{SSD}: concentration addition applied at PNEC or the 5% hazardous concentration of the species sensitivity distribution) typically results in unrealistically high metal mixture risk predictions in soils. Several metals, such as Cu, Co, Ni, Zn, Mo, Pb, and Cd, are data-rich substances, which allows to consider the entire species sensitivity distribution in mixture risk assessment evaluations. More refined and theoretically more consistent models that apply the mixture reference models concentration addition or independent action at the dose-response curve (DRC) of each species individually prior to estimating the fraction of affected species in an ecosystem (i.e. CA_{DRC} and IA_{DRC}) exist. Recently, a tiered freshwater metal mixture assessment framework integrating these more refined models in higher assessment tiers was developed based on evidence from aquatic toxicity tests. Limited evidence from ecotoxicity tests with soil organisms supports the extrapolation of this tiered framework developed for freshwaters to soil ecosystems. Previous research suggested that the concentration addition model overestimated observed metal mixture toxicity at low effect concentrations (i.e. 10% effect concentration) with on average 3.6-fold across 10 different mixture experiments with *Hordeum vulgare*. To build support for the underlying assumptions of the tiered risk assessment framework for soil ecosystems, the conservativeness and general performance of the mixture reference models IA and CA in predicting chronic mixture effects to soil organisms was evaluated in a systematic manner based on published studies. Relevant research questions that were addressed are I) Which reference model is most accurate for predicting chronic metal mixture toxicity to soil organisms; II) How frequently

do statistically significant deviations relative to IA and CA occur; III) How accurate is the standard CA approach for predicting mixture effects at low effect concentrations. In addition, in-silico metal mixture risk predictions will be used to evaluate the order of conservatism of the existing metal mixture risk prediction models (CA_{SSD}, IA_{SSD}, CA_{DRC} and IA_{DRC}) at the community level for soils. The results of the present study will further support the use of a tiered risk assessment framework for metal mixture in (European) soils.

6.05.P-We279 Metal Mixture Risks in European Soils: Application of a Tiered Metal Mixture Risk Assessment Framework for Arable Soils in Europe

Charlotte Nys¹, Koen Oorts¹, Karel De Schamphelaere² and Erik Smolders³, (1)ARCHE Consulting, Belgium, (2)Ghent University (UGent), Belgium, (3)KULeuven -BE0419.052.173, Belgium

Metal contamination in soils occurs generally as mixtures of metals. However, metal mixture risk assessment is complicated due to the influence of bioavailability on metal toxicity, natural background concentrations of metals, and for some metals also essentiality. Given these metal specific characteristics, the most basic mixture reference model available for assessing risks at the ecosystem level (concentration addition applied at the applied at the PNEC or 5% hazardous concentration of the species sensitivity distribution) typically results in unrealistically high risk predictions in soils. Previous research suggested that the concentration addition model overestimated observed metal mixture toxicity at low effect concentrations (i.e. 10% effect concentration) with on average 3.6-fold across 10 different mixture experiments with *Hordeum vulgare*. Based on this observation and similar observations for chronic metal mixture toxicity to aquatic organisms, a tiered metal mixture framework has been developed combining the mixture reference models concentration addition and independent action with either the SSD and PNEC or the single-species dose response curves. The current study applies this metal mixture risk assessment framework on the GEMAS database, a soil database with measured metal concentrations representative for European exposure in arable soils (2108 individual samples under normal agricultural production) to assess the potential risks associated with metal exposure (Cu, Ci, Ni, Zn, Mo, Pb and Cd). All SSDs were fitted with a log-normal distribution and bioavailability corrections were performed according to models reported in the chemical safety reports. Of the 2108 sampling points, 15% were predicted to be at risk by exceedance of the environmental threshold of at least one metal (Tier 0). On the other hand, 36% of the samples are predicted to show no potential risks based on the most conservative model (CA_{SSD}), while 49% of the samples would be considered to be at potential risk due to mixture toxicity when only CA_{SSD} would be considered as mixture risk assessment method (Tier 1). For these samples, more accurate approaches applying either concentration addition or independent action at the species level are integrated in higher tier levels to further refine the metal mixture risk assessment. The current study shows how bioavailability normalized species sensitivity distributions-approaches for metals can be combined with the mixture reference models concentration addition and independent action to refine conservative metal mixture risk predictions in a tiered risk assessment framework using a representative European agricultural soil database.

6.05.P-We280 What Are the Main Drivers That Contribute to Herbicidal Mixture Toxicity in a Landscape That Is Highly Influenced by Agricultural Practices?

Hanna Samantha Schuster¹, Robin Sur², Arnd Weyers² and Nadine Taylor¹, (1)Cambridge Environmental Assessments, United Kingdom, (2)Bayer Crop Science, Germany

In the natural environment chemicals rarely occur as single entities but in undetermined mixtures. Despite this, the environmental risk assessment for plant protection products (PPPs) within the EU focusses on single substance registrations, except for products containing more than one active ingredient. Freshwater bodies in urban and agricultural areas may harbour an infinite number of combinations of anthropogenic chemicals. The assessment and regulation of these mixtures has raised concerns and prompted discussions by researchers, the public and regulators for at least the last three decades. These have included the implementation of a mixture assessment factor (MAF), but also more differentiated approaches e.g., addressing potential risks by managing critical compounds in spatio-temporal hotspots and their common mode of action (MOA). It has been demonstrated that only a limited number of chemicals drive the mixture toxicity, i.e., mixtures are not equitoxic. For photosynthetic organisms, mixture toxicity is primarily related to herbicides. A monitoring program carried out for 3.5 years in a highly agriculturally influenced catchment included sub-daily sampling of 12 herbicides and 1 metabolite. Here, we assess the relevance of this herbicide mixture in surface waters and propose how the data could be used for future regulatory decision-making processes. We identified how often the mixture exceeded the regulatory accepted concentration (RAC), assuming additive toxicity, which herbicide(s) contributed most to the exceedance events and determined if any factors could be identified contributing to these events (e.g., flow, rainfall, seasonality). Additionally, a stewardship program added to the influencing factors by implementing differing farming techniques and avoidance of missuses, spillages, and other point sources during study. The data were analysed separately for algae and macrophytes and although there are a low number of common herbicides driving the potential toxicity in both groups, there were also distinct differences where one group was more sensitive to a compound than the other (i.e. lower RAC). We found a clear seasonal influence driven by the growing season and rainfall and a stark reduction of exceedance events for both algae and macrophytes during the stewardship program. Overall, the analysis illustrates how monitoring projects can enhance the knowledge of the influencing factors that will enable improved decision making in the future.

6.05.P-We281 Masking Persistence - How Solvents Give a False Sense of Security With Respect to Biodegradation

Claire Phillips¹, Alexander Cousins², Nicola Geary², Lynsey Gregory², Olivia Harrod², Cheryl Moran², Alexandra Papachlimitzou² and Malgorzata Wilczynska³, (1)Cefas Lowestoft Laboratory, United Kingdom, (2)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom, (3)Science, Cefas Lowestoft Laboratory, United Kingdom

The aquatic environment is subject to multiple chemical inputs. Many of these chemicals are readily biodegradable, but some are

not. Chemicals such as emulsifiers, flow improvers, paints, tracers, other mixed substances and unknown or variable composition, complex reaction products or of biological materials (UVCBs) have highly biodegradable components such as solvents. Some solvents in mixtures are volatile organics, others are organic acids that increase solubility through pH changes. These not only enhance solubility and handling but also enhance biodegradation potential to exceed regulatory thresholds and thus avoid substitution warnings, even where part of the substance is persistent. Under most regulations the definition of a substance includes “a chemical element and its compounds, in the natural state or obtained by any manufacturing process, including any additive necessary to preserve its stability and any impurity deriving from the process used, but excluding any solvent which may be separated without affecting the stability of the substance or changing its composition.” For substances such as polymer emulsions this is ambiguous and the presence of solvent can allow it to be falsely identified as readily biodegradable, or at worst moderately persistent due to the reactions of the solvent. Once a substance enters the aquatic environment it is diluted and dispersed and smaller mobile molecules, such as those of solvents are stripped out of emulsions or mixtures, through microfluidic interaction at the molecular level, or through volatilisation/evaporation. The smaller molecules are then more readily available for biodegradation, leaving the polymers, or more recalcitrant solutes behind to potentially build up and pollute the environment. Solvent masking of persistence is being addressed by OSPAR’s offshore industry committee after a UK proposal was ratified in 2019. There are several ways of determining biodegradability of substances, either by evaporating volatile solvents from mixtures making them harder to handle and reducing the distribution in a biodegradation test, or by solvent subtraction methods. Either of these approaches will increase the number of substances that are classed as ‘substitutable’ but they represent a more realistic way of classifying the chemicals environmental hazard. Here we use a solvent subtraction method to demonstrate the effect of masking persistence due and consider the implications of such masking.

6.06 Novel Life Cycle and Sustainability Assessment approaches supporting biodiversity in land and water management

6.06.T-01 A Regionalized Species-Discharge Relationship for Assessing the Impact of Water Consumption on Freshwater Biodiversity Globally

Eleonore Pierrat¹, Valerio Barbarossa², Andreas Link³, Laura Scherer², Mattia Damiani⁴, Montserrat Nunez⁵, Francesca Verones⁶ and Martin Dorber⁷, (1)DTU (Technical University of Denmark), Denmark, (2)Leiden University, Netherlands, (3)TU Berlin, Germany, (4)European Commission Joint Research Centre, Italy, (5)IRTA, Spain, (6)NTNU, Norway, (7)Norwegian University of Science and Technology (NTNU), Norway

Freshwater biodiversity is undergoing a mass extinction driven by multiple environmental pressures, including altered river discharges and flow regulation. Existing end-point LCIA methods focusing on freshwater in-stream species richness have modelled the effect of discharge reduction on fish species richness using species-discharge relationships (SDRs). However, their restricted geographical scope and the small amount of species data underlying the models hinder characterization factor (CF) deployment at the global scale, which are needed to assess and compare the environmental impacts of global value chains. A working group within the Global Life Cycle Impact Assessment Method (2020-2023) project of the life cycle initiative hosted by UN Environment works on recommendations for impact assessment of water consumption on biodiversity. The group has developed a new SDR model, i.e., an effect model, with an extended geographical scope. This extended SDR model builds on updated datasets covering 11,500 fish species, simulated river discharges, and other relevant predictors. This model is then used to derive regionalized marginal and average CFs for water consumption impacts on freshwater biodiversity, along with associated uncertainty range estimates. The new SDR model includes river discharge, elevation and climate zones, thus reflecting two large-scale species richness gradients. It was selected among 5 model candidates supported by literature and a 10-folds cross-validation procedure. When testing the SDR robustness on independent observed river discharge data, the goodness of fit was higher (Kling Gupta coefficient KGE=0.6) than from previous global SDR employed in CF calculations (KGE=0.13). The effect factors were integrated with available fate factors and global extinction probabilities to obtain CFs. Marginal and average characterization factors are provided for 1,444 and 1,999 river basins, respectively, where water consumption has reduced the discharge flow and the SDR model is valid. The updated SDR-based CFs provide a more accurate estimate of the potential damage of water consumption on freshwater in-stream biodiversity than previous approaches. They cover more river basins and fish species, as well as specify marginal and average impacts.

6.06.T-02 GLAM Recommendations for Translating Regional Species Loss to Global Loss Within Life Cycle Impact Assessments

Koen Kuipers¹, Francesca Verones², Montserrat Nunez³, Francesca Rosa⁴, Laura Scherer⁵, Alexandra Marques⁶, Ottar Michelsen⁷, Valerio Barbarossa⁵, Stephan Pfister⁴, Benjamin Jaffe⁸ and Martin Dorber⁹, (1)Environmental Science, Radboud University, Nijmegen, Netherlands, (2)NTNU, Norway, (3)IRTA, Spain, (4)ETH Zurich, Switzerland, (5)Leiden University, Netherlands, (6)PBL Netherlands Environmental Assessment Agency, Netherlands, (7)Department of Industrial Economics and Technology Management, Norwegian University of Science and Technology, Trondheim, Norway, (8)ExxonMobil Biomedical Sciences Inc., United States, (9)Norwegian University of Science and Technology (NTNU), Norway

Life Cycle Impact Assessment (LCIA) approaches have made substantial advances in modeling and incorporating spatially explicit environmental impacts on the rate of species loss within a particular area (i.e. “ecosystem quality” area of protection). Despite these advances, there are still gaps in the species coverage and opportunities to more accurately scale damage estimates. A fundamental issue that needs to be addressed is to improve the consistency of damage estimates between impact category indicators. Most state-of-the-art models quantify species loss at the local or regional level. However, for comparisons of global value chains, it is likely more appropriate to incorporate global extinction probabilities rather than regional losses only. We therefore need a consistent scaling approach that translates regional species losses to global species losses (i.e. global extinction).

A working group within the Global Life Cycle Impact Assessment Method (GLAM) project of the life cycle initiative hosted by UN Environment is developing recommendations for such an approach. The working group develops recommendations of how to scale regional to global species losses, within an LCIA framework, based on the Global Extinction Probability (GEP) approach defined in Kuipers et al., 2019). This approach used information on species range areas and the current threat level of the species compiled from IUCN Red List to calculate a scaling factor for translating regional species losses to global species losses. The working group built upon this approach by nearly doubling the number of species covered. The Global Extinction Probability factors can be applied consistently across impact category indicators that report impacts as (regional) “potentially disappeared fractions of species“ (PDF) within the AoP ecosystem quality for scaling them to global extinctions. The GEP factors can be calculated at any chosen spatial unit that is relevant for the impact category in question and with the relevant species groups, and thus provides flexibility to address specific issues. This approach contributes to harmonizing LCIA results. Reference: KUIPERS, K. J. J., HELLWEG, S. & VERONES, F. 2019. Potential Consequences of Regional Species Loss for Global Species Richness: A Quantitative Approach for Estimating Global Extinction Probabilities. *Environmental Science & Technology*, 53, 4728-4738.

6.06.T-03 Sustainable Fisheries: Towards Operationalization of Decision Making Accounting for Biodiversity

Gregoire Gaillet¹, Anne-Claire Asselin² and Aurore Wermeille², (1)Sea Mammal Research Unit, University of St Andrews, United Kingdom, (2)Sayari, France

Rationale: Overexploitation of biotic resources constitutes a major threat on marine biodiversity while demand for seafood will rise in the next decades. Application of Life Cycle Assessment to marine ecosystems needs further research to allow a quantitative characterisation of the impact of sea-based products on biodiversity. Moreover, there is a rising demand for product eco-design, as illustrated in Business @ Biodiversity studies; presently, corporates and policy makers do not have proper tools to decide for sustainable practices regarding seafood production. **Introduction - methods:** This study aims to apply existing assessment methods of the impact of overexploitation on biotic resources (Langlois et al. 2014 and Emanuelsson et al. 2014) to 125 marine stocks fished in the 14 marine areas drawn by the FAO. We present how the results can be reproduced, including what kind of database can provide for the data needed. We discuss how results can be interpreted as a proxy for biodiversity assessment and the ecological limits of the methods. Finally, we propose operational guidelines for sustainable production and efficient conservation policies. **Results:** We show that unsustainable fishing is responsible for a loss of up to 30 times the potential yield of major fish stocks such as Atlantic cod, red snapper and bluefin tuna. We identify depleted fish stocks for which biomass is up to 15 times lower than it should be (yellownose skate; South America) and stocks facing fishing mortality up to 1.9×10^7 times higher than the maximum required to allow sustainable recovery (Pacific Ocean perch, US West Coast). Regarding intrinsic biodiversity, our study shows that we are not able to understand the consequences of overfishing through a cause-effects chain due to lack of science knowledge. However we display how to limit the impacts on biodiversity by using complementary indicators at species and ecosystem level. **Recommendations:** While methods seemed to compete against each other in the impact assessment of marine stock overexploitation on biodiversity, this study shows their complementarity. Hence, in the aim of making seafood more sustainable, a combination of the indicators they provide should be used. The complexity of marine ecosystems and the remaining limits of methods are discussed, showing the compelling need for further data collection and analysis, and opening ways for targeted research.

6.06.T-04 Assessing the Environmental Profile of Sustainable Agricultural Production Systems Towards Biodiversity and Climate

Christian Bogen¹, Christoph Georgi², Kai Holländer³, Veerle Mommaerts² and Virginie Ducro², (1)EMEA Public Affairs, Science & Sustainability, Bayer Crop Science, Germany, (2)Bayer Crop Science, Germany, (3)Tier3 Solutions GmbH, Germany

Agricultural activities have generally major implications on land use and emission of greenhouse gases. Both, land use and climate change have been identified among others as key direct drivers of biodiversity loss. Within the agricultural production context, besides chemical products numerous other tools and methods are used by farmers with the aim to enable a successful harvest and sustainable system. Consequently, the combination of those tools and methods create the major interface to the surrounding nature. The overall decision-making, choice of tools for a specific cropping situation and field context then decides about the more nuanced sustainability profile and the effects on habitats and the environment. The corresponding sustainability and environmental implications of field crop production have been investigated on two farms in Germany. The simultaneous use of selected sustainability metrics in the field trials allow differentiation and therefore can optimize decision-making for various cropping scenarios, increase transparency about environmental synergies but also about trade-offs, not only for the farmer but also within a regulatory context. The key metrics used in this work include crop yields per ha to reflect the land use footprint, the crop quality, an economic assessment of the production scenario, greenhouse gas emissions, biodiversity of carabids as proxy for natural pest control and biodiversity, soil health related to nutrient balance, organic carbon, earthworm populations and biodiversity of plants in habitats adjacent to the fields. The results of the production of winter wheat from the first year of the crop rotation are presented. The sustainability profile, climate and environmental implications of different production scenarios with their corresponding choices of tools and methods have been simultaneously assessed, thus enabling a holistic perspective that takes into account the farmers local agronomic challenges, decision-making and opportunities for improvement. Therefore, the presented approach can inform strategic decisions and outcome-oriented regulations, that help to improve the sustainability profile of agriculture and also drive solutions from an applied nature conservation perspective.

6.06.T-05 SETAC Workshops: "Optimising Agricultural Food Production & Biodiversity in European Landscapes"

Anne Alix¹, Dany Bylemans², Jens Dauber³, Peter Dohmen⁴, Katja Knauer⁵, Lorraine Maltby⁶, Christoph Mayer⁷, Zelie Pepiette⁸ and Balthasar Smith⁹, (1)Corteva Agriscience, Abingdon, United Kingdom, (2)pcfruit, Belgium, (3)Thünen Institute, Germany,

(4)(None), Weinheim, Germany, (5)Federal Office for Agriculture, Switzerland, (6)The University of Sheffield, United Kingdom, (7)BASF SE, Germany, (8)European Commission - retired, Belgium, (9)BVL, Germany

A series of four workshops were organised under the auspices of SETAC Europe dealing with the topic “Optimising crop production and biodiversity in European landscapes”. Stakeholders from industry, academia, government authorities, farmers and NGOs discussed potential pathways for more sustainable agricultural production. In this talk the approach, concepts and results of these workshops are presented. The overarching question, still not fully answered, is how to maintain efficient food production while improving the influence (+ vs. -) of agriculture on biodiversity. The objective of this series of workshops was to contribute to the ongoing debate by helping to inform decisions on multiple levels for the future management of agricultural landscapes, and more particularly, how to achieve the double objective of biodiversity protection and food production. A set of general principles was identified and agreed upon which should be considered when evaluating the various approaches and measures aimed to foster biodiversity in agricultural landscapes while securing agricultural food production. Four scenarios (cropping systems in landscapes) were identified as examples, for which suitable combinations of approaches were developed. A number of approaches are already available and it was possible to identify “low hanging fruits” and hurdles for implementation. Communication and trust building was key in the building of the scenarios with a common objective in mind. Targeted solutions that are fit-for-purpose are needed, through a suite of approaches - in field, on farm, off farm - that consider socio-economic context. i.e. whole system approach. The full proceedings of the workshop will be published in 2022.

6.06 Novel Life Cycle and Sustainability Assessment approaches supporting biodiversity in land and water management (Virtual Only)

6.06.V-01 Biodiversity Damage Assessment Integrating Carbon, WATER and Land Footprint

Kiichiro Takahashi¹ and Norihiro Itsubo², (1)Tokyo City University, Kanagawa, Japan, (2)Tokyo City University, Japan

1. Introduction The 2021 and 2022 Convention on Biological Diversity conference will be held. As a result, new targets for biodiversity will be set and quantitative assessments will be required. In particular, TNFD will be launched in 2021, and companies will disclose their natural capital assessment in 2022. Much of the natural capital to be assessed comes from food, construction, and energy, so it is extremely important to ensure proper procurement of these raw materials in countries where they are shared. 2. Materials and methods Multi-regional input-output tables are expected to be extremely useful in implementing the biodiversity footprint. Although there are several multinational input-output analyses, eora developed by the University of Sydney will be used. In order to consider climate change, land use and water, we will obtain CO₂ emissions, land use area and water consumption for each sector in Japan. Impact assessment will be conducted using LIME3, which allows analysis that reflects environmental conditions in countries around the world. Using both, damage analysis including climate change, land use and water consumption will be conducted. This will enable us to conduct a biodiversity footprint through the final products and services provided in Japan. The results from this study are also intended for use by Japanese companies. In cooperation with Japanese companies, we will try to conduct a footprint analysis of their products and implement a biodiversity version of SCOPE3.

6.06.V-02 Comparing LCIA Methods to Support the Farm to Fork Strategy in Assessing the Biodiversity Impacts of EU Food Consumption

Esther Sanye-Mengual¹, Fabrizio Biganzoli², Antonio Valente¹ and Serenella Sala¹, (1)European Commission - Joint Research Centre, Italy, (2)European Commission - Joint Research Center, Italy

Food production and consumption is the major contributor to global biodiversity loss. The EU Farm to Fork Strategy is targeting the enhancement of sustainable practices to halt current biodiversity loss rates in alignment with the EU Biodiversity Strategy for 2030. These strategies highlight the role of supply chains in transboundary effects and the need to have a consumption perspective when assessing and monitoring the evolution along time. The Consumption Footprint - Food indicator, developed by the European Commission-Joint Research Centre, is a full bottom-up Life Cycle Assessment (LCA)-based indicator that can be employed to identify current biodiversity hotspots, as well as to monitor impacts of the EU food system along time. However, the assessment of biodiversity impacts is still under discussion in the LCA community. The goal of this paper is to assess the biodiversity hotspots of the EU Food system by identifying convergent messages among available LCIA methods to assess biodiversity loss. Eight different LCIA methods and derived characterization factors from other approaches for quantifying biodiversity impacts were compared: Recipe 2016, Impact World+, LC-Impact, Eco-scarcity, Stepwise, a land use intensity-specific model, and two approaches derived from GLOBIO. The Consumption Footprint – Food includes 46 different representative products (i.e., covering 85% of EU food consumption). The year 2015 was analysed in this study. Preliminary results highlighted the role of animal-based products in the biodiversity impacts of the EU food system. Land use and climate change were the major drivers to the overall biodiversity impacts, apart from environmental pollution which had the major role in LC (mainly associated due to the conversion to a common unit, from volume to area). The comparison of operational LCIA methods and a detailed hotspot analysis allows for supporting EU policy-making by identifying hotspots, as well as providing metrics to monitor progress against policy targets. Due to the lack of harmonization, this study compared available methods to provide convergent and more robust messages. Agreement is still required in the LCIA community regarding biodiversity assessment and this study can support further development by analysing the underpinning causes in divergent messages.

6.06.V-03 Life Cycle Assessment Characterization Factors for Land Use Impacts on Biodiversity in Organic and Conventional Farmland in the European Mediterranean Biome

Erica Montemayor¹, Marie Knudesen², August Bonmatí³ and Anton Assumpció³, (1)IRTA Institute of Agrifood Research and

Technology, Spain, (2)Aarhus Universitet, Denmark, (3)IRTA, Spain

Biodiversity loss is on the rise mainly due to one principal driver, agriculture. Agricultural practices such as nutrient input, pesticide use, field operations and field cover, are closely linked with biodiversity, and organic agriculture (ORG) is often seen as one possible solution. However, there remains much difficulty in assessing biodiversity due to its complexity and high specificity on a local scale. The life cycle assessment (LCA) methodology is often used to address this complexity using characterization factors (CF) that predict the potential disappeared fraction (PDF) of organisms in specific land use types and intensities. However, previous LCA studies address intensity with a quite general approach, with broad land use types (e.g. cropland) and intensity levels (e.g. light, intense). Specific CF for ORG and conventional (CONV) arable and pastoral farming exist but are limited to the temperate and mixed forest biomes in Europe, excluding the Mediterranean regions. Moreover, no biodiversity CF are available for permanent ORG and CONV crops. To fill these gaps, new midpoint occupation CF were calculated expressing PDF of vascular plant species per m² in ORG and CONV arable and permanent crops in the European Mediterranean biome. These CF were based on literature studies for plant species richness within ORG and CONV farmland across four European countries. The CF were able to distinguish between different land use types (permanent, arable, hedges, grass strips) and management practices (ORG & CONV) in arable crop systems. However, based on the available studies, CF could not be differentiated in permanent crops, since they were highly dependent on the intensity of management practices, despite if it was ORG or CONV. The CF for ORG and CONV Spanish olives and Italian vineyards were not significantly different due to the extensive management practiced in the CONV farms. Whereas CF for Spanish vineyard and Greek olive production could differentiate between ORG and CONV agriculture due to intensive practices in the CONV farms sampled. Finally, the performance of the new CF was tested using the mean yield data from the same literature studies used to calculate the CF as a simple example to show how the PDF results could be interpreted. CF derived from real field measurements of species richness ensures higher certainty of the results, and given that more data on biodiversity is becoming available, further CF can be calculated using this method.

6.06.V-04 Magnitude of Differences in Characterization Factors for Terrestrial Biodiversity in LCIA: An Overview of Regionalized Research

pınar kavak gılbeyaz and Hatice Şengül, Hacettepe University, Turkey

Regionalized Life Cycle Impact Assessment (LCIA) is a field that needs further research to improve LCIA methodology and practice in order to reduce uncertainty of LCA results. Regionalized research is specifically important for assessing biological diversity due to Land Use and Land Cover Change (LULCC). To date, various methods have been proposed for presentation of characterization factors mainly at the country and ecoregion scales. However, at these scales of assessment, local differences are neglected due to aggregation or averaging of damage factor values. In order to increase the accuracy of the impact assessment, quantification of impacts at smaller spatial scales is needed to determine the differences between local and larger scales. In this review study, we collected current characterization factors presented in peer-reviewed publications, aiming to check the magnitude of differences between evaluations at different spatial scales with the hypothesis that identification of case specific and site specific impacts is important and likely to result in different results from assessment at larger scales. This hypothesis is proven in the literature, however the degree of the difference is not fully covered and evaluated. In order to fill this gap, we performed a literature search using Google scholar and Web of Science databases with relevant keywords and Boolean operators to identify published characterization factors. Comparison among available characterization factors and examination of how local impacts relate with the country or ecoregion scale impacts were evaluated. Emerging themes were identified and compared with themes of core research that links biodiversity and LULCC. Conclusions of the review may provide insights to practitioners for decision-making and evaluation of possible variations.

6.06 Novel Life Cycle and Sustainability Assessment approaches supporting biodiversity in land and water management (Poster)

6.06.P-Tu301 Between the Lines: Quantifying the Life Cycle Impacts of Power Lines on Norwegian Biodiversity

Dafna Gilad¹, Roel May² and Francesca Verones³, (1)Energy and Process Engineering, Norwegian University of Science and Technology (NTNU), Trondheim, Norway, (2)Norwegian Institute for Nature Research, Norway, (3)NTNU, Norway

Recent life cycle impact assessment models have started to consider the impacts of renewable energy production on biodiversity, for instance hydropower and onshore wind-power plants. Although the transition to renewable energy plays an important role in the development of electric grid, the effects of electricity distribution on ecosystems and biodiversity are not addressed to date. Power lines may be considered only as affiliated infrastructure to energy generation, yet their impacts on wildlife are widely known: their construction and operation induce disturbance to species, collision and electrocution risk for birds, landscape fragmentation and habitat loss. We developed four impact pathways to assess the impacts of power lines on birds: collision, electrocution, disturbance and habitat degradation. For collision impacts, we calculated a collision probability risk based on birds' species-specific morphological characteristics (i.e. wing loading and wing aspect). Habitat suitability maps and grid data were used as a basis to quantify species richness loss by the potentially disappeared fraction of species metric (PDF). A final conversion of local PDFs to a global scale with global extinction probabilities indicates species vulnerability. The results of the study show how impacts of power lines vary spatially, identifies important areas for biodiversity and indicate which bird species are most susceptible to collision in Norway. The application of the developed methodology to other geographical areas is possible based on data availability. It can contribute not only to the promotion of sustainability of energy systems within Norway, but also worldwide. An evaluation of the overall biodiversity impacts of both energy production and transmission within the electricity supply-demand network will contribute to a better understanding of how renewable energy can harm biodiversity nowadays and in

the future. Thereby, providing an opportunity to assess how renewable energy can be promoted, while its impacts on biodiversity are minimised.

6.06.P-Tu302 The MarINvaders Tool : A Basis for Marine Biodiversity Impact Assessment and First Step on Closing an Important Gap in Life Cycle Impact Assessment

Philip Gjedde¹, Francesca Verones², Maximilian Koslowski³, John Woods³, Radek Lonka³ and Konstantin Stadler², (1)Norwegian University of Science and Technology (NTNU), Trondheim, Norway, (2)NTNU, Norway, (3)Norwegian University of Science and Technology (NTNU), Norway

Life Cycle Assessment (LCA) is a recognized tool for holistic assessments of environmental impacts, but to this date impacts from marine invasive species have not yet been covered by the LCA framework, even though invasive species cause major impacts on the marine environment. When not included in the LCA framework, decisions and policies based on LCA are likely to overlook these impacts on marine ecosystems. As a first step to overcome this gap, we have collected spatial data on threatened, native and alien marine species in a database and visualized the data in a web toolkit we call MarINvaders. The Ocean Biogeographic Information System (OBIS) is the main building block of our database. Species data from OBIS is used to identify which species are found within each ecoregion. The marine ecoregions defined by Spalding et al. provide the geographic unit of species location. The World Register of Marine Species (WoRMS), the Global Invasive Species Database (GISD), and the Nature Conservancy database on marine invasive species (NatCon) were used to identify the names and locations of marine alien species. The IUCN red list was used to identify which species are threatened by invasives. The MarINvaders database covers 96% of the 232 marine ecoregions and includes 108,787 species. Of these, 1,655 are impacted by invasive species and 909 are alien. We found that the fraction of species which are alien are dominated by fish (*Actinopterygii*, 137), *crustaceans* (140), and red algae (*Florideophyceae*, 71). We also found that more alien species are found in developed regions. The MarINvaders tool can be used for statistical analysis, like where the highest fraction of alien species is found compared to the total number of species or how many native species are affected per alien species. The database is an up-to-date collection of the spatial range of alien and native marine species and marine species threatened by invasives and can be used to identify management strategies of species that are already known to be invasive. Impact assessment modelling within the LCA framework needs global comparable data on the alien and native range, introduction pathways, and impacts of invasives - the MarINvaders tool so far fulfils the first two prerequisites and aids in finding and modelling the two latter. This makes it a basis for future modelling of regionalized LCIA characterisation factors for impacts of marine invasive species on marine ecosystems.

6.06.P-Tu303 Optimising Crop Production and Biodiversity in European Landscapes - a Task for All Stakeholders Involved. Interest Group of Regulators Started

Alf Aagaard¹, Sina Egerer², Katja Knauer³, Mariana Ledesma⁴, Emily McVey⁵, Benjamin Schreiber⁶, Balthasar Smith⁷ and Jacoba Wassenberg⁸, (1)Pesticides and Biocide Division, Italy, (2)Umweltbundesamt, Germany, (3)Federal Office for Agriculture, Switzerland, (4)Swedish Chemicals Agency, Sweden, (5)Ctgb, Italy, (6)Austrian Agency for Health and Food Safety, Austria, (7)BVL, Germany, (8)Ctgb, Ede, Netherlands

Under the auspices of SETAC Europe, a series of four workshops were organised over the last years (2020-2021) dealing with the topic "Optimising crop production and biodiversity in European landscapes". Stakeholders from industry, academia and authorities as well as farmers have had fruitful discussions and summarised potential pathways for a more sustained agriculture. Participating regulators decided to start an informal follow up activity to discuss possible fields of actions for improvement from a regulatory perspective. One outcome was that networking between the regulators offers opportunities to learn from one another. Therefore, the authors [1] of this paper aim to initiate a broader exchange and discussion among regulators from European Member states. On this poster, possible fields of actions for regulatory initiatives are identified. Even though the members of the group work in the field of crop protection and plant protection products (PPP) the agenda of this group is to cover a holistic perspective towards production and biodiversity and on how the regulation of PPP is related to other legislation. This first output of the group presents an overview of the different regulations involved in the management of biodiversity in the agricultural landscape. It aims to show possible gaps in linking of regulations, to present interim approaches already established in Member states to address these and to show an overview of implemented national strategies. It is also an invitation for other regulators to get in touch with this group and share their insights. [1] The members of this interest group thereby do not represent the view of their institutions and the information which is presented is neither binding for the corresponding institution nor the member states represented.

6.06.P-Tu304 What Happens When Everything Fails?

Alan Lawrence, Cambridge Environmental Assessments, United Kingdom

Registrations of plant protection products (PPPs) in the EU are facing pressure due to increased stringency applied to environmental risk assessments by Member State authorities and EFSA. This is already leading to the loss of active substances and products. The proposed consideration of spray calendars at the catchment and landscape scale would lead to further losses of PPPs. On the other hand, EU Regulation 1107/2009 highlights the importance of pesticides for agricultural production, and their continued availability to EU growers helps to prevent export of food production and according environmental disbenefits to other jurisdictions with less stringent authorisation procedures. Therefore, there is a need to find a way forward that ensures that EU growers have the tools required to produce reliable food while a desired level of environmental protection is achieved. Simply making pesticide risk assessments more challenging is not going to reverse declines of farmland wildlife in the EU. Here I outline how enhanced biodiversity at the landscape scale could offset apparent concerns regarding potentially adverse environmental effects of pesticides, providing the required tools for growers, while contributing to real biodiversity gains. The necessary trade-

offs between productivity and enhancement measures will be discussed, also the need to demonstrate environmental benefits beyond those provisioned by current agri-environmental and industry stewardship schemes, the scale of action required, and responsibilities. The aim is to foster discussion which may lead to constructive progress in this challenging area.

6.06.P-Tu305 ENTOSAFE - Edible Insects: From a Sustainable Food Production to a Food Safety Concern

Diogo Filipe Nunes Cardoso¹, Amid Mostafaie², Rita Silva³, Carla Motta⁴, Daniel Murta⁵, Gloria Pinto³, Inês Coelho⁴, Marija Prodana³, Patricia Silva⁶, Paula Alvito⁴, Vania Calisto⁷ and Susana Loureiro⁶, (1)CESAM & University of Aveiro, Portugal, (2)Universidade de Aveiro/CESAM, Portugal, (3)University of Aveiro, Portugal, (4)National Institute of Health Doutor Ricardo Jorge, Portugal, (5)Ingredient Odyssey, Portugal, (6)Universidade de Aveiro, Portugal, (7)Aveiro University, Portugal

The use of insects as a food and feed source is nowadays considered a solution for the increasing food demands in the following years. With that in mind, the recently funded project “ENTOSAFE - Edible insects: From a sustainable food production to a food safety concern” aims to integrate the food safety and the environmental sustainability aspects of edible insect farming. ENTOSAFE will take advantage of a symbiotic multidisciplinary team with members from industry (EntoGreen® - Ingredient Odyssey, Portugal) and academia (Univ. of Aveiro and National Health Institute Doutor Ricardo Jorge, Portugal). The project is committed to provide knowledge on the accumulation and transfer of potential contaminants (e.g., metals, mycotoxins, PAHs, pharmaceuticals) in insects farmed in rearing facilities, contributing directly with data sets to the new legislation and regulatory limits, concerning the presence of these compounds in the substrate. ENTOSAFE brings new approaches, focusing on full bioaccumulation studies through a complete uptake phase, assessing the contaminant into insects in different times during this phase. Considering the lack of information on insects' elimination capacity to excrete contaminants from their body, an elimination phase will be studied in a non-contaminated substrate. ENTOSAFE is also promoting environmentally sustainable strategies while avoiding any wasted components from the process. The application of frass, as an organic fertilizer - produced by the digestion of the agricultural wastes or other residues by insects - on crops is presented as a promising solution to a zero-waste policy. Despite promising, the available information on the benefits that this by-product has on crop productivity is scarce. In this context, ENTOSAFE seeks evidence on the impact of this frass on agricultural soil's main functions and the key processes behind. The project will evaluate the effects in soil quality and functions, soil-biota interactions in soils enriched with organic amendments and plant responses to stressors, by performing a series of experiments from laboratory to greenhouse scale. In summary, ENTOSAFE will contribute to an upscaling on the use of edible insects as feed and food, covering not only safety concerns but also promoting the sustainability of insect rearing processes.

6.06.P-Tu306 Hazard Assessment of an Ento-Based Fertilizer Produced From Olive Pomace

Amid Mostafaie¹, Diogo Filipe Nunes Cardoso², Rita Silva³, Andreia Pereira³, Daniel Murta⁴, Maria Machado⁴, Ivã Lopes⁴ and Susana Loureiro⁵, (1)Universidade de Aveiro/CESAM, Portugal, (2)CESAM & University of Aveiro, Portugal, (3)University of Aveiro, Portugal, (4)Ingredient Odyssey, Portugal, (5)Universidade de Aveiro, Portugal

Olive pomace (OP) is a by-product of the olive oil industry and a problem in Mediterranean countries since it is considered highly toxic for both environment and human health. The use of insects to reduce and convert waste/residues into valuable products is growing as an emerging environmentally friendly solution, promoting a circular economy/agriculture and a zero-waste policy. Insects have the ability to convert and bio-transform different matrixes, producing valuable organic waste due to their metabolic activity, called frass, which consists of valuable biomass with high potential for agriculture (used as organic fertilizer). In this study, OP residues derived from a Portuguese olive oil production site have been used to feed black soldier fly (*H. illucens*) larvae. Thereafter, the obtained digested frass was firstly characterized chemically, looking mainly at phenolic compounds and metals - contaminants commonly present in OP residues. Later, frass was ecotoxicologically tested using standard model organisms (*Folsomia candida*, *Enchytraeus crypticus*), looking at mortality and reproduction using OECD standardized tests. Tests ran for 28 and 21 days, respectively, using soil amendments from 1% to 10% (w/w) ratios with OP frass mixed in Lufa 2.2 soil. As results demonstrated that frass did not affect the survival of soil organisms at the application rates tested, phytotoxicity assays were conducted evaluating the effects of frass on seed germination and the radicle growth of the seeds. For that, different monocotyledonous (e.g. *Lolium perenne*) and dicotyledonous (e.g. *Brassica oleracea*) plant seeds were used. A previously incubated frass with doses of 1%, 2.5%, 5% and 10% (w/w) ratios were added to Lufa 2.2 soil with 80% of the water holding capacity of the soil was conducted to produce testing extraction solutions (1/10 w/v distilled water). Test extraction solutions and the seeds were tested for 72h (28°C) in the darkness. Thereafter, the number of germinated seeds and the length of the roots were used to define the germination index determining whether the frass, as the soil additive, has a toxic effect. Also, to compare the effects of the frass as a soil amendment on the germination of the seeds, the same phytotoxicity experiment was conducted using mineral fertilizer (NPK) as a comparative soil amendment. These results are a screening approach to understand if frass produced from the bio digestion of OP may be used/tested in more complex scenarios.

6.07 Risk assessment, -management and -communication of environmental plastic pollution

6.07.T-01 Assessing Risks of Microplastics in Drinking Water to Inform Risk Communication and Management Strategies in California

Scott Coffin¹, Hans Bouwmeester², Susanne M Brander, (she, her, hers)³, Todd Gouin⁴, Ludovic Hermabessiere⁵, Elaine Khan⁶, Albert Koelmans⁷, Martin Wagner⁸, Stephen Weisberg⁹, Stephanie Wright¹⁰, Pauliina Damdimopoulou¹¹ and Katja Teerds¹², (1)Division of Drinking Water, California State Water Resources Control Board, (2)RIKILT, Wageningen University, Netherlands, (3)Oregon State University, United States, (4)TG Environmental Research, Sharnbrook, United Kingdom, (5)University of Toronto, Canada, (6)California Office of Environmental Health Hazard Assessment, United States,

(7)Wageningen University, Netherlands, (8)Norwegian University of Science and Technology, Norway, (9)Southern California Coastal Water Research Project, United States, (10)Imperial College London, United Kingdom, (11)Karolinska Institutet, Sweden, (12)Wageningen University & Research, Netherlands

Recent findings of microplastics in drinking water prompted concern amongst scientists and policymakers due to the potential harm towards humans. In 2018, the California legislature passed Senate Bill 1422 requiring the California State Water Resources Control Board to (1) define microplastics, (2) develop a standardized method to monitor in drinking water and accredit laboratories, (3) monitor for microplastics in drinking water for four years, and (4) provide consumers with guidance regarding health impacts. Microplastics have been documented in drinking water, but their effects on human health from ingestion, or the concentrations at which those effects begin to manifest, are not established. To assess the available evidence for human health hazards of microplastics in drinking water, we convened an expert workshop, and conducted a systematic literature search. Studies were screened for quality criteria, including particle characterization, experimental design, and applicability for risk assessment prior to undergoing additional expert evaluation. Twelve mammalian toxicity studies were prioritized and subjected to qualitative evaluation by external experts, of which 7 reported adverse effects on male and female reproductive systems, while 5 reported effects on various other physiological endpoints. No single study met all desired quality criteria, but collectively toxic effects with respect to biomarkers of inflammation and oxidative stress represented a consistent trend. While it was possible to derive a conservative screening level to inform monitoring activities, it was not possible to extrapolate a human–health-based threshold value for microplastics, which is largely due to limited studies on polymers and shapes other than polystyrene spheres, uncertainties with measured apical endpoints, and missing exposure information. Findings from this assessment inform monitoring strategies for microplastics in California’s drinking water supplies. To aid consumers in interpreting detections of microplastics in drinking water, the expert workshop developed qualitative health-based guidance language.

6.07.T-02 Risk Assessment of Microplastics in Marine Ecosystems; From detection of Presence to Quantitative Assessment of Effects

Ricardo Beiras¹, O Alonso-López², I Moreno², A Olmos², L Vidal-Liñán², Alejandro Vilas da Fonseca³, S López-Ibáñez² and Alexandre M Schonemann², (1)University of Vigo, Afghanistan, (2)UVigo, Afghanistan, (3)University of Vigo, Vigo, Spain

Conventional plastic objects do not decompose but they weather and fragment into increasingly small secondary microplastics ubiquitous in all marine environmental compartments, from arctic ice to deep sea sediments. Therefore, a quantitative assessment to know whether this presence reach levels that support ecological effects, and thus to quantify the risk posed by microplastics to marine ecosystems, is urgently needed. On the other hand, search for biodegradability have placed in the market compostable plastic materials. An ecotoxicological assessment of these alternatives is needed to see whether they reduce the potential impact compared to conventional plastics such as PE. Using standard marine models, we found no toxic effects of polyethylene (PE) bags, either conventional, recycled or oxodegradable. In contrast, all bags labelled as compostable tested showed a certain but moderate degree of toxicity on plankton organisms. Concerning expression of biomarker genes, no clear differences in the patterns of alteration were identified between both groups of bags. According to FTIR analysis the major component of the compostable bags were aliphatic-aromatic polyesters, most likely polybutylene-adipate-terephthalate, an oil-based polymer whose resin showed very low toxicity. According to GC-MS analysis, the qualitative composition of conventional vs. compostable additives was similar, including restricted low molecular weight phthalates such as DEHP and DBP. Therefore it can be concluded that replacement of PE by compostable plastic carrier bags do not represent any improvement but may even increase the hazard of these materials on the marine environment. On the other hand analyses of a microplastic aquatic toxicity database gathered from the literature supported that currently monitored plastic particle sizes pose a negligible risk to the global oceans, but techniques to assess smaller fractions are urgently needed to conduct ERA for those more hazardous sizes. In conclusion, replacement of polyethylene by compostable plastic materials do not warrant any improvement in the ecotoxicological hazard posed by plastics to the marine environment.

6.07.T-03 Policy Initiatives Targeting Plastic Pollution: Unfolding the Science Behind

Maria Bille Nielsen¹, Lauge Clausen², Steffen Hansen³, Richard Cronin⁴, Nikoline Oturai⁵, Jakob Strand⁶ and Kristian Syberg⁷, (1)DTU (Technical University of Denmark), Denmark, (2)Technical University of Denmark, Denmark, (3)Technical University of Denmark DTU, Denmark, (4)Department of Housing, Planning and Local Government, Ireland, (5)Science and Environment, Roskilde University, Roskilde, Denmark, (6)Ecoscience, Aarhus Universitet, Denmark, (7)Roskilde University, Denmark

The intensive global plastic use and associated plastic pollution have caused concern for the potential risks to human health and the environment which. This has led to the adoption of numerous regulatory initiatives aiming to combat plastic pollution. Despite the considerable regulatory activity in the field of plastic, it appears that the actual risks of plastic to humans and the environment are still uncertain. This raises the question of to what extent the current plastic regulation is evidence-driven, a declared goal in the European Union. Therefore, the aim of this study was to investigate the scientific foundation for some of the key regulations targeting plastic pollution. Furthermore, we examined whether the knowledge base that the regulations rely on are considering the latest “state of the art” and discuss the different scientific foundations for guiding policy actions of environmental plastic pollution. Key regulations were selected based on both their importance with respect to regulation of plastics as well as their historical importance as drivers for societal actions on plastic pollution. We found that scientific evidence appears to be generally present in the scientific evidence for the policy initiatives analyzed in this study, and to a large extent for many initiatives. All the initiatives are supported by scientific articles and reports about among others plastic sources, ecological impacts of plastics and production and consumption patterns. Marine litter monitoring data was found to contribute to the evidence base for 4 out of the 6 policy initiatives and thereby appears to be one of the central scientific drivers behind the societal actions on plastic pollution. Other scientific tools applied when shaping the policy initiatives include risk assessment, impact assessment and life cycle

assessment. Despite the prevalent consideration and application of scientific evidence, there appears to be a broad recognition in the preparatory work of the initiatives that there is still a lot of uncertainty related to determining the harm of plastic pollution. In these cases, taking precautionary actions seems however to be justified, recalling not least the precautionary principle – a fundamental principle of European environmental regulation.

6.07.T-04 Examining Public Perspectives on Microplastic Pollution

Stephen Burrows¹, Rebecca Olive², Kelly Fielding², Stacey OBrien², Kevin Thomas² and Tamara Galloway³, (1)Biosciences, University of Exeter, Exeter, United Kingdom, (2)The University of Queensland, Australia, (3)University of Exeter, United Kingdom

The topic of plastic pollution commonly encourages discussion regarding how environmental science is communicated. Public engagement with microplastic pollution has been significant and is arguably stronger than for other environmental issues such as climate change and ocean acidification. This has led to various hypotheses as to why this is and what social aspects may be influencing such trends. This study aimed to investigate public perceptions of microplastic pollution and to better understand how science communication could be improved to encourage greater public engagement with environmental protection strategies. A questionnaire assessing the perceived risk, control, progress and hope relating to microplastic pollution was developed in survey writing software Qualtrics. These themes of perception were based on previous related literature. The questionnaire also assessed environmental identity based on self reported factors of concern, emotional connection and consumer choice relating to the environment. In addition, self reported knowledge was recorded with a brief post-answer assessment to validate results. Both quantitative and qualitative responses were recorded. The questionnaire was distributed by third-party market research company PureProfile to collect as representative a sample of the Australian population as possible. Preliminary results revealed general public perceptions and misconceptions which highlighted a distance between the public and scientific perception of microplastic pollution. This calls attention to the effectiveness of environmental science communication itself, as well as to the challenges of adapting scientific findings for the wider media. The findings are of particular importance when considering the modern proliferation of misinformation and the effects of industry marketing. These factors are significantly affecting the perception of science communication and so need to be addressed with adapted strategies. To this end, interdisciplinary approaches to science communication are crucial for environmental scientists to be successful in their endeavours to promote public awareness and to support the uptake of effective environmental remediation strategies. To improve science communication will require a concerted effort between STEM (science, technology, engineering and mathematics) and HASS (humanities, arts and social sciences) disciplines to collaborate and communicate more effectively.

6.07.T-05 How Can We Test Plastic Pollution Perceptions and Behavior? A Feasibility Study With Danish Children Participating in "the Mass Experiment"

Nikoline Oturai¹, Sabine Pahl² and Kristian Syberg³, (1)Science and Environment, Roskilde University, Roskilde, Denmark, (2)University of Vienna, Austria, (3)Roskilde University, Denmark

Research suggests that behavior change programs can be fast and cost-effective solutions to plastic pollution alongside traditional environmental policy-making. Furthermore, encouraging change in perception and behaviour can be a tool to change consumption and waste handling towards increased circularity, which is of high concern in the EU. Beyond *knowledge*, predictors of pro-environmental behavior include *concern, social norms, nature-connectedness, identity* and *self-efficacy*. Citizen Science (CS) as a way to raise awareness and potentially change behavior show promise within plastic litter monitoring. We tested the feasibility of evaluating a nation-wide citizen science intervention, 'the Mass Experiment' (ME), with school students (age 7-16) in Denmark. With more than 57,000 students signed up for ME, this is to our knowledge one of the largest CS activity on plastic debris targeting young people. As an addition to the core CS activity we developed a voluntary and anonymous questionnaire to study the perceptions and behaviors of the students. We hypothesized that the intervention would increase *risk perception, self-efficacy* and *empowerment* as well as *self-reported actions*. Through 931 pre-surveys and 838 post-surveys aggregated at the team level (n=48), we found that the intervention had no significant overall effect on team, risk-perception, pro-environmental behaviors, nor self-efficacy or empowerment. However, unexpected patterns emerged for age effects, potentially advising some caution over the design of such CS activities particularly for younger children. We discuss methodological limitations, the high baseline for nearly all variables, the Danish context and the intervention itself and make recommendations for studying future CS interventions.

6.07 Risk assessment, -management and -communication of environmental plastic pollution (Virtual Only)

Presentation 6.07.V-01 was moved to session 4.15 (Virtual Only)

6.07 Risk assessment, -management and -communication of environmental plastic pollution (Poster)

6.07.P-We282 Flows of Seven Plastic Polymers Within Products in Norway From 2000 to 2050 As a Basis for LCA on Future Waste Management Practices and Recycling Targets

Marina Hauser¹, Golnoush Abbasi², Babak Ebrahimi¹ and Evert Bouman¹, (1)NILU - Norwegian Institute for Air Research, Norway, (2)Norwegian Institute for Air Research, Norway

Once considered a blessing for society, plastic is now increasingly being viewed as a burden to society. Production of plastic relies almost entirely on fossil fuels. In order to decrease dependence on fossil fuels and the associated emissions of greenhouse gases, the Norwegian government in their new plastic strategy calls for increased recycling of plastic. To achieve the Norwegian plastic strategy and increase recycling in Norway, the current and future flows of plastic need to be mapped out. Therefore, we

estimated the expected flows of plastic in Norwegian society from 2000 to 2050 of the seven most used polymers (low-density polyethylene (LDPE), high-density polyethylene (HDPE), polypropylene (PP), polystyrene (PS), expanded polystyrene (EPS), polyvinyl chloride (PVC), and polyethylene terephthalate (PET)) using a dynamic probabilistic material flow analysis (DPMFA). The model starts with the raw material, considers trade of the raw materials, unfinished and finished products and ends with the collection of recyclable material and waste and the subsequent waste treatment. In addition to the main categories of plastics, the model includes synthetic textile products and products related to fishing and maritime industry. Thus, the model considers the whole lifecycle of plastic and provides a comprehensive overview of the consumption of each polymer type. For the flows from 2000 to 2020, current data was used, while for the projection to 2050, a business-as-usual approach was applied assuming a linear trendline based on data from 2016 to 2020. Our model predicts the amount and polymer composition of future waste flows in Norway from production to waste. This research gives policy makers a basis for future waste management practices and increased recycling targets for plastic. It also allows waste collectors and processors to identify where in the value chain large amounts of high quality recyclable plastic products will become available for reuse and recycling.

6.07.P-We283 Will Increased Recycling of Plastic Also Increase the Exposure to Additives and Hazardous Chemicals Under Circular Economy? An Inventory of Chemical Additive in Plastic Products in Norway

Marina Hauser¹ and Golnoush Abbasi², (1)NILU - Norwegian Institute for Air Research, Norway, (2)Norwegian Institute for Air Research, Norway

To achieve the European Green Deal objectives and facilitating the green transition, the Norwegian government set stringent targets to increase recycling rates. Regarding plastic products, at least 50% of plastic waste should be recycled in Norway from 2025 onward. Consequently, 50% of plastic products entering Norwegian market must be made of recycled plastic. However, the growing concern regarding the presence of hazardous chemicals in post-consumer plastic (PCP) products, poor quality of PCP, lack of knowledge on additives used in PCP and shortage in supply of PCP create massive challenge for plastic producers. This in turn, can counteract the objectives of some well-intended policies in increasing circularity by unintentionally increasing the recycling of hazardous chemicals in PCP and worsen the quality, which then shortens the lifespan of plastic products. Further, more additive chemicals must be added to PCP to improve their qualities for given applications, which will exacerbate the recycling of PCP and associated products under circular economy. In this work we established an inventory of chemical additives in consumer products. Using Norwegian status-quo data, we characterized the flows of additive chemicals within plastic products entering the Norwegian market and their subsequent flows to the waste stream. Plastic products are classified into 41 individual plastic products groups, within which the fraction of polymers was estimated. Several databases (e.g., ECHA, NORMAN) were used to quantify the presence of chemicals in plastic products. By coupling these data with waste treatment data at municipality level, we estimated the probability by which chemicals of concern can re-enter the market within recycled products. The results of this work can serve as a valuable tool for authorities in developing more effective targets for polymers and plastic products based on their potential chemical contents and applications.

6.07.P-We284 Reduction of Plastic Waste From Operation Rooms

Tiffany Ramos¹, Kristian Syberg² and Thomas Christensen², (1)Science and Environment, Roskilde University, Roskilde, Denmark, (2)Roskilde University, Denmark

Plastic production and pollution continue to grow regardless of the well documented negative impacts on the environment. Healthcare facilities have shifted from multiple use products and tools to single use in recent years, accelerating the use of single use plastic products. This shift can be attributed to the low associated cost of plastic, sterile capabilities of plastic, and efficiency for the staff. The healthcare industry is responsible for emitting copious amounts of CO₂ globally due to resource intensive procedures and facilities. Currently there is a gap of knowledge when accounting for the specific types and amounts of plastic products and packaging being used in the operation rooms (ORs). This project aims to analyze how a reduction in the amount of plastic waste in ORs can be achieved by facilitating a transition towards a more circular economy of products used in the operation rooms. To do this, identification, quantification and polymer analysis of relevant plastic products and packaging was performed at ORs in two Danish hospitals (Næstved Sygehus and Slagelse Sygehus) in Region Zealand, Denmark. Direct observations of surgeries within both hospitals were conducted, FTIR polymer analysis of the identified products and packaging was conducted, and key informant surveys were conducted including nurses, doctors, and anesthesiologists of both hospitals. The direct interaction of the staff with these products makes their opinions highly valuable, it enables an analysis of perceived barriers for the circular transition. Preliminary results suggest that there are slight differences of plastic waste generation between hospitals. The observed deviations in plastic use are suggestive to differences in procedure of the different surgical departments. Results also suggest that the most prominent type of plastic waste found in both hospitals was composite plastic and paper packaging. Up to 38% of plastic waste in Slagelse Sygehus operation rooms, and up to 26% in Næstved Sygehus. However, product design of the composites makes recycling them currently impossible in procedure, according to staff. Further analysis will suggest products for redesign, recycle, or reuse, to reduce overall plastic waste. The current value chain of medical plastic products has mostly followed a linear value chain which continues to exacerbate the plastic crisis. By including more circularity among products, fractions of medical plastic waste can be mitigated.

6.07.P-We285 Microplastics in Agricultural Soil - Experiences of Agricultural Plastics Users

Milja Räisänen¹, Sari Kauppi² and Salla Kristiina Selonen³, (1)Finnish Environment Institute (SYKE), Finland, (2)Finnish Environment Institute, Finland, (3)Suomen ympäristökeskus, Finland

Various plastic products are used in horticulture and agriculture. For example, plastic can protect, control and accelerate growth of plants, and it can be used to transport and store products. Despite numerous benefits, agricultural plastics are also potential

sources of microplastics to soil. The MicrAgri project, funded by the Ministry of Agriculture and Forestry of Finland by Makera Fund, identifies the main sources of emissions of microplastics to agricultural land in Finland, assesses the effects of plastic particles in the soil and proposes measures to reduce microplastics emissions in agriculture and horticulture. This presentation shows the results of an open online survey conducted within the framework of the project during the fall of 2021. The survey examines the agricultural plastics used by agricultural and horticultural producers, landscapers and home gardeners, users' remarks on degradation of conventional and biodegradable plastics into plastic particles and suggestions on how to prevent the release of plastics into the environment. The survey also draws respondents' attention to the plastic challenges in agriculture, provides information on the subject and on the other hand helps to find out what kind of information on plastics is needed by the agricultural and horticultural producers, landscapers and home gardeners.

6.07.P-We286 Human Risk Assessment of Organophosphate Ester Plasticizers in Drinking Water and Other Beverages

Julio Fernández-Arribas¹, Teresa Moreno² and Ethel Eljarrat³, (1)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Barcelona, Spain, (2)Institute of Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain, (3)IDAEA-CSIC, Spain

According to the latest available data, plastic production has reached almost 370 million tons worldwide, which 58 million tons correspond to Europe. Packaging is the main application for plastics, mostly for food and beverages. Plastic materials contains chemical additives, which may release to the environment during its use and manufacturing, and also may migrate from the package to the contained food. This issue is an associated outcome of plastic pollution, and it is a human exposition path for organic and inorganic contaminants that must be explored. Organophosphate esters (OPEs) are a group of chemicals commonly used as plastic additives and flame retardants. Their reported toxic effects, such as the development of asthma and allergies, has led to an increasing concern for these emerging pollutants. Tri-n-butyl phosphate (TNBP) has been shown to be an endocrine disruptor. In fact, human exposure to TNBP, 2-ethylhexyldiphenyl phosphate (EHDPP) or triphenyl phosphate (TPHP) seems to be associated with cervical cancer. Additionally, the USEPA have recently established oral reference doses (RfD) and oral cancer slope factors (SFO) for some of the OPEs. Based on these values, an assessment of the non-carcinogenic (non-CR) and carcinogenic (CR) risks of human exposure to OPEs can be performed. Multiple studies about OPE occurrence in air or ground water have been done. Nonetheless, there is a lack of data about OPE exposure through beverages or food ingestion. The main objective of the present study is to evaluate OPE occurrence in different beverage samples, such as tap water, bottled water, cola drinks, juices, wines, tea and coffee infusions. Likewise, an assessment of human risk impact will be carried out. OPEs were detected in most of the analysed samples. The highest levels were found in cola drinks, with a mean value of 2906 ng/L. EHDPP was the major contributor, with ranges between 29.3 and 5855 ng/L. Taking into account these results, it is possible to accomplish an assessment of estimated daily intakes (EDIs) related to water and beverages ingestion. Based on Spanish *per capita* consumption, the highest values for EDI in adults were obtained for EHDPP in cola drinks, with 2.18 ng/kg body weight/day. These results showed up the human exposure to plastic additives in drinks and, hence, the importance of focusing on chemicals associated to plastic pollution, in order to contribute to the development of legislation to restrict the use of plastics.

6.07.P-We287 Methodological Approach to Assess Measures to Reduce Microplastics in the Environment

Aybüke Özdamar¹, Daniel Maga² and Jürgen Bertling², (1)Fraunhofer UMSICHT, Oberhausen, Germany, (2)Fraunhofer UMSICHT, Germany

Microplastics are found in nearly every compartment of the environment: air, urban, rural and agriculture soil, sediments, sea, surface and river water, shorelines, even in the arctic, in animals and the humans. Hence, the topic of microplastics is getting increasingly more attention from research community. Although there are ongoing efforts to increase our understanding about microplastics, there are still some important research gaps. One of which is connecting the knowledge from experimental research to propose mitigation measures. The present work intends to tackle the microplastics issue from broader perspective. The aim of this research is to develop robust proposals on how to assess and to mitigate the impacts of microplastics. In order to do that the researcher investigates the point and quantities of microplastics losses along the whole life cycle of selected products / applications. This is combined with a subsequential fate modelling to understand the pathways of microplastics from point of loss to environmental compartments and to estimate the amounts that reach final environmental compartments. In order to understand the effectiveness of measures (e. g. restriction, ban, information education), various intervention scenarios will be developed. These scenarios will be evaluated by prospective life cycle assessments including a new impact assessment methodology, which addresses the plastics persistence in the environment. It is anticipated that the researcher comes up with a ranking of possible behavior and policy recommendations to mitigate microplastics' impacts. The developed methodology will be applied to three field of plastic application: tires, textiles and construction insulation material (expanded polystyrene). Main reason for selecting these microplastics sources is that to look into different point of loss and pathways to environmental compartments, as well as difference in material properties (in particular density, shape and size). Although the research focuses on certain microplastics sources as a case study, it is expected that the methodology developed and used can be also adapted to other microplastics sources.

6.07.P-We288 How Environmental Regulation Can Drive Innovation - Examination of Three EU Environmental Regulations

Lauge Clausen¹, Maria Bille Nielsen², Nikoline Oturai³, Kristian Syberg⁴ and Steffen Hansen¹, (1)Technical University of Denmark, Denmark, (2)DTU (Technical University of Denmark), Denmark, (3)Science and Environment, Roskilde University, Roskilde, Denmark, (4)Roskilde University, Denmark

Regulation is often seen as a barrier to innovation. However, if done properly, it can serve as a driver of innovation. To understand how environmental regulation can be designed to stimulate innovation, we scrutinise the scientific literature related to

regulation, innovation and the environment. Fifty carefully selected studies are examined with regard to their scope, results and geographical affiliation, and their findings are distilled into ten lessons on how to design environmental regulation to stimulate innovation: 1) Environmental regulation should guide innovation; 2) The transition period is vital for industry if it wishes to adapt and find innovative solutions; 3) Clear and concise regulations; 4) Flexible regulation and compliance deadlines; 5) Provide economic incentives and other benefits for (doing more than) complying; 6) A regulatory process where all voices are heard; 7) Evaluation of effects on innovation; 8) Secure support and capacity-building; 9) Multiple regulatory measures are needed; 10) Minimise the costs of compliance: the proportionality principle. Subsequently, we analyse three recent EU environmental regulatory initiatives (Nano-specific REACH annex revisions, the Single-Use Plastic Directive and the Waste Framework Directive) and evaluate them against identified lessons learned. In conclusion, the three regulations do support most of the lessons learned; however, none of them supports economic incentives for doing more than complying, meaning that regulatory-driven innovation is at a risk of stalling or coming to a halt when compliance requirements are met.

6.07.P-We289 The European Union Against Plastic Pollution: How to Shift From a Fragmented to a Cohesive Legal Framework?

Giorgia Carratta, HHL gemeinnützige GmbH, Leipzig, Germany

Since the beginning of mass production, plastic items have been crucial in our daily lives. Thanks to their physical and chemical properties, plastic materials have proven almost irreplaceable in a number of economic sectors: packaging, automotive, building and construction, textile and many others. At the same time, the “overaccumulation” of plastics in the environment, and its adverse effects on habitats, wildlife and (potentially) human health, represent a call for action to decision-makers around the globe. The situation in the EU27 Member States is not dissimilar: almost 26 million tonnes of plastic waste is generated herein every year, whose 24,9% is still destined to landfill. Thanks to the new *Circular Economy Action Plan*, approved in March 2020 by the Commission, EU countries are slowly but steadily shifting to a carbon neutral, circular economy, in the attempt to reduce the pressure on natural resources and, parallelly, facilitate sustainable economic growth. The EU’s *Plastic Strategy* is a crucial part of such vision, and it is promising to change the way plastic is designed, produced, used and treated after consumption. Positive effects of the Strategy include: a more effective protection of our environment, especially the marine one, the reduction of greenhouse gas emissions, a reduced need for imported fossil energy sources, more sustainable production and consumption patterns. As promising as it may sound, the road ahead is still long. From a regulatory perspective, the design of new legal instruments, the amendment of existing ones, and the coordination among the several relevant policy areas, would require a considerable effort. An analysis of the current European Union legal framework on plastic, inclusive of both binding and voluntary instruments, could serve to detect blind spots in the current governance and move toward an improved plastic management in the EU.

6.07.P-We290 Are Europeans Worried About Microplastic Pollution? Attitudes, Actions, and Factors Behind

Renata Dagiliute and Aušra Dikšaitytė, Vytautas Magnus University, Lithuania

Microplastic pollution attracts research and policy attention due to its negative human health and environmental impacts. Though many of microplastics is intentionally added into the products, the majority of the microplastic particles found in the environment is a result of use and pollution of bigger plastic units. The study, referring to the Eurobarometer survey on environmental attitudes (2020), aims to analyse the trends in attitudes toward marine pollution, microplastic pollution, behavioural response and factors influencing attitudes and actions taken regarding plastic and microplastic pollution reduction. Results show that in general marine pollution is considered as important environmental issue only by 36.5% Europeans. However, 49% respondents totally agree and 38.6% tend to agree that they are worried about microplastic pollution. The most concerned are citizens of Cyprus and Spain. Some 52.4% Europeans indicated that protection of the environment is personally very important to them. Regarding the actions related to the plastic and microplastic pollution, respondents indicated to avoid of single use plastic products (except plastic bags) (43.8%) and overpacked products (28.4%), and most often Europeans separated waste (65.5%). Regression analyses indicate that those considering marine pollution as important environmental problem and environmental protection being an important thing personally more often are worried about microplastic pollution ($p < 0.05$). In turn, those from small households, with higher incomes, women, older and from the bigger towns as well as those thinking that marine pollution is an important problem and considering environmental protection personally very important take more actions to reduce environmental pollution in general ($p < 0.05$). The most important in reducing plastic waste and littering for the Europeans appeared to be the role of industries and retailers, as well as product design (66.3%), extra charges for single use plastic products are acknowledged as very important measure only by 33.3% respondents. The main source of environmental information remains traditional channels: TV and newspapers, but internet and social media is gaining attention. In-between social media channels, Facebook is the leading source of the environmental information for respondents.

6.08 Tackling Marine Pollution on the Road to Sustainable Use of Marine Ecosystem (Virtual Only)

6.08.V-01 From Past to Future - Longterm Trends of Marine Pollution in the German Bight of the North Sea

Matthias Hasenbein¹, Simone Hasenbein² and Torben Kirchgeorg³, (1)German Federal Maritime and Hydrographic Agency (BSH), Hamburg, Germany, (2)Technical University of Munich, United States, (3)German Federal Maritime and Hydrographic Agency, Germany

Pollution has been an environmental issue for decades and great efforts have been made to monitor, identify and survey contaminants of concern over a number of years. The main objective of the European Marine Strategy Framework Directive is to achieve “Good Environmental Status” of EU waters by 2020. However, this goal was not yet met for the German North Sea, also

due to increased concentrations of contaminants. This highlights the need for a better understanding of pollution as a stressor in general and calling for targeted action in order to improve ecosystem health. The Federal Maritime and Hydrography Agency has monitored contaminants in the German EEZ for the past decades ranging back to the mid 70ies for selected substances and sampling sites. Our contaminant monitoring efforts focus on heavy metals and a wide range of organic compounds (e.g., organochlorines, polycyclic aromatic hydrocarbons and pesticides). This data was analyzed for two different time periods (1980 – 2000; 2001 – 2020) to evaluate changes over time. Here, we present long-term trends for several contaminants of concern such as heavy metals and organic compounds in the sediment and water column. Furthermore, we compared the long-term changes in the spatial distribution of selected contaminants between the two periods to identify potential sites of elevated pollution (“Hot-spots” of pollution). This analysis forms the basis for multiple stressor modeling approaches for future changes and management scenarios that will be conducted in the wide spanning project MuSSEl (Multiple Stressors on North Sea life). Our findings will aid future monitoring efforts and help make informed decisions for managing the marine environment.

6.08.V-02 Global Governance in Arctic Waters - New Times. New Stressors. Catching up With Pharmaceuticals

Emily Cowan¹, Thea Lurås Oftebro², Roland Kallenborn³, Geir Gabrielsen⁴, Ida Beathe Overjordet¹, William Tiller¹ and Rachel Tiller¹, (1)SINTEF Ocean, Norway, (2)SINTEF Ocean, Trondheim, Norway, (3)Norwegian University of Life Sciences, Norway, (4)Norwegian Polar Institute, Norway

Arctic ecosystems are increasingly under pressure, not only from climatic stressors, resource extraction, and long-range transport of Persistent Organic Pollutants (POPs), but also from an increased use and release of Pharmaceuticals and Personal Care Products (PPCP). In Svalbard, an archipelago under Norwegian sovereignty in the High North, urbanization and expanded tourism has exacerbated the issue of PPCPs accumulation in the region. The primary source of its release into aquatic ecosystems stemming from untreated sewage and lack of Wastewater Treatment Plants (WWTPs). This study applies the research surrounding sources of hazardous bioaccumulation and discusses mitigation alternatives for PPCPs within a governance framework since today, few regulations regarding human waste disposal are enforced in the Arctic. We held in-depth interviews and a participatory stakeholder workshop in Longyearbyen and Ny-Ålesund in 2021 to learn from experts about their perceptions of challenges, opportunities and synergies in terms of PPCP governance in Svalbard. This study found that overall, governance is severely lacking at all levels of analysis, from local to global, to prevent the harmful release of PPCPs in the waters and environment surrounding Svalbard. An inclusive approach with co-production of policy solution options is necessary to find a suite of solutions that will ensure that this new emerging environmental threat is handled so that the Arctic biodiversity is protected against it, and the local community of Longyearbyen may be a future good example of this for further research.

6.08.V-03 Heavy Metal Exposure in Bottlenose Dolphins (*Tursiops truncatus*): Differences in Blood Concentrations of Hg, Cd, Pb and As Between Captive and Wild Dolphins

Isabel Navas¹, Mar Felipo-Benavent², Consuelo Rubio-Guerri³, José O'Connor-Blasco⁴, Alicia Martínez-Romero⁵ and Antonio Juan Garcia-Fernandez¹, (1)University of Murcia, Spain, (2)Oceanografic Foundation, Valencia, Spain, (3)CEU Cardenal Herrera University, Spain, (4)University of Valencia, Spain, (5)Príncipe Felipe Research Center, Valencia, Spain

Bottlenose dolphin as a top predator species may serve as a good monitor of contaminants in marine ecosystem. Heavy metals concentrations in blood of 30 bottlenose dolphins (*Tursiops truncatus*) have been investigated in this study. Two groups of animals have been considered: captive dolphins under human care (n=14, group 1) and wild dolphins (n=16, group 2). Group 1 was composed of 14 captive dolphins (4 males and 10 females) from two specialized centers in Valencia (Spain). Group 2 was composed of 16 wild dolphins inhabitants of the Sarasota Bay in the context of Sarasota Dolphin Research Program carried out in Sarasota (Florida, USA). Veterinarians participated in the health control of the animals and no dolphin presented lesions or active health concerns during the sampling. As a part of the health assessment, citrated and heparinized whole blood samples were collected. Finally, the animals were released to the sea. Dolphin samples were collected under National Marine Fisheries Service Scientific Research Permit No. 20455, and it was approved by the Mote Marine Laboratory Institutional Animal Care and Use Committee (IACUC). For analysis of Pb, Cd and As blood samples were digested using an Ultrawave system (Milestone, Inc. USA). Metal concentrations were analysed by ICP-MS. Analysis of Hg were carried out with a direct mercury analyser (DMA80, Milestone, USA). Hg showed the highest concentration, followed by As, Pb and Cd. Significant differences were observed when the blood metal levels were compared between captive and wild dolphins. Concentrations of mercury, arsenic and cadmium in wild dolphins were higher than in captive dolphins (Hg: 387.5±236.8 ng/g vs 25.5±6.9 ng/g; As: 46.1±40.68 vs 17.39±9.12 ng/g; Cd: 10.18±22.9 ng/g vs non-detected). On the contrary, in the case of lead, mean concentration was lower in wild (23.4±51.0) than in captive (44.3±35.6 ng/g) dolphins. No significant differences in metal concentrations were found between sexes. Correlations with age and weight of the dolphins were evaluated with the blood metal concentrations. A negative correlation was found between As concentration and the weight of the dolphin (-0.661, p=0.01), but only in captive dolphins. On the other hand positive correlations were found between mercury concentrations of wild dolphins with the age (0.775, p< 0.01) and the weight (0.736, p< 0.01, n=14), respectively. Between metal concentrations only a high correlation cadmium-lead was found (0.961, p< 0.001).

6.08.V-04 Integrating Ecotoxicology Into Decommissioning Offshore Oil and Gas Infrastructure Decision Making

Tom Cresswell¹, Amy MacIntosh², Darren Koppel³, Libby Howitt⁴ and Francesca Gissi¹, (1)ANSTO, Australia, (2)Macquarie University, Australia, (3)Australian Institute of Marine Science, Australia, (4)AddLib Environmental Consulting, Australia

There has been a substantial body of work investigating the benefits of leaving offshore oil and gas infrastructure *in-situ* as part of decommissioning operations, such as the provision of artificial reefs that increase marine organism biomass, biodiversity and potentially support fisheries. Such research has been conducted in Europe, the US and the Asia Pacific. However, there is no

framework to address potential contaminants within the decommissioned infrastructure (e.g. scale and associated bound contaminants on internal surfaces of production pipelines) and even less is known about the long-term environmental fate of associated contaminants. Consequently, there is little publicly available information on contaminant assessments for offshore infrastructure. Although contaminants are initially contained in the infrastructure, corrosion may lead to them being released to the surrounding environment, where bioaccumulation and subsequent ecotoxicological effects could occur. Current assessments of infrastructure-associated contaminants rely on model predictions with untested assumptions, therefore model validation and supporting data are urgently required to inform risk assessments. Given that governments and industry around the world have a significant future liability in ensuring safe decommissioning of offshore infrastructure, successful decommissioning should maximize environmental benefits and cultural and economic value, while minimising the costs and risk of the activity. SETAC members represent a range of disciplines (ecology, chemistry, ecotoxicology, risk assessments etc) required to address critical data gaps about contaminants in offshore oil and gas infrastructure. We propose the formation of a SETAC interest group (IG) to leverage the expertise in our society and to facilitate knowledge exchange needed to maximise environmental benefit and inform key decisions around decommissioning. This poster will present an overview of the offshore decommissioning process and highlight the need to integrate ecotoxicology, facilitated by a new SETAC IG, into decommissioning policy frameworks.

6.08.V-05 Produced Water Discharge and Impact on Marine Environment

Kirit Wadhia, National Oilwell Varco (NOV), United Kingdom

The discharge of produced water is of concern in view of potential environmental impact. Approach involving mere chemical analysis is no longer considered sufficient. A holistic approach entailing whole effluent toxicity (WET) assessment from an ecotoxicological perspective has been increasingly advocated. Moreover, there is a need to employ a risk-based approach/assessment (RBA). RBA has been instigated under OSPAR initiative and member countries have put in place appropriate implementation programmes. This presentation provides a comprehensive perspective of the UK RBA process. An insight into the development of the initial trial to the formulation of the current stepwise programme process involving chemical analysis, ecotoxicity testing, modelling and reporting. Key considerations of the produced water risk management elements are discussed. The aspect of intrinsic toxicity contribution from production chemicals and naturally occurring substances is examined. Essential considerations of the key regulatory criteria and drivers are analysed. The implication of the findings of the initial phase of the UK risk-based approach (RBA) programme are highlighted and how these impact future sustainable developments. A definitive evaluation of the global RBA panorama is presented to rationalise top-down and bottom-up strategies conveying the global disparity that exists in the regulatory approach and existing infrastructure to consolidate the way forward. The predictions are that major oil companies not only will continue with current level of production but will expand their operations that extract and refine fossil fuels. The realisation is becoming all too apparent that in order to have a stable and safe planet reaching net zero emission is imperative. Whilst renewables are viewed favourable in terms of significant growth area, indubitably the issues and considerations pertaining to safe discharge of produced water remain at the forefront. The intrinsic elements of importance for evaluation including production chemicals and naturally occurring substances play a key part. Methodology for assessment and inference from a global regulatory perspective lacks definitive approach and the disparity that exists inevitably compounds issues and instils lack of confidence. Scope for pragmatic and prudent solutions to address pertinent issues will be highlighted. **RBA Toxicity Marine Ecosystem**

6.08 Tackling Marine Pollution on the Road to Sustainable Use of Marine Ecosystem (Poster)

6.08.P-Mo263 Acute Toxicity of Arsenic-Based Chemical Warfare Agent Clark I to Aquatic Primary Producers

Tomasz Brzezinski¹, Michał Czub², Daniel Dziedzic³, Jakub Nawał^{a3}, Stanisław Popiel³, Wojciech ?liwakowski² and Wojciech Wilczyński², (1)Department of Hydrobiology, Faculty of Biology, University of Warsaw, Warsaw, Poland, (2)University of Warsaw, Faculty of Biology, Poland, (3)Military University of Technology, Faculty of Advanced Technologies and Chemistry, Poland

Sea-dumping of Chemical Warfare Agents (CWAs) was a common practice worldwide during the 20th century. CWAs dumped in the seas and freshwaters pose a potential environmental hazard. The greatest concerns are raised by the presence of submerged arsenic-based CWAs, due to their persistence in aquatic environment and the fact that after degradation in water they may be a source of secondary pollution and release of toxic inorganic arsenic. The ecological effects of these CWAs on aquatic primary producers have not been studied yet. In standardized laboratory bioassays we quantified the inhibitory effects of Clark I (diphenylchloroarsine) – an incapacitating agent, which was used in combat during World War I and after world wars as a riot control agent, on population growth rates of three species of green-algae (*Scenedesmus obliquus*, *Chlorella vulgaris*, *Chlamydomonas klinobasis*) and three species of cyanobacteria (*Synechococcus elongatus*, *Anabaena cylindrica* and *Aphanizomenon gracile*). Clark I was found to be very toxic to all of the tested species of primary producers. The species differed from each other in susceptibility to the presence of Clark I, the variation among species in LOEC spanned the range of three orders of magnitude. Green-algae on average seemed to be less susceptible than cyanobacteria. The effects of Clark I on aquatic primary producers should be taken into account in assessments of the impact of organic-arsenic CWAs on aquatic ecosystems.

6.08.P-Mo264 Acute Toxicity of Arsenic-Based Chemical Warfare Agents to Danio rerio Embryos

Wojciech Wilczynski¹, Tomasz Brzezinski², Piotr Maszczyk², Antoni Ludew³, Michał Czub⁴, Daniel Dziedzic⁵, Jakub Nawał^{a5}, Stanisław Popiel⁵, Jacek Bełdowski⁴ and Monika Radlińska⁶, (1)University of Warsaw, Faculty of Biology, Institute of Microbiology, Poland, (2)University of Warsaw Faculty of Biology, Poland, (3)Medical University of Warsaw, Poland, (4)Instytut Oceanologii PAN, Poland, (5)Military University of Technology, Faculty of Advanced Technologies and Chemistry, Poland,

(6) *Institute of Microbiology, Faculty of Biology, University of Warsaw, Poland*

During the 20th century, several hundreds of thousands tons of munitions containing chemical warfare agents (CWAs) were dumped in the seas and oceans. Recently, CWAs have started to leak from the corroded munitions and their concentrations in the bottom waters are expected to peak in the next decades. Based on the physical and chemical parameters of sea-dumped CWA and their effects on aquatic invertebrates, it has been established, that among CWA, arsenic-based agents, and their degradation products are the most threatening chemical hazards with long lasting effects on aquatic ecosystems. However, as of yet, there is still a lack of knowledge about the toxicity of these arsenic-based CWA on aquatic vertebrates, such as fish, which are not only crucial for the marine ecosystems but also for human economy. There is a lot of ambiguity regarding the toxicity of CWA to marine life, as existing studies do not comply to full track of OECD (Organisation for Economic Cooperation and Development) toxicity establishment procedure. The aim of this study was to address this gap, by providing real-data quantification of arsenic based CWAs toxicity to the embryos of fish (using a model species, *Danio rerio*), which is essential for further environmental risk assessment. In order to estimate the toxicity thresholds (NOEC, LC50) of arsenic-based CWAs (Clark I, Adamsite, phenyldichloroarsine (PDCA)), a CWA-related compound (triphenylarsine - TPA), as well as two arsenic-based CWA degradation products (Adamsite[ox] and TPA[ox]), standardized assays were performed, following OECD guidelines (Fish Embryo Acute Toxicity Test, no. 236). The tested concentrations of arsenic-based CWA caused lethal effects to *Danio rerio* embryos either after 24, 48, 72 or 96h exposure. However, the tested CWA-related compound (TPA) showed no adverse effects even at maximum solubility and the CWA degradation products have shown no adverse effects at concentrations up to 100 mg × L⁻¹.

6.08.P-Mo265 Plastic Pollution in the South Eastern Pacific Region: Identifying "Hot-Spots" to Inform Sustainable Solutions

Francisca Ribeiro¹, Jen Jones², Jessica Howard², Brendan Godley³, Nicole Becerra⁴, Eliana Alfaro⁵, Joanna Alfaro⁵, Jeffrey Mangel⁶, Ceri Lewis⁷ and Tamara Galloway³, (1)Queensland Alliance for Environmental Health Sciences (QAEHS), The University of Queensland, United Kingdom, (2)Galapagos Conservation Trust, United Kingdom, (3)University of Exeter, United Kingdom, (4)Ichthion, United Kingdom, (5)ProDelphinus, Peru, (6)ProDelphinus/ University of Exeter, United Kingdom, (7)Biosceinces, University of Exeter, Exeter, United Kingdom

Plastic pollution is a well-known and persistent threat in oceanic environments worldwide. In the South Eastern (SE) Pacific, ocean plastic pollution is particularly concerning due to the region's unique habitats and exceptional biodiversity. The coastal communities here are highly dependent on the marine environment for their livelihoods, sustenance, and wellbeing (e.g. tourism or fishing). It is therefore imperative to understand the sources and extent of plastic contamination in the area to help build local and sustainable solutions. Thus, to better understand the extent of plastic contamination in the region and help to find solutions for this emerging issue, we conducted a meta-analysis of peer-reviewed literature on macro- and microplastic debris in the ocean and coastal beaches of nine countries in the SE Pacific region (Mexico, El Salvador, Nicaragua, Costa Rica, Panama, Colombia, Ecuador, Peru and Chile). We combined quantitative abundance data on macro- and microplastics with unpublished results from two partners of this project: Ichthion (Ecuador) and Pro Delphinus (Peru). The present study had three main aims: (1) assess the status of plastic contamination in the SE Pacific region, (2) overlay the identified "hot-spots" of plastic contamination with Marine Protected Areas (MPAs) and (3) provide solutions and mitigation actions based on economics and societal change. Our analysis revealed that over 8 years of research, a considerably low number of studies on plastic pollution have been published, especially for some countries such as Nicaragua, Panama, El Salvador, Colombia and Peru. There is also a significant data gap for microplastic assessment in the region, mainly due to technical limitations and lack of resources. Nevertheless, the current data suggests that many of the MPAs in the SE Pacific may be affected by plastic, requiring urgent action. The results of this study will hopefully help to build and promote solutions informed by robust science, and influence policy makers in future decisions.

6.08.P-Mo266 Effects of Plastic Associated Chemicals on the Development and Settlement of Early Life Stages of Four Common Coral Reef Invertebrates

Gal Vered¹ and Noa Shenkar², (1)Tel Aviv University, Israel, (2)Tel-Aviv University, Israel

Plastic materials are currently recognized as an emerging issue of international concern threatening marine environments worldwide. Plastic additives (PAs) are chemical compounds incorporated into plastics during production, many of these chemicals are known endocrine disruptors and can potentially leach out of plastic debris into the environment. In the marine environment, biota-debris interactions are more likely to occur in coastal marine habitats featuring high biological activity such as fringing coral reefs. While coral reefs provide important ecosystem services that benefit society, our knowledge of plastic pollution impact on coral-reef organisms is still scarce, and no data exist on PAs effect on key reef-building species. As reef population structure is directly linked to reproduction and offspring settlement processes, the endocrine disruptor properties of PAs can play an important role in a coral reef community structure, even more so, if these effects differ among species. This study examines the effects of exposure to environmental and high concentrations of dibutyl phthalate (DBP), dimethyl phthalate, (DMP), 4-nonylphenol (4-NP), and bisphenol A (BPA), on early life stages of four coral reef invertebrates common in the Red Sea. We measured the following parameters: (1) Larvae settlement of the solitary ascidian *Herdmania momus*, the soft coral *Rhytisma fulvum fulvum*, and the stony coral *Stylophora pistillata*, (2) Fertilization success, and larvae development of *Herdmania momus*, and the calcifying hydrozoan *Millepora dichotoma*. All applied PAs affected negatively and unevenly the success of the development or settlement of one or more of the tested species, where the high concentration of 4-NP had the largest effect on all species. Although environmental concentrations of PAs found in seawaters are far below the high concentrations used in our experiments, it is the level of PAs within the body of the organism that the gametes and brooding planulae are exposed to. Each of the chosen organisms represents a major taxonomical group that can be found in tropical coral reefs around the world. Our findings

demonstrate for the first time the negative effects of PAs on coral-reef organisms, and specifically, the significant effect found during exposure to environmental concentrations of DBP and 4-NP on reef-building corals. This study is an alarm call for future investigation on the effects of PAs on coral reef organisms.

6.08.P-Mo267 Citizen Observation of Plastic Pollution in African Coastal Ecosystems to Address Data Gaps in Marine Litter Distribution

Ana I Catarino¹, Edem Mahu², Lailah Gifty Akita³, Kouame Lazare Akpetou⁴, Pavanee Angelee Annasawmy⁵, Francis Emile Asuquo⁶, Fiona Beckman⁷, Mostapha Benomar⁸, Gert Everaert⁹, Annette Jaya-Ram¹⁰, Lilian A. Krug¹¹, Mohammed Malouli⁸, Ivanice Monteiro¹², Péricles Neves Silva¹², Nubi Olubunmi Ayoola¹³, Sophie Seeyave⁷, Marine Severin¹⁴, Zacharie Souhou¹⁵, Aileen Tan Shau Hwai¹⁰, Soukaina Zizah⁸, Sau Pinn Woo¹⁰ and Yee Kwang Sim¹⁰, (1)Flanders Marine Institute, VLIZ, Belgium, (2)University of Ghana, Ghana, (3)University of Ghana, Greece, (4)Université Félix Houphouët-Boigny, Côte d'Ivoire, (5)Lynker Technologies, France, (6)University of Calabar, Nigeria, (7)Partnership for Observation of the Global Ocean (POGO), United Kingdom, (8)Institut National de Recherche Halieutique, Morocco, (9)Flanders Marine Institute, Belgium, (10)Universiti sains Malaysia, Malaysia, (11)Partnership for Observation of the Global Ocean (POGO), Portugal, (12)IMAR- INSTITUTO DO MAR, Cape Verde, (13)Nigerian Institute for Oceanography & Marine Research, Nigeria, (14)Flanders Marine Institute VLIZ, Belgium, (15)Institut de Recherches Halieutiques et Oceanologiques du Benin, Benin

The accumulation of plastic litter in coastal environments has become an issue of high priority for policymakers around the globe, due to the potential hazardous effects to biota and human health, and the impact on ecosystem services and in local economies. To develop effective mitigation measures, it is critical to acquire knowledge on the distribution and levels of plastic litter. However, in many regions, such as West Africa, the exact quantity of plastics reaching coastal areas is still poorly known. To address the data gaps in marine plastic litter distribution worldwide, citizen science programs are instrumental in complementing shoreline assessments, and are effective in increasing public awareness of plastic pollution. The Citizen Observation of Local Litter in coastal ECosysTems (COLLECT) project is a citizen science initiative which aims to acquire distribution and abundance data of coastal plastic debris in seven countries, in Africa (Benin, Cabo Verde, Côte d'Ivoire, Ghana, Morocco, Nigeria) and Asia (Malaysia). The project consists of training local students (15-18 years old) from secondary cycle institutions on sampling and analysing macro, meso and microplastic in beach sediments, using scientific procedures. The project will also measure the impact of the citizen science intervention by assessing shifts in ocean literacy and pro-environmental behaviour, while simultaneously considering gender differences. The COLLECT project contributes to the United Nations' Sustainable Development Goals by focusing on #11 the sustainability of communities and #14 the sustainable use of the ocean. Besides, the project relates to #3 the impact on good health and wellbeing and #5 gender equality, while #12 promoting a responsible disposal of consumer goods. COLLECT also reaches to the UN Ocean Decade challenges #1 understanding and beating marine pollution, #9 skills, knowledge and technology for all, and #10 change humanity's relationship with the ocean. The results from COLLECT will contribute to establishing baseline information on coastal plastic debris, with citizen science being an enabler of open science, allowing data to be freely available to the public, academics and policymakers. Results will further contribute to the identification of hotspots of plastic coastal litter, and bring awareness to local communities on the potential consequences of plastic pollution.

6.08.P-Mo268 Integrated Assessment of Chemical Contamination and Its Biological Effects Through Monitoring of Sediment, Mussels and Flatfishes

Vincent Roubeix¹, Farida Akcha², Yann aminot², Melanie Brun², Thierry Burgeot², Tiphaine Chouvelon³, Anne Grouhel-Pellouin⁴, Tiphaine Mille¹, Catherine Munsch², Nathalie Wessel², Tifanie Briaudeau⁵, Urtzi Izagirre⁵, Kelig Mahe² and aourell Mauffret⁶, (1)IFREMER, RBE-BE, France, (2)IFREMER, France, (3)IFREMER, RBE-BE-LBCM, France, (4)IFREMER, RBE-BE-ROCCH, France, (5)University of the Basque Country, Spain, (6)BRGM, France

A program to monitor chemical contamination and its effects in the marine environment (SELI) has been implemented in France within the European Marine Strategy Framework Directive context. Campaigns organized around estuaries of major French rivers, Seine and Loire, have provided measurements of various ecotoxicological parameters including contaminant concentrations in three matrices (sediment, mussels and soles) and biomarkers (in mussels and soles). The large number of these parameters complicates the overall ecotoxicological assessment and the comparison of different marine areas. The integration of the parameters in the form of synthetic indicators enables the information to be condensed in a comprehensible manner. Two approaches based on the comparison of parameters to thresholds were used. The first one counts the threshold exceedances of the parameters (derived from ICES 2012 method) while the other one calculates an average ratio of the values of these parameters on their environmental threshold (derived from HELCOM CHASE method). Graphical representations of the results and the use of quality classes allow for a quick visualization of the impacts of contamination over several sites. Between Loire and Seine, despite different levels of contamination, preliminary results suggested that biological effects were similar. This integrated multi-matrix approach, chemical and biological, could be extended to other marine regions to monitor the evolution of marine ecosystems with respect to chemical contamination.

6.08.P-Mo269 Critical Review of the Risk Based Approach for Produced Water Discharges From Offshore Oil Production

Lars Skjolding¹, Ann Nielsen², Simon Andersen² and Anders Baun³, (1)DTU, Denmark, (2)Technical University of Denmark, Denmark, (3)Department of Environmental and Resource Engineering, Technical University of Denmark, Kgs. Lyngby, Denmark
Produced water constitutes the largest wastewater stream associated with offshore oil extraction. In 2018 the estimated discharge from offshore activities in the North East Atlantic was 300 million m³. Produced water is a complex mixture of chemicals potentially causing adverse effects on the receiving marine environment if not managed properly. The compounds of specific concern includes metals, benzene, toluene, ethylbenzene and xylene, polycyclic aromatic hydrocarbons, phenol, alkyl phenol,

organic acids and naturally occurring radioactive materials and production chemicals (e.g. biocides). The discharge must comply with governing regulations of the respective area. Common limit values are defined by the Oil in Water (OiW) content by either a daily maximum of 20 to 100 mg/L or a monthly average ranging from 29 to 40 mg/L. Often the OiW criteria is fulfilled as an example the reported annual average since 2010 for the Danish Underground Consortium was 7 mg/L. However, there is concern of adverse effects related to the aqueous fraction independent of the OiW content. Consequently, produced water discharges in the North East Atlantic has since 2010, been managed using a Risk Based Approach (RBA) considering the risk of the whole discharge in relation to the sensitivity of the receiving environment. The RBA consists of six steps, 1) Data collection, 2) Hazard Assessment, 3) Exposure Assessment, 4) Risk Characterization, 5) Risk Management and 6) Monitoring. Inherently, complex mixtures such as produced water are difficult to characterize both in terms of chemical constituents but also in terms of behavior in standardized test setups. Consequently, data curation and reporting criteria is key to avoid introduction of unnecessary uncertainties carrying over and amplifying in the following steps of the RBA. This poster presents the results of a literature review considering the regulatory adequacy of the data available in the scientific literature for use in the RBA. Additionally, the poster highlights limitations to the current iteration of the RBA and propose recommendations to improve the RBA for a more transparent evaluation of the risk associated with the produced water discharge.

6.08.P-Mo270 Effects of Copper and 4-Tert-Octylphenol in Acute and Chronic Exposure on Biomarkers in Amphipod Crustaceans (Baltic Sea)

Evita Strode¹, Nadezhda Berezina² and Ieva Barda³, (1)Latvian Institute of Aquatic Ecology, Riga, Latvia, (2)Russian Academy of Sciences, Russian Federation, (3)Latvian Institute of Aquatic Ecology, Latvia

Alkyl-phenols, the group of nonionic surfactants, are industrial pollutants commonly found in wastewater. Octylphenol, one of the most toxic compounds to aquatic organisms, is not easily degraded in the environment, and has the potential to cause significant endocrine disruption effects. Copper is among the main active substances contained in antifouling paints on boats used for many years in Europe. Amphipods are important components of aquatic ecosystems and nowadays have been widely used to assess environmental pollution. This study aimed to determine potential risks of copper < st1:citation w:st="on">(Cu) and 4-tert-octylphenol < st1:citation w:st="on">(4t-OP) at acute and chronic exposure on various amphipod species and assess their health status by responses of different biomarkers < st1:citation w:st="on">(oxidative stress, reproductive health and others). The acute < st1:citation w:st="on">(96-hour) or chronic < st1:citation w:st="on">(42 Days) toxicity of copper and 4-tert-octylphenol were detected using different amphipod species based on ISO standards < st1:citation w:st="on">(16712:2005 and 16303:2013). Selected biomarkers (AChE, GST, CAT and reproductive disorders) were measured at the end of acute and chronic tests to represent different types of biological responses. The sublethal concentrations < st1:citation w:st="on">(LC₅₀) varied from 0.2 mg/l to more than 10 mg/l after 96-h exposure of Cu and were higher than 0.5 mg/l after 96-h exposure of 4t-OP. The chronic toxicity of 4t-OP was more pronounced to native species: *Monoporeia affinis* (LC₅₀ 0.65 µg/L) and *Gammarus oceanicus* < st1:citation w:st="on">(5 µg/L) than laboratory cultivated *Hyaella azteca* < st1:citation w:st="on">(294 µg/L, respectively). Enzymatic biomarkers showed significant (ANOVA p< 0.05) influence of chemicals on organisms at elevated concentrations compared to control. The reproductive potential < st1:citation w:st="on">(fecundity) in *H. azteca* averaging 5.7 eggs/per female and body size of organisms after 42 days exposure to 4t-OP did not show significant (ANOVA p>0.05) differences in *H. azteca* development compared to control. However, high reproductive disorders as malformed embryos per females (1.3-10%), as well as undeveloped and dead eggs < st1:citation w:st="on">(5-25%) were detected in higher 4t-OP concentrations. Using another species, *Gmelinoides fasciatus*, high mortality of embryos and number of them that stopped development < st1:citation w:st="on">(>50%) were identified after chronic exposure to 0.5 µg/L of 4t-OP. In general, Cu and 4t-OP concentrations of ecotoxicity tests and biomarker responses indicate the negative effects on amphipods' health or reproductive quality in long-term exposure. Research is supported by ERDF post-doctoral research grant 1.1.1.2/16/I/001 < st1:citation w:st="on">(application No 1.1.1.2/VIAA/3/19/465).

6.08.P-Mo271 Preliminary Insights on Sea Surface Currents and Primary Production Roles to the Surface Distribution of Polycyclic Aromatic Hydrocarbons at the Southern Okhotsk Sea

Rodrigo Mundo¹, Tetsuya Matsunaka², Mutsuo Inoue², Saki Tanaka², Yukiko Taniuchi³ and Seiya Nagao², (1)Department of Chemistry, Institute of Nature and Environmental Technology, Kanazawa University, Kanazawa, Japan, (2)Kanazawa University, Japan, (3)Japan Fisheries Research and Education Agency, Japan

Southern Okhotsk Sea is a fishing ground for many economically important species such as natural Pacific salmon. Polycyclic aromatic hydrocarbons (?PAH_{diss}) at surface water of Okhotsk Sea were firstly studied in 1993 by Nemirovskaya. ?PAH_{diss} ranged from 2 to 8 ng L⁻¹, except for the northeast of Sakhalin where offshore oil extraction takes place (?PAH_{diss} reached 338 ng L⁻¹). The latest report (Chizova et al., 2013) from Russian side was from 2006, northern of the Sakhalin island, where ?PAH_{diss} were 33-78 ng L⁻¹. Research on the environmental behavior of organic pollutants is essential for assessing ecological risks of anthropogenic stressors to marginal seas, especially when transboundary transport may be implicated. The Southern Okhotsk Sea is fed by three main oceanographical currents; Forerunner Soya Warm Current (Spring) and Soya Warm Current (Summer) starts at Soya Strait while East Sakhalin Current (Autumn-early Winter) starts northern of the Sakhalin Island. The present study aimed to evaluate the impact of PAHs surface migration around Southern Okhotsk Sea by the monitoring of the surface distribution of PAHs in seawater. More than 20 samples (~10 L) were collected from July 2017 to September 2021 with collaboration of the Japan Fisheries Research and Education Agency. Particulate and dissolved phases were separated by 0.5 µm pre-combusted glass-fiber filters and dissolved PAHs were concentrated using C18 disk. PAHs were measured in a HPLC-fluorescence system. The ?PAH_{diss} averaged 1.87 ng L⁻¹ (1.7-4.4 ng L⁻¹). Using isomers ratios, sources were inferred to be majorly pyrogenic in all samples. ?PAH_{diss} vs Salinity plot suggest that dissolved PAHs distribute into a high salinity (> 32.4 PSU) / low PAHs (< 3 ng L⁻¹) coastal

area and a low salinity / high PAHs offshore area. However western of Soya Strait, Σ PAH_{diss} were not necessarily low (2.85-5.56 ng L⁻¹) between 2017 and 2019 at summer seasons. Coastal and offshore areas are also characterized by their nutrients loads and primary productivity. The former has higher chlorophyll-a (1.2±1.2 mg m³) and less inorganic nutrients (PO₄ 0.13 ± 2.8 μM, SiO₂ 3.5±2.8 μM) while the latter has lower chlorophyll-a (0.6±0.5 mg m³) but more inorganic nutrients (PO₄ 0.29±0.11 μM, SiO₂ 13.0±3.9 μM). Preliminary, we conclude that surface migration does not fully explain PAHs distribution at Southern Okhotsk Sea, and factors such as bio-/photo-degradation and scavenging could be equally or more important.

6.08.P-Mo272 The Derivation of a Maximum Acceptable Concentration (MAC) for Azamethiphos

Dean Leverett¹ and Iain Berrill², (1)WCA-Environment Ltd, Faringdon, United Kingdom, (2)Salmon Scotland, United Kingdom
Azamethiphos (CAS No. 35575-96-3) is an organophosphorus pesticide, which acts on insects and other arthropods by inhibition of acetyl cholinesterase activity. It has been authorised for use in Scotland as a veterinary medicine for the control of external parasites in farmed fish for over 20 years. Regulatory Maximum Acceptable Concentrations (MAC) for application to the marine environment in the vicinity of Scottish fish farms are available for azamethiphos (SEPA 1998). These Environmental Quality Standards (EQS) incorporate a temporal element to account for the dispersal and dilution of azamethiphos over time in the local marine environment following its use to treat farmed fish, and represent the concentration of azamethiphos that should not be exceeded in the vicinity of fish farms at 3, 24 and 72 hours post-treatment. The short-term ecotoxicity dataset for azamethiphos has been updated to include all data that could be identified, obtained and confirmed as reliable and relevant for EQS derivation. This dataset now covers a large number of species and higher taxonomic groups. This updated short-term ecotoxicity dataset has been used to derive new MAC values for azamethiphos according to the current European guidance on EQS derivation (EC 2018). Since generic MACs derived in this way do not incorporate a specific temporal element such as are required to assess environmental risk at defined time periods post-treatment of fish farms with azamethiphos, updated fish farming-specific MAC have also been derived, using the approaches previously applied for the derivation of such temporally-defined MACs (SEPA 1998). This poster presentation will detail the dataset and assessments undertaken in deriving the MACs, and updated temporally-defined marine MACs will be proposed.

6.08 Tackling Marine Pollution on the Road to Sustainable Use of Marine Ecosystem (Poster Corner)

6.08.PC-Mo13 Chemical Warfare Agents (CWA) in the Baltic Sea Food-Web: Clark I Bioaccumulation Modelling Using ECOPATH With ECOSIM (EwE)

Michał Czub¹, Jacek Bezdowski², Lech Kotwicki², Marc Silberberger² and Maciej Tomczak³, (1)Instytut Oceanologii PAN, Poland, (2)Institute of Oceanology of the Polish Academy of Sciences, Poland, (3)Stockholm University, Sweden
Sea dumping of chemical warfare in the Baltic Sea area took place soon after the World War II and resulted in disposal of approx. 50 000 tons of CW containing up to 15 000 tons of chemical warfare agents (CWA). There is a growing concern regarding the environmental impact of weaponized compounds that are now known to be environmentally persistent and very toxic for model aquatic organism *D. magna*. Furthermore, one of the recent discoveries puts phenylarsenicals in the spotlight due to the first detection of CWAs degradation products in fish samples collected in the CW Primary Dumpsite in the Bornholm Deep area of the Baltic Sea. The aim of this study was to simulate possible pathways, behaviour and future spreading of Clark I in the Baltic Sea food web under various scenarios. This has been achieved by putting together all existing information about the CW dumping loads and laboratory-derived measurements with *in-situ* observations and measured values of detected bioconcentration of Clark I to perform bioaccumulation modelling using ECOPATH with ECOSIM Baltic Sea Food-Web Model with Ecotracer module. Scenarios simulations are based on chain of biogeochemical and ocean-climate models for the Central Baltic Sea. Separate modelling scenarios were performed for two reported loads: 711 and 1500 tons of Clark I. When normalized by the real-data organic matter content in the sediments from contaminated areas of the Baltic Sea, the modelled accumulation of Clark I by detritus never exceeded the highest detection in analyzed sediments. Regardless of the applied release ratio for Clark I it reaches the concentrations per biomass matching real measurements in adult cod already in first months of modelling and increases over time reaching top predators. As assumed, various socio-economic scenarios, including the type and extents of fishing result in different rates of contamination spreading and influence vectors and residues of contamination in various functional groups. *Saduria entomon*, Atlantic cod, Grey Seal (*Halichoerus grypus*) are the contamination hot-spots, while due to the detritus-based pathways, several pelagic species and fish-feeding birds seem not to be significantly affected by Clark I bioaccumulation. Studies provide a novel and interesting insight into future contamination spreading and indicate new target species for future monitoring of this particular type of xenobiotics in the Baltic Sea food web.

6.08.PC-Mo14 An Interdisciplinary Approach to Assess the Impacts of Shipping Emission Control Technologies on the Marine Environment: EMERGE Project and the Northern Adriatic Case Study

Loris Calgario¹, Elisa Giubilato¹, Mattia Boscherini², Adriano Coutinho de Lima², Roberto Pastres², Marco Picone², Annamaria Volpi Ghirardini², Elena Semenzin³ and Antonio Marcomini⁴, (1)University Ca' Foscari of Venice, Italy, (2)University Ca' Foscari of Venice, Italy, (3)Ca' Foscari University of Venice, Italy, (4)University of Venice, Italy
Following the adoption of the global limits on sulphur content for marine fuels, the use of shipping emission abatement technologies such as exhaust gas cleaning system (scrubbers) has been predicted to increase significantly in the next decades as an alternative to the use of cleaner but more expensive fuel types. Since acidified and contaminated scrubber discharge water are presumed to cause a deterioration of the marine environment, there is the need for an integrated assessment framework to evaluate the impacts of these emissions on marine ecosystems, while considering also the environmental and health benefits of reducing emissions of air pollutants, and associated costs. This is the main objective of the H2020 EMERGE project, which evaluates

environmental and health impacts of shipping emissions reduction technologies under future scenarios by integrating modelling and experimental approaches. The EMERGE framework is being applied to five EU case-studies, including the Northern Adriatic Sea, a shallow marine basin that includes zones of high ecological value and hosts various anthropic activities such as fishing, aquaculture and port activities, which, along with land-based activities, pose chemical pressures on the marine environment. The first component of the modelling chain is the STEAM model, which provides shipping emission estimates of pollutants and nutrients based on Automatic Identification System data and includes updated emission factors from scrubber water analysis. High resolution models are used for predicting the transport of selected substances in the air and water compartments, and the obtained fluxes of contaminants in the case study area are then used for investigating: (i) the effects of changing nutrients loads on biogeochemical processes using the Biogeochemical Flux Model, (ii) the concentration, persistence, and fate of target pollutants using the OpenDrift suite and (iii) the bioaccumulation of pollutants using the MERLIN-Expo model. Ecotoxicological tests carried out on real scrubber water using planktonic bioindicators (i.e. *Aliivibrio fischeri*, *Acartia tonsa* and *Mytilus galloprovincialis*) and considering different life stages and exposure times will complement the modelling activities and support the comprehensive impact assessment for the case study area.

6.08.PC-Mo15 Development of Indicators Related to Chemical Contamination of Marine Biota (Fish, Birds, Mammals) Within the Marine Strategy Framework Directive

Tiphaine Mille¹, Nathalie Wessel², Melanie Brun², Gauthier Poiriez³, Paco Bustamante³, Aurelie Blanck⁴, Paula Mendez⁵, Jérôme Spitz⁶ and aourell Mauffret⁷, (1)IFREMER, RBE-BE, France, (2)IFREMER, France, (3)Université de La Rochelle, France, (4)Office Français de la Biodiversité, France, (5)Observatoire Pelagis, France, (6)Observatoire Pelagis Université de La Rochelle/CNRS, France, (7)BRGM, France

Good Environmental Status (GES) for the descriptor 8 (D8) of the Marine Strategy Framework Directive is reached when concentrations of contaminants are at levels not giving rise to pollution effects. Offshore chemical impregnation by both inorganic (metals) and organic contaminants (e.g., polychlorinated biphenyls) is monitored in three group of species: fishes, birds and mammals. An indicator is defined by the couple of matrix*substance at the subregional level, the objectives of this study are: 1) to develop indicators for each group of species in offshore waters (as defined in the present study, as the waters beyond 1 milles or the water framework directive (WFD) waterbodies); 2) to develop an integrated method to assess GES achievement for criteria 1 of D8 in biota in offshore waters including the three developed indicators. Each indicator is built in three steps: (i) a contamination index for each studied species which is the upper limit of 95% confidence interval of the mean value based on substance concentration measured in fishes muscle or birds feathers. For mammals, metals concentrations are measured in liver or kidney, and in blubber for polychlorinated biphenyls; (ii) a contamination ratio, informing on the distance to thresholds, is calculated as the ratio between the contamination index and the thresholds. Thresholds used to assess whether concentration could harm marine life, are the ones developed within regional sea convention and the Environmental Quality Standard (EQS) for secondary poisoning for Hg in fish. (iii) a contamination score, integrating the different species in one group of species, is determined by the sum of contamination ratio of each species divided by the square root of the number of contamination ratio. To achieve GES for each matrix, contamination score has to be lower than 1. To assess GES at biota level in offshore waters, the one-out-all-out method is used. Preliminary results in Mediterranean French seas showed that concentrations in mercury are higher than thresholds in fishes and in birds with a contamination score equaled to 132.2 and 1.03, respectively. Therefore, for mercury, GES at biota level in offshore waters is not reached.

6.08.PC-Mo16 New Biological Effect Indicators in the Nationwide Monitoring Programme for the Aquatic and Terrestrial Environment (NOVANA) in Denmark

Zhanna M. Tairova¹, Jakob Strand² and Martin Larsen³, (1)DEPARTMENT OF ECOSCIENCE, Aarhus Universitet, Denmark, (2)Ecoscience, Aarhus Universitet, Denmark, (3)Aarhus Universitet, Denmark

The strategy for monitoring of biological effects (BE) of contaminants in biota in marine areas employed in NOVANA, and promoted in international conventions as HELCOM (Baltic Marine Environment Protection Commission) and OSPAR (Oslo and Paris Convention), is integrated environmental monitoring. Within the frames of this monitoring, chemical measurements in marine biota and sediment are conducted in parallel with BEs, in selected species of organisms. Different types of BE indicators are included in the marine part of the NOVANA in Denmark (1) and the Danish Marine Strategy (2), as part of Descriptor 8. Here we present the results in development of a set of biological effect indicators that have potential to be included in NOVANA - biliary metabolites of polycyclic aromatic hydrocarbons (PAHs) in fish species, i.e. european flounder (*Platichthys flesus*), round goby (*Neogobius melanostomus*), and malformed embryos of amphipods (*Gammarus spp.*). PAHs are widespread contaminants in the marine environment, and PAH metabolites in fish bile and enzymatic CYP1A activity in fish liver (EROD) are established and internationally identified as relevant indicators for e.g. HELCOM and OSPAR assessments. The results presented, include response levels in PAH metabolites and EROD in european flounder and round goby, as alternative to viviparous eelpout (*Zoarces viviparus*), which is currently employed within NOVANA, since the use of eelpout is challenged by locally decreasing populations. SFS (synchronous fluorescence spectrometry) and HPLC/F (high-performance liquid chromatography with fluorescence detection), were used for identification and quantification of three specific types of PAH-metabolites – 1-hydroxy-compounds of phenanthrene, pyrene and benzo(a)pyrene. Amphipod embryos are sensitive to pollution exposure during the embryogenesis (3), and therefore the reproduction in amphipods as BE indicator is recommended within HELCOM. We present results on Danish pilot study where embryo aberrations were examined according to ICES TIMES guidelines (3). 1. 1. Miljøstyrelsen, DCE, & GEUS. (2017). NOVANA - Det nationale overvågningsprogram for vandmiljø og natur 2017-2021. Programbeskrivelse. 2. 2. Miljøstyrelsen. (2020). Danmarks Havstrategi II Anden del Overvågningsprogram. 3. 3. Sundelin, B.,

Track 7: Think-outside-the-box (fundamentally new concepts, innovative and controversial ideas, and interdisciplinary issues)

7.01 Being prepared for the effects of future technologies – studying the environmental risk and life cycle impacts as well as the recycling potential of so-called Critical Raw Materials

7.01.T-01 REE Interactions With Organo-Mineral Colloids As a Control of the REE Environmental Dissemination

Yasaman Tadayon¹, Mélanie Davranche¹, Julien Gigault² and Delphine Vantelon³, (1)Université de Rennes 1, France, (2)TAKUVIK CNRS, Université Laval, France, (3)SOLEIL synchrotron, France

Production of high technology products consumes large quantities of rare earth elements (REE), and subsequently increasing their extraction and dissemination. As a consequence, concerns have arisen about the environmental safety of using REE. The dissemination of rare earths in the environment is the result of transfer mechanisms that depend on environmental physio-parameters and REE speciation, which is largely controlled by their binding to solid surfaces and notably to colloids. Here, we are interested in colloids of organic matter and iron (Fe) because they are ubiquitous and their abundance is increasing in natural waters in response to the global climate change. Recent studies have shown that their structural organization consists of Fe nano-beads with a fractal organization that leads to different aggregates associated with OM molecules or colloid. This organization, which evolves with the major cations, controls the reactivity of the colloids. Our objective is therefore to explore the intimate bonds between REE and these colloids in order to study their impact on REE mobility. Three different colloids were synthesized using Leonardite humic acid (OM) and Fe(II) at a Fe/ OM molar ratio of 0.25 without or with calcium (Ca) used as a coagulant (Ca/Fe ratio 0.1 and 0.5). Adsorption experiments of REE by colloids (REE/Fe ratio from 0.1, to 0.0008) were carried out at pH 6.5. The adsorption of REE varied between 50 and 99% with the decreasing REE/Fe ratio. The adsorption patterns exhibited a middle REE downward concavity, indicating that REE were potentially bound to both the Fe phases and OM. At low REE loading, the pattern on the colloids is controlled by small but strongly complexing organic molecules (< 3kDa). Calcium weakly promotes REE adsorption by colloids by increasing the availability of the colloid binding sites, which is due to a decrease in the interactions between the Fe phase and OM. Finally, A4F-UV analysis showed that the addition of REE to the colloids affects their structural organization by promoting the formation of a colloids network. Although it must be admitted that colloids increase the mobility of the associated metals. The present study provides evidence that REE binding to Fe-OM colloids promotes the formation of a colloid network that severely restricts their mobility in the environment.

7.01.T-02 Sensitivity of Different Microalgae Species Towards Rare Earth Elements

Chantal Kimberley Eline van Drimmelen¹, Marion Revel², Andrew Hursthouse³ and Susanne Heise⁴, (1)HAW Hamburg, Germany, (2)Hamburg University of Applied Sciences, Germany, (3)University of the West of Scotland, United Kingdom, (4)Hamburg University of Applied Sciences, Hamburg, Germany

Rare earth elements (REE) are a series of chemical elements represented by 15 lanthanides, yttrium, and scandium. Their application in green and sustainable technology as well as their anthropogenic activities mean an increase in the global demand and concern about the environmental safety of these metals. REE are now labelled as 'emergent' contaminants due to their apparent disruption of biogeochemical cycles. Only a few studies who have looked into the toxicity of REE on microalgae. However, there it appears that a lot of different algae species are used for the toxicity assessment. Hence, the objective of the study presented here is the comparison of the sensitivity of 3 microalgae species with regard to lanthanum (La) and gadolinium (Gd). We hypothesize 1) similar sensitivity towards the two metals as the mode of action of REE is assumed to be similar. 2) a strong difference in sensitivity among species with *Scenedesmus vacuolatus* having the lowest sensitivity as it will be least affected by phosphate limitation as a consequence of REE-PO₄-complex formation. Toxicities to Gd and La were determined applying the algae growth inhibition (AGI) test in a DIN media with phosphate. Three different freshwater microalgae species, *Scenedesmus vacuolatus*, *Chlorella vulgaris*, and *Raphidocelis subcapitata* were exposed for 72 hours at nominal concentrations of 100, 10, 1, 0.1, and 0.01 mg/L of Gd and La. Biomass increase and growth rate were determined by fluorescence. *R. subcapitata* and *C. vulgaris* are species commonly used in ecotoxicology laboratories. *S. vacuolatus* was chosen because it is known for its ability to accumulate phosphate and store it internally. This makes it an interesting species for the algae growth inhibition test as Ln are known to form complexes with phosphates which may cause PO₄-depletion. Results indicate that Gd exposure causes higher absolute toxic values of up to 95% inhibition, while La leads to no more than 50% of fluorescence inhibition. The sensitivity of the microalgae species in this bioassay varies strongly (*C. vulgaris*, *S. vacuolatus* >> *R. subcapitata*.) Our hypothesis, that *S. vacuolatus* would be the least sensitive cannot be validated. Therewith, phosphate limitation does not seem to be the major cause of growth inhibition. We suggest that these observations are caused by differences in toxicokinetics or -dynamics of *R. subcapitata* compared to the other species used. We will elaborate further on this in the presentation.

7.01.T-03 Implications of Speciation on Rare Earth Element Toxicity Assessment: A FOCUS on Organic Matter Influence in Daphnia magna Normalized Test

Nicolas Lachaux¹, Charlotte Catrouillet², Rémi Marsac², Laurence Poirier³, Sandrine Pain-Devin⁴, Elisabeth Maria Gross⁵ and Laure Giamberini⁶, (1)LIEC, France, (2)Géosciences Rennes, France, (3)Nantes Université, France, (4)Université de Lorraine - UL, France, (5)CNRS UMR 7360 / Université de Lorraine, France, (6)Université de Lorraine, CNRS UMR 7360, France

Rare Earth Elements (REE) became essential in high- and green-technologies. Their increasing use lead to the release of anthropogenic REE into the environment including aquatic systems. Limited data concerning REE aquatic ecotoxicology indicate their biological effects are highly dependent on their speciation, which prevents the establishment of a reliable environmental risk assessment. The current study assessed the influence of speciation on the toxicity of neodymium (Nd), gadolinium (Gd) and ytterbium (Yb) by the *Daphnia magna* mobility inhibition test (ISO 6341, 2012). Toxicity was assessed for each element individually and in ternary mixture, as well as in the absence and presence of dissolved organic matter (DOM). Speciation was predicted by modeling. REE bioaccumulation by *D. magna* was measured to better understand the relationship between REE speciation and toxicity. DOM decreased significantly the toxicity of Nd, Gd and the mixture towards the freshwater crustacean. This was explained by a lower REE bioaccumulation in the presence of DOM due to REE-DOM complexation, which reduced REE bioavailability. DOM effects on Yb toxicity and bioaccumulation were limited because of Yb precipitation and the potential contribution of Yb-hydroxide nanoparticles to Yb bioaccumulation and toxicity. We demonstrated that the way of expressing EC50 values changed drastically REE toxicity assessment, and that these changes were influenced by REE speciation. This study demonstrates for the first time that REE speciation, and especially REE-DOM complexation, influences significantly REE bioaccumulation toxicity towards *Daphnia magna*.

7.01.T-05 Is Lithium Toxic to Freshwater Organisms? Focus on the Zebra Mussel As a Representative of Filter-Feeders *Nicolas Dupuy¹, Laetitia Minguez² and Carole Cossu-Leguille³, (1)LIEC - Université de Lorraine - CNRS, Metz, France, (2)LIEC (CNRS UMR 7360, Université de Lorraine), France, (3)Université de Lorraine, France*

Lithium is the first of the alkali metals. Due to specific physicochemical properties, this metal is increasingly used in a context of energy transition, particularly in the manufacturing of lithium-ion batteries. The demand is estimated to grow by more than 30% per year up to 2030, and the long-term sustainability of this resource is at risk. Lithium is thus considered as a critical material. Anthropogenic inputs of lithium in aquatic ecosystems have already been observed, and are likely to increase in the coming years. This increase raises the question of the potential impacts of lithium on chronically exposed organisms. Information about lithium biological pathways are more abundant for humans than for aquatic organisms, due to its use in medicine to treat bipolar disorders. Although several biological targets are documented in the literature, lithium mode of action shows great complexity, affecting several cross-related signaling pathways and complex cascades of events. Moreover, most of the data in the literature are acute toxicity data, and few of them are conducted with freshwater organisms. In this context, we studied the long-term effects of lithium in a freshwater bivalve, *Dreissena polymorpha*. Mussels were exposed for four weeks to four concentrations of lithium: 0, 40, 100 and 250 $\mu\text{gLi}^+/\text{L}$ as LiOH. Several physiological parameters were regularly assessed in parallel to exposure concentrations and bioaccumulation, related to energetic metabolism, antioxidant defenses and cell damages. Effects at the individual scale were assessed by monitoring the filtration rate, oxygen consumption and the scope for growth. We observed high mortality during the experiment, which was lower in lithium-exposed conditions than in controls. First results show a lower energy expenditure in organisms exposed to lithium than in controls. Analyses still in progress will allow us to depict an integrative vision of lithium interaction with exposed organisms, and to understand whether lithium is toxic to aquatic organisms or whether, in particular conditions, it can help them to cope with other stressors.

7.01 Being prepared for the effects of future technologies - studying the environmental risk and life cycle impacts as well as the recycling potential of so-called Critical Raw Materials (Virtual Only)

7.01.V-01 A Framework for Assessing the Damages of Resource Services Loss in LIFE Cycle Assessment

Titouan Greffe¹, Manuele Margni² and Cecile Bulle¹, (1)Ciraig UQAM, Canada, (2)CIRAIG - École Polytechnique de Montréal, Canada

Purpose Several modelling perspectives are identified in the literature to assess the impact of resources depletion in LCA (Sonderegger et al. 2019). Some methods consider the loss of an inherent property of resources, such as energy or exergy. Others assess additional societal efforts required in the future due to current extraction or the decreasing natural availability due to extraction. Today there is a consensus about the need to evaluate the instrumental value of resources to humans as described by the area of protection “Natural resources” in the life cycle impact assessment framework (Verones et al. 2017). Unlike proposed by some LCIA methods, extraction alone does not contribute to resource depletion. In fact, abiotic resources may remain in the technosphere and stay available for future uses. Therefore, all mechanisms affecting the loss of services should be considered and not restricted to the extraction from the environment, but also substitutability for the same function needs to be accounted for. This presentation aims to present a novel framework for assessing the damages related to the loss of instrumental value of resources in life cycle assessment. **Methods and Results** First, a cause-effect chain for the assessment of the potential loss of services provided by abiotic resources is proposed. It links the fate of resources to a potential service loss and then to its effect of potential recovery cost to be paid by society. Second, we present a systematic approach for the identification of services provided by each resource. It requires to (i) identify resources end-uses and (ii) map each end-use with a final service that answer to human needs. Finally, we propose an interface to link the proposed life cycle impact assessment (LCIA) framework with the life cycle inventory (LCI). It implies adapting the current structure of LCI databases by including new elementary flows that not solely cover extraction from the environment but also change in functionality and other losses within the technosphere. Then, both new elementary flows and the required additional information in EF, other than the name of the resource, that would enable the quantification of services gain or loss, is presented. **Conclusions** This framework can be useful to enhance a sustainable management of the provision of resource services that are contributing to human well-being.

7.01.V-02 Novel Empirically-Derived Freshwater Ecotoxicity Characterization Factors for Rare Earth Elements: Nd, Gd & Yb

Thomas Schaubroeck¹, Elorri Igos¹, Nicolas Lachaux², Christophe Hissler¹, Davide A.L. Vignati³, Loïc Martin⁴, Laure Giamberini⁵, Carole Cossu-Leguille⁶, Enrico Benetto⁷ and Arno Gutleb⁷, (1)Luxembourg Institute of Science and Technology, Luxembourg, (2)LIEC, France, (3)CNRS, France, (4)OMP/GET/IRD, France, (5)Université de Lorraine, CNRS UMR 7360, France, (6)Université de Lorraine, France, (7)Luxembourg Institute of Science and Technology (LIST), Luxembourg

Rare Earth Elements (REE), used in industrial and human activities, find their way to aquatic ecosystems, where they can be potentially harmful for its species. In this study, we assess this cause-effect chain for Neodymium (Nd), Gadolinium (Gd) and Ytterbium (Yb). In life cycle assessment (LCA) methodology, the freshwater ecotoxicity impact due to a pollutant is equal to the released emissions amount multiplied by so-called Characterization Factors (CFs). The latter are provided by impact assessment methods, and USEtox is the consensual one to characterize ecotoxicity. While USEtox covers more than 3000 substances, CFs for Nd, Gd, and Yb are still lacking. This work aims at filling this gap for the cationic state of the REE, based on empirical data to represent more accurately CF for specific conditions. Material & Methods: In USEtox, the ecotoxicity CF is retrieved by multiplying a fate factor with a toxicity effect factor. For the first, partitioning coefficients are needed to specify the distribution among environmental compartments. Hereto, site-specific compartmental concentrations from measurements were used. The studied system is the upper Alzette River basin (LU) and the average between upstream and downstream measurements are considered retrieved in 2019, while for soil particles this was retrieved for 2007 through alluvial soil samples. The Bioaccumulation Factors (BAF) were retrieved through experiments for the fish *Danio rerio*, the crustacean *Daphnia magna* and the Bivalve *Corbicula fluminea*. For the ecotoxicity characterization, acute EC50-values for the three REE were experimentally derived using standard procedures for the following two species: the crustacean *Daphnia magna* and the alga *Raphidocelis subcapitata*. The use of chronic-to-acute ratios led to estimates for chronic ecotoxicity. Results & Discussion: The obtained CFs are consistent with USEtox CFs for metals. The differences between the three REE is mostly influenced by fate factors (higher affinity for soil, sediment and DOC leads to lower exposure to freshwater species) and could be explained by their typology (light, medium or heavy REE). Further reflections are needed to fully understand the results, in particular due to the complexity of REE chemistry in ecotoxicological test media (e.g. bonding with (in)organics). We will further perform uncertainty & sensitivity analyses to better specify influential factors, and also better compare with the results of other metals.

7.01 Being prepared for the effects of future technologies – studying the environmental risk and life cycle impacts as well as the recycling potential of so-called Critical Raw Materials (Poster)

7.01.P-Mo273 A Proof-Of-Concept Study on Potential Per- and Polyfluoroalkyl Substance Emissions From Relevant Recycling Processes of Lithium-Ion Batteries

Amanda Rensmo¹, Eleni Savvidou², Xianfeng Hu³, Mats Zackrisson⁴, Ian Cousins⁵, Jonathan Benskin⁵ and Steffen Schellenberger⁴, (1)Uppsala University, Sweden, (2)Department of Environmental Science, Stockholm University ACES, Stockholm, Sweden, (3)SWERIM AB, Sweden, (4)RISE Research Institutes of Sweden, Sweden, (5)Stockholm University, Sweden

In 2019, the Nobel Prize for Chemistry was awarded to the development of the lithium-ion battery (LIB) – an invention that is considered to be a main element in the increasing electrification of society and a key component for overcoming the ongoing climate crisis. But even this promising application, which can facilitate the transition to fossil-free transportation, is facing environmental and ethical challenges, in particular with regards to metals scarcity. Recycling of LIBs in order to recover and re-use precious materials plays an important role in moving towards a circular society. However, the recycling process is still under development, and the by-products from this process (some of which may be hazardous) are not fully characterized. The use of fluorinated components in LIBs represents a particular concern. The so-called per- and polyfluoroalkyl substances (PFAS) are a broad class of synthetic chemicals which are highly persistent and mobile. Some well-studied PFAS have been detected in wildlife and humans globally and some have been linked with adverse health effects. Consequently, several PFAS have been regulated internationally in order to prevent further emissions. This study aims to investigate potential formation and emissions of PFAS during LIB recycling using a fluorine mass balance approach. Samples were collected at different steps in the recycling process of common LIBs (e.g. LiNiMnCoO₂), including the recovered electrolyte components, exhaust gas cleaning solutions, and shredded materials from the pre-treatment process (black mass). In order to capture the broadest range of organic and inorganic fluorine species, samples were extracted sequentially with solvents of different polarities, and then characterized for organofluorine (EOF), target PFAS, and suspect PFAS. Total fluorine was also determined in unextracted samples. This study provides clarity into recycling processes of fluorinated materials, thus indicating if post-treatments or change of conditions are necessary to avoid the formation and emission of PFASs. Additionally, the results can indicate if LIB research should focus on fluorine-free materials to help phase-out PFAS, and guarantee more environmentally friendly applications.

7.01.P-Mo274 Probing the Effect of Aluminium Substitution in Goethite on Rare Earth Element Adsorption

Anne Buist¹, Camille Rivard², Mélanie Davranche³, Karine Chaouchi⁴, Martine Bouhnik-Le coz⁵, Francois Brisset⁶, Erwan-Nicolas Paineau⁶, Stephan Rouzire⁶ and Delphine Vantelon⁴, (1)SOLEIL synchrotron, Saint Aubin, France, (2)Synchrotron Soleil - INRA, France, (3)Université de Rennes 1, France, (4)SOLEIL synchrotron, France, (5)Géosciences Rennes, France, (6)Université Paris-Saclay, France

The extraction and use of Rare Earth Elements (REE) has been increasing at a rapid pace in the last couple decades due to their critical importance in the technological sector. As a result they have been deemed an emerging pollutant. However, little is known about REE's behaviour in the environment. There have been studies done on REE adsorption on Fe (hydr)oxides, but they were performed under lab conditions using pure phases. Since REE adsorption and patterns vary according to the adsorbent phase, one

can expect that substitutions in a given structure would impact its adsorption capacity. As aluminium (Al) is a major element of the Earth surface that can easily enter Fe-oxihydroxide structure, this study looks at the effect of Al substitution in goethite to see if and how it may affect the REE adsorption; goethite being chosen as a well crystallised phase allowing modelling of sorption and surface interactions. For this purpose, a pure goethite and a goethite with 5% Al substitution were synthesized. The impact of Al substitution on their structural organisation was characterized by TEM, XRD, and XAS. The results show that Al enters into the goethite structure, forming clusters, without modifying the goethite needle shape but slightly increasing the specific surface area and the point of zero charge. Hereafter, REE adsorption kinetics and isotherms were performed to determine the effect of Al substitution on REE adsorption. This was done by measuring the REE in solution with an ICP-MS. The results show that even an Al substitution rate as low as 5% has an effect on REE adsorption. Substitution causes an overall decrease in adsorption of REE, although both adsorbents reach the adsorption equilibrium after 24h. In addition, while the MREE and HREE are still enriched compared to the LREE, the enrichment is less pronounced. The impact of Al substitution on the REE surface binding was investigated by XAS. These results evidence the impact of even low Al substitutions in Fe-oxihydroxides on their adsorption and thus on the fate of REE as pollutants in the environment.

7.01.P-Mo275 Influence of pH in the Toxicity of Rare Earth Elements Lu, Sm, Y, and Yb to Model Organisms

Edith Guadalupe Padilla Suárez¹, Antonios Brouzotis², Marco Guida², Marco Trifuoggi², Antonietta Siciliano² and Giovanni Libralato³, (1)University of Naples Federico II, Germany, (2)University of Naples Federico II, Italy, (3)Veneto Nanotech SCpA, Italy

Rare earth elements (REEs) have become vital in today's technology as they are widely used in the manufacture of ceramics, magnets, petroleum, electronics, among other uses. With the increase of their importance in today's technology, they also have become the focus of many studies, being recognized as emerging contaminants. However, because of the rapid increase of the environmental concentrations caused by the extraction processes and the electronic waste, there is still a gap in the knowledge related to their ecotoxicological effects. This study aims to contribute to filling the gaps of the associated individual REEs toxicities. Therefore, the focus of this study is the ecotoxicological effects of four of the least studied REEs: Lu, Sm, Y, and Yb on bioassay model organisms of different groups of the trophic level (e.g., *Daphnia magna*, *Raphidocelis subcapitata*, *Sinapis alba*, and *Alivibrio fischeri*). To evaluate the effects of REEs under laboratory conditions, the organisms were exposed to various ranges of concentrations diluted with the organism's culture medium to determine the relative concentration-response curves. Scenarios including acidic pH values (i.e., acid mine wastewater) were considered. Preliminary results indicated: 1) higher toxicity at lower pH values; 2) Sm as the element with the highest toxicity, followed by Y, Yb, and Lu; 3) *A. fischeri* as the most sensitive species, followed by *R. subcapitata*, *D. magna*, and *S. alba*, in decreasing order.

7.01.P-Mo276 Rare Earth Element Speciation and Bioaccumulation in Estuarine Ecosystem

Lortholarie Marjorie¹, Aurore Zalouk-Vergnoux², Christine Herrenknecht² and Laurence Poirier³, (1)laboratory Mer, Molécule, Santé, France, (2)Nantes University, France, (3)Nantes Université, France

Rare earths elements (REE) are a group of 17 metallic elements used in various industrial and medical applications. For several years, their use has been expanding rapidly, leading to numerous observations of enrichment in aquatic ecosystems. This study focused on studying the concentrations and speciation of REEs in the abiotic compartment of the Loire estuary ecosystem: sediment and water column (dissolved and particulate phases) in order to qualify the REE bioavailability for organisms. Their bioaccumulation by two species of benthic fish, the European eel (*A. anguilla*) and the Common flounder (*P. flesus*), revealed intraspecific and interspecific variations in muscle concentrations. In addition, the quantification of REEs in different organs and tissues allowed to determine their organotropism in eels. A particularly marked bioaccumulation of gadolinium in the gonads of female silver eels was thus demonstrated. Finally, a spatiotemporal study conducted on eel muscles showed a slight influence of the fishing area, but a significant temporal increase of REE concentrations between 2011 and 2019. This temporal difference was not observed in sediments collected at the same periods. The status of eel as a sentinel species is thus underlined, since it seems to be particularly suitable for monitoring the evolution of REE contamination in dynamic environments, such as estuaries, influenced by current and tides.

7.01.P-Mo277 Ree-Enriched Sediments Impacts on Life History Traits of Gammarus fossarum (Crustacea Amphipoda)

Kahina Mehennaoui¹, Quentin Bachelet², Ana Romero-Freire³, Vincent Felten² and Laure Giamberini⁴, (1)Laboratoire Interdisciplinaire des Environnements Continentaux (LIEC) UMR 7360 CNRS, Luxembourg, (2)Université de Lorraine, France, (3)CSIC - Spanish National Research Council, Spain, (4)Université de Lorraine, CNRS UMR 7360, France

The growing importance and use of rare earth elements (REE) are attracting interest from society, policy makers and scientists. The intense mining activities for commercial purposes is globally increasing and leading to the disruption of REE biogeochemical cycles with anthropic abnormalities already observed and reported in aquatic ecosystems. Nonetheless, REE remain less studied and their mechanisms of toxicity actions are not fully understood. As amphipods, *Gammarus fossarum* represent an important part of the aquatic macroinvertebrate assemblages, present a large distribution, and are generally used in ecotoxicological studies for their high ecological relevance (i.e., leaf litter breakdown). However, their use for the study of REE effects has been rather limited so far. The aim of the current study is the assessment of potential effects of two naturally REE-enriched sediments on *G. fossarum*. Effects on life history traits, behavioral and physiological responses of *G. fossarum* have been evaluated. Two experiments were performed on a water/sediment system. REE-enriched sediments were selected based on the concentrations of their parent's material and were collected in North Quebec, Canada. First, *G. fossarum* males were exposed for 72h to two naturally-REE enriched sediments, namely N2 and B4, and one control group. Physiological (osmoregulation) and behavioural (locomotion and ventilation) responses were evaluated. The second experiment consisted on exposing *G. fossarum* pre-copula

pairs with females at the same reproductive stage to the naturally REE-enriched sediments, for one molt cycle duration (~30 days) to assess potential effects on life history traits such as survival, growth and reproduction. The short-term exposure of *G. fossarum* males to sediments N2 and B4 led to a decrease in haemolymph osmolality and number of gammarids in movement while an increase in ventilatory activity was observed. The chronic exposure led to a significant uptake of REE and a significant decrease in proportion of female with oocytes and total number of juveniles were observed in organisms exposed to sediment B4. The physico-chemical analyses of sediments showed that B4 contains the highest amount of REE with a higher proportion of light REE. The present study gives first insights about the potential toxicity of REE on *G. fossarum* as they may have deleterious effects on *G. fossarum* population's dynamics, which may alter the functioning of aquatic ecosystems.

7.01.P-Mo278 Lithium Ecotoxicity in Aquatic Environment: A Meta-Analysis to Identify Gaps

Nicolas Dupuy¹, Laetitia Minguez² and Carole Cossu-Leguille³, (1)LIEC - Université de Lorraine - CNRS, Metz, France, (2)LIEC (CNRS UMR 7360, Université de Lorraine), France, (3)Université de Lorraine, France

Lithium is an alkali metal naturally found in brines and minerals of some rocks (pegmatites, granitic domes and greisens). This metal is historically used in the treatment of psychological disorders such as bipolarity. Because of its particular physicochemical properties (high energy density and lightness), lithium is also increasingly used in a context of energy transition, particularly in the manufacturing of lithium-ion batteries. A contamination of aquatic environments is likely to be expected in the coming years. What will be the impact of this contamination on aquatic organisms? To answer this question, a meta-analysis was conducted on the data available in the literature, in order to identify gaps of knowledge about the bioaccumulation and ecotoxicity of lithium in aquatic environments, and to better understand the mechanisms underlying these phenomena. We also completed the existing literature by performing standardized tests on the decomposer *Aliivibrio fischeri*, the primary producer *Raphidocelis subcapitata* and the primary consumer *Daphnia magna*, with different lithium salts used in industry. The available data on bioaccumulation and ecotoxicity of lithium in aquatic environment show a strong heterogeneity. Although most EC50 values are above average environmental concentrations, very few chronic toxicity data are available. The organisms we used for our standardized tests showed a range of sensitivity comparable to the ranges found in the literature, and our results highlight differences in toxicity between salts and tested organisms. Concerning lithium bioaccumulation data, some studies report an accumulation of lithium similar to other elements known to be toxic (As, Cd). However, information is scarce on lithium bioaccumulation in freshwater organisms, which are potentially more exposed to lithium discharges because they are closer to anthropogenic sources. This work highlights the need to assess the ecotoxicity of different forms of lithium and to better understand their mechanisms of action.

7.01.P-Mo279 Approaches to Reduce the Negative Influence of Aquafarming on the Biodiversity and Water Quality of Coastal Ecosystems

Guido Gonsior, Aquaculture, Ecotox, Marine Science, GG BioTech Design, Homberg (Ohm), Germany

Our focus is to build up new complex aquatic systems, which can be stabilised under different environment conditions. The interaction of several species in one system gives us the chance to avoid monoculture systems with high risk of biological collapse. In a multi-complex system, resources can be shared between different species and wastewater can be strongly reduced. We are currently working on resource protection technology, where we bring aquatic, marine, and ecotoxicological sciences together. The basic idea behind this approach is that standardised systems that we know e.g., from the ecotox science allows us to calculate environmental risk and predict responses of animals and plants to environmental change. This knowledge is useful for assessing potential risks in aquaculture and simulating effects under laboratory conditions. It is now very apparent that climate change significantly affects most ecosystems resulting in potentially dramatic changes of food webs. Our focus is to effectively use aquaculture and at the same time protect natural resources. This might be realised by circulation systems with minimum input of natural resources and avoidance of waste products having toxic effects on the environment. Here we present first circulation systems combining algae, water plants, invertebrates, and fish species from salt and freshwater ecosystems.

7.01 Being prepared for the effects of future technologies – studying the environmental risk and life cycle impacts as well as the recycling potential of so-called Critical Raw Materials (Poster Corner)

7.01.PC-Mo19 Evaluation of Chronic Toxicity of REE on Life Cycle and Proteomic Responses of *Daphnia magna*

Kahina Mehennaoui¹, Celine Leclercq², Justine Flayac³, Sébastien Cambier², Arno Gutleb², Laure Giamberini⁴, Benedicte Sohm⁵ and Tommaso Serchi², (1)Laboratoire Interdisciplinaire des Environnements Continentaux (LIEC) UMR 7360 CNRS, Luxembourg, (2)Luxembourg Institute of Science and Technology (LIST), Luxembourg, (3)Université de Lorraine, France, (4)Université de Lorraine, CNRS UMR 7360, France, (5)LIEC - Université de Lorraine - CNRS, France

Rare earth elements (REE) are considered as emerging contaminants due to their large-scale exploitation and use in the high-technology sector. So far, no regulatory thresholds are available for REE. Compared to trace elements with well-documented environmental impacts, REE remain less studied and their toxicity mechanisms are not fully understood. Therefore, the aim of the current study is the investigation of chronic toxicity of REE on the reproductive cycle of the model organism *Daphnia magna* and the study of their molecular toxicity mechanisms through a proteomic approach. Effects of REE were investigated using a non-targeted approach at proteome level of *D. magna* juveniles (shotgun analysis). In this study, *D. magna* were exposed for 21 days to up to 600 µg.L⁻¹ to a mixture of Gadolinium (Gd), Neodymium (Nd) and Ytterbium (Yb). Effects on survival, growth rate, bioaccumulation and reproduction have been assessed. At the end of the exposure, juveniles from the fifth brood were kept and exposed for 48h to up to 600 µg.L⁻¹ to REE mixture (Gd, Nd and Yb). Effects of REE on protein expression have been assessed. Long term exposure of *D. magna* to the mixture of REE led to a decrease of the number of juveniles produced by organisms exposed to 600 µg.L⁻¹ of REE. Proteomic analysis allowed the identification of 862 proteins among which 171 were differentially

expressed among exposure conditions. REE led to the alteration of expression of protein modifying enzymes and metabolite interconversion enzymes. The highest concentration of REE (600 $\mu\text{g}\cdot\text{L}^{-1}$) led to the alteration of expression of calcium-binding proteins. This study gives first insights about the chronic toxicity of REE and their potential impact on *D. magna* population dynamics. Further analyses are ongoing at the gene expression level to identify the molecular mechanisms of action of REE on *D. magna*.

7.01.PC-Mo20 Using Biomass As an Alkaline Agent in Remediating Acid Mine Drainage From the Iberian Pyrite Belt and Removal Efficiencies for Rare Earth Elements

*Dilesha Kotte Hewa*¹, *Delphine Durce*², *Sonia Salah*², *Carlos Ruiz Cásonava*³ and *Erik Smolders*⁴, (1)Division of Soil and Water Management, Belgian Nuclear Research Centre (SCK CEN), Belgium, (2)Belgian Nuclear Research Centre (SCK CEN), Belgium, (3)University of Huelva, Spain, (4)Katholieke Universiteit Leuven, Belgium

The continuous generation of acid mine drainage (AMD) has a severe impact on the environment because of having low pH (<~3) and high concentrations of Fe, Al, and sulfates. In addition, Rare Earth Elements (REE), which are considered as technology critical elements, are also present in higher concentrations than those found in natural water bodies like for examples, rivers, lakes and oceans. All these factors together make AMD highly toxic and thus remediation is deemed a necessity. Remediation of AMD generated particularly from abandoned mines is typically achieved through the establishment of passive treatment systems (PTS) in which alkaline reagents are often used to neutralize the pH and to precipitate metals. Replacing commercial alkaline reagents by industrial waste products is an economically and environmentally promising alternative considering the reduction of waste volumes and the cost associated to alkaline reagents. One promising industrial waste product is biomass ash (BA) whose efficiency in remediating AMD generated at the Iberian Pyrite Belt (IPB) while retaining REE were tested in this study and compared with a commercial $\text{Ca}(\text{OH})_2$ reagent. In doing so, AMD samples collected from Poderosa mine (PM) located in IPB were first kept in contact with BA at different solid:liquid ratios of 1:2, 1:5 and 1:10. At different time intervals, supernatants were separated from the solids by centrifugation and analyzed using ICP-OES and ICP-MS. Removal efficiencies estimated for Al, Fe, Zn, Cu and REE. In a different set of experiment, PM were neutralized by the continuous addition of a solution 0.01 M $\text{Ca}(\text{OH})_2$. BA showed high removal efficiencies for Al (=99.9%), Fe (=98.9%), Zn (=99.9%), Cu (=99.9%) and REE (=99.9%) at the solid:liquid ratio of 1:2 similar to efficiencies obtained using 0.01 M $\text{Ca}(\text{OH})_2$. At this solid:liquid ratio, BA was able to neutralize pH within 96 hrs until a value of 7. This indeed shown that the BA is suitable to be used as an alkaline agent in treating highly acidic and metal rich AMDs and in retaining REE. The high retention of REE indicates the possibility for recovering REE contained in the AMD. Further, precipitated solids are to be characterized by XRD, SEM and LA-ICP-MS to identify the nature of the precipitated solids and the association of REE with the mineral phases contained.

7.01.PC-Mo21 Assessing Supply Disruption Impacts of Future Technologies Within Life Cycle Sustainability Assessment

*Marcus Berr*¹, *Roland Hischer*² and *Patrick Wäger*³, (1)EMPA Technology & Society Lab, Switzerland, (2)Empa – Swiss Federal Laboratories for Material Science and Technology, Technology and Society Laboratory, Lerchenfeldstrasse 5, 9014 St. Gallen, Switzerland, (3)EMPA, Switzerland

Switzerland and 193 other states have declared to become carbon neutral by 2050 by signing the Paris Agreement. An important step towards reaching this goal is to implement and upscale clean future technologies such as photovoltaics or batteries. However, these technologies often have complex supply chains, which may be disrupted by events such as the COVID-19 pandemic, the Brexit and the China-US trade war causing demand surge or supply reduction along supply chains. Existing criticality assessment approaches for raw materials allow for evaluating potential supply disruption impacts, but mostly for the early supply chain stages and in the short-term (i.e. next 5 years) only. In the framework of a Swiss National research project, the SPOTTER approach has been developed - representing the integration of criticality as an additional impact assessment aspect into the Life Cycle Sustainability Assessment framework. SPOTTER allows assessing supply disruption impacts along the complete supply chain of product systems in the medium-term (i.e. in 5 to 15 years). Within this approach, future supply scenarios are modelled and country-specific inventory flows are defined for individual product systems, each representing one selected technology consumed in a specific country. The inventory flow amounts are then multiplied with respective regionalized characterization factors to determine impact scores from different supply disruptions for each unit process along the supply chain of these technologies. Unit processes represent here single country-specific supply chain processes. Finally, relative supply disruption impacts and hotspots along the supply chains are illustrated for the different technologies as well as uncertainties of the impact scores, which have been defined using a Pedigree matrix and Monte Carlo Analysis, are visualized. In the frame of this presentation, results from the application of the SPOTTER approach are presented showing supply disruption impacts and related uncertainties as single scores and in boxplots, respectively as well as supply disruption hotspots on global maps. The hotspots and impacts are assessed along supply chains for strategically relevant technologies consumed in Switzerland including amongst others electric vehicles and photovoltaics. Supply chains of amongst others Rare Earth Elements and cobalt as well as supply disruptions caused by for example demand growth, resource depletion and limited recycling content are analyzed.

7.02 Characterizing the chemical (eco)exposome and associated environmental and health risk throughout the life span in the era of omics

7.02.T-01 Bioanalytical Measurement of Passive Sampling Extracts of Different Organs From Marine Mammals

*Eva Barbara Reiter*¹, *Beate Escher*², *Elisa Rojo-Nieto*³, *Ursula Siebert*⁴ and *Annika Jahnke*⁵, (1)Helmholtz-Zentrum für Umweltforschung GmbH - UFZ, Leipzig, Germany, (2)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (3)Department of Ecological Chemistry, Helmholtz Centre for Environmental Research GmbH - UFZ, Leipzig, Germany,

(4)University of Veterinary Medicine Hannover, Germany, (5)Helmholtz Centre for Environmental Research - UFZ GmbH, Germany

In their natural habitat marine mammals are exposed to a large number and variety of environmental pollutants. To understand how these complex chemical mixtures of pollutants distribute and accumulate within the organism, different organs of marine mammals need to be examined. Studying the chemical burden of organs with key functionality like liver, kidney, brain and fat tissue can help in characterizing the internal exposure and effects of chemicals. Passive equilibrium sampling (PES) transfers environmental mixtures of chemicals into an extract without changing their composition, which allows one to study the mixture effects of environmental pollutants extracted from marine biota without major bias. Polymer samplers such as the silicone polydimethylsiloxane (PDMS) can be used for PES of nonpolar, hydrophobic organic chemicals in biota. Bioanalytical assessment of this extract then provides information about the activation of important toxicity pathways of the overall chemical mixture. In this study the mixture effects of PES-PDMS extracts from liver, kidney, brain and fat from five harbour porpoises (*Phocoena phocoena*), one common seal (*Phoca vitulina*) and one orca (*Orcinus orca*) were characterized with three *in vitro* cell-based reporter gene bioassays. To cover the cellular toxicity and metabolic pathways, effects on the activation of the xenobiotic metabolism (aryl hydrocarbon receptor (AhR) and peroxisome proliferator-activated receptor gamma (PPAR γ)) and the adaptive Nrf2-dependent oxidative stress response were evaluated. In all three bioassays and for all paired samples the observed mixture effects of the liver extracts (and partly kidney and brain extracts as well) were higher than those of the fat extracts. Activation of PPAR γ was elevated by a mean factor of 12.9 for liver extracts relative to the corresponding fat extracts. Activation of the oxidative stress response was also slightly reduced in fat extracts by a factor of 2.3. No activation of the AhR with the fat extracts were detected whereas all liver extracts triggered an effect. These observations indicate that the chemical activity in liver tissue is higher than in fat tissue. In this ongoing study we will further compare the results from the bioanalytical study to the chemical composition analyzed using gas chromatography/high-resolution mass spectrometry. Using iceberg modeling, we can then determine how much of the observed effect is explained by the detected chemicals.

7.02.T-02 In Vitro Bioassays for Detecting the Human Exposome

Beate Escher¹, Andreas Baumer¹, Sandra Jäsch², Nadin Ulrich², Ingo Bechmann³, Julia Landmann³ and Andreas Stöver⁴,
(1)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (2)Helmholtz Centre for Environmental Research – UFZ, Germany, (3)Leipzig University, Germany, (4)Ludwig-Maximilians University Munich, Germany

Conventional biomonitoring programs have been criticized on the basis that they cannot include the full range of chemical pollutants that make up the exposome. Bioanalytical tools may therefore complement chemical analysis for cost-efficient and comprehensive biomonitoring in diverse tissue types. We investigated human post-mortem tissues (liver, brain, adipose tissue as well as blood) from 16 individuals after dynamic equilibrium sampling with polydimethylsiloxane by instrumental analysis with direct sample introduction (DSI) GC-MS/MS and bioanalytical profiling with reporter gene bioassays targeting the activation of the aryl hydrocarbon receptor (AhR) with the AhR-CALUX assay. The concentrations of persistent organic pollutants increased with age while non-persistent chemicals did not show any age dependence of concentrations in blood, liver and brain and were often present at lower concentrations in adipose tissue. The activity in the AhR-CALUX bioassay also increased with age and was higher in liver and brain than in blood. The sum of concentrations of the detected chemicals was positively correlated with the bioassay responses but mixture modeling showed that the detected chemicals explained less than 2% of the activation of the AhR and less than 0.5% of cytotoxicity. This means that more than 10,000 chemicals would need to be included in an analytical method to capture all the effects with many chemicals potentially being below detection limits but still contributing to mixture effects. This comparison demonstrates how *in vitro* bioassays are a powerful complement to chemical analysis that captures the complexity of the exposome.

7.02.T-03 Combined Effects of Chemical Mixtures Are Predictable for the Whole Transcriptome - a Proof of Concept Study With Zebrafish Embryos

Wibke Busch¹, Gianina Jakobs², Janet Krüger³, Rolf Altenburger⁴ and Andreas Schuetzler⁵,
(1)Helmholtz centre for environmental research - UFZ, Germany, (2)Gianina Jakobs, Germany, (3)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (4)UFZ Centre for Environmental Research, Leipzig, Germany, (5)Helmholtz Centre for Environmental Research - UFZ GmbH, Germany

Humans and environmental organisms are constantly exposed to complex mixtures of chemicals. Extending our knowledge about the combined effects of chemicals is thus essential for assessing the potential consequences of these exposures. In this context, comprehensive molecular readouts as retrieved by omics techniques are advancing our understanding of the diversity of effects upon chemical exposure. This is especially true for effects induced by chemical concentrations that do not instantaneously lead to mortality, as is commonly the case for environmental exposures. However, omics profiles induced by chemical exposures have rarely been systematically considered in mixture contexts. In this study, we aimed to investigate the predictability of chemical mixture effects on the whole-transcriptome scale. We predicted and measured the toxicogenomic effects of a synthetic mixture on zebrafish embryos. The mixture contained the compounds diuron, diclofenac, and naproxen. To predict concentration- and time-resolved whole-transcriptome responses to the mixture exposure, we adopted the mixture concept of concentration addition. Predictions were based on the transcriptome profiles obtained for the individual mixture components in a previous study. Finally, concentration- and time-resolved mixture exposures and subsequent toxicogenomic measurements were performed and the results were compared with the predictions. This comparison of the predictions with the observations showed that the concept of concentration addition provided reasonable estimates for the effects induced by the mixture exposure on the whole transcriptome. Although nonadditive effects were observed only occasionally, combined, that is, multicomponent-driven, effects were found for mixture components with anticipated similar, as well as dissimilar, modes of action. Overall, this study demonstrates that using a

concentration- and time-resolved approach, the occurrence and size of combined effects of chemicals may be predicted at the whole-transcriptome scale. This allows improving effect assessment of mixture exposures on the molecular scale that might not only be of relevance in terms of risk assessment but also for pharmacological applications. The study is published in EHP: <https://doi.org/10.1289/EHP7773>.

7.02.T-04 A Step Forward Toward Harmonization of QA/QC Criteria for Chemical Exposomics - Lessons Learned From the HBM4EU Multi-Site SPECIMEn Study

Chiara Maria Vitale¹, Arjen Lommen², Carolin Huber³, Kevin Wagner⁴, Borja Garlito Molina⁵, Rosalie Nijssen⁶, Elliott James Price¹, Marco Blokland², Frederike van Tricht⁶, Hans Mol⁶, Martin Krauss⁷, Laurent Debrauwer⁴, Olga Pardo Marin⁸, Nuria Leon⁸, Jana Klanova¹ and Jean-Philippe Antignac⁹, (1)Masaryk University, Czech Republic, (2)Wageningen Food Safety Research, Wageningen University & Research, Netherlands, (3)Department of effect directed analysis, Helmholtz Centre for Environmental Research- UFZ, Leipzig, Germany, (4)INRAE, Toxalim, France, (5)Foundation for the Promotion of Health and Biomedical Research of the Valencia Region, Spain, (6)Wageningen Food Safety Research, Wageningen University & Research, Nederland, (7)Helmholtz centre for environmental research - UFZ, Germany, (8)FISABIO, Spain, (9)LABERCA UMR 1329 INRA, France

QA/QC provisions to assess the quality of data produced by suspect screening and non-target analysis workflows have been proposed and applied across five laboratories within the European Human Biomonitoring Initiative (HBM4EU) multi-site Survey on PEStiCide Mixtures in Europe (SPECIMEn) study. Within SPECIMEn, over 2000 urine samples were analyzed to investigate pesticide exposure in residents of five EU countries. The present work focused on the elaboration and application of harmonized QA/QC provisions to monitor the overall quality of the data generated and assess whether the raw data is acceptable for subsequent data pre- and post-processing. Standard solutions and fortified QC urines were prepared in a centralized way, distributed to all participants, and used to monitor the retention times, mass accuracy and signal intensities of selected QA/QC markers. Overall, the QA/QC procedures and quality of the data acquired provided an adequate basis for further data processing. Use of the proposed criteria allowed for the identification of analytical issues, instrumental failures, and sample handling errors. Space for improvement was identified, and refined QA/QC criteria proposed, building upon the lessons learned from the multi-laboratory study.

7.02.T-05 Endocrine Disrupting Chemicals in Plastic Food Packaging - In Vitro Toxicity and Chemical Composition

Sarah Stevens¹, Zdenka Bartosova¹, Johannes Völker² and Martin Wagner³, (1)Norwegian University of Science & Technology (NTNU), Norway, (2)NTNU University, Switzerland, (3)Norwegian University of Science and Technology, Norway

While there is abundant scientific evidence that some chemicals used in plastic products, such as bisphenols, phthalates and nonylphenols, are endocrine disruptors, plastics are chemically much more complex. For instance, more than 10,000 substances are intentionally used in the production of plastics (e.g., plasticizers, antioxidants) and even more non-intentionally added substances (e.g., reaction byproducts, impurities) are associated with them. Since little is known about the chemical composition and the toxicity of these complex mixtures of plastic chemicals, this study aims at characterizing both using plastic food contact articles (FCA) as relevant sources of human exposure. Thirty-nine FCAs from Germany, Norway, South Korea the UK, and the US, covering the seven polymer types with the highest global market share were extracted and analyzed with reporter gene assays for a set of nuclear receptors (NRs) relevant for human health, including pregnane X receptor (PXR), peroxisome proliferator receptor gamma (PPAR γ), estrogen receptors alpha (ER α) and androgen receptor (AR). Further, these plastic extracts were analyzed using non-target high-resolution mass spectrometry to quantify the number of chemical features and tentatively identify the chemicals present in the FCAs. The chemicals extracted from 36 out of 39 FCAs activated or inhibited one or more receptors with activities up to 100% of the respective positive controls. The PXR was activated by 36, the ER α by 25, the PPAR γ by 23 samples, while the AR was inhibited by 14 of 39 samples. In total, we detected > 16,000 unique chemical features with the number of features per sample ranging from 37 to 9,936. Only 16% of the chemical features were tentatively identified using spectral libraries and *in silico* tools. Our results confirm that many FCAs contain endocrine disrupting chemicals that interfere with diverse NRs. Future research should aim at identifying the active compounds in these complex mixtures. Our work highlights the importance of analyzing whole mixtures of finished products and contributes to improving our understanding of plastics as a source of exposure to endocrine disrupting chemicals. *Acknowledgement* - This project has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No 860720.

7.02 Characterizing the chemical (eco)exposome and associated environmental and health risk throughout the life span in the era of omics (Poster)

7.02.P-Tu307 Early-Life Exposure to Formaldehyde Through Textile Materials

Marta Herrero Casado¹, Nieves González¹, Joaquim Rovira², Montse Marques¹, Marti Nadal² and Jose Domingo¹, (1)Universitat Rovira i Virgili, Spain, (2)University Rovira i Virgili, Spain

Clothes may contain a wide range of chemicals, most of them intentionally added. In recent years, there has been a growing interest in eco-friendly clothing, including the use of organic cotton. However, the process of eco-friendly fabric production may involve the use of toxic chemicals of special concern, such as formaldehyde, a known human carcinogen. The present investigation aims to determine the presence of formaldehyde and its associated dermal exposure risk in the eco-friendly and conventional clothing of pregnant women, babies and toddlers from the Catalan (Spain) market. In this study, 120 clothing samples bought in different on-line shops, stores and malls from Catalonia (Spain) were analysed. One-half of the samples corresponded to eco-friendly garments, while the remaining samples were conventional clothes. Garments from pregnant women,

babies aged < 1 year and toddlers aged < 3 years were considered within the investigation, as the human exposure study was focused on vulnerable population groups. Formaldehyde was detected in 30.6% of the samples, with a mean of 8.96 mg/kg. The two individual garments with the highest formaldehyde content were samples of pregnancy panties (55.7 and 37.3 mg/kg) followed by a sample of babies socks (24.5 mg/kg). Although the values found are within the legal EU limits (< 75 mg/kg), formaldehyde levels were surprisingly higher in the eco-friendly garments (10.4 vs. 8.23 mg/kg). However, these differences were only statistically significant ($p < 0.05$) for bras (11.6 vs. 7.46 mg/kg) and panties (27.1 vs. 6.38 mg/kg) of pregnant women. Dermal exposure and health risks were assessed for three vulnerable population groups: pregnant women, babies and toddlers. In general, the exposure was higher in toddlers (up to $1.66 \cdot 10^{-4}$ mg/kg/day). Both noncarcinogenic and carcinogenic risks were below safe limits, according to international regulations. Furthermore, although formaldehyde levels are below the legal limits (< 75 mg/kg) and health risks within acceptable ranges, clothing may contain other toxic substances apart from formaldehyde, thus increasing the risks. Therefore, future health risk assessments should be performed under multi-exposure and multi-chemical scenarios. This study is part of a large investigation focused on determining the co-occurrence of formaldehyde and other toxic substances (trace elements, aromatic amines, polychlorinated biphenyls and bisphenols) in clothing.

7.02.P-Tu308 Over 40 Years of Monitoring and Research for the Protection of a World-Heritage Estate From the Potential Impacts of Uranium Mining

Andrew J Harford¹, Chris Humphrey² and Katherine Smith², (1)Dept. of Agriculture, Water and the Environment, Eaton, NT, Australia, (2)Dept. of Agriculture, Water and the Environment, Australia

In 1979, the Ranger Uranium Mine began operating in the Alligator Rivers Region, which included the area now known as World-Heritage listed Kakadu National Park (Northern Territory, Australia). It followed a far-reaching parliamentary inquiry that recommended the establishment of a "Supervising Scientist" to oversee the environmental management of the mining operation, and provide scientific advice to the regulatory authorities and the stakeholders. Importantly, the stakeholders included the Traditional Owners of the land, the Mirrar First-Nation people, who wish to recommence their traditional hunting, gathering and ceremonial practices on the rehabilitated mine-site. Forty years on, the Supervising Scientist Branch has conducted a comprehensive research and monitoring program that has provided assurance to stakeholders that the health of the environment and people near the mine remains unimpacted. The operational phase of the mine officially ended when the last barrel of uranium oxide was packed in January 2021, and the rehabilitation of the mine is now the focus, which will require different research needs and monitoring approaches. This presentation will showcase the Supervising Scientist Branch's integrated research and monitoring program for receiving waters and demonstrate how this unique regulatory model has ensured that contemporary research practices are used for informed decision-making. It will cover the full life-cycle of the mine and show how risk-based frameworks facilitated the acquisition of the multitude of knowledge needed for the successful rehabilitation of the mine. The presentation will discuss how new technologies and leading-edge practices can potentially empower the Traditional Owners to conduct the monitoring of the mine following decommissioning. This presentation will demonstrate how the Australian government's investment in scientific expertise results in better environmental outcomes.

7.02.P-Tu309 Optimization and Monitoring of QuEChERS Simultaneous Multi-Residue Analysis method for Multi-Residue Analysis of Pharmaceuticals and Pesticides in Aquaculture Products

KIM Kihwan, Changwon National University, Korea, South

Korea has the highest consumption rate of seafood in the world. Aquaculture represents the largest production in Korea's fishery production. However, pollution of the coastal area, where aquaculture farms are concentrated, threatens the safety of aquatic products. The aim of study was to optimize an QuEChERS analytical method for simultaneous determination of organic pollutants. The QuEChERS extracts were then measured using LC-HRMS. The target substances include 32 pesticides and 20 pharmaceuticals have not been regulated with maximum residual levels in aquaculture products. The method was validated according to CODEX guideline (CAC/GL 71-2009). Linearity of matrix-matched calibration curves were generated with $R^2 > 0.99$. Limits of detection (LOD) and limits of quantification (LOQ) for all matrices ranged from 0.1 to 2 $\mu\text{g}/\text{kg}$ and from 0.5 to 5 $\mu\text{g}/\text{kg}$, respectively. Intra-day ($n = 5$) and inter-day ($n = 9$) accuracy (i.e. recovery rate) and precision (RSD) were estimated at three different spiking concentrations (pharmaceutical: 5, 10, and 20 $\mu\text{g}/\text{kg}$; pesticide: 10, 20, and 50 $\mu\text{g}/\text{kg}$). All target compounds were satisfactory in terms of accuracy and precision according to CODEX guideline. The validated method was applied to aquaculture products ($n = 303$) collected from domestic farms. As a result, 14 pesticides and 8 pharmaceuticals were detected. The most frequently detected compound results revealed 3.7-35 $\mu\text{g}/\text{kg}$ of fluxapyroxad in saltwater fish, 3-46 $\mu\text{g}/\text{kg}$ of fluxapyroxad in freshwater fish, 1-2.5 $\mu\text{g}/\text{kg}$ of propafenone in shellfish, 2.4-60 $\mu\text{g}/\text{kg}$ of fluxapyroxad in crustacea, and 1.4-3.1 $\mu\text{g}/\text{kg}$ of terbutryn in seaweed. Further study should be followed to identify the source of the detected substances.

7.02.P-Tu310 Chemical Analysis of Micro and Nanoplastic in Human Blood

Marthinus Brits¹, Martin van Velzen², Feride Öykü Sefiloglu³, Lorenzo Scibetta⁴, Quinn Groenewoud², Heather Leslie⁵, Juan Garcia-Vallejo⁶ and Marja Lamoree⁷, (1)Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (2)Vrije Universiteit Amsterdam, Netherlands, (3)Environment and Health, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (4)A-life, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (5)VU Amsterdam, Netherlands, (6)Amsterdam UMC, Netherlands, (7)VU University, Department Environment & Health, Netherlands

Characterization of the chemical exposure often focuses on 'classical' organic contaminants and metals, among other classes of chemicals. In the past years, it has become evident that plastic particle fragments from synthetic polymer materials are prevalent in all environmental compartments. The widespread occurrence of micro and nanoplastics in our living environment fuels the expectation that human are exposed to these particles in their daily life. There is limited information on the effects of micro- and

nanoplastic particles (MNPs) on human health. Human exposure is evident by the detection of microplastics in drinking water, food, air, and evidence confirms the entry and presence of microplastics in the human system. The toxicity threshold of MNP ingested, in terms of physical characteristics such as shape, size, mass, and polymer composition is unclear. With increased usage of plastic products, the levels of microplastics in our living environment are expected to increase in the coming years. Thermo-analytical methods coupled with mass spectrometry allow for the simultaneous, selective, and sensitive analysis of micro(nano)plastic and permit quantification in addition to detection. Pyrolysis-gas chromatography coupled to mass spectrometry (Py-GC-MS) has been successfully applied for the simultaneous detection of several polymers in environmental samples. In this study we present an analytical method for MNPs in human blood which involve enzymatic digestion followed by microfiltration and analysis using Py-GC-MS. The method was validated through spiking experiments at concentration levels in the same range as the measured data. Pyrolysis parameters and GC separation conditions were optimised to improve the specificity and sensitivity of the method. Strict identification and quantitation criteria for the low detection limits of unique pyrolysates of polyvinyl chloride, poly(methyl methacrylate), polypropylene, polymer materials containing styrene units, polyethylene and polyethylene terephthalate were applied. Further aspects of calibration, recoveries, and potential matrix effects are discussed. Results from the pilot study showed that high production volume polymers applied in plastic were identified and quantified in blood.

7.02.P-Tu311 Analytical Workflow for Chemical Exposomics in Human Serum by Gas Chromatograph Mass Spectrometry

Hongyu Xie¹, Kalliroi Sdougkou², Stefano Papazian² and Jonathan Martin², (1)Stockholm University, ACESx, Sweden, (2)Stockholm University, Sweden

The human exposome is defined as all environmental exposures throughout an individual's lifespan^[1], and techniques to measure it are of increasing importance with knowledge that most chronic disease has environmental etiology^[2]. The chemical exposome is a particular challenge because of 350,000 chemicals in commerce, and only a few hundred of these have historically been biomonitored in blood by targeted methods^[3]. To better understand health risks of the chemical exposome, a workflow was developed that combines sensitive multi-target quantification with nontarget discovery for environmental contaminants in small volumes of individual blood serum samples. An extraction and cleanup method was optimized for 106 target analytes (log K_{ow} range, 1.7 - 11.2) from 6 classes, including polychlorinated biphenyls, halogenated flame retardants, dioxins, polycyclic aromatic hydrocarbons, organochlorine pesticides, phthalate plasticizers. The absolute recoveries for the majority of targets with the optimized sample preparation method were in the range of 70-80%. Gas chromatograph (GC) - high resolution mass spectrometry (Orbitrap) parameters were tuned for maximum method sensitivity, and instrumental detection limits reach as low as 0.025 pg on-column. The developed workflow had high sensitivity, recovery, and reproducibility for target analytes and showed promise for simultaneous nontarget chemical discovery using an open-science data processing tool (MS-DIAL) and spectral matching to various public libraries (NIST, MassBank, GNPS). Application to strategic samples from Swedish cohort studies revealed inter- and intra-individual variation of the exposome, including based on lifestyle and dietary habits. Technol.*, 54(5), 2575-2584.

7.02.P-Tu312 Emerging Contaminants in Shellfish and Sediments Along the Chinese Coastline

Junjie Zhang¹, Hebo Peng², Veerle Jaspers³ and Alexandros Asimakopoulos⁴, (1)Norwegian University of Science and Technology (NTNU), Trondheim, Norway, (2)University of Groningen, Netherlands, (3)Norwegian University of Science & Technology, Norway, (4)Norwegian University of Science and Technology (NTNU), Norway

Emerging contaminants (ECs) are chemicals that are not commonly monitored and not regulated in the environment, but many classes have known or suspected adverse effects on the environment and human health. There are many studies published in relation to their environmental occurrence and potential for toxic effects. However, the knowledge on the occurrence of ECs along the coastal areas of China is still limited. In addition, the coastal areas of China are key stopover sites for migratory shorebirds to feed and rest, many shorebird species are in serious decline potentially linked to habitat degradation along the Yellow Sea and Bohai Sea of China. As a part of the COAST-IMPACT project, the present study aims to comprehensively investigate the environmental occurrence of several ECs, including per- and polyfluoroalkyl substances (PFASs), parabens, organophosphate flame retardants (OPFRs), bisphenols and benzophenones (BPs), and benzotriazoles and benzothiazoles (BTs) in shellfish and sediments at key stopover sites along the coast of China. 67 shellfish and 37 sediment samples were collected in the intertidal mudflats of 13 sites along the coast of China (3 samples from each location) in 2018. The shellfish (soft-tissue) and sediments were freeze-dried and stored at -20 °C until analysis. Samples were pretreated with liquid-solid extraction and solid phase extraction and analyzed by LC-MS/MS analysis. The concentrations (in dry weight, d.w.) were in the ranges of < 0.12-2508 for PFASs, < 0.09-4179 for parabens, < 0.09-149 for OPFRs, < 0.036-279 for BPs and < 0.036-27.3 ng/g for BTs, respectively. The concentrations (in d.w.) in sediments were in the ranges of < 0.11-306 for parabens, < 0.015-64.4 for OPFRs, < 0.03-25.5 for BPs and < 0.03-99.2 ng/g for BTs (d.w.), respectively. The concentrations of parabens, OPFRs, and BPs in shellfish were higher than those in the corresponding sediments. Shellfish collected from Diaokou and Nanhaipu contained higher concentration of PFASs. Shellfish collected from Yalujiang, Panjin, Nanpu, Diaokou, Changyi west (all around the Bohai Sea) and Leizhou (South China) contained a higher concentration of BPs. The concentrations of parabens were higher in shellfish from Yalujiang, Panjin, Nanhaipu, Changyi west, Xiuzhenhe and Qidong (around the Bohai sea and Yellow sea). It was thus observed that the shellfish samples with high concentrations of ECs are mostly collected from the coast of the Bohai Sea. The geographic patterns of the occurrence of these contaminants were assessed and significant associations were established among the target analytes. ECs were found ubiquitous in shellfish and sediments along the coast of China, while concentrations in sediments were found lower than

those in shellfish (except for BTs). PFASs and parabens were the dominant ECs in shellfish. We will focus on the areas with high pollutant concentrations for further research.

7.02 Characterizing the chemical (eco)exposome and associated environmental and health risk throughout the life span in the era of omics (Poster Corner)

7.02.PC-Tu07 From Biotransformation Products to Altered Metabolites & Lipids - Lc-Tims-Hrms Combined With a Sophisticated Annotation Workflow for Xeno- and Endo-Metabolome Coverage of Zebrafish Exposed to Xenobiotics *Dimitrios E. Damalas¹, Eleni Panagopoulou¹, Adamantia Agalou², Dimitris Beis² and Nikolaos Thomaidis¹, (1)National and Kapodistrian University of Athens, Greece, (2)Biomedical Research Foundation Academy of Athens, Greece*

Given the large number of xenobiotics, there is an important gap in the literature concerning their adverse effects on aquatic organisms. The impact of xenobiotics in the aquatic ecosystem is evaluated in more depth when the whole xeno-metabolome (xenobiotics and their biotransformation products (bio-TPs)) and endo-metabolome (metabolites & lipids) of aquatic organisms is studied. HRMS-based workflows appear to be a powerful tool for the identification of bio-TPs and metabolites/lipids. Beyond the cases that identification fails because of reduced ionization efficiency, false negatives arise from the inadequate separation. Despite HRMS's high applicability and accuracy, separation of isomers/isobars is not always possible, as they may pose identical chromatographic and spectral profiles. Thus, identification remains a challenging task. Additional "dimensions" of separation are required to provide additional evidence and reliable identifications. Combining complementary chromatographic modes with HRMS seems a powerful alternative tool for the comprehensive and high-throughput identification of unknowns. Lately, Trapped Ion Mobility Spectrometry (TIMS) has been proved an up-and-coming technology, separating molecules based on their three-dimensional size and charge in the gas phase. The development of comprehensive annotation workflows that utilize the analytical evidence to their maximum is also imperative. The objective of this study is to highlight a high-end analytical platform (LC-TIMS-HRMS) that combines multiple dimensions of separation with HRMS, in order to provide extensive experimental evidence for the identification of bio-TPs and endogenous metabolites/lipids. In addition, we developed a data treatment workflow, consisted of suspect and non-target screening approaches combining different annotation tools. Overall, the aim was to highlight a holistic approach for comprehensive xeno- and endo-metabolome coverage to facilitate toxicity assessment of aquatic organisms exposed to xenobiotics. ZFE exposed to xenobiotics were used as case studies. The developed workflow encompasses a wide range of tools to identify i) bio-TPs of xenobiotics ii) endogenous metabolites and iii) lipids in the same dataset. Examples highlighting the added value of TIMS in the identification of bio-TPs will be presented. Finally, the annotation of several lipids will be showcased, leading to the observation of lipid accumulation as a toxic response to triclosan exposure

7.02.PC-Tu08 Enhanced Chemical Exposomics of Human Plasma by Phospholipid Removal and LC – HRMS

Kalliroti Sdougkou¹, Hongyu Xie², Stefano Papazian³, Bénilde Bonnefille⁴, Ingvar Bergdahl⁵ and Jonathan Martin⁶, (1)ACESx, Stockholm University / Science for Life Laboratory, Stockholm, Sweden, (2)Stockholm University, ACESx, Sweden, (3)Stockholm University, ACES, Stockholm, Sweden, (4)ACES, Stockholm University, Stockholm, Sweden, (5)Department of Public Health and Clinical Medicine, Occupa, Umeå University, Umeå, Sweden, (6)Stockholm University, Sweden

The exposome is the sum of all environmental exposures over an individual's lifespan. Measuring the chemical exposome in blood is a challenging task due to its inherent chemical complexity and wide concentration ranges of endogenous and exogenous small molecules. Untargeted high-resolution metabolomics methods have been directly adapted for investigating the chemical exposome by liquid chromatography (LC) and high-resolution mass spectrometry (HRMS), thereby allowing detection of thousands of features. However, when it comes to human serum these signals are dominated by high concentrations of endogenous lipids. To achieve higher sensitivity for discovery and profiling of the chemical exposome, we hypothesized that enhanced chemical exposomics could be achieved with a sample preparation workflow focused on the removal of major phospholipid components. Here, following protein precipitation a simple solid phase extraction (SPE) step was optimized using small volumes of human serum. Satisfactory recoveries were maintained for multiple classes of environmental contaminants, including 70 of the major serum contaminants and their metabolites, such as flame retardants, per- and poly-fluoroalkyl substances, phthalates and pesticides. The resulting phospholipid-free extracts allowed injecting higher volumes of serum on column for LC-HRMS analysis, compared to routine HRMS methods, thereby assisting the detection of trace chemicals. Method limits of quantification (MLOQ) for the target analytes reached as low as 0.025 ng/ml for a 200 µL serum sample, making the method's sensitivity comparable or superior to targeted methods. Analytes were quantified or semi-quantified using isotope internal standards or the reference standardization method, respectively. An added benefit was the ability to profile endogenous steroid and thyroid hormones which may be impacted by the endocrine active component of the chemical exposome, thereby allowing measurements of exposure and effect in the same LC-HRMS analysis of individual biofluid samples. The selective nature of the phospholipid removal makes the method also suitable for suspect screening and unbiased untargeted analysis. Application of the method in cohort studies will be discussed with respect to variation of the exposome between and within individuals.

7.03 How to assess sustainability of chemicals and operationalize 'safe operating space for chemicals', 'do no harm' principle, and 'safe and sustainable by design' concepts?

7.03.T-01 Finding the Toxic Free Environment - Feasible?

Leo Posthuma¹, Jaap Postma², Rineke Keijzers², Jaap Slootweg¹ and Bas Wal³, (1)RIVM, Netherlands, (2)Ecofide, Netherlands, (3)STOWA, Netherlands

Finding a toxic free environment may seem like finding a needle in a haystack. For now. Or not. Who knows? The present research ventures into the environment, to find the needles out there. What can we learn from contemporary chemical pollution in surface water systems? What do the data tell us regarding concepts and themes such as the toxic-free-ness (or absence thereof), dominant chemical groups, spatiotemporal variability and alike, and on exceedance of thresholds of effects and the consequences of that? What do those lessons learn us on the needs for and approaches to safe and sustainable by design, and the zero-pollution ambition? Before carrying more haystacks full of uncertainties, the present research just looked at a snapshot ('photo') of chemical pollution, with Dutch surface waters as an example. We collected monitoring data from >8500 locations, to characterize current pollution. Mixture toxic pressures were quantified, and classified according to ecological impact phenomena. Results provided insights into the absence of toxic-free-ness, and spatial variability of dominant chemical groups. The toxic-free environment ambition would have been reached if we would have found no chemicals, no exceedances of local or regional thresholds, and no impacts. As we found variable distances to target, we asked ourselves not only about the causal agents, but also about systematic ways to explore the solution space. Solutions are 'inside the box', and we discuss how to identify and prioritize them. Field data inform us on where to act, and on what – along all events that shape a contemporary chemical economy.

7.03.T-02 Determining the Fraction of Regional Carrying Capacities Occupied by Pesticide Use

Marissa B Kosnik¹, Olivier Jolliet², Michael Z. Hauschild³ and Peter Fantke³, (1)Technical University of Denmark (DTU), Denmark, (2)University of Michigan, United States, (3)Technical University of Denmark, Denmark

Chemical pollution can exert adverse effects on ecosystems. To determine the safe operating space for chemicals, methods are needed to both calculate and link the actual chemical pressure on ecosystems (as a result of chemical usage) and the capacity for ecosystems to withstand that pressure without irreversible adverse effect (the carrying capacity). However, challenges in developing these methods include variability in where chemicals are used, and spatial differences in features of ecosystems (e.g., location of water bodies). Additionally, regions with seemingly distinct ecosystem carrying capacities may be interconnected as chemicals emitted into one region may occupy the safe operating space in other (e.g., downstream) regions. To address this gap, we introduce a spatially explicit framework to relate chemical pressure to region-specific carrying capacities. We quantify the fraction of ecosystem-specific carrying capacities that is occupied (and potentially exceeded) by toxicity-related pressure from chemicals. As a demonstration of this approach, pesticide application data for 409 chemicals at the county level for the United States (US) were collected from the US Geological Survey, and were used as proxies for emissions to agricultural soil. These data were integrated into the Pangea spatial multi-scale model to determine the freshwater concentration of each chemical in 45,576 different catchments in the US. Chemical pressure and carrying capacity were combined, so the final output for each chemical in a region is the fraction of a freshwater ecosystem's carrying capacity occupied by that chemical, $F_{cc,o}$ (considering both direct and indirect contributions into that region). For each region, the $F_{cc,o}$ can be analysed per chemical (e.g., 6×10^{-4} of catchment 20819's carrying capacity is occupied by atrazine in Scott County, Missouri) and across chemicals (6.6×10^{-4} of catchment 20819's carrying capacity is occupied by 10 pesticides) to assess cumulative chemical impacts on ecosystems. Results indicate that pesticide pressure varies widely across both pesticides (e.g., due to differences in chemical persistence) and catchments (e.g., due to differences in available water volume). This framework can be used to assess the pressure of current chemical emissions on ecosystems with consideration of spatial variability to meet the chemical pollution-related targets of the EU Chemicals Strategy for Sustainability and the European Green Deal.

7.03.T-03 Prioritizing Hazardous Chemicals in Food Contact Materials

Lisa Zimmermann¹, Birgit Geueke¹, Justin Boucher¹, Ksenia J Groh², Lindsey Parkinson¹ and Jane Muncke¹, (1)Food Packaging Forum Foundation, Switzerland, (2)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland

Over 12,000 chemicals are possibly used in the manufacture of food contact materials (FCMs), and several thousand chemicals have been detected in the extracts or migrates of FCMs. By transferring into food, these chemicals become directly relevant for human exposure. Concepts like the 'do no harm' principle have been adopted within the European Union's Green Deal and Chemicals Strategy for Sustainability (CSS), implying the need to identify hazardous chemicals, including those in FCMs. However, an easily accessible overview of chemicals of concern used to manufacture FCMs is missing, although this would be important for policymakers and other stakeholders. Therefore, we compiled a list of food contact chemicals of concern (FCCoC) by cross-checking databases on chemicals used in FCMs against publicly available hazard properties mentioned in the CSS such as being carcinogenic, mutagenic, or toxic to reproduction (CMRs), endocrine-disrupting chemicals (EDCs), and chemicals with persistence-related hazards. For each FCCoC, we compiled data describing the material types it is potentially used within, its hazard properties, production volume, and whether there is empirical evidence for migration and/or extraction from FCMs. We identified 388 FCCoC that have hazard properties mentioned in the CSS. The data show that the manufacturing of plastics, paper & board, and printing inks potentially use more than half of these chemicals. Moreover, around one-third of these FCCoC have been detected in migrates or extracts of at least one FCM type, including roughly 100 CMRs and 14 EDCs. This demonstrates that a large number of chemicals known to be hazardous is present in different types of FCMs and are relevant for human exposure. Taken together, we present an approach for how to identify chemicals in food packaging that could pose the greatest risk to human health. The compiled list of FCCoC can help to prioritize substances that are of particular concern for further in-depth assessment and regulatory action in frame of the CSS. Thus, our data can contribute to the safe and sustainable use of chemicals.

7.03.T-04 First Steps Toward Sustainable Circular Uses of Chemicals: Advancing the Assessment and Management Paradigm

Zhanyun Wang and Stefanie Hellweg, ETH Zurich, Switzerland

Environmental and human health impacts associated with chemical production and losses from value chains make the current

linear produce-use-dispose model no longer an option for chemicals. In this study, we explore next steps on how to embed the concept of “sustainable circularity” into practice (including the design phase) to foster systemic transition toward sustainable circular uses of chemicals. We first analyze major causes of chemical losses throughout their life cycles. Then, we propose to advance the current chemicals assessment and management paradigm by introducing (1) the consideration of multiple use cycles in the hazard and risk assessment stage and (2) an additional “sustainable circularity” assessment stage subsequent to the hazard and risk assessment stage, as a critical first step to guide systematic decision-making at all levels toward sustainable circular use of chemicals. We discuss how these new assessment stages may look like, and then we further look into how to enable the proposed changes and a larger systemic transition, both on the technical and socioeconomic sides.

7.03 How to assess sustainability of chemicals and operationalize 'safe operating space for chemicals', 'do no harm' principle, and 'safe and sustainable by design' concepts? (Virtual Only)

7.03.V-01 Retrospective Analysis of Environmental Classification & Labelling Under CLP Regulation (EC) No 1272/2008

Madeline Carsique¹, Flavio Marchetto², Marco Mattiuzzo³, Konstantinos Prevedouros³, Marta Sobanska⁴, Simon Uphill⁵ and Stella Jones³, (1)ANSES, France, (2)ICPS, Finland, (3)European Chemicals Agency (ECHA), Finland, (4)European Chemical Agency, Helsinki, Finland, (5)European Chemical Agency (ECHA), Finland

The widespread use of chemicals often comes along with harmful effects to humans and the environment. The Classification, Labelling and Packaging (CLP) Regulation (EC, No 1272/2008) obliges actors in the supply chain to appropriately classify, label and package hazardous chemicals. It is a solely hazard based process which uses the Globally Harmonized System of Classification and Labelling of Chemicals (GHS) as a basis for hazard assessment within the EU. Regarding the classification for environmental hazards, CLP focuses on the aquatic compartment, notably on the results of aquatic toxicity tests performed on fish, aquatic invertebrates and algae or other aquatic plants, which are considered as surrogates for all aquatic organisms. During the hazard assessment of a substance, its degradation and bioaccumulation behaviour are also taken into account as elements of long-term hazard assessment. In general, the hazard assessment is based on comparisons of available data with the CLP criteria. Harmonised classification and labelling (CLH) is the regulatory mechanism assuring the consistent and scientifically sound hazard identification and communication. It addresses hazards of the highest concerns such as carcinogenicity, mutagenicity, reproductive toxicity (CMR), respiratory sensitizers and other hazards on a case-by-case basis. All substances with harmonised classifications are listed in Annex VI of CLP which triggers various obligations for manufacturers, importers, and professional users of those substances. The objective of the current analysis is to present a historical perspective of the harmonised classification process under CLP for environmental hazards and an in-depth analysis of the key information since the adoption of CLP in 2008. It presents the overall statistics of the process until August 2021, including total numbers of substances classified for environmental hazards, types and severity of adopted classifications, numbers of new or updated classifications, analyses of the involved actors, classifications per substance function, species sensitivity, etc. It further explores the effectiveness of the CLH process as the regulatory risk management tool by analysing implications under the current regulatory system as opposed to the previous system. It is hoped the analysis will facilitate regulatory authorities in evaluating the hazards to aquatic environment and to assist authorities in a consistent decision-making process.

7.03.V-02 Sustainability Index - a Chemical Sustainability Metric

Hans Plugge, Safer Chemical Analytics LLC, United States

Sustainability of chemical compounds is often ill described (if at all). To truly green our chemical footprint we first must quantify the environmental and health footprint of chemical enterprises. Most chemicals in commerce are chemical products i.e., mixtures (even so-called pure chemicals as technical grades often contain up to 5% impurities.) Hazard and risk assessment methods for mixtures are few and far between. How then to assess the greening of an enterprise that distributes dozens or even thousands of products? As part of the ESG dynamics, chemical sustainability i.e., the impact from chemicals and how to measure these across hundreds or more products, is a daunting, but necessary task. We need an index that tracks the potential risk of an enterprise's total inventory as it greens over the coming years. Note here the dichotomy between risk and hazard, where environmental health measures risk as the product of hazard and exposure, i.e. quantity matters (most systems consider only hazard i.e. don't distinguish between test tubes and tanker trailers). Our Sustainability Index (SI) measures both hazard and risk across numerous chemicals – software being the only limitation. The resulting SI's for single chemical and facilities are expressed such that they can be summed across chemicals and indeed facilities to wrap up into a single corporate SI. But what about growth – as long as growth occurs in greener chemical inventory, a company can both grow and improve its SI. Given the lead-time for developing true green alternatives to existing chemicals, intermediate substitution of less hazardous “analogues” may drive initial SI reduction. Exposure here is measured as the total of chemical X within a facility. The hazard portion is less straightforward – although many hazard assessment/ranking systems exist, they generally do not allow compounding effects into a single score. There is however a hazard assessment system that is globally embraced: the so-called GHS (Globally Harmonized System) chemical classification system. We developed a metric based on the various endpoint ratings. Such metrics are then pooled across endpoints using a weighting system to result in a single hazard score for each chemical. Facility SI's can thus be established by simple summing of chemical specific risk estimates. A next step in the process would be to incorporate LCA elements into the SI.

7.03 How to assess sustainability of chemicals and operationalize 'safe operating space for chemicals', 'do no harm' principle, and 'safe and sustainable by design' concepts? (Poster)

7.03.P-Mo280 Environmental Impact Reduction of Crop Protection - How to Model, How to Measure, How to Achieve?

Anja Gladbach¹, Yuyue Zhang², Peter Fantke³, Luke Settles⁴ and Daniel Glas¹, (1)Bayer Crop Science, Germany, (2)DTU (Technical University of Denmark), Denmark, (3)Technical University of Denmark, Denmark, (4)Bayer Crop Science, United States

Agricultural activity has always had an impact on the environment. Efforts to make fields more productive and increase the efficient use of land and resources include tools like the use of pesticides to protect crops from (yield) losses due to weeds, diseases, and insect damage. Each tool that a farmer applies has benefits and drawbacks, and this is generally true for crop protection. And while crop protection products are not only developed to achieve efficacy, but as well rigorously tested to be safe for people and to pose no unacceptable impact on the environment, they still have an effect. Bayer thus in 2019 committed to reduce the environmental impact of our agrochemical uses by 30% by 2030. Reducing the environmental impacts of agrochemicals requires a coherent and efficient metrics system that allows a standardized quantification of the level of sustainable measures implemented and the extent of the associated impact. Therefore, impact indicators within a shared framework of regulation, practice, verification, and certification are needed to drive change. Based on a comprehensive and spatially resolved application dataset for >90% of the global crop protection market we quantified pesticide emissions and ecotoxicity impact, building on PestLCI and USEtox as state-of-the-art, consensus-based models for application in life cycle assessment (LCA) and environmental footprinting. After initial identification of global hotspots and drivers, we will assess the effects of reduction levers (e.g., emission management and mitigation, precision application, combination of chemical and biological crop protection, substituting high-impact chemicals by functionally equivalent more sustainable alternatives). We will use the results to achieve impact reduction ambitions and to guide company efforts within the safe and sustainable-by-design framework for crop protection. In this talk, we not only want to share how we approached this commitment (eg. identification and selection criteria of suitable models, setting of a reliable baseline scenario, associated data needed and the evaluation of the suitability of related impact reduction options), but as well the limitations, challenges, and learnings so far. With the proposed assessment framework, we aim to contribute to the discussion on how to achieve environmental impact reduction for agricultural production as well as to outline current limitations like data availability or incentivization systems for farmers.

7.03.P-Mo281 Framework for Evaluating Emerging Chemical Issues for Prioritising Management

Olivia Lin Tran¹, Graham Merrington², Adam Peters³, Therese Manning⁴, Anna Ramarosandratana⁵, Julie Cattle⁶ and Janina Beyer⁷, (1)wca, Faringdon, United Kingdom, (2)WCA Environment Limited, United Kingdom, (3)wca, United Kingdom, (4)Enriska, Australia, (5)NSW Environmental Protection Authority, Australia, (6)NSW Environment Protection Authority, Australia, (7)NSW DPE, Australia

Regulatory organisations operate within budget and resource constraints, whilst having increasing responsibilities to protect human health and the environment with evidence-based actions. This poster will provide a simple, intuitive, evidence-driven framework to support the identification of chemical issues to assist regulators target their resources to reduce potential human and environmental risks from chemicals. The framework can be used to support the evaluation of chemical issues at varying organisational levels (e.g. global, national or state-level) and help regulators understand what chemical issues and risk management options are within their departmental remit. A critical part of this framework is defining the chemical issue to give a workable scope for evaluation and targeted intervention. Chemical issues are identified where there is a source, pathway and receptor linking a chemical to an adverse or undesirable outcome. It is not simply a chemical or group of chemicals but must have an evidenced source, pathway and receptor. It is critical that the identification of chemical issues is supported by robust evidence in the source-pathway-receptor framework to justify regulatory intervention to mitigate risk. Assessment of issues for further risk management can then take place considering the strength of evidence in each group, the linkages between them and the local and/or regulatory context. Equally, gaps in the evidence can act as a critical driver for targeted studies and monitoring by both the regulator and the scientific community. An Excel-based tool has been developed to capture the range of chemical issues under consideration for assessment. Issues can be filtered (using standard category labels under each of the groups) to determine frequently occurring categories for evaluation, if any interventions can be made to target multiple issues having the same categories. Additional information, such as spatial and temporal scope, economic and social impacts and other non-chemical factors contributing to the issue can be captured and considered in the assessment process. Example evaluations will be presented to illustrate the assessment process and next steps for risk intervention or information gathering.

7.03.P-Mo282 Polymeric and Monomeric Brominated Flame Retardants: Degradation Behaviour and Ecotoxicological Effects

Esther Smollich¹, Valentina Merkus², Torsten Schmidt² and Bernd Sures³, (1)University Duisburg-Essen, Germany, (2)University of Duisburg-Essen, Germany, (3)University of Duisburg Essen, Germany

Conventional brominated flame retardants (BFRs) are widely used and have been subject to thorough scientific investigation and regulatory attention due to concerns about their behaviour in the environment. Thus, in recent years the development of novel brominated flame retardants has been intensive, while the research on these compounds lags behind. Improvements of the environmental behavior are commonly stated as the reasons for the development of such novel BFRs. To evaluate the success of these substances, more studies are needed on characteristics such as the bioaccumulation, mobility, degradation or toxicity of novel BFRs. One example of a BFR explicitly designed for greater sustainability is PolymericFR, a brominated copolymer whose large structure leads to a decreased mobility and bioavailability when compared to conventional BFRs. However, it has been shown that abiotic degradation processes result in the formation of smaller, more mobile degradation products of this polymeric BFR, facilitating releases by the chemical at the end-of-life phase. Therefore, in this study we examine the photolytic degradation of PolymericFR and compare it to the degradation of the monomeric alternative BFR Tetrabromobisphenol A-bis(2,3-dibromo-2-

methyl-propylether) (TBBPA-Ether). Our methods combine chemical analysis and ecotoxicological testing of photolytic degradation mixtures derived under various conditions. Both BFRs were irradiated in an aqueous environment for a range of time intervals, simulating the UV exposure of the compounds for up to nine days in sunlight. The resulting degradation mixtures were filtered, stored and subsequently applied in further analysis. The analyses included high-resolution mass spectrometry (LC-HRMS) and ecotoxicological tests with *Desmodesmus subspicatus*, *Daphnia magna* and *Lumbriculus variegatus*. Depending on the test organisms, acute effects (*D. subspicatus* and *D. magna*) or chronic effects and physiological reactions (*L. variegatus*) were studied as ecotoxicological endpoints for the testing. Where possible, median effective concentrations (EC₅₀ values) were calculated and compared for the different degradation conditions and the two BFRs. The newest results of our evaluation will be presented and discussed. Overall, our study deepens the current understanding on the degradation behavior of two novel BFRs and exemplifies the relevance of degradation and transformation processes in ecotoxicology.

7.03.P-Mo283 Multi-Criteria Assessment of Pesticide Use, Ecotoxicological Risks, Ecological and Economic Impacts of Swiss Apple Production

Marcel Mathis¹, Judith F. Blom², Thomas Nemecek¹, Esther Bravin¹, Philippe Jeanneret¹, Otto Daniel¹ and Laura De Baan¹, (1)Agroscope, Switzerland, (2)Plant Protection Products - Impact and Assessment, Agroscope, Switzerland

The European Commission's «Sustainable Use of Pesticides» Directive aims to better protect human health and the environment by reducing the risks and impacts of pesticide use and promoting lower-risk alternative approaches or techniques. Such alternatives may include the use of less hazardous pesticides or non-chemical alternatives such as mechanical techniques or biocontrol measures. However, these alternatives are not always equally effective and may finally result in yield losses. They also require additional material, energy or labor inputs, which can lead to additional undesirable environmental or economic impacts. Understanding potential trade-offs is crucial to initiate a sustainable pesticide use. In this study, we have analysed such trade-offs using apple production in Switzerland as an example. Apples are very susceptible to diseases and pests and are currently among the fruit with the highest intensity of pesticide use. We conducted a multi-criteria assessment of exemplary crop protection strategies, including different chemical and non-chemical alternatives to standard pesticides, in different apple production systems (conventional, integrated, and organic). An assessment of pesticide use, local ecotoxicological risks to next-to-field habitats, global environmental impacts (life cycle assessment) and an economic analysis was performed based on 13 quantitative indicators. Compared to the standard crop protection strategy, the integrated strategy with reduced pesticide use performed better in terms of ecotoxicological risks and biodiversity, but was not profitable due to high investments, resulting in negative hourly wages for farmers. The organic strategy showed higher impacts per kg of apples produced for most global environmental indicators, but performed better for ecotoxicological risks, biodiversity and also farmer's hourly wage. The conventional strategy performed worse in terms of biodiversity, global warming potential and investment costs, but resulted in higher hourly wages for farmers. This study shows that reducing pesticide use and the associated ecotoxicological risks comes with trade-offs in other environmental aspects and can be an economic challenge. None of the strategies examined performed better than the others in all the 13 indicators assessed. However, our comprehensive approach can help develop more sustainable crop protection systems and evaluate alternatives to pesticide use from an environmental and economic perspective.

Track 8: Special Sessions

8.01 Chemicals and Sustainability

Special session with no abstracts.

8.02 Going MAD – Communication and goals of mechanistic effect models in regulatory ERA

Special session with no abstracts.

8.03 The European Green Deal (Chemicals Strategy for Sustainability)

8.04.V-01 A Comparison of the Variability Across Bumblebee Colony Parameters Using Manual and Automated Methods: How Accurately Can We Measure *Bombus* Colony Development?

Maryam Qureshi¹, Lukas Materne², Catherine Borrek¹, Nina Exeler¹, Frederic Tausch², Klaus Thoiss¹, Katharina Schmidt², Peter Trodtfeld¹ and Maria Teresa Almanza¹, (1)Bayer Crop Science, Germany, (2)apic.ai, Germany

Bumblebees are important wild and managed pollinators of agricultural crops and other plants. Some bumblebee species can be reared, and their colonies are commercially available. Thus, testing material for ecotoxicological studies is readily available. Recently validated testing methods have been developed for individual adult bumblebees (OECD 246/247) but the development of higher tier studies that would allow the assessment of colony development has proven to be more challenging. In situ-evaluation of colony development in higher-tier testing approaches would be crucial, since existing data reveal a very high inter-colony variability, even under identical test and exposure conditions. Various approaches have been developed with some success to overcome this issue. Yet, it is still technically challenging to accurately measure parameters such as colony strength, individual's mortality and size and foraging activity at regular intervals in the field without disturbing colony development. Therefore, we have jointly been developing an approach to compare "conventional" assessment methods like manual counting of

individual bumblebees or estimation of brood areas, and novel automated, sensor-based methodologies to survey these parameters. The conventional methodologies are time-consuming, and their accuracy can be compromised by the limited frequency and duration with which they can be conducted due to technical constraints. The automated sensor-based methodologies, in contrast, may offer a more efficient and more accurate option. In this work, we are presenting the comparison of conventional and sensor-based measurements done in parallel in an exemplary trial on 6 colonies per treatment group (control and 2 concentrations of a toxic reference) for different parameters. Our work contributes to a better understanding of between-hive variability in bumblebees, and the influence of different assessment methods to the outcome of the measurements.

8.04.V-02 A Sustainable Solution for the Use of Leaching Agents in the Indirect Mineral Carbonation

Yoonah Jeong¹, Ye-Eun Lee² and I-Tae Kim², (1)KICT, Korea, South, (2)Korea Institute of Civil Engineering and Building Technology (KICT), Korea, South

Carbon capture, utilization, and storage (CCUS) is widely used to reduce CO₂ emissions and handle industrial solid waste. Indirect carbonation is one of the CCUS techniques, which convert gaseous CO₂ into thermodynamically stable carbonates form by using alkaline oxides or hydroxides. Although indirect carbonation is efficient as well as reliable approach to store CO₂, sustainability issues arise due to the use of various leaching agents. Indirect carbonation needs the elution of alkali earth metals (Ca and Mg) from raw material using various solvents, which leads to the use of a high amount of chemicals and the generation of chemical wastes. Therefore, this study aims to derive a sustainable solution for the process of indirect mineral carbonation. We investigated the various leaching agents and concentration settings to find an optimized process of indirect carbonation while producing carbonates as a final product.

8.04.V-03 Advancing the In Situ Toxicity Identification Evaluation (iTIE) Technology for Identifying Toxicants

G. Allen Burton Jr.¹, D. Bart Chadwick², Gunther Rosen³ and Marieene Colvin⁴, (1)University of Michigan, United States, (2)Coastal Monitoring Associates, San Diego CA 92107, United States, (3)SPAWAR Systems Center San Diego, United States, (4)Naval Information Warfare Center (NIWC) Pacific San Diego, CA 92152, United States

The iTIE is being optimized to: (1) improve use in sediments via developing diverless deployment modifications, (2) modifying the water intake system for porewater extractions, (3) developing a gentle aeration system to allow for toxicity testing of anoxic pore and surface waters, (4) refining chemical targeting (including PFAS) and separation via new resins, (5) expand marine and freshwater fish and invertebrate chronic toxicity, and (6) further field validate the usefulness of the technology. The iTIE system (iTIES) is a biological fractionation protocol that systematically identifies chemical classes causing toxicity in overlying water, pore water, and outfall effluents (i.e., industrial/municipal point source and stormwater). The system separates chemical classes of contaminants of concern (i.e., various types of organics, metals, ammonia), frequently linked to adverse biological effects. The iTIES prototype 3 is now a robust deployable system that allows for consistent and sensitive adjustments to pumping rates of ambient waters through a diagnostic array of resin treatments. The current battery of resins separates the following potential toxicants: ammonia, problematic heavy metals (Ag, Cd, Cu, Ni, Pb, Zn), and organics of various characteristics, including PCBs, PAHs, and PFAS. It provides a unique diagnostic tool for used in a tiered risk assessment. The iTIES diagnostic tool is to be used once Tier 1 assessments suggest chemical toxicity may be a concern.

8.04.V-04 Approach to Inform About the Representativeness of Climatic Conditions During Foliage RESIDUE Decline Studies

Joachim Nopper¹, Tim Haering¹, Eduard Szöcs¹ and Kai Ristau², (1)BASF SE, Germany, (2)APD/EE, BASF SE, Germany

In the wildlife risk assessment for the registration of plant protection products, foliage residue decline (DT50) studies are often used as a higher-tier refinement for providing more realistic estimates of the residue decline of a plant protection product on the herbivorous portion of an animal's diet. In EFSA's draft of the updated birds and mammals guidance document from 2021 a mandatory relevance and reliability check of this study type is proposed. One critical element of this assessment is the determination of the representativeness of the locations of residue decline studies for the geographical region which is specified in the GAP. To facilitate this check, we present an approach that is based on publicly available spatial data for cumulative precipitation, average air temperature and land use for informing about the representativeness of the climatic conditions at the trial site during the study period. Weather data measured at the trial site, namely cumulative precipitation and average daily temperature, are compared with reference data from the last decade provided at a 0.31x0.31 degrees grid resolution for the European Union. Spatio-temporal buffers can be also included to have a greater extent of reference values. Agricultural production can act as a filter to exclude references from the comparison. Simple graphical representations and statistics of the representativeness check are proposed.

8.04.V-05 Assessment of Cement Production on Water Quality in Sagamu, Ogun State, Nigeria

Catherine Adeniji¹, Omotayo Sindiku² and Oluwaseun Oduguwa², (1)Environmental Management and Toxicology, Lead City University, Ibadan, Ibadan, Nigeria, (2)Lead City University, Ibadan, Nigeria

The contamination of groundwater by organic and inorganic compounds are severe worldwide problems because groundwater serves as a universal source of water. Contaminated water is unsuitable for various purposes and can be harmful for human health and the environment. This study aimed at determining water quality parameters in borehole water around Lafarge cement factory, Sagamu, Ogun State. Water samples were collected from twenty residential houses in all four cardinal locations around the factory while distilled water served as control. Physicochemical parameters such as pH, Turbidity, salinity, chloride, sulphate, nitrate and phosphate were determined using standard method of analysis, while heavy metals such as calcium, magnesium, lead, cadmium, nickel, iron, copper, and zinc were determined using Flame Atomic Absorption Spectrophotometer (FAAS). Data were

analyzed using statistical techniques (mean±standard deviation), Pearson product moment correlation at 5% ($P < 0.05$) level of significance and ANOVA. Physicochemical parameters results were obtained in the following range; pH (7.71-8.07), salinity (0.11–0.43 µg/L), turbidity (6.5–7.74 NTU), conductivity (230-460µohms/cm), phosphate (0.01-0.018), magnesium (0.03–0.13 mg/L) calcium (9.18–30.4 mg/L), chloride (10.4-75.4 mg/L), and nitrate (3.01-4.89 mg/L). Values of pH, conductivity, chloride and phosphate were all below the permissible limits of the WHO standard. Nitrate and turbidity were above the WHO permissible limits. The concentration of heavy metals (mg/L) were in the following range; Fe (0.005-0.507), Pb (0.012-1.33), Cu (0.001-0.014), Cd (0.002-0.005), Ni (0.006-0.008), and Zn (0.003-0.258). The average concentration of lead (0.2567±0.34 mg/L), and cadmium (0.0036±0.0007 mg/L) exceeded WHO guideline for lead (0.01) and cadmium (0.003) in water. A significant correlation existed only between Cd and Fe ($p < 0.005$). ANOVA showed no significant variations ($p < 0.05$) among the different sampling locations. Risk estimation analysis indicated that consumption of 2.567 litres of water from this area exposes inhabitants to the risk of lead toxicity, consumption of 0.36 litres of water exposes them to cadmium toxicity. Pollution Index (PI) value greater than 1.0 was obtained for lead (25.7 Pi), nitrate (4.85 Pi), turbidity (1.44 Pi), cadmium (1.17 Pi) and pH (1.05 Pi), which shows significant degree of pollution. Borehole water quality from this location is compromised and vulnerable to pollution, hence, it is important to treat it before consumption.

8.04.V-06 Big Brother.....in the Sediment: First Application of the Multispecies Freshwater Biomonitor in Sediment and Soil

Almut Gerhardt, LimCo International GmbH, Konstanz, Germany

Behavioural endpoints are amongst the most sensitive test parameters of sublethal ecotoxicology, often linked to both biochemical biomarker responses at the molecular level and to ecological consequences for the population at higher organization levels. Non-optical quantitative behavioural recording allows to monitor the animals (individual or in groups) also in soil, sludge and sediments, where visual methods fail. See here the 1st results of the application of the Multispecies Freshwater Biomonitor (MFB), based on the non-optical quadrupole impedance technology, using different aquatic benthic invertebrate species and sediments.

1) Firstly, quantitative behavioural signals were generated equally in water, sludge, soil and sediment: For example, in freshwater sediments signals of *Chironomus* spp. and *Hydropsyche* spp. approve the method. 2) Secondly, the grain size composition of the sediments used for culture and maintenance of your test organisms might be important factors for their behavioural performance: For example, the behaviour of *Lumbriculus variegatus* was compared when reared in sediments of different grain sizes. After several weeks of exposure the medium sized grain sizes were preferred, here the animals were more active compared to coarse or fine grain sizes (1). 3) Toxicity experiments were performed to study avoidance of *Eisenia fetida*, exposed to different dilutions of sewage sludge in choice setups in the MFB over 48 hours. Increasing concentrations of sewage sludge led to increased avoidance of the worms (2). 4) The marine amphipod *Corophium volutator* was exposed to different types of toxicants, water accommodated fraction of oil and the pesticide Bioban in short term experiments in the MFB. In both cases, the activity of the amphipods increased with increasing concentrations of the toxicants (3,4). These initial studies show the potential for the non-optic behavioural recording technology of the Multispecies Freshwater Biomonitor as an appropriate tool for sediment and soil ecotoxicology in the future. 8.04.V-07 Cumulative Chronic Exposure Assessment of Carbamate and Pyrethroid Pesticides in Thai Population Through Commonly-Consumed Vegetable Consumption

Weeraya Karnpanit¹, Elizabeth Jara-Torres², Marta Riquelme-Betanzo³ and Yaohua Feng⁴, (1)Institute of Nutrition, Mahidol University, Nakhon Pathom, Thailand, (2)Food Science and Tecnology, Universidad de Concepción, Concepción, Chile, (3)Universidad de concepcion, Chile, (4)Purdue University, United States

Consumers could expose to more than one pesticide at a time, and the risk of adverse health effects would be increased if the pesticides share the same mechanism of toxicity or have the same mode of action affecting the same target organ. Carbamate (CB) are compounds widely used in agriculture and exhibit neurotoxicity via inhibition of the acetylcholinesterase enzyme in the nervous system. Pyrethroids (PYR) are used as agricultural and household insecticides and interact with voltage-gated sodium channels, resulting in disruption of membrane excitability in the nervous system. This study aims to estimate the risk of chronic exposure to CB and PYR cumulative dietary exposure of 7 population subgroups of Thai consumers from vegetable consumption. The cumulative dietary CB and PYR exposure was estimated using a deterministic approach and considered pesticide residue and food consumption data. Pesticide residue data were obtained from a peer-reviewed study by Wanwimolruk *et al.* 2016. Food consumption data were obtained from a validated questionnaire-based national dietary survey from Mahidol University published in 2016. Three commonly-consumed vegetables were included in the assessment: Chinese kale, pak choi, and water morning glory with a total of 397 samples. The relative potency factor (RPFs) approach was used to estimate cumulative dietary exposure using oxamyl and deltamethrin as Index Compound (IC) for CB and PYR, respectively. The RPF were derived from BMD₁₀ or NOAEL to solve the CB and PYR data availability. The chronic cumulative dietary CB and PYR exposure estimates at 97.5th do not exceed the reference dose (RfD) of the IC of Oxamyl and Deltamethrin, respectively. Children between 3 - 6 years old were the most CB and PYR exposed population; however, the hazard quotients of exposures to CB and PYR were less than 1 % of IC RfD. The major contribution to the chronic CB exposure for the Thai population subgroups was made by morning glory which

ranged between 49% to 61% additionally, the pesticide that contributes the most was carbaryl. While the main contribution to the chronic PYR exposure for the Thai population subgroups was made by Chinese kale which ranged between 66% to 79%, and cypermethrin was the major contributor. Exposure estimates suggest insignificant dietary risk from the three commonly-consumed vegetables in Thailand.

8.04.V-08 Developmental Effects of 700 and 3500 MHz Cellphone Frequencies on the Zebrafish Embryo Model

Monica Torres-Ruiz¹, Mercedes De Alba Gonzalez², Victoria Lopez², Pablo Marina², Oscar Suarez³, Ana Cañas Portilla², Isabel Liste² and Victoria Ramos², (1)CNSA, CNSA ISCIII, Majadahonda, Madrid, Spain, (2)Instituto de Salud Carlos III, Spain, (3)Ministerio de Asuntos Economicos y Transformacion Digital, Spain

Data integration and improvement in connectivity have been achieved by the development of the 5G telecommunication spectrum. The spectrum < 1000 MHz will be used for connection between remote areas, whereas the bands of 1000 - 6000 MHz and above will improve connectivity to individual devices and small zones. In order to assess potential health effects, and developmental effects due to these radiofrequencies we have exposed zebrafish embryos to 700 MHz and 3500 MHz (~ 45 V/m) at the beginning of their development for 1 and 4 h. Toxicity endpoints were evaluated up to 120 hpf. Exposure was performed in a controlled exposure chamber GTEM ETS-LINDGREN 5402 coupled with a Signal Generator (250 kHz-6000 MHz) that produces pure sinusoidal signals at the stated frequencies with required power during the exposure. The generator is connected to an amplifier ZHL-42W (10 MHz-4200 MHz). Zebrafish (96 embryos/treatment) were located in an area of maximum field uniformity. Control embryos were located outside the chamber and were evaluated for background exposition by means of the MVG EME SPY Evolution Dosimeter. Temperature was maintained at 25°C both inside and outside the GTEM. Results show no effect on mortality or heart rate with exposure. However, neurodevelopmental effects were observed. Exposed animals were hypoactive both at the 24 hpf tail coiling assay and the 120 hpf visual motor response test, with stronger effects at 700 MHz. In addition, decreased stress response was observed in larvae exposed to 700 MHz. Neurodevelopmental effects are the most probable cause of behavior alterations by exposure to these radiofrequencies. In this study, we have demonstrated a valid and robust setup for biological model exposure to radiofrequencies. Future studies will include exposition to other wavelengths in the 5G technology, lower levels of signals associated to environment exposition and increased exposure time.

8.04.V-09 Eco-Toxicity of Northern Ontario Petroleum Hydrocarbon Contamination Using Native Boreal Plants and Invertebrates

Prama Roy¹, Barbara Zeeb² and Allison Rutter¹, (1)Queens University, Canada, (2)Royal Military College, Canada

Petroleum hydrocarbons (PHCs) are a class of organic pollutants that may pose environmental risks if left unaddressed. They can be toxic to numerous organisms including plants, invertebrates, amphibians, reptiles, and mammals. Soils collected from a site in northern Ontario were solvent extracted using 1:1 acetone/hexane to reveal 16,000+ ppm (F2: 10300 ppm; F3: 4960 ppm; F4: 1440 ppm) total petroleum hydrocarbons. The F2 and F3 concentrations exceed both provincial guidelines outlined in the Canadian Environmental Protection Act (2011) and Canada-Wide Standards outlined by the Canadian Council of Ministers of the Environment (2001). To derive site-specific environmental guidelines, a series of toxicity experiments were carried out using the procedure provided in Environment Canada's Biological Test Method: Test for Growth in Contaminated Soil Using Terrestrial Plants Native to the Boreal Region (2013). Briefly, five plant species were grown from seed in multi-concentration laboratory mixtures of contaminated and control (uncontaminated) soil from the site: i) *Elymus trachycaulus*, ii) *Achillea millefolium*, iii) *Picea mariana*, iv) *Salix bebbiana*, and v) *Alnus viridis*. The experiments revealed that *P. mariana* and *A. millefolium* had the highest germination success and growth of shoot and root endpoints in the contaminated soil (IC₅₀: 25% - 62%), while the germination (chi-square test; p=0.004) and growth of *S. bebbiana* (IC₅₀: 8.7% - 22%) was significantly impaired relative to the control soil. Reference tests using boric acid as a reference toxicant revealed high seed quality and sensitivity to soil contaminants at the time of the toxicity tests. Survival and reproduction tests using age-synchronized native *Folsomia candida* and *Proisotoma minuta* springtails in accordance with standardized testing methods outlined in Environment Canada's Biological Test Method: Test for Measuring Survival and Reproduction and Springtails Exposed to Contaminated Soil (2014) will also be reported on.

8.04.V-10 Ecotoxicological Evaluation of Engineered Biochars

Marta Marcińczyk¹ and Patryk Oleszczuk², (1)Maria Curie-Skłodowska University, Poland, (2)Maria Curie Skłodowska University, Poland

Biochar is a solid material produced by the carbonization of biomass in the pyrolysis process. In recent years biochar gained attention in various areas of life. Type of biomass, pretreatment method, and pyrolysis condition (temperature, duration, carrier gas) affect physicochemical properties of biochars. Although biochar properly fulfils its functions generally, in some cases it needs modifications to enhance effectiveness. One of the methods of biochar modification is impregnation or coating the surface of the biochar with metal oxides. The metal modification enhances biochar sorption capacity to heavy metal elements, nutrients, and organic pollutants. As many works were published recently considering pristine biochar toxicity, there is a knowledge gap regarding the safeness of modified biochars to different organisms. In this work, three ecotoxicological tests were applied to determine the toxicity of engineered biochars to bacteria (*Aliivibrio fischeri*) and invertebrates (*Folsomia candida* and *Daphnia magna*). Willow or sewage sludge were impregnated with Zn or Mg and pyrolysed at 500 or 700°C. The content of toxic substances (e.g., polycyclic aromatic hydrocarbons and heavy metals) in biochars and engendered biochar was determined. Metal modification resulted in lower polycyclic aromatic hydrocarbons content compared to pristine biochar. Heavy metal content in biochars and their pH affected ecotoxicological properties of biochars. A dependence on the applied dose of biochar was also observed. Obtained results can be useful for finding solutions for safe biochar application, compatible with a circular economy and the requirements set by the European Union.

8.04.V-12 Effects of Pesticides Combination on the Development of Stingless Bees *Scaptotrigona postica*

Graziele Grando, Universidade Federal de São Carlos (UFSCar), Brazil

Stingless bees are important pollinators of natural areas and agricultural crops, due to their crucial role in maintaining biodiversity and economics. During foraging the bees are exposed to different pesticides which can have direct action on them and in colony health, once collected resources may contain pesticide residues that will be taken inside and used to feed larvae and adults. Many studies have demonstrated the effects of different pesticides on bees, but studies using combinations of molecules are still scarce/limited, especially with stingless bees, which is closer to the reality of the field conditions and Brazil. In this way, we provide possible effects of residual field doses of the insecticide imidacloprid and the herbicide glyphosate on the development of stingless bees *Scaptotrigona postica*, *in vitro*. The 1st instar larvae subjected to acute exposure larval food containing pesticides at the following concentrations: (a) control (without addition of pesticides), (b) 0.02 µg/µL of glyphosate, (c) 0.02 µg/µL of imidacloprid and (d) 0.02 µg/µL of imidacloprid + glyphosate. Effects on mortality, pupation, emergence rate, and survival were evaluated. We also evaluated the head width and intertegular span morphometry of newly emerged bees. In the bioassays, no rejection of the diets with pesticides by the larvae was observed. The exposure of the larvae to pesticides did not affect the defecation rate or development time. Experiments with the diets showed a mortality rate of (a) 0%, (b) 3%, (c) 30% and (d) 13%, where the diet (c) there was a significant increase ($p>0.05$) in the mortality rate when compared to the control. When intertegular span distance and head width measurements were evaluated, bees exposed to diets (b) and (d) showed significantly higher measurements when compared to the control. This study demonstrates that chronic exposure of stingless bees to glyphosate and imidacloprid can have effects on colony survival, asymmetries in their body structure that result in maladjustments in the bees' flight ability and even disability for flight. FAPESP 2017/21097-3; CNPq 400540/2018-5.

8.04.V-13 Evaluation of Existing Models for Estimating the Bioaccumulation of Pesticides in Earthworms Using a Large Experimental Dataset

Jun Li¹, Mark Hodson², Colin Brown², Roman Ashauer³ and Tania Alvarez⁴, (1)Environmental Department University of York, United Kingdom, (2)University of York, United Kingdom, (3)Syngenta Crop Protection AG, Switzerland, (4)EcoRisk Solutions Ltd, Switzerland

Pesticides can accumulate in earthworms and exert adverse effects on earthworms and top predators (Van Hoesel *et al.*, 2017; Reed *et al.*, 2016; Reinecke and Reinecke, 2007). Standardized laboratory procedures for determining the bioaccumulation of contaminants into earthworms such as the OECD guideline 317 (OECD 2010) are very labour intensive and time-consuming. There is an ongoing community effort (see 'Mind the gap – on the way to a spatial and temporal explicit TKTD model for earthworms'; Roeben 2019) to produce a spatially and temporally explicit toxicokinetic-toxicodynamic (TKTD) model for the uptake of pesticides by earthworms. Several predictive models, including empirical and dynamic mechanistic models (Torralba-Sanchez, 2016; Jager, 1998; Belfroid *et al.*, 1993; Connell and Markwell, 1990; Armitage and Gobas, 2007; Jager, 2004; Jager *et al.*, 2003) have been developed during the last three decades to predict the bioconcentration or bioaccumulation of organic chemicals in earthworms. However, the applicability of these models in predicting body residues for a variety of pesticides and earthworm species in various soil environments is uncertain, in part due to the lack of independent data sets to test the models. We are currently generating kinetic uptake and elimination data, for five pesticides (lenacil, flutriafol, dieldrin, hexachlorobenzene and p,p'-DDT) with varying K_d values (0.2-3.4 L/kg, 0.7-10.7 L/kg, 8.9-145.4 L/kg, 178.8-2929 L/kg and 2097-34346 L/kg, respectively) by the earthworm *Eisenia fetida*, *Aporrectodea caliginosa* and *Lumbricus terrestris* in five contrasting soils. Here we present the *L. terrestris* data. The data are used to evaluate and refine existing models and identify chemical and soil properties influencing earthworm uptake. Refined models could be highly beneficial for environmental risk assessment of pesticides and provide a rapid solution for regulators to support environmental decision-making.

8.04.V-14 Exploring Methylmercury Demethylation in the Human Gut Microbiome

Jacob Drouillard¹, Laurie Chan² and Alexandre Poulain², (1)Biology, University of Ottawa, Ottawa, ON, Canada, (2)University of Ottawa, Canada

Methylmercury is a potent neurotoxin that bioaccumulates in individual organisms and biomagnifies up the food chain. This toxin is found in lakes and rivers worldwide, and climate change is expected to increase its concentration in these environments. This poses a significant risk for those who rely on methylmercury-contaminated sources of predatory fish for food. Although methylmercury metabolism has been studied extensively, it remains unknown why the half-life of methylmercury can range from < 30 to >120 days in the body across individuals after ingestion. The gut microbiome is a topic of rising interest in the field of toxicology, particularly its impact on the metabolism of ingested environmental contaminants. Individuals' gut microbiomes can vary greatly depending on environmental factors, and these differences may contribute to the wide range methylmercury half-lives observed in humans. Here we present strong evidence that the human gut microbiome contributes to the metabolism/demethylation of methylmercury. Using batch incubations of healthy individuals' fecal samples with methylmercury, we observed large variations in the ability of the microbiomes to degrade/demethylate the toxin. Some microbiomes degraded virtually all methylmercury present, others only half. The degradation phenotype appears to be associated with i) fermentation capacity of the microbiome and ii) the nutrient profile of the assay medium. Alteration of metabolism with changes in nutrient profiles have implications for the effect of diet on neurotoxin transformation. This work offers a novel perspective on the role of human microbiomes in altering neurotoxin exposure and highlights the importance of gut health to an individual's overall well-being.

8.04.V-15 Honey Bee Toxicological Responses Do Not Accurately Predict Environmental Risks of Agrichemicals

Felicia Fui Kueh Tai¹, David Pattemore¹, Ashley Mortensen¹, Jacqueline Beggs², Mateusz Jochym¹ and Grant Northcott³, (1)The New Zealand Institute for Plant & Food Research Limited, New Zealand, (2)The University of Auckland, New Zealand,

(3)Northcott Research Consultants Ltd, New Zealand

Historically, the European honey bee, *A. mellifera*, has been used as an ecotoxicology model in pesticide risk assessments and has been assumed to be a representative species to predict the risk to all other bee and invertebrate pollinator species. However, considering the vast diversity of bees, their remarkable differences in life histories, and the paucity of non-eusocial bee data, this approach could underestimate risk. To account for non-*Apis* bees in pesticide risk assessments, the European Food Safety Authority (EFSA) has proposed the solitary, cavity-nesters *Osmia bicornis* and *Osmia cornuta* as model species. However, these cavity-nesting, solitary bees do not represent 60% of the solitary bees that nest and spend their life cycle in the ground. Furthermore, the proposed model species are from the family Megachilidae, and are relatively closely related to the *Apis* bees (Apidae). The EFSA has also suggested that a 10-fold safety factor is applied to current *A. mellifera* toxicity data to estimate risk for non-*Apis* bees. In order to improve our understanding of inter-species sensitivity variability and to test if the 10-fold safety factor is sufficient, we conducted acute oral and contact bioassays of imidacloprid (neonicotinoid) and dimethoate (organophosphate) on *A. mellifera* and a New Zealand solitary, ground-nesting bee species, *Leioproctus paahaumaa*. The bees responded inconsistently: *L. paahaumaa* were 36 and 194 times more susceptible to oral and topically applied imidacloprid than *A. mellifera*, but showed equal sensitivity to dimethoate. Furthermore, the proposed safety factor of ten applied to honey bee endpoints did not cover the interspecific sensitivity difference. Additionally, OECD protocols for honey bee risk assessments were fraught with methodological issues, making standardization problematic. Our standard-setting study highlights the inadequacy of using honey bees as surrogates for all non-target species; the urgent need for more comparative inter-species toxicity studies; and the development of standardized toxicity protocols to ensure regulatory pesticide risk assessment frameworks are protective of diverse pollinators.

8.04.V-16 Investigation of Microbial Communities in Indoor Air in Multi-Use Facilities Using NGS

bong Gu Lee, Kyung Sil Choo and Min-Kyeong Yeo, Kyung Hee University, Korea, South

Indoor air quality can significantly affect the health of residents since modern people spend more than 90% of their time indoors. The most common indoor air pollutants include biological pollutants, asbestos, particulate matter (PM), volatile organic compounds, combustion products, excessive moisture, and formaldehyde. Microbes can cause infectious diseases, asthma, allergies, etc. Some microbes are closely related to human health, such as the human microbiome. Also, the Hygiene hypothesis indicates the link between infants' exposure to environmental microorganisms and the development of the immune system. Therefore, the effects of microbial communities existing in the indoor environment on humans are known to be diverse but not clearly identified. In addition, the importance of indoor air management in multi-use facilities has increased due to the global epidemic of infectious diseases. In this study, bio-aerosol was collected using an air sampling pump and filter in multi-use facilities and measured concentration of PM using a light-scattering type dust counter. The microbial community was confirmed using a genetic analysis method. Next-Generation Sequencing (NGS) was performed to analyze the diversity of the microbial community in each sample. The composition of bacterial and fungal communities was confirmed, and dominant or keystone species were selected. Quantitative Polymerase Chain Reaction (qPCR) was performed to confirm the total amount of microbial DNA and a specific species. In addition, endotoxin and particulate matter concentration were analyzed. The correlation between various factors (room temperature, relative humidity, endotoxin, PM concentration) and diversity indices was confirmed through correlation analysis and based on results, we intend to lay the foundation for indoor air management in multi-use facilities.

8.04.V-17 Is There a Difference in the Antioxidant Defense Response of Freshwater and Marine Bivalves to Wildfire Ash-Associated Contaminants?

Fatima Jesus¹, Andreia Filipa Mesquita¹, Elisa Aldama², Ana M. M. Gonçalves³, Luísa Magalhães¹, Ana Ré¹, Isabel Campos¹, Nelson Abrantes¹, Joana Luisa Pereira¹, Fernando J. M. Gonçalves¹ and Dalila Serpa¹, (1)CESAM & University of Aveiro, Portugal, (2)Faculty of Veterinary and Experimental Sciences, Catholic University of Valencia, Spain, (3)University of Coimbra, MARE (Marine and Environmental Sciences Centre), Department of Life Sciences, Portugal

Wildfires constitute a diffuse source of contamination to aquatic ecosystems mainly due to the mobilization of ash-associated hazardous substances, like metals and PAHs, by post-fire runoff. Bivalves are particularly vulnerable to ash contaminants due to their reduced mobility, filter-feeding behavior and benthic life cycle. Still, the effects of ash contaminants on this group of animals have been overlooked, especially regarding marine species. Although wildfires are more common in forest watersheds, they have been reported to affect coastal areas, with potential negative impacts for the associated biota. This study aims to assess the antioxidant defense response of freshwater (the Asian clam – *Corbicula fluminea*) and marine (the cockle – *Cerastoderma edule*) bivalves to wildfire ash. Organisms were exposed to different concentrations (0, 12.5, 25, 50 and 100%) of aqueous extracts of Eucalypt ash (AAEs) from a moderate severity wildfire. The activity of various enzymes, including catalase (CAT), glutathione peroxidase (GPx; total and selenium-dependent), glutathione reductase (GRed) and glutathione S-transferase (GST) were determined in the soft tissues of both species, as well as lipid peroxidation (by quantification of thiobarbituric acid reactive substances - TBARS) and protein content. A significant increase in the protein content of soft tissues from *C. edule* was observed for AAE concentrations >25%, whereas for *C. fluminea* no significant differences were found. Likewise, significant effects were observed on the activity of GRed and on TBARS for *C. edule*, unlike for *C. fluminea*. For both species, a significant decrease in total GPx activity was observed at AAE concentrations >25%, whereas selenium-dependent GPx activity was decreased at AAE concentrations >12.5%. The activity of CAT and GST, on the other hand, was not significantly affected by exposure to AAEs, for either species. These results suggest that *C. edule* suffered oxidative stress and consequently lipid peroxidation, after exposure to ash extracts, due to the activation of antioxidant defense mechanisms. Conversely for *C. fluminea*, the antioxidant defense mechanisms were effective in avoiding significant oxidative stress. The fact that negative effects were observed at low AAE

concentrations (?12.5%), suggests that bivalve species are highly sensitive to ash-associated contaminants, which might have repercussions for the aquatic trophic webs of both freshwater and coastal ecosystems.

8.04.V-18 Many-Mums Emissions & Fate of Organophosphate Esters From 19 Megacities Estimated Using the Multimedia Urban Model

Tim Frederick Mainguy Rodgers¹, Miriam L. Diamond², Amanda Giang³ and Amandeep Saini⁴, (1)Institute for Resources, Environment and Sustainability, University of British Columbia, Vancouver, BC, Canada, (2)University of Toronto, Canada, (3)University of British Columbia, Canada, (4)Environment and Climate Change Canada, Canada

Organophosphate esters (OPEs), chemicals that are used as flame retardants and plasticizers, are found at relatively high levels globally in air and surface waters. Many OPEs undergo long-range transport, are persistent in the environment, and can cause adverse health impacts, leading them to be called “regrettable substitutes” for restricted flame retardants. Cities are important sources of OPEs to the surrounding environment due to high OPE production and usage. OPEs released from cities undergo transport within urban environmental compartments (e.g. air, water, soil), but most are exported to surrounding regions and ultimately remote regions via long range transport. We estimated the atmospheric emissions and fate of OPEs from 19 global “megacities”. Emissions were back-calculated using versions of the Multimedia Urban Model (MUM) parameterized for each city, based on OPE air concentrations from the Global Atmospheric Passive Sampling (GAPS) – Megacities network. Our preliminary results estimated that the 19 megacities collectively emitted ~120,000 kg yr⁻¹ of 10 OPEs in 2018. OPE fate varied substantially between cities. Per capita emissions varied from ~ 5.0 to 10,000 mg capita⁻¹ for Istanbul and London, respectively. In a model scenario using a constant air concentration across cities, cities with high rain rates, like Lagos, Bogota, and São Paulo, required emissions that were 2 – 2.5 fold higher than in drier cities like Santiago, Beijing and Cairo, to maintain the same air concentration. Under this same scenario, a larger proportion of the higher octanol-air partition coefficient chemicals accumulated in the soil and in the urban films of the “wetter” cities than in the drier cities. This led to 7.5 and 4.5 fold higher predicted concentrations in soil and film, and up to a 7-fold greater predicted mass transfer of these compounds to surface waters in those cities, particularly those with higher proportions of built-up areas. This is expected to increase the exposure of associated aquatic ecosystems surrounding wetter, more urbanized cities and to cause accumulation in water cycles for the more soluble OPEs that are known to be poorly treated by conventional water treatment processes. Together, these large inter-city differences in the predicted emissions and fates illustrate how the climatic and geographic characteristics of a city can be drivers of large differences in aquatic and urban terrestrial ecosystem exposures.

8.04.V-19 Mercury Releases to Environment From Mercury-Containing Products

Anahit Aleksandryan¹ and Artak Khachatryan², (1)Ministry of Environment of the Republic of Armenia, Armenia, (2)Hydrometeorology and Monitoring Center SNCO, Armenia

Mercury is a silvery-gray glittery metal liquid at room temperature. It has a high thermal expansion coefficient and forms alloys with several metals, including gold and silver. These characteristics led to several important applications, such as its use in thermometers, blood pressure measuring devices, electrical switches, in gold and silver mining operations. Mercury is among the top ten dangerous chemicals, its hazardous effects pose a serious threat to human health and the environment, as entering the latter mercury undergoes various transformations. One of the main factors among dangerous effects of mercury on humans is the mercury-contaminated natural environment, components of which penetrate into the human body with atmospheric air, surface and ground- and underground waters through respiratory tract, skin, and, with food, to gastrointestinal tract. Mercury is a rare element in nature. One-third of mercury enters the environment from natural sources, while two-thirds are due to human activity. For comparison, in the earth’s crust and main types of rock, the average mercury content is 0.03-0.09 mg /kg, while one mercury lamp, depending on its design, may contain 20-560 mg mercury. Fluorescent lamps contain mercury vapors, which can cause harm to the human body upon lamp breaking down and inability to take timely measures to neutralize it. Other hazards are due to the spectrum of ultraviolet rays emitted by fluorescent lamps, which can cause inflammation of skin (dermatitis), eye mucous membranes (cataracts), and tumors. If broken in a closed area, over time the density of mercury vapor from the lamp exceeds the allowable limit. When inhaled, mercury vapors easily pass through airways to lungs, enter the brain with the bloodstream and bring forth symptoms of poisoning. From 2016 to 2020, import of fluorescent lamps to Armenia decreased 9 times, import of sodium lamps - 10 times. Mercury emissions/ releases decreased as well. Mercury emissions/releases from fluorescent lamps through different pathways estimated in kg/year in 2016-2018 were as follows: 2016: 0.0493 to air; 0.148 to water; 0.296 to waste; total of **0.4993**; 2017: 0.021 to air; 0.063 to water, 0.126 to waste; total of **0.21**; 2018: 0.0116 to air; 0.0349 to water; 0.0697 to waste; total of **0.116**. In order to prevent mercury emissions from fluorescent lamps to different matrices, their environmentally sound collection and treatment /recovery are required

8.04.V-20 Potential Risk of Bioaccumulation of Heavy Metals in Fish Tissues of the Tunal River in Durango, Mexico

Leticia de Jesus J Velazquez-Chavez¹, Martin Emilo Pereda Solis¹, Jorge Armando Chavez-Simental¹, Ixchel Abby Ortiz-Sanchez², Gerardo Antonio Pamanes-Carrasco¹ and Artemio Carrillo-Parra¹, (1)Universidad Juarez del Estado de Durango, Mexico, (2)Tecnologico Nacional de Mexico, Mexico

Heavy metals pollution is a major environmental problem in water resources as it threatens public health due to its toxicity and high persistence in the environment. Water pollution supplies metal transportation to other organisms by dietary or surrounding water. Also, this effect allows bioaccumulation of metals in fish tissues. Limited data of bioaccumulation of toxic elements in fish is currently available in some freshwater systems in Mexico, where the Tunal River is one of them. Importance of bioaccumulation monitoring relies in health risk of polluted fish intake, considering that this river receives wastewater effluents. For this reason, this study aims to assess the concentration of As, Cd, Pb and Zn in water and common carp (*Cyprinus carpio*) in a

fishing area of the Tunal River in Mexico. The Tunal River is located in Durango, in the northern of Mexico. This river supplies hydric resources for different activities. Also, this river receives sewage discharges. Samples of water and muscle and liver fish tissue were taken in dry (n=7) and rainy season (n=10), as seasonal variation might influence the availability of metals in the river. Heavy metals were analyzed with an Atomic Absorption Spectrophotometer. The presence of heavy metals was confirmed in all fish samples. Only arsenic was the metal detected in water. As and Zn (>1.0 ug/g w.w) are the predominant metal in both tissues. None of the elements exceeded the maximum residual levels (MRL) allowed in Mexico. However, As and Cd in fish tissues exceed the limits allowed by international agencies. Bioaccumulation Factor (BAF) in muscle and liver for arsenic during dry season was 33.6 and 161; during rainy season 87.8 and 66.5, respectively. Some factors such as length, weight, and accumulation in other tissues, could contribute to these results. Bioaccumulation rate of Cd, Pb and Zn was not evidenced. The risk to accumulate toxic elements in liver is higher compared to muscle, indicating that common carp from the Tunal River represents a strong organism accumulative of arsenic. This study remarks the importance to carry out periodical monitoring research in order to minimize toxic effects of heavy metals in fish that habits the Tunal River.

8.04.V-21 Prospective Environmental Assessment of Cathode Active Material for Cobalt-Free Cell Battery

Victor Ferreira¹, Gabriela Benveniste² and Cristina Corchero³, (1)IREC, Sant Adria de Besos, Spain, (2)IREC, SANT ADRIA DE BESOS, Spain, (3)IREC, Spain

This study explores the environmental performance of active material for cathode for the next generation of Co-free LIB for EVs following the ISO 14044:2006 standard for LCA, which can evaluate the different stages over the lifetime of a product. Environmental metrics with their respective methods are used for the evaluation of material, involving climate change and mineral resources depletion and scarcity concerns, among others. The cathode active material is the main environmental contributor and Co-free oxides being studied currently in the European COBRA project can reduce considerably the environmental impact by 53% compared to the conventional NMC111 and NMC622 powder production, measured in the Metal Surplus Ore Potential (kg Cu eq), that reflects the depletion and material scarcity issues. These results contribute to the promotion of Co-Free lithium-ion compositions to provide new insights into the role of cobalt, and its corresponding impacts in EVs to support the renewable energy transition.

8.04.V-22 Selection of Biocidal Active Substance Relevant to an Adverse Outcome Pathway Focusing on Endocrine Disruption Effects

Jiyun Lee and Kyong-Whan Moon, Korea University, Korea, South

Considering that the hypothalamic-pituitary-thyroid axis and the hypothalamic-pituitary-gonadal axis interact in the case of terrestrial and aquatic vertebrates, it is necessary to present a comprehensive mechanism for thyroid dysfunction and reproductive toxicity; it may help to understand the overall endocrine system. This study aims to establish an adverse outcome pathway of endocrine-disrupting effects and to select biocidal substances related to the AOP using a big data platform (ECOTOX and ToxCast). In this study, hyperandrogenism, an endocrine-disrupting effect in females, was set as the final AOP endpoint. Based on the previously constructed AOP No. 271, additional literature research was conducted, and we proposed to extend the AOP network that organically connects thyroid dysfunction and reproductive toxicity. Finally, several biocidal substances were selected relevant to AOP. As a result, 76 biocidal active substances (e.g., Deltamethrin, Cyfluthrin, Pyrethrins, Bromadiolone Bifenthrin, Etc.) were associated with AOP. It is confirmed that exposure to these biocidal active substances could cause thyroid and reproductive toxicity by reacting with androgen receptors or thyroid hormone receptors. Future studies need to expand the list of AOP-related biocidal active substances by using an artificial neural network model for substances that do not have toxic data on the predictive toxicity big data platform. Acknowledgment: This research was supported by the Korea University Graduate School Junior Fellow Research Grant.

8.04.V-23 Should and Can Ozone Exposure Be Better Assessed?

Honorine Gauthier-Manuel¹, Frédéric Mauny¹, Mathieu Boilleau², Marie Ristori², Sophie Pujol¹, Florent Vasbien³, Anne-Laure Parmentier¹ and Nadine Bernard¹, (1)Laboratoire Chrono-environnement - Université de Franche-Comté/CNRS, UMR6249, France, (2)ATMO Bourgogne-Franche-Comté, France, (3)ATMO Grand Est, France

Ground-level ozone (O₃) is a secondary air pollutant that is a major public health and environmental issue. There is a need to precisely and exactly assess its spread in the environment and the exposure of humans and organisms. Modeling tools have been developed for this purpose but regional models need to be improved. The objective of this study was to optimize a transnational modeling defined daily at the kilometric scale (9 km²) and to quantify its capability to better estimate ozone exposure. The transnational modeling platform PREV'EST, covering eastern France and the boundary areas of Germany, Switzerland, and Luxembourg, produced daily estimations of ozone levels from 2008 to 2019 on a 3 km x 3 km grid mesh. First, we compared the daily modeled ozone concentrations (PREV'EST) to the daily values measured at 6 air quality monitoring stations. The following performance indicators were used: MBE (mean bias error), MAE (mean absolute error), RMSE (root mean square error), r (Pearson correlation coefficient). Second, three optimizations were built using multivariate adaptive regression splines (MARS). Each optimization was based on different sets of environmental variables (among mean temperature, rainfall amount, wind speed, relative humidity, elevation) including the date. Performance was assessed using the same indicators as cited previously. Third, external validation was performed using 6 additional air quality monitoring stations. The raw modeling data presented a lack of precision (RMSE = 23.18 µg.m⁻³, MAE = 19.23 µg.m⁻³) and exactitude (MBE = 14.67 µg.m⁻³), and thus needed to be improved. The optimizations improved both precision (RMSE = 11.92 - 13.60 µg.m⁻³, MAE = 9.40 - 10.81 µg.m⁻³) and exactitude (MBE = 0.01 - 0.04 µg.m⁻³), and the interday variability of the ozone levels. The external validation confirmed the performance improvement using these corrections. We propose a validated methodology that improves the model's performance and better

depicts the temporal variability of O₃. This methodology is accessible, fast-processing, and presents low computational cost and better performance. The better detection of ozone peaks will be of paramount importance to assess the potential association between acute ozone exposure and human and organism health effects, particularly in the climate change context.

8.04.V-24 The Effect of a Planktivorous Fish on the Vertical Flux of Microplastics

*Ewa Babkiewicz*¹, *Kamil Dębrowski*², *Anna Wiewiorowska*², *Marcin Zebrowski*³, *Piotr Maszczyk*⁴ and *Szymon Pukos*⁵,
(1)University of Warsaw, Warsaw, Poland, (2)University of Warsaw, Poland, (3)Department of Hydrobiology, Uniwersytet Warszawski, Warsaw, Poland, (4)University of Warsaw Faculty of Biology, Poland, (5)University of Warsaw, Faculty of Biology, Poland

Microplastic pollution of both marine and freshwater environments is currently one of the most intensely studied issues in the field of ecology and environmental protection. Many studies have attempted to estimate the distribution and concentration of microplastic particles (MP) in various environments, and determine how they affect the organisms inhabiting these environments. Decidedly less research concerns the opposite dependence, i.e. how living organisms affect the distribution, concentration and qualitative characteristics of MP. We have tested the hypothesis that fish increase the vertical flux of MP to sediments, which would be the result of the combined effect of increased sedimentation rate and the active transport resulting from vertical migration of the fish in the simultaneous presence of a thermal gradient (and in turn water density gradient) with lower meta- and hypolimnetic temperature. We conducted eight 5-day-long experiments in twin 2-metre-long vertical water columns, one of which continuously held four planktivorous fish inside. Both columns had suspended polystyrene microbeads of 25 and 250 μm in size, with density of 1000 and 200 × L⁻¹, respectively. In addition, both columns held sediment traps inside at depths of 30, 60 and 150 cm. The fish inside the column were fed small portions of dry food (immediately eaten) five times per day, and their depth selection behaviour was monitored before and after feeding by cameras. At the end of experiments, we counted the MPs caught in sediment traps as well as MPs that were still suspended in the water column at depths of 0, 30, 60, 90, 120, 150 and 160 cm. We found that the presence of planktivorous fish significantly increased the number of both larger and smaller MP that settled down in sediment traps and reduced the number of MP suspended in water. This effect is most likely attributed to increased sedimentation rate of MP in the fish treatment, rather than to their active transport, since we found that MP in the fish treatment were covered to a greater extent with a detritus than in the control, and the fish resided constantly in the subsurface layer in the water column. The study was financed by Polish National Science Centre grants (2018/31/N/NZ8/03269 and 2019/35/B/NZ8/04523).

8.04.V-25 Understanding the Contribution of Coatings to Nanoparticles Toxicity in Zebrafish

*Elizabeth Bigorra*¹, *Ana Matos*², *Elza Fonseca*³, *Laura Rodriguez-Lorenzo*⁴, *Begoña Espina*⁵, *Vitor Vasconcelos*⁶ and *Alexandre Campos*², (1)Center of Marine and Environmental Research CIIMAR, Matosinhos, Portugal, (2)CIIMAR - University of Porto, Portugal, (4)INL International Iberian Nanotechnology Laboratory, Portugal, (5)International Iberian Nanotechnology Laboratory, Braga, Portugal, (6)Faculty of Sciences and CIIMAR - Porto University, Portugal

For improving their physicochemical properties, nanoparticles (NPs) are coated with chemical compounds. Titanium dioxide (TiO₂) NPs have been modified by sodium citrate or silane molecules to enhance their colloidal stability and their photocatalytic properties. Understanding the contribution of the coatings for the toxicity of NPs is still lacking. Therefore, the aim of this work was to assess the effects of TiO₂ NPs coated with either N-(Trimethoxysilylpropyl)ethylenediaminetriacetate (silane-EDTA) or sodium citrate in embryos of zebrafish “Danio rerio”. Two embryo toxicity assays were performed to evaluate the effects at the individual and molecular levels: a development assay and a Nile red staining assay. In each assay, the exposure to TiO₂ NPs with a diameter of 45 nm combined with each one of the coatings (ratios TiO₂:coating: 1:1.5 wt for citrate and 1:0.004 wt for silane-EDTA) was compared to groups exposed only to the coatings (“single exposure”) and to the negative control group (no coating). Firstly, in the development assay, zebrafish embryos were exposed to TiO₂ NPs (5, 50 and 200 mg/L) with one of the two coatings, from 0 to 96 hours of post-fertilization (hpf), following OECD guideline nr. 236. Every 24 hours the mortality, hatching, development and malformations were checked and the length and the heartbeat were measured at the end (96hpf). To study the expression of target genes by qPCR (i.e. genes related to oxidative stress, lipid and energetic metabolism) the larvae were stored in RNA later at -80 °C. Secondly, the effect of TiO₂ NPs in lipidic biomolecules was analysed from 48 to 120 hpf with the Nile Red assay (25 and 500 mg/L). The results of the Nile Red assay allowed us to quantify effective regional adiposity by fluorescence stereomicroscopy. The results of this work will allow us to understand whether different coatings have additive, synergistic or antagonistic effects comparing to the toxicity of TiO₂ NPs in zebrafish.

8.04 Extended submission WED (Poster)

8.04.P-We291 A Non-Target Screening-Directed Long-Term Time-Trend Study of Organic Contaminants in the Baltic Top Consumers

Andriy Rebryk and *Peter Haglund*, *Umea University, Sweden*

The key species of the Baltic ecosystem suffer from impaired health. It is believed that anthropogenic hazardous substances along with some halogenated natural products are one of the reasons for that, as they accumulate in organisms. Since international restrictions on hazardous chemicals went into force in the 1970-80s, time trends of many environmental persistent organic pollutants (POPs), including PCBs, DDT and its metabolites, and others, have been decreasing constantly for decades. However, the amounts of legacy POPs in the Baltic Sea region have leveled off and stopped declining recently and new contaminants are frequently discovered. There is, hence, a need for comprehensive approaches to study the occurrence and time trends of the legacy POPs and contaminants of emerging concern (CECs), amounts of which are increasing, in the ecosystem. Here, we report the first

time-trend study which utilizes a non-target screening (NTS) approach for this purpose. The studied samples included common guillemot egg extract (1986-2019, 12 samples), white-tailed sea eagle muscle (1965-2017, 8 samples), and harbor porpoise blubber (1988-2019, 9 samples). A major challenge in NTS of biota is the removal of matrix components, like lipids that may interfere with the detection and identification of analytes. A sufficient level of lipid removal was achieved by a combination of high-resolution gel permeation chromatography and Florisil fractionation. The data were acquired using GC-QTOF/MS in both electron ionization (EI) and electron capture negative ionization (ECNI) mode to maximize contaminant coverage. Acquired EI data sets were processed using a new highly-automated adjustable workflow. The ECNI data were manually processed and reviewed. The Mann-Kendall test was used to discover time trends and the Theil-Sen regression was used to estimate annual change for the features exhibiting significant time trends. Altogether, more than 300 tentatively identified contaminants were found to have significant time trends in samples studied. Significant decreases were found for many regulated chemicals, as could be expected, e.g., PCBs, DDT, and other organochlorine pesticides. Significant increases were observed for, e.g., small PAHs, heptaBDEs, and CECs. The CECs include, among others, a novel plasticizer tributyl acetylcitrate and two compounds used in polymer production trimethyl isocyanurate and 2-mercaptobenzothiazole, which have not previously been reported in biota.

8.04.P-We292 Analytical Method to Measure Gases That Contribute to Climate Change and Impact COP26 Glasgow Climate Pact

Tarun Anumol¹, Madslundgren Petersen², Abbey Fausett¹ and Juan Aybar³, (1)Agilent Technologies, Inc., United States, (2)Agilent Technologies, Inc., Denmark, (3)Agilent Technologies, Inc., Spain

Fossil fuel consumption increases the concentration of greenhouse gases (GHGs)— such as carbon dioxide (CO₂), methane (CH₄) and nitrous oxide (N₂O)—in the Earth's atmosphere. These gases trap heat, thereby affecting our planet's temperature. Recently, at the Glasgow Climate Change Conference (COP26) nations came together to make decisions and limit global temperature rise to 1.5 C. GHG's are a large contributor of climate change and temperature increase. To help mitigate climate change caused by increased concentrations of atmospheric GHGs, regulatory institutions (such as the EPA and CEN) have initiated programs to inventory GHG emissions through continuous measurement which are even more important now. GHG analysis requires GC detectors specific for each of the targeted gases. Methane is analyzed by Flame Ionization Detectors (FID), carbon dioxide by thermal conductivity (TCD)m and nitrous oxide by electron capture (ECD). In addition to these detectors, sample introduction is an important consideration. Detection ranges for these compounds often ranges from ppb on the trace side and extending well into percent levels. Historically, GHG samples were introduced to a GC system by gas sampling valve utilizing either a pressurized sample container or a gas tight syringe. Increased interest in GHG levels around the globe have created a need for more capacity and higher levels of automation, in addition to faster run times. A custom GC option for GHG analysis is evaluated here in this study as the 8890 Greenhouse Gas Analyzer. Detection capabilities, improvement in run time, and sampler considerations are discussed to demonstrate compliance with current EPA and CEN methodologies and regulations. A flexible, yet fast and robust GC configuration for measuring CH₄, N₂O and CO₂ from ppb to % level on three dedicated detectors in less than 5 minutes was developed and method performance criteria will be shown as well.

8.04.P-We293 Antibiotic REsistanNce and Pathogenic Signature in Marine and Freshwater Aquaculture Systems. ARENA Project

Jose Maria Castano-Ortiz¹, Elisa Baldrighi², Pierluigi Strafella², Gian Luna², Stefano Amalfitano³, Andrea Di Cesare³, Michael Schoening⁴, Frank Delvigne⁵, Patrick Wagner⁶, Alessio Gomiero⁷ and Sara Rodriguez-Mozaz¹, (1)Catalan Institute for Water Research (ICRA), Spain, (2)National Reseach Council of Italy, Italy, (3)National Research Council of Italy, Italy, (4)FH Aachen, Germany, (5)University of Liège?Gembloux Agro-Bio Tech, Belgium, (6)KU Leuven, Belgium, (7)International Research Institute of Stavanger, Norway

An increasing number of studies have reported the widespread occurrence of antibiotic residues (ABs) in freshwater and marine environments, raising concern on potential ecological and human health risks. Aquaculture represents a key source of fish and other foods for human consumption and a suspected hotspot for AB release and product contamination. In this scenario, the ARENA project aims at improving the quality assessment of aquaculture practices and products by exploring sources, reservoirs and pathways of antibiotic and microbial contamination across the water cycle. Contamination levels will be addressed from sources to end points and final food products (e.g., cultured fish fillets), within recirculating (i.e., RAS) and open aquaculture systems (i.e., mariculture), as well as in the surrounding marine environment. Sampling at two seasons with contrasting anthropogenic pressure will be performed to account for possible seasonal variations. Specifically for AB analysis (WP3), a multi-residue LC-MS/MS method will be implemented to monitor the presence and concentration of selected ABs and their metabolites in different environmental matrices from both RAS systems (i.e., water, farmed fish, feed) and mariculture in the Adriatic Sea (i.e., water, farmed fish, feed, sediment, and benthic meio- and macroinvertebrates below farm cages). A suspect screening strategy based on High-Resolution Mass Spectrometry (HRMS) will also be applied to identify additional ABs, metabolites, and transformation products. In addition, a novel flow-cytometric tool will be tested for the rapid detection of AB residues in edible fish products, and its performance compared against the targeted LC-MS/MS method. Alongside with the screening of ABs, early-warning tools will be optimized for the rapid detection and quantification of antibiotic-resistance genes (high-throughput sequencing-based) and microbial pathogens (impedance spectroscopy-based) in environmental and fish food samples. Altogether, we expect that the ARENA project will provide a cross-disciplinary approach for AB risk assessment and contribute to mitigate AB resistance and pathogenicity in aquaculture settings.

8.04.P-We294 Are Accumulated PFAS Concentrations in Benthic Macroinvertebrates Related to the Ecological Quality of Aquatic Environments?

Cara Byns¹, Thimo Groffen² and Lieven Bervoets², (1)Systemic Physiological and Ecotoxicological Research (SPHERE), University of Antwerp, Belgium, (2)University of Antwerp, Belgium

Benthic macroinvertebrates play a key role in freshwater ecosystems by driving ecosystem services such as nutrient cycling, sediment mixing, and energy flow through the food web. Because some taxa are more sensitive to pollution than others, the macroinvertebrate community structure can show the cumulative impact of short- and long-term pollution events. However, monitoring micropollutants in aquatic ecosystems is still mainly based on measurements in the abiotic environment. Sediment and water samples represent only a momentary pollution status and do not take into account differences in bioavailability driven by fluctuating abiotic and biotic factors. Consequently, derived water and sediment quality criteria might not always be adequate for the protection of aquatic communities. Despite the increasing awareness of the widespread usage and ubiquitous presence of Perfluorinated alkyl substances (PFAS) in the environment, little is known about their effects on macroinvertebrate communities. The aim of this research is to study the relationship between accumulated PFAS levels in three benthic invertebrate species (*Chironomus* sp., *Asellus* sp., and *Gammarus* sp.) and the aquatic ecological status. Therefore, resident invertebrate taxa are collected at 28 sites in rivers and watercourses across Flanders, Belgium. To assess the invertebrate community responses, the ecological water quality index, also known as the Multimetric Macroinvertebrate Index Flanders (MMIF), is calculated. Simultaneously, sediment and water samples are collected to investigate possible relationships between accumulated PFAS in the biotic and abiotic environment. In addition, we aim to identify threshold body burdens of PFAS in order to protect aquatic communities.

8.04.P-We295 Assessing the Risk to Freshwater Ecosystems From Water-Soluble Polymers

Eve Tarring¹, Ben Ward², Isabelle Durance², Michael Harbottle², Robert Lucas³ and Daniel Read⁴, (1)Chemistry, Cardiff University, United Kingdom, (2)Cardiff University, United Kingdom, (3)GlaxoSmithKline, United Kingdom, (4)Centre for Ecology and Hydrology, United Kingdom

Over the last decade, concerns over water-insoluble polymers such as micro and nanoplastics have dominated the field of environmental plastic pollution, but until recently, water-soluble polymers (WSPs) have been largely excluded from the conversation. WSPs are a wider umbrella for a range of polymer classes differing in their chemical behaviour as well as their direct and indirect toxicities to freshwater organisms. Their use in personal care products (PCPs), industry, agriculture and more is expected to increase, particularly with new legislation reducing the use of micro and nanoplastics. Commonly used WSPs such as polyacrylamide are expected to see a market growth of 6.2% from 2019-2025 which supports an output of around 2.5 million tons globally per year. Therefore, due to their high production volumes, vast applications and solubility their discharge into the environment is inevitable. One of the major routes of environmental exposure is likely to be through wastewater systems, with evidence of WSPs not being fully removed in the treatment process, along with the increasing issue of raw sewage discharge into freshwater. As well as this route, usage in fertiliser and pesticide formulations and widespread application as a soil conditioner could also see run-off into nearby water bodies. In addition to point sources, non-point source (NPS) applications in cements and paints could also contribute to further leaching. Despite their expected prevalence in the environment, research into WSPs is hindered by the lack of prior research and availability of analytical methods. Size-exclusion chromatography methods such as gel-permeation chromatography (GPC) require the concentration of the polymer to be known to calculate an accurate molecular weight, while common mass spectrometry used in the analysis of polymers, such as matrix-assisted laser desorption/ionisation time-of-flight (MALDI-TOF), require precise sample preparation to detect a range of WSP classes. Here, we propose a novel sample extraction and separation utilising both GPC and MALDI-TOF to identify WSPs. Alongside analytical methodology, the development of a mass spectral PCP database can be used to assist in the identification of WSP molecular fingerprints. Utilising a combination of novel extraction methods and market products is aiding the identification of WSPs present in wastewater and could be used on environmental samples to identify polymers of concern in freshwater ecosystems.

8.04.P-We296 Boreal Lake Ecosystem Responses to a Chronic Venlafaxine Exposure

Heather Jovanovic¹, Jonathan Challis², Vince Palace³, Mark Hanson¹ and Jose Luis Rodriguez Gil³, (1)University of Manitoba, Canada, (2)University of Saskatchewan, Canada, (3)IISD Experimental Lakes Area (IISD-ELA), Canada

Antidepressant drugs are present in freshwater ecosystems worldwide. Venlafaxine, a serotonin norepinephrine reuptake inhibitor, has been detected in freshwater at >2.0 µg/L. Its effects have been well studied in laboratory settings and it is known to alter neurological genetic expression and behavioural responses in fish. However, its possible effects have not been investigated in a whole ecosystem context where indirect effects of chronic exposure could pose a risk to long-term ecosystem health. Here we show the response of primary producers and consumers after a 10-week exposure to venlafaxine. Sediment-inclusive mesocosms were deployed in-lake at the International Institute for Sustainable Development – Experimental Lakes Area (IISD-ELA), a boreal lake research facility in northwestern Ontario, Canada. Mesocosms (n=10, 2m diameter, 1.5m deep) contained a native assortment of plankton and invertebrates and were each stocked with five finescale dace (*Chrosomus neogaeus*). After acclimating, mesocosms were spiked weekly with venlafaxine at seven nominal concentrations ranging from 0.004 µg/L to 100 µg/L (n=1 per treatment), plus 0 µg/L (control; in triplicate). Simultaneously, in-lab, standard 7-day embryo-larval assays were conducted using wild collected fathead minnow eggs exposed to mesocosm water, which were used for behaviour response testing. Treatment effects assessed were the biomass of periphyton, abundance of benthic and emergent macroinvertebrates, behaviour of larval fathead minnows, and condition of finescale dace after 10 weeks of exposure to venlafaxine. For most endpoints minimal responses were observed at environmentally relevant concentrations, although behavioural and water quality impacts were observed in our higher treatments. Our study provides higher tier effects data on the integrated responses of a whole ecosystem to the nuanced and sublethal effects of one of the most commonly detected psychoactive contaminants.

8.04.P-We297 Ecotoxicological Assessment of Surface WATER Samples Contaminated by Tailings From Iron Ore Dam Rupture

Maria Clara Starling¹, Camila Amorim², Beatriz Gasparini Reis², Fernando Silva², Alessandra Martins² and Ana cristina Mendes², (1)Department of Sanitary and Environmental Engineering, UFMG- Universidade Federal de Minas Gerais, Belo Horizonte, Brazil, (2)Universidade Federal de Minas Gerais, Brazil

The rupture of tailing dams causes numerous environmental impacts to the watershed in the affected region. As tailings reach surface water, water turbidity, suspended solids, dissolved solids and biological oxygen demand increase instantaneously, thus impacting aquatic life. Increased levels of iron have also been associated to the rupture of iron mining dams in Brazil. These effects may be seen hundreds of kilometers from the former dam as tailings are transported by river water. This work aimed at the analysis of acute and chronic toxicity of surface water impacted by the rupture of an iron ore dam in the Southeastern region of Brazil (currently under secrecy). Microtox® acute toxicity test and chronic toxicity test using *Raphidocellis subcaptata* (72h) were performed as according to national standards (ABNT NBR 15411-3:2021 and ABNT 12648:2018) for twelve surface water sampling points (3 reference points and 9 sampling points in the affected region) in the dry (September) and wet (December) seasons. Samples were taken months after the rupture event. No acute toxicity was observed for any of the sampling points as expected due to long interval between the dam rupture and sampling since tailing settle in the river sediments. However, chronic toxicity to green algae was detected for 6 sampling points in the dry season (2 reference points, 2 inside the former dam area and 2 downstream the former dam) and two sampling points in the rainy season (one reference point and one inside the former dam area). Chronic effect to green algae had been detected with samples taken days in the same watershed after the rupture event and this organism was the most sensitive to the effect of tailings components when compared to crustaceans and fish. Dilution of samples during the rainy season may have affected chronic toxicity as less points were toxic. Despite the detected effect, chronic toxicity may not be directly associated to the rupture as chronic toxicity was also detected in reference points probably due to the influence of other activities performed in the watershed (agriculture, sewage disposal, industrial wastewater disposal). These results reveal the need for continuous monitoring of toxicity in this watershed along the years considering the long-term effect of mining and other human activities performed in the watershed.

8.04.P-We298 Effects of Cadmium and Copper, Isolated and Combined, to a Freshwater Neotropical Copepod - a Short-Term Exposure

Giseli Swerts Rocha¹, Laís Lopes² and Evaldo Espindola³, (1)SHS - Hidráulica e Saneamento, EESC - USP, São Carlos, Brazil, (2)EESC - USP, Brazil, (3)University, Brazil

Metal contamination is of great concern in aquatic ecosystems and can result from anthropogenic and natural processes. These contaminants interfere in biological processes, affecting the whole trophic chain. We evaluated the impact of cadmium (Cd) and copper (Cu), isolated and combined, to a Neotropical freshwater Calanoida Copepoda (*Notodiaptomus iheringi*), assessing the responses of lethality, dry weight, and lipid classes. The animals were exposed for 48 h to control, five concentrations of each metal and six mixtures (Cu+Cd). The lethality results were evaluated using the MixTox tool, and two-way ANOVA was used to assess the lipid and dry weight responses, with $p < 0.05$ and Fisher LSD test. One concentration of each metal and its combination were assessed for the lipid class composition. The LC50 of Cu and Cd was 27.7 and 8.0 $\mu\text{g L}^{-1}$, respectively. The metals combination resulted in antagonistic effects in the lethality to the copepod, with the independent action and S/A fitting better the results. The contaminants decreased the mean dry weight of the organisms and presented significant differences from the control ($p < 0.05$). The organisms from control presented phospholipids (PL; $\approx 50\%$), triacylglycerols (TAG; $\approx 30\%$), and acetone mobile polar lipids (AMPL; $\approx 11\%$) as the main lipid classes. Compared to control, Cd decreased the TAG ($\approx 20\%$; $p < 0.05$) and increased the sterols (ST; $\approx 6\%$; $p < 0.05$) without affecting PL ($\approx 51\%$; $p > 0.05$) or AMPL ($\approx 11.5\%$; $p > 0.05$). Cu significantly decreased PL ($\approx 31\%$; $p < 0.05$) and AMPL ($\approx 7\%$; $p < 0.05$) and increased TAG ($\approx 51\%$; $p < 0.05$) and free fatty acids (FFA; $\approx 7\%$, $p < 0.05$). The combined metals did not affect significantly PL ($\approx 42\%$; $p > 0.05$), decreased AMPL ($\approx 7\%$; $p < 0.05$) and increased TAG ($\approx 48\%$; $p < 0.05$). The change in lipid classes in Cd treatment can indicate an alteration in membrane conformation (increasing ST) to reduce metal internalization. In contrast, the changes in Cu and mixture treatments indicate a redirection to reserve lipids (increasing TAG) instead of structural lipids (decreasing PL) to deal with the stress. Our results suggest that Cu and Cd, isolated or combined, affected survival, with antagonism and independent action observed; besides affecting the dry weight and lipid composition of *N. iheringi* in 48 h. Ecotoxicology studies using copepods are scarce. As far as we know, this is the first study using this species; thus, we suggest more studies to evaluate this species as a new test organism in Brazil.

8.04.P-We299 Evaluating the Use of Cattail (*Typha latifolia*) Wetlands for Land-Based Aquaculture Wastewater Effluent Remediation

Nicholas Blandford¹, Richard Grosshans², Bruce Hardy³, Nazim Cicek⁴ and Vince Palace⁵, (1)University of Manitoba, Winnipeg, MB, Canada, (2)International Institute for Sustainable Development, Canada, (3)Myera Group, Canada, (4)University of Manitoba, Canada, (5)IISD Experimental Lakes Area (IISD-ELA), Canada

An increasing demand for fish and fishery products has been met by a steady increase in aquaculture production, making it one of the fastest growing food production sectors in the world. Land-based aquaculture systems continue to rise in popularity as they offer the benefit of controlling diseases, managing water quality, and minimizing threats to wild populations. However, aquaculture systems generate wastewater high in nitrogen and phosphorous. As with any agricultural output, the nutrient-rich effluent generated in aquaculture systems have the potential to lead to eutrophic conditions in receiving waters and threaten the health of aquatic ecosystems. Consequently, a number of conventional wastewater treatment methods have been applied to aquaculture systems. Constructed wetlands are a promising and cost-effective strategy for treating wastewaters, and offer the

additional benefit of recycling nutrients that would otherwise be wasted. Here we show how cattail (*Thypha latifolia*), an abundant and resilient wetland plant, can be used to remediate wastewater effluent from land-based aquaculture systems. Model cattail wetlands were established in mesocosms (2 m diameter) and had a gradient of aquaculture wastewater applied weekly, for a total of five weeks. Five wetlands received wastewater (in low to high concentration) and three received no wastewater (i.e. reference treatments). Model wetlands were robust to changes in water quality; a $\sim 0.15 \text{ mg L}^{-1}$ increase in each of total phosphorous, total dissolved phosphorus, and soluble reactive phosphorus was detected for wetlands dosed the largest volumes of wastewater. As wetlands proliferated over time, these concentrations returned to background levels ($< 0.05 \text{ mg L}^{-1}$). Mean plant biomass was found to be $\sim 70\%$ greater in the high treatment relative to the reference treatment. Nutrient analysis of plant material revealed increases in total Kjeldahl nitrogen, total nitrogen, and total phosphorous among high treatments. No trends were observed among other nutrients analyzed (i.e. total sulfur, nitrate, B, Ca, Cu, Fe, K, Mg, Mn, Zn). Our results suggest that cattail wetlands are a viable option for treating effluent from land-based aquaculture operations. Additionally, the implementation of this remediation strategy shows potential for nutrients to be recycled in cattail plants, which can then be harvested for use in subsequent applications (e.g. as biofuel, as fertilizer following composting).

8.04.P-We300 Exploration of Abundance, Distribution and Composition of Microplastics ($>10\mu\text{m}$) in Marine WATER *Yuanli Liu¹, Claudia Lorenz¹, Alvise Vianello¹, Kristian Syberg², Asbjørn Nielsen¹, Torkel Gissel Nielsen³ and Jes Vollertsen¹, (1)Aalborg University, Denmark, (2)Roskilde University, Denmark, (3)DTU Aqua, Denmark*

The sea between Denmark and Sweden, the Kattegat, was mapped for microplastics (MPs) in its upper water layers. Samples were taken by pump filtration along a continuous transect of 900 km, filtering a total volume of 19.344 m^3 on $10 \mu\text{m}$ steel filters. The transect was divided into 13 individual samples and analyzed down to $11 \mu\text{m}$ in MP size applying μFTIR hyperspectral imaging. MP concentrations spanned from 18.93 to 289.78 MP/m^3 with an estimated mass concentration of 0.6 to $84.1 \text{ } \mu\text{g/m}^3$. Concentrations tended to be high in and ‘downstream’ of the Øresund region, which has a population of nearly 4 million, indicating an MP footprint on the coastal waters. There was however no correlation between closeness to urban sources and particle size distribution nor polymer composition. Most of the identified MPs (57%) were below $100 \mu\text{m}$ in their largest dimension and the most common polymer was Polyester, followed by Polypropylene and Polyethylene. The correlation between concentrations measured as MP number and MP mass was weak, indicating that calculating one based on the other should be done with care.

8.04.P-We301 Exploring Stakeholders' Attitudes and Use of Swedish Knowledge Support Databases for Pharmaceuticals and Environment: A Qualitative Study

Elkanah Linder¹, Johanna Villén¹, Marmar Nekoro², Björn Wettermark¹ and Sofia Källemark Sporrang¹, (1)Uppsala University, Sweden, (2)Swedish Medical Products Agency, Uppsala, Sweden

Introduction: Pharmaceuticals are vital for human and animal health, but can pose a threat to the environment. Moving towards a reduced pollution society requires mitigation strategies to reduce the risk of pharmaceuticals in the environment. In Sweden, two publicly available databases exist that offer knowledge support and information on the effect of pharmaceuticals in the environment. They are referred to as “Pharmaceuticals and Environment” (www.Janusinfo.se), and “Environmental Information” (www.Fass.se). The objective of this study was to explore stakeholders' attitudes, and use of these two databases, as well as discuss related initiatives to mitigate the negative effects from pharmaceutical residues in the environment. **Methods:** Two interviewers conducted semi-structured interviews with 21 stakeholders regarding the Swedish knowledge support databases for pharmaceuticals and environment. Interviews were conducted from November 2021 – December 2021. Stakeholders represented the pharmaceutical industry, regional, and national authorities. The interviews encompassed the development, use, strengths and limitations regarding the databases as well as other initiatives. The two interviewers independently conducted thematic analysis on the first interviews to derive the themes, which were validated by the last author. The first author completed the remaining analysis using NVIVO®, a qualitative analysis software. **Results:** Major themes that emerged from the interviews included 1) challenges and opportunities faced with using the environmental information on the knowledge support databases, 2) transparency, 3) user-friendliness, and 4) other initiatives related to the knowledge support databases. **Conclusions:** In general, stakeholders appreciated the availability of the databases. Stakeholders stated that they mainly used the databases to decide which pharmaceutical to recommend in their treatment guidelines when two pharmaceuticals had equal efficacy and safety profiles, and for research. Stakeholders preferred using the environmental information on *Janusinfo* for treatment guidelines because of how the information was presented, and due to credibility. Stakeholders spoke about other initiatives relating to transparent manufacturing practices, and fixing the data gap. With the experiences from this study, opportunity exists for collaboration on international knowledge support databases to reduce the risks from pharmaceutical residues in the environment.

8.04.P-We302 Fate of Single Use Plastics (SUP) Exposed to Weather, Placed in Seawater and Buried in Sediment

Yvonne Shashoua¹, Asal Peydaei², Anders Kanstrup¹, Martin Mortensen¹ and David Gregory¹, (1)Environmental Archaeology and Materials Science, National Museum of Denmark, Denmark, (2)Environmental Archaeology and Materials Science,, Nationalmuseet, Kongens Lyngby, Denmark

Single-use plastics (SUP) comprise the most frequent materials in plastic litter collected in more than 700 European surveys of terrestrial, beach and marine environments since 2016. As a result, the EU's Directive on single-use plastics was implemented in July 2021 to restrict their availability and reduce their impact on the natural environment. Despite the focus on SUP, there is a significant lack of data describing degradation pathways and -rates of SUP on land, underwater and in marine sediments. In this research, we establish for the first time the primary drivers and timescales of fragmentation for new SUPs in the form of cups, coffee lids, bottles, containers and cable ties with similar thicknesses, dimensions and profiles. Our SUP set comprised

polyethylene (PE), polypropylene (PP), polystyrene (PS), polyethylene terephthalate (PET) and polyamide-66 (PA) in transparent, white and black. As part of research project, Velux MarinePlastic, the SUP were mounted on frames and exposed to Danish weather, underwater (ca. 1m) and buried in sediment (75cm) in Lynæs Harbour. Accurate temperature, ultraviolet and visible light measurements were recorded at 12-hour intervals. Plastics were also exposed to accelerated thermal ageing at $70\pm 2^\circ\text{C}$ to estimate the period for new SUP to fragment to microplastics, smaller than 5mm. Changes in dimensions and appearance were examined at 6-month intervals using optical microscopy, changes in chemical structure were determined using Attenuated Total Reflection Fourier Transform infrared spectroscopy and the loss of additives and formation of degradation products detected using Gas Chromatography-Mass Spectrometry. After 24 months, results indicate that both environment and plastic formulation are important factors in the degradation of SUPs. Degradation was fastest at 70°C , followed by exposure to Danish weather, underwater and sediment. Chemical markers suggested oxidation to be the primary degradation pathway for all SUPs. Plastics exposed to Danish weather degraded faster than those underwater or in sediment due to the difference in light levels. Black SUPs degraded significantly slower than their white or transparent equivalents. SUPs composed of PE, PS and PP developed measurable chemical and physical degradation markers in all environments, while PET and PA showed greater resistance to oxidation. Exposure of SUP to thermal ageing, Danish weather, underwater and sediment continues.

8.04.P-We303 Food Contact Materials: An Effect-Based Evaluation of the Presence of Hazardous Chemicals in Paper and Cardboard Packaging

Erica Josefina Selin¹, Agneta Oskarsson² and Johan Lundqvist², (1)Swedish University of Agricultural Sciences, Uppsala, Sweden, (2)Swedish University of Agricultural Sciences, Sweden

Food contact materials can contain hazardous chemicals that may have the potential to migrate into food and pose a health hazard for humans. Previous studies have mainly focused on plastic materials, while data on packaging materials made from paper and cardboard are limited. We used a panel of cell-based bioassays to investigate the presence and impact of bioactive chemicals on human relevant endpoints like oxidative stress, genotoxicity, inflammation, xenobiotic metabolism and endocrine system effects in extracts made from paper and cardboard. In total, twenty-three methanol extracts of commonly used paper and cardboard available on the Swedish market were extracted as a whole product using methanol to retrieve polar substances, and tested at concentrations 0.2 – 10 mg/mL. At the highest concentration bioactivities were observed in a high proportion of the samples: oxidative stress (52%), genotoxicity (100%), xenobiotic metabolism (74%), antiandrogenic- (52%) and antiestrogenic receptor (39%). Packages of potential concern included cake/pastry boxes/mats, boxes for infant formula/skimmed milk, pizza boxes, pizza slice trays and bag of cookies. It should be noted that the extraction for packages like cake/pastry boxes can be considered exaggerated, as the exposure usually is shorter. It can be hypothesized that the observed responses may be explained by inks, coatings, contaminants and/or naturally occurring compounds within the material. To summarize, an effect-based approach enables hazard identification of chemicals within food contact materials, which is a valuable tool for ensuring safe use of these types of package materials.

8.04.P-We304 Investigation and Analysis of Microplastics in Sewage Sludge and Biosolids: A Case Study From One Wastewater Treatment Works in the UK

Daisy Amy Harley-Nyang Harley-Nyang, University of Exeter, UK

There is an increasing concern about the impacts of microplastic pollution in the terrestrial environment. The recycling of biosolids to land can create a pathway for microplastic contamination of agricultural soils and in the UK alone, 3.5 million tonnes (wet weight) of biosolids from the wastewater industry are recycled each year to agricultural land. This raises the possibility that recycling of biosolids could be a significant source of microplastic pollution to the terrestrial environment. To address this issue, the present study determined the occurrence and characteristics of microplastics from across the whole sludge treatment stream from one exemplar wastewater treatment works in the UK and assessed what this may mean in terms of soil contamination. Both sewage sludge (a liquid by-product produced from the wastewater treatment processes) and biosolids (sewage sludge that has undergone a treatment process) were examined as a source of microplastics to the terrestrial environment. A catalytic wet peroxide oxidation process (30% H_2O_2 and 0.05 M FeSO_4) was performed on each of the dried samples followed by density separation (1.5 g cm^{-3} ZnCl_2). Microplastics 5000 μm and 50 μm were quantified and characterised and a subsample was subjected to chemical analysis via μFTIR spectroscopy for microplastic confirmation and polymer identification. Microplastics were detected in all samples taken from across the treatment process with concentrations ranging from 37.7–286.5 MPs/g sludge (dry weight). The microplastic load in the final biosolid products produced at the site ranged from 37.7–97.2 MPs/g of sludge (dry weight). The wastewater treatment works in this study produces 900 tonnes of anaerobically digested sludge cake and 690 tonnes of lime stabilised cake per month. Based on the results from this study, the application of these biosolids to agricultural land as fertilisers can potentially release 16.1 billion and 10.2 billion microplastics in anaerobically digested and lime stabilised sludge respectively, every month (equivalent to the same volume as >20,000 plastic bank cards). The results illustrate the extent to which microplastics may enter the terrestrial environment through this route. The work carried out in this study was a preliminary investigation and paves the way for further research into the presence of microplastics in the whole sludge treatment stream.

8.04.P-We306 Localization and Impact of Perfluorooctanoic Acid (PFOA) In Vitro and In Vivo by High-Resolution Chemical Imaging

Charlotte Stoffels¹, Hervé Robert², Mathilde Lévêque², Fabiana Oliviero², Laila Lakhal², Tom Wirtz³, Muriel Mercier-Bonin², Arno Gutleb³ and Jean-Nicolas Audinor³, (1)Luxembourg Institute of Science and Technology (LIST), Sanem, Luxembourg, (2)INRAE, Toxalim, France, (3)Luxembourg Institute of Science and Technology (LIST), Luxembourg

Perfluoroalkylated substances (PFASs), such as perfluorooctanoic acid (PFOA), have been extensively used for many industrial

applications and are therefore ubiquitous in our surroundings. However, these chemicals are toxic and persistent. They accumulate in living organisms including humans, leading to major health problems. Upon oral exposure, the first physical barrier against these pollutants is the gastrointestinal tract. Unexpectedly, little is known about their impact on the intestinal wall. This study endeavors to discover the fate, uptake and impact of PFOA using *in vitro* and *in vivo* assays combined with new imaging methodology. Besides common light/electron microscopy, we use Secondary Ion Mass Spectrometry (SIMS) which has both an excellent spatial resolution and an excellent detection limit, allowing sub-cellular localization of low-level toxicants. For the *in vitro* assay, an intestinal cell line (Caco-2) was grown on inserts and acutely (24h) exposed to PFOA (0-100 μ M). Next to various toxicity assays, cells were chemically fixed and stained for high-resolution elemental SIMS imaging and electron microscopy. The samples were analyzed using a Helium Ion Microscope combined with a SIMS (HIM-SIMS, sub-20nm lateral resolution) and a Scanning Electron Microscope (SEM). For the *in vivo* assay (first approved by an ethical committee), adult male mice were acutely exposed to PFOA via oral gavage (0-100 mg/kg body weight/day for 3 days). Next to weekly follow-ups and key biomarkers analyses, the intestines (jejunum and colon) and the liver were cryo-fixed for molecular SIMS imaging. Following optical observations, the tissues were analyzed using a Time-of-Flight SIMS (TOF-SIMS, 1 μ m lateral resolution). We effectively localized PFOA inside tissues and cells. At the tissue level, PFOA is homogeneously distributed in the liver while it is localized in some specific areas in the jejunum and in the colon. In addition, we observed colocalization of PFOA with some fatty acids, probably due to their structural similarities. At the cellular level, PFOA is only localized in the cytosol of intestinal cells, but not in cytosolic lipid droplets. The combination of mass spectrometry images with usual electron/light images provides insightful information about the fate, uptake and impact of PFASs in the gastrointestinal tract and the liver and opens new opportunities in toxicology and pharmacology.

8.04.P-We307 Mercury Levels in the Wabigoon River System

Beatriz Bento and Holger Hintelmann, Trent University, Peterborough, ON, Canada

Mercury (Hg) is a toxic trace metal that bioaccumulates in the food chain. Due to its toxicity, it has been subject to several international treaties and remediation actions. The Wabigoon River is known for an historic mercury pollution source, caused by a chlor-alkali facility operating in the 60's. As legacy Hg contamination continues to cause serious adverse health effects to the local communities living in the Wabigoon River region, further research is crucial to understand the deposition and transport of the historical Hg in this system. To answer these questions sediment cores and water samples were collected at different locations along the river, including different ecosystems such as lakes, wetlands, and riverbed/river. Current Hg levels in water allows to identify critical locations of mercury hot spots, which could be sources for transport within the system. Besides that, concentrations of total Hg and methylmercury (MMHg) were quantified in sediment cores. The analysis of cores in different locations spread around the Wabigoon River System allows to also examine the temporal variation of THg and MMHg concentrations within the ecosystem. This analysis permits to establish baseline as well as current Hg and MMHg concentrations for sediments. Results from this project are important to effectively monitor the pollution spread.

8.04.P-We308 Microplastics in the Pelagic Environment: Their Presence in Lanternfish (Myctophidae) From the Western Mediterranean and Potential Transference up in the Food Web

Olga Novillo Sanjuan, Jesús Tomás and Juan Antonio Raga, University of Valencia, Spain

Microplastics are already ubiquitous in the marine environment, although their distribution along the water column and their circulation in the marine food webs is yet to be fully understood. Here, we analyze microplastic content in the digestive tract of three pelagic lanternfish species, an important group of fish in terms of biomass that occupies an intermediate position in the marine food web. We also explore their role as a vector of microplastics for one of their predators, the striped dolphin (*Stenella coeruleoalba*). Almost half of the analyzed lanternfish contained microplastics, mostly blue and black fibers (40.9% and 34.66%, respectively). The median of microplastics found per fish, in fishes with at least one microplastic, was 3 (CI 95% = 3.46 – 6.8); similar to other studies performed in other fish species in the area. Biometric parameters of fish, such as total length and body condition, were not correlated with number of microplastics. However, microplastics' frequency of occurrence in our samples (40.21%) were significantly different from the occurrence in the digestive tracts of striped dolphins from the same area (90.5%). The amount of microplastics per individual among these species was also significantly different, with a median of 1.907 items/fish (CI 95% = 3.46 – 6.8) and a median of 7 items/dolphin (CI 95% = 3 - 13), suggesting the possible biomagnification role of lanternfish in the food web in the study area. Data presented here contributes to quantify the severity of microplastic pollution in the understudied pelagic environment and in wild, non-commercial and protected species. It will also help to build modelling scenarios together with studies that target microplastic retention and egestion rate in these species.

8.04.P-We309 Microplastics Pollution in Oyster Bed Ecosystems: An Assessment of the Northern Shores of the United Arab Emirates

Meera Talal AlHammadi, Fatin Samara, Sandra Knuteson and Sofian Kanan, American University of Sharjah, United Arab Emirates

Microplastics are a subgroup of the smaller plastics and have emerged as a pollutant of concern. This study assesses microplastics pollution in the largest oyster bed ecosystem in the Northern Emirates, a region of the United Arab Emirates (U.A.E). Oyster beds are important ecological, cultural, and economical ecosystems in temperate regions. The accumulation of microplastics in sediments can influence the surrounding ecosystem, therefore affecting the surrounding oyster beds. As oysters are one of the many sources of food consumption, monitoring the abundance of microplastics is important as they can pose a potential health threat to humans. Microplastics in both the sediments and oysters, were assessed for abundance, shape, size, color, and composition. Sediment samples were prepared and digested using KOH, followed by a high- density gradient separation. Oysters

samples were treated on a similar manner, with the aid of hydrogen peroxide to ensure a stronger digestion. Subsequently, samples were filtered under vacuum filtration and analyzed under the microscope. Overall, the mean abundance in the sediment samples was 191.7 +/- 95.5 particles/ Kg of d.w.; while the mean abundance in the oyster samples was 101.2 +/- 93.8 particles/ Kg of sample. No correlation was observed between the abundance of oyster and sediment samples. Fibers accounted for 93% of microplastics found in both oysters and sediments in all sites. Additionally, black microplastics were the most abundant, accounting for 53% in both the sediment and oyster samples. The most dominant size range was 1.0-2.0mm, accounting for 34% in both sediment and oyster samples. Samples were further identified using FTIR analysis, to identify the potential sources of microplastics. This is the first study to investigate the presence of microplastics in oyster beds and it provides baseline information for monitoring the microplastics pollution in coastal ecosystems of the region.

8.04.P-We310 Mycotoxins From Corn Silage Suspected As a Cause of Yellow-Headed Blackbirds Mortality in the City of Durango, Mexico

Martin Emilio Pereda Solis, José Martínez Guerrero, Fernando Flores-Morales, AIXA BUJDUD LEÓN, Manuel Armando Salazar Borunda and Javier Palacios-Torres, Universidad Juarez del Estado de Durango, Mexico

An unestimated amount of yellow-headed blackbirds (*Xanthocephalus xanthocephalus*) died in the urban green areas of Durango city between January and March of 2021. The birds were observed debilitated, lethargic, blindness, lack of awareness of environments, inability to fly, tremors, and flapping wings. Birds were often simply found dead. The aim of this work was to determine the possible causes of the mortality of these birds. So we collected dead birds and carried out diagnostic tests that included necropsy, cultures for the determination of bacteria and fungi, RT-PCR analysis for viruses (Newcastle and Influenza type A), analysis of gas chromatography coupled to mass spectrometry (GC/MS) for the detection of organochlorine and organophosphate pesticides. The activity of acetylcholinesterase (AChE) and glutathione-S-transferase (GST) was also measured as biomarkers of exposure to contaminants in different tissues of dead birds and in apparently healthy live birds for comparison. The most relevant results were that all specimens were in good physical condition with large layers of subcutaneous fat. Analysis of esophageal and proventricular contents which consisted entirely of corn grains, no other unusual findings were seen at gross necropsy. Bacterial cultures of the birds revealed *E. Coli*, *Enterococcus* spp. and *Staphylococcus* spp. Fungi cultures of esophageal and proventricular contents revealed the presence of filamentous fungi with morphological characteristics compatible with *Aspergillus* spp. Analysis for viruses and pesticides resulted negative. Brain AChE in birds suspected of poisoning was lower than in apparently healthy birds. GST activity was higher in suspect birds. Aspergillosis in wild birds is associated with feeding birds unharvested grains and silage because *Aspergillus* fungi live on dead or decaying organic matter. Around the city of Durango, there are some farms where it is common to see the blackbirds consuming corn silage. Aflatoxins are a metabolic product of *Aspergillus flavus* and *A. parasiticus*, their distribution could not be uniform in a given sample of corn silage, some portions could be more toxic than others. This means that some birds which ingested corn silage may be found healthy birds showing no signs of intoxications, but others who ingested aflatoxins to develop subclinical or acute intoxication and death. Report of aflatoxicosis in blackbirds are not present in the literature. However, we can speculate that this species is highly vulnerable to this toxin, unlike other species of birds and mammals.

8.04.P-We311 Natural Organic Matter (NOM) and Ionic Composition Dictate Mercury (Hg(II)) Removal From Contaminated WATER by a Wood-Based Biochar

Sampriti Chaudhuri¹, Gabriel Sigmund², Sharon Bone³, Naresh Kumar⁴ and Thilo Hofmann², (1)Environmental Geosciences, Centre for Microbiology & Environmental Systems Science, University of Vienna, Vienna, Austria, (2)University of Vienna, Austria, (3)SLAC National Accelerator Laboratory, United States, (4)Wageningen University, Netherlands

Despite the Minamata Convention, generation of Hg(II) laden waters from anthropogenic activities continue to pose a risk in many countries. To effectively treat these waters, novel sorbent materials are being developed. But, adopting these materials on a large scale can be economically challenging. Biochar, as a cost-friendly sorbent, can be used to remove Hg(II). Multiple removal mechanisms for aqueous Hg(II) using biochar have been reported. However, removal in “clean” systems comprising of Hg(II) as ionic Hg²⁺ cannot be directly extrapolated to complex systems, where Hg(II) co-exists with NOM and/or Cl. Also, NOM can block biochar pores, and background cations can screen the negative surface charge over biochar and increase the hydrophobicity of NOM. The interrelated effects of NOM and ionic composition on Hg(II) removal, which are highly relevant in complex systems remain unclear. In this study, we investigated Hg(II) removal via a wood-based biochar beyond “clean” systems towards complex aqueous matrices. Laboratory batch experiments combined Pahokee Peat extract as a NOM representative, with major ions (Cl, NO₃, Ca, and Na) and the interaction was examined using EXAFS, 2D-μ-XRF and SEM-EDS analysis. In the absence of NOM, Hg(II) removal was driven by access to sorption sites containing S within the porous biochar. Ca enhanced removal through cation bridging between the negatively charged biochar surface and Hg(II)-chloro complexes. NOM decreased Hg(II) removal, but large variations observed in removal depending on different background ions suggested that these ions played a role as well. NaCl systems unlike NaNO₃ systems, showed high Hg(II) removal, indicating that Cl was a determining factor in Hg(II) removal. EXAFS data suggested that Hg(II) was finally bound to S in the biochar. We thus propose a stepwise removal mechanism in Cl rich systems: O groups in NOM weakly bound to Hg(II) were competitively displaced by Cl. Smaller sized Hg(II)-chloro complexes were then able to permeate into the biochar pores, where S outcompeted Cl, immobilizing Hg(II) as Hg-S in the biochar. Also, in Ca systems, aggregation and increased hydrophobicity of NOM, including Hg-NOM complexes, promoted Hg(II) removal by biochar. Our results highlighted that NOM is a crucial inhibitor for Hg(II) removal using biochar. However, in saline and Ca rich systems, Hg(II) clean-up can still be effective, even at high NOM levels.

8.04.P-We312 Optimization of Plant Species Composition and Nutrient Additions to Enhance Engineered Floating Wetland Bioremediation of Crude Oil Spills in Freshwater Environments

Aidan Guttormson¹, Madeline Stanley, MSc¹, Adam Scott², Lisa Peters¹, Gregg Tomy³, Richard Grosshans⁴, David Levin¹ and Vince Palace⁵, (1)University of Manitoba, Canada, (2)University of Manitoba, Winnipeg, Manitoba, Canada, (3)Fisheries and Oceans Canada, Canada, (4)International Institute for Sustainable Development, Canada, (5)IISD Experimental Lakes Area (IISD-ELA), Canada

The transportation of crude oil creates a risk of accidental spills into freshwater ecosystems. Such spills must be remediated to limit negative effects on local communities and biota. Conventional mechanical and chemical cleanup methods can exacerbate the negative impacts of spills, delaying ecosystem recovery and leaving residual oil in the environment. One minimally invasive alternative is the use of engineered floating wetlands (EFWs) – artificial vegetated platforms which promote microbial colonization and biofilm formation in their underwater rootzones – to enhance biodegradation of oil. In 2021, research conducted at the International Institute for Sustainable Development Experimental Lakes Area, Ontario, Canada investigated the optimization of EFW design for the bioremediation of freshwater oil spills. Two aspects of EFW design were studied: 1) the composition of vegetation species (*Typha* sp., *Carex atherodes*, and *C. lasiocarpa*) planted on the EFW; and 2) the carbon to phosphorus (C:P) ratio resulting from additions of slow-release fertilizer alongside an EFW. Twenty-six mesocosm tanks (1600 L) were exposed to equal-volume spills of water accommodated fraction (WAF) produced by weathering conventional heavy crude oil. Each mesocosm contained an EFW which was either populated with a different ratio of the three plant species or evenly planted with the species and augmented with slow-release fertilizer to achieve a different C:P ratio. WAF was applied in June 2021 and the mesocosms were monitored over 13 weeks for concentrations of 44 polycyclic aromatic compounds (PACs), nutrient chemistry, and the composition and activity of the rootzone microbial community. Preliminary results indicate a rapid reduction in concentrations of sixteen parent PACs in all treatments in the first 35 days of the exposure. Analyses of PAC chemistry and the microbial community will be used to identify EFW design parameters which promote a robust oil-degrading microbial community in the rootzone and enhance the biodegradation of PACs. Ultimately, results from this study will be used to support the application of EFW-enhanced bioremediation as an alternative or supplement to conventional oil spill cleanup techniques.

8.04.P-We313 POPs Home and Away: Targeted PFAS Analysis Using UPLC - MS/MS in UK Cetaceans and Sub-Antarctic Seabirds

Imogen Bailes¹, Jonathan Barber², Sara Losada³, Philippe Bersuder³, Jacqui Hamilton⁴, Christopher Green⁵, Liz Lawton⁵ and Andrew Sweetman⁶, (1)Lancaster Environment Centre, Lancaster University, Lancaster, United Kingdom, (2)Cefas Lowestoft Laboratory, United Kingdom, (3)Cefas, United Kingdom, (4)University of York, United Kingdom, (5)DEFRA, United Kingdom, (6)Lancaster University, United Kingdom

Poly- and perfluoroalkyl substances (PFAS) are a large group of chemicals that are characterised by a hydrophilic moiety (e.g. SO_3^- or COO^-) and a hydrophobic perfluorocarbon chain that varies in length. PFAS display unique properties due to combined oil and water repellence, extreme stability, and hence are used in a wide range of industrial processes and consumer products. These chemicals can be problematic in the environment due to their potential to undergo long-range transport, persistence and toxicity. However, only some of these substances have been regulated by the Stockholm Convention; therefore, there is a growing need to document evidence of these emerging chemicals of concern in the environment. Here, we employ an ultra-performance liquid chromatograph coupled to a triple quadrupole mass spectrometer to analyse a total of 39 PFAS compounds, including 11 PFCAs (C4-C14), 9 PFSAAs (C4-C10), 3 FASAs, 3 PFPiAs and 6 fluorotelomer acids, among others, in the livers of a range of less commonly studied cetaceans sampled over the last decade from around the UK; and in albatrosses and petrels collected from the South Atlantic Ocean from the early 2000s to the mid 2010s. The data are used to assess spatial and temporal trends between different species and compounds; in particular to draw comparisons between trophic levels by employing stable isotope analysis, in seabird species in the sub-Antarctic. Our research addresses the need to understand exposure levels in wildlife to PFAS compounds in areas close to and far away from sources, and also how PFAS fingerprints vary between different species over time.

8.04.P-We314 Quantifying the Wet and Dry Atmospheric Deposition of Microplastics in Switzerland Using Analytical Methods Harmonized Across Environmental Matrices

Narain Ashta¹, Ralf Kaegi², Thomas Bucheli³, Matthias Philipp² and Christoph Hueglin⁴, (1)Swiss Federal Laboratories for Materials Science and Technology (Empa), Dübendorf, Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (EAWAG), Switzerland, (3)Agroscope, Switzerland, (4)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland

Microplastics (MPs) are found virtually everywhere – in the atmosphere, waterbodies, landmasses, mountaintops and at the poles. Organisms of all forms, including humans, are exposed to these MPs. Exposure to atmospheric MPs specifically may have implications for human health as some of these airborne particles are small enough to enter the lungs when inhaled and may cause inflammatory responses. Moreover, atmospheric MPs are transported to locations far from their emission sources and contaminate pristine ecosystems. However, accurate quantification of MPs in different environmental compartments is currently hampered by the lack of harmonized analytical methods. This makes it difficult to compare data generated for MP samples collected from different environmental matrices. We will therefore work towards a harmonized analytical method. The method will use optical microscopy to determine the number of MPs in atmospheric deposition samples and identify their shapes and sizes. Fourier transform infrared spectroscopy, cross-validated with Pyrolysis-Gas Chromatography/Mass Spectrometry, will be used to identify the chemical composition of the MPs. The sampling and analytical processes will be quality controlled using surrogate standards. This work will be done in close collaboration with two other research projects that will investigate MPs in soil and sewage sludge

to harmonize the method across environmental media. The method will be used to monitor the amount and types of MPs in wet and dry atmospheric deposition as collected over a one-year period in urban, semi-urban, rural and remote locations across Switzerland. By doing so, we seek to identify the major emission sources of atmospheric MPs and their relative importance. Gathering this information will be useful for environmental authorities to gain a better understanding of the role of the atmosphere for the distribution of MPs in the environment and also to define appropriate policy measures to prevent or mitigate the effects of MP contamination.

8.04.P-We315 The Assessment of Environmental Risk Related to the Occurrence of Pharmaceuticals in Bottom Sediments of the Odra River Estuary (SW Baltic Sea)

Dawid Kucharski¹, Grzegorz Nalecz-Jawecki², Przemysław Drzewicz³, Artur Skowronek⁴, Agnieszka Strzelecka⁴, Kamila Mianowicz⁵ and Joanna Giebu?towicz², (1)Faculty of Pharmacy, Department of Bioanalysis and Drugs Analysis, Medical University of Warsaw, Warsaw, Poland, (2)Medical University of Warsaw, Poland, (3)Polish Geological Institute-National Research Institute, Poland, (4)University of Szczecin, Poland, (5)Interoceanmetal Joint Organization, Poland

The Odra River estuary is a north-western region of Poland of high economic and ecological value. The northern part of the estuary is the Natura 2000, a special nature protection area. It is situated at the contact point between freshwater and seawater and has special significance for fish living in these habitats. On the other hand, the Odra River estuary is a highly urbanized and industrialized area with shipyards and two deepwater seaports. The occurrence of pharmaceutically active compounds (PhACs) in the aquatic environment is of great concern due to the potential risk to the ecosystem and human health. The main source of PhACs in the environment is treated municipal wastewaters. Currently, available treatment technologies in wastewater treatment plants (WWTPs) do not remove completely PhACs from wastewaters; thus a certain amount of the compounds remain in the treated effluents which are released to the environment. This study was aimed to find new emerging substances of very high concern that should be covered by surface water monitoring. The occurrence of 130 PhACs in sediments collected from 70 sampling sites in the Odra River estuary was investigated. PhACs were selected after the qualitative screening of sediments with the use of the HPLC system, Dionex Ultimate 3000, coupled with a Q-Exactive hybrid quadrupole-Orbitrap mass spectrometer system (Thermo Fisher Scientific, Waltham, MA, USA), and the literature data. Quantitation of selected PhACs was performed in multiple reaction monitoring (MRM) and positive ionization (ESI +) modes with the use of HPLC, Agilent 1260 Infinity (Agilent Technologies, Santa Clara, CA, USA) equipped with a degasser, thermostated autosampler, and binary pump, and coupled to Hybrid Triple Quadrupole/Linear Ion trap mass spectrometer (QTRAP@4000, AB SCIEX, Framingham, MA, USA). The highest concentration levels of the compounds were found in the vicinity of effluent discharge from two main Szczecin wastewater treatment plants: "Pomorzany" and "Zdroje", and nearby the seaport and shipyard. The high environmental risk was observed in 30 sampling sites for clindamycin, 22 sampling sites for pseudoephedrine, 19 sampling sites for nalidixic acid, 4 sampling sites for carbamazepine, and 3 sampling sites for fexofenadine. Due to the scarcity of toxicological data related to benthic organisms, only an approximate assessment of the environmental risk of PhACs is possible. Nevertheless, the compounds with medium and high risk should be considered as pollutants of high environmental concern whose occurrence in the environment should remain under close scrutiny. The project was financed by National Science Center Poland OPUS 11 (UMO-2016/21/B/ST10/02391)

8.04.P-We316 The Presence of Pharmaceuticals in Our Surface Waters and the Development of Effective Monitoring Strategies

Dylan O'Flynn¹, Blanaid White², Imogen Rose Hands¹, Anne Parle-McDermott¹, Jenny Lawler¹, Denise Harold¹, Thomas Mc Cloughlin¹, Linda Holland¹ and Fiona Regan², (1)Dublin City University, Ireland, (2)DCU Water Institute, Dublin City University, Ireland

Pharmaceuticals play a pivotal role in human and animal health. The ever-increasing use and availability of pharmaceuticals in the last decade have led to the contamination of surface water ecosystems from ng/L to µg/L concentrations. The environmental fate and toxicological implications of many pharmaceuticals and their residues remain generally unknown. Additionally, the stability and biological activity of these "micro-pollutants" can lead to a "pseudo persistence" in the environment, with ensuing behavioural and health-related effects. This project highlights the occurrence, movement, and impact pharmaceuticals may have on surface water catchments. Findings from this review will highlight the importance of monitoring pharmaceuticals in surface waters, potential sources and factors that influence their concentrations. Furthermore, detailing strategic monitoring strategies will show the practicality of passive (long-term continuous) and grab (snapshot) sampling techniques in conjunction with effect based biomonitoring tools to give a detailed account of the passage of pharmaceuticals through an aquatic ecosystem. Outcomes from this research will aim to provide information on the relevant concentrations of pharmaceuticals in surface water systems while improving education surrounding appropriate use, disposal and waste management of pharmaceutical products.

8.04.P-We317 Tissue Metal Concentrations and Antioxidant Enzyme Activity in Sharks

Gretchen K. Bielmyer-Fraser¹, Bryan Franks¹ and Chris Fischer², (1)Jacksonville University, United States, (2)OCEARCH, United States

Metals occur naturally in the environment; however, anthropogenic practices have resulted in increased metal concentrations in coastal ecosystems. Sharks are important species, ecologically, recreationally and commercially. Reference levels of metal contaminants in the tissues of sharks, particularly, great whites, is lacking. In this study, concentrations of copper, cadmium, nickel, lead, selenium, silver, and zinc were measured in the muscle tissue of great white and tiger sharks. Metal exposure in various species has been correlated with oxidative stress. Therefore, activities of antioxidant enzymes (superoxide dismutase, catalase, and glutathione peroxidase) were also examined in the shark muscle tissue with the objective of identifying a nonlethal bioindicator of metal pollution. Metal-specific differences in tissue metal concentrations were detected based on sex, age class,

and collection site. This study provides new data on metal concentrations in the muscle tissue of great whites collected over the past three years and provides insight into oxidative stress defenses in these top-level carnivores.

8.04.P-We318 Trace Analysis of Pesticides and Assessment of Their Occurrence in MBR Post-Treatment Effluent, After a Pilot-Plant of Potable WATER Reuse and in Drinking WATER

Jessyca Medeiros and Cassiana Montagner, UNICAMP - University of Campinas, Brazil

The water reuse for potable purposes can represent a realistic source for the supply of drinking water in areas with water scarcity. Therefore, it is necessary to combine conventional technologies in the wastewater treatment with advanced technologies for the removal of trace contaminants to have high quality and safe water. The contamination of pesticides is a key point to be addressed in countries like Brazil, where the agriculture business is strong, and the sanitation condition is still poor in many regions. The aim of this work was to validate an analytical method using SPE and LC-MS/MS for the determination atrazine, hydroxyatrazine (ATZOH), desethylatrazine (DEA), ametryn, simazine, diuron, 2,4-D, fipronil, fipronil sulfide and fipronil sulfone in aquatic matrices. The method has been applied to evaluate the concentration of these contaminants in real samples collected from a water reclamation plant and drinking water. All analytes were quantified by internal calibration, except for fipronil and its metabolites, which were quantified by external calibration. The calibration curve determination coefficients (R^2) were at least 0.99 for all analytes. The limits of quantification were between 0.5 and 2.5 $\mu\text{g L}^{-1}$. SPE recoveries were assessed in three levels of concentration (20, 50, and 100 ng L^{-1}) using spiked ultrapure water, drinking water, effluent after membrane bioreactor (MBR) treatment and effluent after advanced treatment. The recoveries ranged between 27 and 141%, with a maximum RSD of 31%. The matrix effect in effluent after MBR, effluent after advanced treatment and drinking water ranged from 3.8 to 59.1%, 6.2 to 20.4% and 3.1 to 27.7%, respectively. Pesticides were quantified in drinking water samples collected in different tap water of the urban city and in a water reclamation plant in two steps: (1) MBR post-treatment and (2) from a pilot-plant of potable water reuse after the follow treatments: reverse osmosis, UV- H_2O_2 and activated carbon. The mean concentration of atrazine, OHATZ, DEA, diuron and fipronil, fipronil sulfide and fipronil sulfone in the MBR post-treatment was 71.2, 49.6, 19.1, 121.0, 43.5, 7.6, 3.6 ng L^{-1} , respectively. After the advanced treatment, only fipronil was quantified with a concentration of 0.7 ng L^{-1} . In drinking water, atrazine, ATZOH, DEA, diuron and 2,4-D were quantified with mean concentration of 33.5, 26.9, 12.1, 8.1 and 138.1 ng L^{-1} , respectively. Therefore, it is possible to conclude that the advanced treatment used in a pilot scale is promising to be applied in a water reclamation plant for potable purpose. However, more studies should be done to classify it as a drinking water.

8.04.P-We319 Designing tools to predict and mitigate impacts on water quality following the Australian 2019/2020 wildfires: Insights from Sydney's largest water supply catchment

Jonay Neris^{1,2}, Cristina Santin^{3,4}, Roger Lew⁵, Peter R. Robichaud⁶, William J Elliot⁶, Sarah A Lewis⁶, Gary Sheridan⁷, Ann-Marie Rohlf⁸, Quinn Ollivier⁸ and Stefan Doerr⁹, (1)Universidad de La Laguna, La Laguna, Spain, (2)Swansea University, Swansea, United Kingdom, (3)Swansea University, United Kingdom, (4)UMIB-CSIC, Spain, (5)University of Idaho, (6)Rocky Mountain Research Station, US Forest Service, (7)University of Melbourne, Australia, (8)WaterNSW, Australia, (9)Swansea University, UK

The 2019/2020 Australian bushfires (or wildfires) burned the largest forested area in Australia's recorded history, with major socio-economic and environmental consequences. Among the largest fires was the 280 000 ha Green Wattle Creek Fire, which burned large forested areas of the Warragamba catchment. This protected catchment provides critical ecosystem services for Lake Burragorang, one of Australia's largest urban supply reservoirs delivering ~85% of the water used in Greater Sydney. Water New South Wales (WaterNSW) is the utility responsible for managing water quality in Lake Burragorang. Its postfire risk assessment, done in collaboration with researchers in Australia, the UK, and United States, involved (i) identifying pyrogenic contaminants in ash and soil; (ii) quantifying ash loads and contaminant concentrations across the burned area; and (iii) estimating the probability and quantity of soil, ash, and associated contaminant entrainment for different rainfall scenarios. The work included refining the capabilities of the new WEPPcloud-WATAR-AU model (Water Erosion Prediction Project cloud-Wildfire Ash Transport And Risk-Australia) for predicting sediment, ash, and contaminant transport, aided by outcomes from previous collaborative postfire research in the catchment. Approximately two weeks after the Green Wattle Creek Fire was contained, an extreme rainfall event (~276 mm in 72 h) caused extensive ash and sediment delivery into the reservoir. The risk assessment informed on-ground monitoring and operational mitigation measures (deployment of debris-catching booms and adjustment of the water supply system configuration), ensuring the continuity of safe water supply to Sydney. WEPPcloud-WATAR-AU outputs can prioritize recovery interventions for managing water quality risks by quantifying contaminants on the hillslopes, anticipating water contamination risk, and identifying areas with high susceptibility to ash and sediment transport. This collaborative interaction among scientists and water managers, aimed also at refining model capabilities and outputs to meet managers' needs, exemplifies the successful outcomes that can be achieved at the interface of industry and science. *Integr Environ Assess Manag* 2021;17:1151–1161. © 2021 The Authors. *Integrated Environmental Assessment and Management* published by Wiley Periodicals LLC on behalf of Society of Environmental Toxicology & Chemistry (SETAC).

8.04.P-We320 Zebrafish as a model to screen Thyroid Disruption

Maria José Mazón¹, Andoni Cruz², Jorge Hurtado de Mendoza³, Iñaki Iturria¹, Celia Martí¹, Arantza Muriana¹ and Oihane Jaka¹, (1)BBD BioPhenix - Biobide, Spain, (2)Direction, BBD BioPhenix - Biobide, Spain, (3)GRILab, Spain

There is an increasing concern about the environmental impacts of chemicals that can disrupt the endocrine system, which can result in adverse effects on developmental, reproductive, neurological, and/or immune functions in both humans and wildlife. The negative impact of these Endocrine Disrupting Compounds (EDCs) is becoming a real public health issue, therefore the necessity of tests to assess the potential risk of new chemicals before they are marketed is increasing. In vitro tools are inexpensive and

scalable for high-throughput platforms, however, they pose low relevance to vertebrate species. On the other hand, working with adult animals is expensive and represents ethical issues. Small fish like zebrafish (*Danio rerio*) are an excellent alternative to in vitro and in vivo models. They offer a unique experimental system where screening assays can be performed at the whole animal level, being at the same time compatible with the 3R principles (Replacement, Reduction, and Refinement in animal testing). In this work, we present a three-phase assay to screen the endocrine disrupting potential of chemical compounds. First, thyroid disrupting (TD) chemicals are evaluated using the transgenic line tg(tg:mcherry), which expresses red fluorescence in the thyroid gland under the thyroglobulin promoter. The fluorescence of the reporter gene allows monitoring in vivo the upregulation of the thyroglobulin gene expression as a compensatory reaction to thyroid gland disruption. The signal intensity is assessed in vivo to screen and characterize potential TD, either directly or after metabolization by the zebrafish embryo. Second, a gene expression analysis is carried out to characterize the thyroid disrupting effect by measuring three thyroid-related genes (*tsh?*, *tg*, and *tpo*). And third, the thyroid hormone (TH) levels of T4, T3, 3,5-T2, and 3,3'-T2 are quantified by liquid chromatography (LC/HRMS) in whole-embryo extracts. Our data show that reference compounds (such as potassium perchlorate and propylthiouracil), and environmental pollutants (such as benzophenone-2) induce an increase of the fluorescence of thyroglobulin in the tg(tg:mcherry) transgenic line, and overexpression of thyroid-related genes *tsh?*, *tg*, and *tpo*. These results were confirmed in TH level measurements by LC/HRMS. This screening methodology showed to be a sensitive and cost-effective assay to screen and evaluate potential EDCs chemicals.

8.04.P-We321 Risk Reductions During Biotransformation and Mobilisation of Pyrene in a Model Plant-Bacteria-Soil System

*Jose Carlos Castilla Alcantara Sr*¹, *Rosa Posada*², *María Balseiro-Romero*¹, *Carmen Fernández-López*³, *Jose Luis Garcia*², *Alicia Fernández-Vázquez*⁴, *Manuel Cantos*² and *Jose Julio Ortega-Calvo*⁵, (1)IRNAS CSIC, Sevilla, Spain, (2)Instituto de Recursos Naturales y Agrobiología de Sevilla CSIC, Spain, (3)UCAM, Spain, (4)Instituto de Recursos Naturales y Agrobiología de Sevilla. IRNAS-CSIC, Spain, (5)Instituto de Recursos Naturales y Agrobiología, Spain

The productive application of motile microorganisms for degrading soil contaminants is one of the most promising processes in modern remediation due to its low cost and efficiency. However, the incomplete biodegradation of the pollutants and the formation of the intermediary metabolites in the process, may increase the toxicity in soil during bioremediation (*Environ. Sci. Technol.* 12: 421-444, 2013; *Sci. Total Environ* 689: 390-397, 2019). Therefore, controlling these factors should be a fundamental part of soil remediation approaches. The aim of this study was to evaluate the sources of risk associated with the transformation by cometabolism of ¹⁴C-labelled pyrene by inoculated *Pseudomonas putida* G7, and identify ways for risk minimization. Our model scenario tried to increase bio-accessibility to a distant source of contamination through the chemotactic bacteria attraction exerted by sunflower (*Helianthus annuus* L.) root exudates. A biochar trap for mobilized pollutant metabolites and bacteria has also been employed. The experimental design consisted of pots comprising a layer of sand with ¹⁴C-labelled pyrene (88 mg/kg) placed approximately at mid-height as contamination source. Half of the pots included a biochar layer at the bottom. The pots were incubated in a greenhouse with sunflower plants and *P. putida* G7 bacteria (*Sci. Total Environ* 760: 143408, 2021). The results showed that those pots with sunflower plants evidenced a higher bacterial mobilisation towards the source of contamination by chemotaxis, resulting in the biodegradation of pyrene and its mobilization as metabolites through the percolate and the roots. In addition, the biochar layer efficiently reduced the concentrations of pyrene metabolites collected in the leachates. Therefore, the combination of plant, bacteria and biochar safely reduced the risks caused by the biological transformation. Although this is a preliminary greenhouse-scale model, progress in this field will undoubtedly open up new possibilities for low-cost control and treatment of contaminated soils.

8.04.P-We322 Chemotactic Pseudomonas Putida G7 Facilitates the Co-Mobilization of Immotile Pollutant-Degrading Bacteria in Restricted Porous Regimes

*María Balseiro-Romero*¹, *Angeles Prieto-Fernandez*², *Subhasis Ghoshal*³ and *Jose Julio Ortega-Calvo*⁴, (1)IRNAS CSIC, Sevilla, Spain, (2)Instituto de Investigaciones Agrobiológicas de Galicia (IIAG), Consejo Superior de Investigaciones Científicas (CSIC), Spain, (3)McGill University, Canada, (4)Instituto de Recursos Naturales y Agrobiología, Spain

Dispersal of degrading microorganisms within porous media is one of the key drivers of bioremediation of heterogeneously polluted environments (*Curr Opin Biotechnol* 24, 451–456, 2013). Recent studies have identified a unique form of bacterial dispersal by hitchhiking on motile microbes (*Trends Microbiol* 29, 542–550, 2021). The dispersal enhancement and co-motility of immotile cells of a HCH-degrading bacterial strain, *Sphingobium* sp. D4, in the presence of a chemotactic and naphthalene-degrading strain, *Pseudomonas putida* G7, was investigated using glass bioreactors. They comprise two chambers separated by membrane filters of different micrometer-sized pores (3, 5 and 12 µm): the lower chamber (LC), where cells were injected, and the upper chamber (UC), where transported cell quantification was performed. Chemoeffectors in the UC (sodium salicylate, a naphthalene degradation product, or γ -aminobutyric acid–GABA-, a common component of root exudates) induced the tactic motility of G7 in the direction of a positive concentration gradient. D4 cells were transported to UC by means of two fluxes: Brownian dispersion and co-mobilization through the G7 tactic front. These fluxes changed in intensity with time: Brownian dispersion was the main mechanism within the first 1-2 h, while G7 co-mobilization was more significant after 4-6 h, when the maximum G7 transport to the UC occurred. After 8 h (initial cell rate 1:1, D4/G7), ca. 6% and 7% (using salicylate), and ca. 13% and 16% (using GABA) of D4 initial cells were co-transported to UC, using 5 and 12 µm membrane pore sizes, respectively. Only 3% (salicylate) and 7% (GABA) of D4 cells were mobilized in the absence of G7. A higher proportion of initial G7 cells (1:10, D4/G7) lead to a higher co-mobilization: e.g., 9% of initial D4 cells were mobilized to UC in 5 µm-membrane bioreactors. Microscope observations confirmed that the main mechanism for D4 hitchhiking was mechanical pushing by the G7 front, due to cell collisions and the turbulences generated: neither multimicrobial aggregates were observed nor direct attachment to G7 cells,

dismissing those mechanisms under our experimental conditions. The results reflected the potential of chemotactic microbes for enhancing the dispersal of immotile microorganisms in restricted pore systems. Carefully selected bacterial consortia (degrader/s+carrier/s) could, therefore, significantly enhance the accessibility to contaminant sources in remediation procedures.

8.04 Extended submission THU (Poster)

8.04.P-Th213 A Complex Mixture of Polyaromatic Compounds From a Contaminated Soil Cause Embryotoxic Effects and Alter the Behavior and Gene Expression in Zebrafish Embryos (*Danio rerio*)

*Greta Nilen*¹, *Maria Larsson*² and *Steffen Keiter*³, (1)School of Science and Technology, Örebro University, Sweden, (2)School of Science and Technology, Örebro university, Örebro, Sweden, (3)MTM, Örebro University, Sweden

Environmental contamination is usually comprised of a complex mixture of pollutants, and each of them has the potential of causing different toxic responses towards humans and wildlife. One approach to study complex mixtures in environmental samples is to use effect-directed analysis (EDA), combining fractionation, bioassays, targeted and non-targeted chemical analysis. In the present study, toxicity tests with zebrafish embryos (*Danio rerio*) were performed to investigate acute toxicity, molecular, and adverse effects of an extract from a contaminated soil collected at a former gasworks site contaminated with polyaromatic compounds (PACs). For this purpose, three replicates were conducted in 96-well plates, and each replicate consisted of 192 individuals divided into five concentrations and three control groups. The chemical composition and distribution were determined by measurements of the concentrations of 87 PACs (including polycyclic aromatic hydrocarbons (PAHs), oxygenated PAHs, alkylated PAHs, and heterocyclic PACs (NSO-PACs)) in the water phase, the fish, and sorbed to the plate material. Based on the data for acute toxicity and sub-lethality, gene expression and behavioral alterations were investigated to study the underlying toxic mechanisms. The zebrafish behavior was measured as larvae movement during exposure to interchanging light and dark periods. In addition, the response to mechanical stimuli was recorded using a tapping device. Quantitative gene expression analyses were conducted on the set of 36 selected genes that are known to be directly linked to certain adverse outcomes. The complex mixture was acutely toxic to the embryos and the exposure resulted in several teratogenic effects as divided yolk-sac, edema on the heart, and reduced pigmentation. In addition, the mixture altered the behavior of the larvae and caused hyperactivity in darkness and hypoactivity in light. The larvae were also hypoactive after the mechanical stimuli. The qPCR analysis showed that eleven genes were differentially regulated. For instance, one gene connected to pigmentation in the eye (*opn1sw1*) was downregulated and a gene involved in cardiomegaly and heart failure (*fpgs*) was upregulated. In the next step of this study, an EDA is performed with the extract to identify (novel) PACs or other organic compounds causing the observed toxic effects. The results will increase the knowledge of PACs present at contaminated sites, their identity, and toxicity.

8.04.P-Th214 A New Oil Spill Dispersant Developed According to Efficacy and EcoToxicological Criteria

*Walter D. Di Marzio*¹, *Elena Sáenz*², *Tiziana Di Lorenzo*³, *santiago martinez*⁴ and *José Luis Alberdi*⁵, (1)CONICET-UNLU- PRIET, Argentina, (2)CONICET PRIET UNLU, Argentina, (3)Istituto per lo Studio degli Ecosistemi CNR, Italy, (4)CONICET PRIET UNLU, United States, (5)UNLU PRIET CONICET, Argentina

Dispersants are specially designed oil spill mixtures that are composed of detergent-like surfactants in a variety of organic solvents. Dispersants do not remove oil from the water, but instead break the oil into small droplets. In Argentina, the environmental legislation authorizes the applications of dispersant formulations based in three characteristics: efficacy, biodegradation and ecotoxicity. Based on this, we designed a dispersant mixture taking the following components: 2-Butoxy-Ethanol, Polisorbate 80/60, Span80, Tween80, Ethanol, lecithine and diocetilsulfosuccinate. A combination of design of experiments (DOE) using a Central Composite Design (CCD) and Mixtox models for ecotoxicity was used to test all dispersant formulations. Efficacy was evaluated by Barrel shaker method, biodegradation by OECD 301 method and ecotoxicity was evaluated on one fish species of Poeciliidae (*Cnesterodon decemmaculatus*), *Artemia franciscana* and *Metacyclops gracilis* a widespread hyporheic copepod species. The new dispersants were applied on the follow types of petroleum extracted in Argentina wells: Caleta Córdoba, Caleta Olivia, Hydra Total and Cruz del Sur – YPF. And were compared with the response of Corexit 9500A and 9527A. Final formulations were also characterized for Interfacial tension and droplet sizes distribution. A discussion is made about how changes in proportions of each component determines the % of Efficacy and drop interactio forces; also % of biodegradability and ecotoxicity. A final formulation is proposed as fourth generation dispersants.

8.04.P-Th215 Acute Toxicity of the Tire Rubber-Derived Chemical 6ppd-Quinone to Four Fishes of Commercial, Cultural, and Ecological Importance

*Markus Hecker*¹, *Steve Wiseman*², *David Montgomery*¹, *Summer Selinger*¹, *Justin Miller*³, *Eric Stock*³, *Alper James Alcaraz*¹, *Jonathan Challis*¹, *Lynn Weber*¹, *David Janz*¹ and *Markus Brinkmann*¹, (1)University of Saskatchewan, Canada, (2)University of Lethbridge, Lethbridge, Alberta, Canada, (3)University of Lethbridge, Canada

Stormwater runoff from urban landscapes has recently been linked to mass mortalities of coho salmon on the U.S. West Coast, also dubbed urban runoff mortality syndrome (UMRS). The chemical responsible for UMRS has been identified as *N*-(1,3-dimethylbutyl)-*N'*-phenyl-*p*-phenylenediamine-quinone (6PPD-quinone), a transformation product of the rubber tire antioxidant 6PPD, with a median lethal concentration (LC₅₀) <0.1 µg/L for coho salmon. Interestingly, subsequent studies have failed to confirm comparable sensitivity in a few other select fish species including chum salmon, medaka and zebrafish, highlighting an urgent need for assessing the potential hazard of 6PPD-quinone to fishes in general. Here, we investigated the acute toxicity of 6PPD-quinone to four fishes of commercial, cultural, and ecological importance in North America, rainbow trout, brook trout, Arctic char, and white sturgeon. Fish were exposed under static renewal conditions and exposure concentrations were verified analytically. Mortalities in brook trout occurred between 1.2 and 20 h, while mortalities began after 7 h and spanned 60 h in

rainbow trout. The LC₅₀s in brook trout (24 h) and rainbow trout (72 h) were 0.87 and 1.00 µg/L, respectively. Both species showed characteristic symptoms (increased ventilation, gasping, loss of equilibrium) shortly before death. No mortalities were observed after 96 h of exposure for either char or sturgeon at measured concentrations as high as 14.2 µg/L. This is the first study to demonstrate acute toxicity of 6PPD-quinone to other fishes of commercial, cultural, and ecological importance at environmentally relevant concentrations and will provide urgently needed information in support of environmental risk assessments of this contaminant of emerging concern.

8.04.P-Th216 Aged NanoPlastics for Laboratory Testing

Gabriella Schirinzi¹, Francesco Fumagalli², Douglas Gilliland³, Justin Gorham⁴, Jennifer Lynch⁴, Dora Mehn⁵, John Pettibone⁴, Katherine Shaw⁴, Li-Piin Sung⁴, Eric Windsor⁴ and Andrea Valsesia⁶, (1)European Commission, Ispra, Italy, (2)European Commission Joint Research Centre, Italy, (3)European Commission, Joint Research Centre / Directorate F Health, Consumers and Reference Materials, Italy, (4)National Institute of Standards and Technology, United States, (5)European Commission-Joint Research Centre, Italy, (6)European Commission DG Joint Research Centre, Italy

Reference particle models are essential to obtain an accurate perspective of how environmental nanoplastics behave in natural systems and to generate data on their environmental fate and impact on living organisms. However, although the current available models are particularly important for filling the initial knowledge gaps on nanoplastics, they do not demonstrate enough diversity and/or accuracy to represent the actual heterogeneity of the physical and chemical properties of environmental nanoplastics. In this framework, the Joint Research Centre (JRC) and the National Institute of Standards and Technology (NIST) are collaborating on a challenging project, which aims to identify a novel strategy for the production of aged nanoplastics. These new test materials are designed to become environmentally relevant models made by the combination of mechanical abrasion and artificial UV exposure for ageing. The objective is to obtain nanoplastics, which mimic naturally weathered ones in size distribution and surface chemistry. The scalable production of these nanoplastics is investigated to make them available to stakeholders. This test material will have applications for the development of new analytical methodologies to detect nanoplastics, to better understand their role in carrying other pollutants and increase knowledge related to their behaviour and fate in the environment.

8.04.P-Th217 Algae Wracks on Coastline of Baltic Sea As Potential Accumulation Points of Microplastic Particles

Ieva Putna-Nimane¹, Ligita Abele², Elina Vecmane² and Liene Spilva², (1)Latvian Institute of Aquatic Ecology, agency of DU, Riga, Latvia, (2)Latvian Institute of Aquatic Ecology, agency of Daugavpils University, Latvia

Plastics have become an essential part of our everyday life since the beginning of their mass production in the 1940s. With the increasing world population, the demand for plastic products is rising. The predicted increase of plastic production will reach 33 billion tons by 2050. As a result, the amount of plastics (and microplastics) that enter the surrounding environment is increasing. Due to this, coupled with an estimated half-life at sea between 1.4 and >2500 years, plastic pollution in oceans and seas is recognized as a severe environmental issue. It is also the reason for importance to obtain more information on the way it is transported and places of possible accumulation, including beach-cast algae on the sea coastline. The aim of this study is to assess potential of algae wrack in shoreline to be an accumulation spots of microplastic as well as try to define whether macrophyte algae species composition have impact on microplastic amount in algae wracks. In order to reach scientific targets of the study in July, August and September of 2021 sampling was performed in the Latvian coastline of Baltic Sea and Gulf of Riga. In eight places samples for microplastic detection in algae wrack, control sand and algae wrack samples were taken. Microplastic sample preparation from algae wracks included several steps including treatment with sodium hydroxide (10 %), peroxide (15%), enzymes (protease, cellulase, viscozyme) and two steps of density separation (SPT - 1,75 g/ml). Control sand sample treatment included only density separation (SPT - 1,75 g/ml). For both microplastic sample matrices final step is filtration on GF/C filters for visual identification under the microscope and analysis. All particles, excluding fibers, that could be handled manually were picked up for further chemical composition analysis. Thereafter, these particles are analysed with the ATR-FTIR spectroscopy method. For macrophyte algae species composition samples were analysed by sorting the macroalgae according to species, which are detected by morphological characteristics as well as dry weight of each species was detected. Preliminary results show that algae wracks in coastline of Baltic sea have potential to accumulate of microplastic particles. Research was performed in the framework of EU Interreg Latvia-Lithuania project "Estimation, monitoring and reduction of plastic pollutants in Latvian-Lithuanian coastal area via innovative tools and awareness raising" (LLI - 525)

8.04.P-Th218 An Agent-Based Model of Epigenetic Mechanisms to Mitigate Environmental Stressors

Kristin Crouse and Valery Forbes, University of Minnesota, United States

Identifying how organisms respond to environmental stressors remains of central importance as human impacts continue to shift the environmental conditions for countless species. Some mammals are able to mitigate these environmental stressors at the cellular level, but the mechanisms by which cells are able to do this and how these strategies vary among species is not well understood. At the cellular level, it is difficult to identify the temporal dynamics of the system through empirical data because fine-grained time course samples are both incomplete and limited by available resources. To help identify the mechanisms by which animal cells mitigate extreme environmental conditions, we propose an agent-based model to capture the dynamics of the system. In the model, agents are regulatory elements and genes, and are able to impact the behaviors of each other. Rather than imposing rules for these interactions among agents, we will begin with randomized sets of rules and calibrate the model based on empirical data of cellular responses to stress. We will apply a common-garden framework to cultured cells from 16 mammalian species, which will yield genomic data and measures of cell morphology and physiology when exposed to different levels of temperature, glucose, and oxygen. These species include humans, dolphins, bats, and camels, among others, which vary in how they respond to environmental stressors, offering a comparative approach for identifying mechanistic rules whereby cells achieve

robustness to environmental stressors. For calibration of the model, we will iteratively select for rules that best lead to the emergent outcomes observed in the cellular assays. Our model is generalized for any species, any cell type, and any environmental stressor, offering many applications of the model beyond our study. This study will increase our understanding of how organisms mitigate environmental stressors at the cellular level such that we can better address how organisms are impacted by and respond to extreme environmental conditions.

8.04.P-Th219 An Optimized Method for the Identification of Ciguatoxins in Fish Using High Resolution Mass Spectrometry

Natasha Grace Prytulka, Trent University, Peterborough, ON, Canada

Ciguatera fish poisoning is a major health issue affecting food sustainability and security for populations located in tropical and subtropical regions, primarily in the Pacific and Caribbean regions. This neurological, foodborne illness is caused by consuming fish that has been contaminated by ciguatoxins (CTX). CTX are a class of toxic polyethers that are similar in molecular structures (analogues) produced by marine dinoflagellates in the genera *Gambierdiscus* and *Fukuya* and bio-transform throughout the food web. Low-resolution mass spectrometry is the most common and preferred method for ciguatoxin identification in fish, however, there is limited standard availability for this approach and it does not allow for the study of the complete array of ciguatoxin analogues that can also contribute to the toxic levels for consumption of the fish. The development of a sensitive method using High-Resolution Mass Spectrometry (HRMS) could be used to help unambiguously identify all CTX analogues even when analytical standards are restricted due to the spectrometer's increased mass accuracy. We have altered and evaluated the changes in four parameters (solvent makeup, voltage, collision energy, resolution) that influence ionization and ion transmission to observe and optimize the behaviour of the sodium and ammonium adducts, protonated molecules, and water losses of CTX-3C on the electrospray ionization source coupled with the Orbitrap mass spectrometer. We will analyze a store-bought fish fillet spiked with the CTX-3C standard to test for the optimized method through the confirmation of the presence of CTX-3C. This optimized method will be further evaluated for identifying numerous CTX analogues by observing similar fragmentation patterns to CTX-3C in a contaminated Caribbean fish supplied to us from the Caribbean Public Health Agency (CARPA). The advantages of having a sensitive HRMS method for CTX identification will allow confirmation of CTX in fish despite having limited standards available, and the further discovery of new CTX analogues that have not been identified. This method may give us new opportunities to delve deeper and gain a greater insight into the fate and cycling of CTX so that we can implement better protective measures against ciguatera fish poisoning.

8.04.P-Th220 Analytical Challenges in Analysis of Pharmaceutical Residues From Sewage Sludge and Soil Samples

Marja Hagström¹, Heidi Ahkola¹, Lauri Aysto², Päivi Fjäder² and Sari Kauppi¹, (1)Finnish Environment Institute, Finland, (2)Finnish Environment Institute, Finland

Active pharmaceutical ingredients (APIs) are a chemically diverse group of compounds that end up to the environment largely due to the proper use of medicines. At wastewater treatment plants, APIs are either degraded, retained to sludge or released into recipient waters via effluent wastewater. In Finland, most of the nutrient rich sludge is used in agriculture or landscaping, and especially persistent APIs and their metabolites can end up in soils. Before reuse, the sludge is commonly digested or composted, but it may also be chemically treated, pyrolyzed to biochar or incinerated to ash. Reliable analytical techniques to detect APIs from soil, sludge, biochar or ash samples has to be developed to assess the occurrence and environmental risk caused by these compounds. In general, tens or even hundreds of APIs and their metabolites having differing chemical characteristics has to be determined in one sample, which brings challenges to analytical methods. SUDDEN (Sustainable Drug Discovery and Development with End-of-Life Yield) is a multidisciplinary project studying e.g., emissions, life cycle and ecological risk assessment of certain APIs. In SUDDEN project we optimized pre-treatment, purification and analysis technique to analyse 74 APIs and 12 metabolites from soil, sludge, biochar and ash samples by taking account the chemical characteristics of each compound. The APIs were divided in different groups with similar chemical characteristic and the optimization was conducted for each group. Analytical challenges deriving from complex matrix were tackled with optimizing cleaning processes which were based on solid-liquid extraction followed by solid phase extraction, but also with adjusting chromatographic separation. Basic and acidic conditions were used in both cleaning and liquid chromatography tandem mass spectrometry (LC-MS/MS) runs. High matrix effect was observed in soil and sludge samples. Ash and biochar samples were less complex, presumably due to their lower organic matter content. However, sorption of the analytes to the ash and biochar materials reduced their recoveries remarkably. The developed methods will be used in the SUDDEN project to produce novel information on the occurrence of APIs and their selected metabolites in sludge-based fertilizers and in sludge-amended soils. The work will help identify substances causing the highest risks in the soil environment.

8.04.P-Th221 Analytical Techniques and Associated Challenges in the Determination of Trifluoroacetic Acid and Other Very Persistent and Very Mobile Substances in Aqueous Environmental Samples

Maria Björnsdotter¹, Ingrid Ericson Jogsten², Leo Yeung², Anna Kärrman² and Marinella Farré Urgell³, (1)MTM Research centre Örebro University, Spain, (2)Örebro University, Sweden, (3)Institute of Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain

Interest in analyzing small and polar molecules has increased over the past decade. This is a result of the increased attention on substances that are considered persistent, mobile, and toxic (PMT), or very persistent and very mobile (vPvM), due to their expected accumulation in the water cycle. A well-known example is trifluoroacetic acid (TFA), which has been found in environmental samples around the world. Recent attention to substances such as TFA has resulted in the emergence of analytical techniques suitable for the analysis of polar molecules, such as mixed-mode liquid chromatography (MMLC), hydrophilic

interaction liquid chromatography (HILIC), and supercritical fluid chromatography (SFC). The analysis of polar molecules is often hampered by matrix effects due to co-elution with inorganic ions, and mass-labelled standards are not often available. Blank contamination is a common challenge associated with the analysis of TFA, and large variations in recovery during extraction by weak anion exchange solid-phase extraction (WAX-SPE) have been observed. The aim with the present study was to compare different analytical methods for the analysis of TFA and other PMT/vPvMs in aqueous samples, and to address some of the associated challenges. Chromatographic separation of TFA and other PTM/vPvMs was tested using SFC, MMLC, and HILIC. A method based on direct injection analysis with SFC coupled to tandem mass spectrometry after 1:1 dilution in methanol was applied for the determination of TFA in various water samples ($n = 33$). The method was evaluated and compared to a method based on WAX-SPE in terms of method performance. All of the chromatographic techniques tested were shown to be suitable or potentially suitable for the separation of TFA and related substances. While large variations in extraction recovery of TFA (7–42 %) was observed by WAX-SPE in selected test samples ($n = 3$), the recovery by direct injection (due to ion signal effects), was consistent (81 ± 0.4 %). The observed concentrations were up to 600 times lower by WAX-SPE, and the detection frequency was 30 %, compared to 61 % by direct injection. Direct injection using SFC was shown to be advantageous in terms of method performance and is suitable for the analysis of TFA in samples in which the concentration meets the relatively high detection limit. It is a fast and cost-effective method which may be further optimized to include other target analytes of interest.

8.04.P-Th222 Are PMOCs Less Toxic? Linking Physicochemical Compound Properties With Measured Toxicity

Milo Leon de Baat¹, Renske Hoondert¹, Tessa Pronk² and Thomas L ter Laak³, (1)KWR Water Research Institute, Netherlands, (2)KWR Water Research Institute, Netherlands, (3)KWR, Netherlands

Persistent and mobile organic chemicals (PMOCs) are gaining attention as a threat to the quality of water resources. The high mobility (i.e. polarity) of these chemicals allows them to pass through subsurface environments and evade sorption-based water treatment processes. Their persistence means that (bio)degradation processes have only a very limited effect on their concentrations throughout the water cycle. This leads to the presence and likely accumulation of PMOCs in water that may also act as a source for drinking water production. Yet, given the only recent attention to this vast group of compounds and the analytical challenges that researchers face, little is known about their toxicity. As a result, despite the growing body of environmental concentration data, risk assessment of PMOCs remains in its infancy. To address this knowledge gap, the present study aimed to gain insight into the toxicity and toxic mechanisms in relation to the physicochemical properties that determine the persistence and mobility of chemicals in the environment. The high polarity of these compounds may mean that they interact less with tissues, cell membranes, and receptors than their lipophilic counterparts, leading to lower compound toxicity. Therefore, it was hypothesized that the mobility of PMOCs makes them inherently less toxic than non-polar compounds. To test this hypothesis, a dataset was compiled matching physicochemical data for 3360 water-relevant compounds with their measured effects in 534 unique toxicity tests from the ToxCast program. A random forest analysis identified the physicochemical properties that relate most strongly to the induced effects and regression analyses quantified the strength and direction of these relationships. This indeed showed that compound properties related to polarity, particularly K_{ow} and K_{oc} , are inversely related to effect concentrations, confirming that more polar compounds are, generally, less toxic. The mechanistic clustering of the toxicity tests allowed the derivation of trends and mechanisms explaining the observed results. Although PMOCs appear to be inherently less toxic than more hydrophobic compounds, their diversity and pervasiveness in water cycles warrant further investigations into their potential threat to water quality. The here acquired mechanistic understanding of the link between compound properties and toxicity can aid the (environmental) health risk assessment of PMOCs to safeguard valuable water resources.

8.04.P-Th223 A Comparison of Species Sensitivity Distributions (SSDs) for Fish and Aquatic LIFE Stages of Amphibians

Lea Weinisch¹ and Lennart Weltje, Prof. Dr.², (1)BASF SE, Germany, (2)Ecotoxicology, BASF SE, Germany

Acute fish testing is a standard data requirement for crop protection product registration. The fish acute test yields a 96-h LC50 which is used with an assessment factor (AF) of 100 in the EU aquatic risk assessment (RA). A common refinement option for the acute RA is the species sensitivity distribution (SSD), a cumulative distribution fitted to at least 5 LC50 values from different fish species. Then, the hazardous concentration for 5% of species (HC5) is derived from the SSD and used in the RA with an AF of 9. There is no requirement to test aquatic life stages of amphibians, but there is a requirement to assess available data (e.g., from public literature). The common approach is to assume that fish cover the sensitivity of the aquatic life stages of amphibians, which has been confirmed by several data reviews (EFSA, 2013; Weltje et al., 2013). However, it has also been suggested to increase the AF further to include all retrieved data points from the public literature (Ortiz-Santaliestra et al., 2018). Additionally, the scientific opinion on RA for amphibians and reptiles (EFSA, 2018) urges to perform toxicity tests with aquatic amphibian life stages. However, this suggestion clearly contradicts the wish to reduce animal testing as per regulation EU 1107/2009. Finally, the AGD (EFSA, 2013) states that it should be checked whether a refined fish RA (e.g., with an SSD) still covers the aquatic amphibian life stages. Therefore, we constructed SSDs for fish and amphibians for 15 insecticides and fungicides, using active substance and formulation data. Herbicides were not included due to (known) formulation effects. LC50 values for amphibians and fish were obtained from the U.S. EPA ECOTOX database, supplemented with scientific and regulatory literature. SSDs were calculated for fish and amphibians separately and for the combined dataset to investigate 1) sensitivity differences and 2) if fish and amphibians are part of the same aquatic vertebrate SSD. Our analyses suggest that fish and amphibians are indeed part of the same aquatic vertebrate SSD, and that fish are often more sensitive than amphibians. **References** EFSA 2013. *EFSA J*, 11, 3290EFSA 2018. *EFSA J*, 16, e05125Ortiz-Santaliestra et al., 2018. *Ecotoxicol*, 27, 819 Weltje et al., 2013. *Env Toxicol Chem*, 32, 984

8.04.P-Th224 Behavioral Alteration in Zebrafish Following Early LIFE Exposure to Perfluoroalkyl Substances

Jonas Zetzsche¹, Coralie Yon², Steffen Keiter² and Manon Fallet³, (1)Goethe University Frankfurt am Main, Sweden, (2)Orebro

University, Sweden, (3)MTM Research centre Örebro University, Örebro, Sweden

Poly- and perfluoroalkyl substances (PFAS) have received worldwide attention due to their persistent, toxic and bioaccumulative properties. PFAS were used extensively in firefighting foams, textiles, and paper products and can nowadays frequently be detected across all environmental matrices. Among PFAS, perfluorooctane sulfonic acid (PFOS) is the most studied compound. Among other effects, it has been shown to cause developmental toxicity and neurotoxicity in many different vertebrate species including zebrafish. Present research found that PFOS accumulates in the brain, hinders neuronal growth, and causes behavioral alterations. These alterations include hyperactivity in stressful situations. Perfluorobutane sulfonic acid (PFBS) is now often used as a replacement for PFOS, since it's considered as less toxic and bioaccumulative. However, preliminary own results show an adverse effect on an individual level of PFBS. However, the effect of PFBS on the nervous system of fish and related alterations of the behavior with direct consequences on the survival remains unknown. Therefore, the major aim of this project is to investigate behavioral alterations of zebrafish (*Danio rerio*) at different early life stages caused by PFOS and PFBS. Zebrafish embryos were exposed from 1 hour post fertilization (hpf) to 28 days post fertilization with two concentrations of PFOS and PFBS. The behavior of zebrafish larvae was investigated at 120 hpf and 144 hpf using a larval photo-motor response analysis (LPMR) and a vibrational stimulus (VS) test. At adult stages, anxiety response was analyzed with a novel tank diving test (NTT). The results indicate a concentration dependent effect of PFBS, though this should be validated in future projects. Moreover, PFOS induces a reduction in fish mobility when faced to a stimulus mimicking a predator presence (light off) and an anxiety increase in response to tapping stress. Our results show that PFOS and PFBS alter the behavioral responses of zebrafish larvae in the presence of predators or in stressed situations. The NTT test is still ongoing. With our results we will decipher further the understanding of the toxicity of both chemicals and their adverse effect on behavior.

8.04.P-Th225 Bioaccumulation of Pharmaceuticals and Endocrine Disrupting Chemicals in Macrophytes

Marina Veseli¹, Iva Kokotović², Ivana Grgić³, Antun Alegro², Marko Rožman³ and Ana Previsić², (1)University of Zagreb, Faculty of Science, Department of Biology, Zagreb, Croatia, (2)University of Zagreb, Faculty of Science, Department of Biology, Croatia, (3)Ruđer Bošković Institute, Croatia

Pollution with sewage effluents causes the presence of various emerging contaminants, like pharmaceuticals (PhACs) and endocrine disrupting chemicals (EDCs), in surface waters worldwide. Their environmental fate and effects on aquatic biota are still largely unexplored. Macrophytes, aquatic plants and mosses, are often used in phytoremediation experiments, due to their ability to accumulate various contaminants from the environment. Macrophytes could, therefore, potentially act like storage units for some of the PhACs and EDCs and could reintroduce them into environment through food webs. In order to examine the bioaccumulation patterns of the PhACs and EDCs in macrophytes, we conducted a field study on five rivers in Croatia. We selected 10 sampling sites to represent effluent impacted watercourses and clean controls. In addition to macrophytes, we also sampled water and biofilm at each site. Samples were screened for contaminants using an ultra-performance liquid chromatography (UPLC) system coupled to a quadrupole time-of-flight mass spectrometer. A total of 23 compounds were detected, mostly additives and industrial chemicals. Water samples from impacted sites had generally highest numbers of detected compounds, followed by macrophyte samples, whereas lowest number was detected in biofilm samples. We also aimed at testing the potential variation of PhACs and EDCs bioaccumulation patterns between mosses and higher aquatic plants, however, preliminary results indicate that there are no differences. Furthermore, in order to assess possible differences in distribution of accumulated PhACs and EDCs in different parts of aquatic plants, roots and leaves were analysed separately. Similarly, lower (older) and upper (new) shoots of mosses were analysed separately. Nevertheless, there were no clear trends in number of compounds detected in different parts of both macrophyte groups. The current study contributes to providing understanding on the role of primary producers, such as macrophytes, in accumulation of PhACs and EDCs in aquatic environments.

8.04.P-Th226 Biodegradation of Weathered PE and Bioplastic Films in Seawater

Frederik Agger¹, Karin Mattsson², Martin Hassellöv², Tabea Meyerjuergens², Juliana de Lima², Eva Sonnenschein¹ and Nanna B. Hartmann¹, (1)Technical University of Denmark (DTU), Denmark, (2)University of Gothenburg, Sweden

It is widely documented, that plastic debris is present in the marine environment: from coastal areas to the open ocean, from surface to seabed. It has been estimated that millions of tons of plastic waste enters the ocean due to waste mismanagement. Floating plastics, and beached plastic litter, are continuously exposed to UV light, causing surface alterations. Also, biofilms are formed through the attachment of natural marine bacteria and other microorganisms. In this study, we have investigated the biodegradation of plastic films in seawater: pristine polyethylene (PE) films, UV-weathered PE films and bioplastic (starch blend) films. UV weathering was performed using an ATLAS Suntest XLS+ chamber, with a cycle of flooded and dry conditions, to imitate tidal waters. Material characterization of the UV-weathered PE films in the SEM and FTIR showed oxidative degradation by formation of cracks and oxidized functional groups. Formation of anhydrides as reaction product of carbonyl groups suggests a high degree of degradation for the UV-weathered PE compared to the pristine material. Biodegradation tests were carried out following ISO 23977-2:2020 with modifications based on OECD TG306F. The tests were performed using an Oxitop® closed bottle system incubated for 28 days at 20 deg C. Biodegradation was investigated in natural seawater (collected at Kristineberg, Sweden) as well as in seawater with addition of marine bacteria isolated from plastics (bioaugmentation). The biological oxygen demand (BOD) was monitored based on the generation of CO₂, absorbed by NaOH pellets, and measured as a decrease in pressure inside the bottles. The biodegradation was then expressed as BOD in percentage of Theoretical Oxygen Demand (ThOD). Results demonstrate a microbial activity of the seawater, sufficient to degrade a known biodegradable reference material (cellulose). Biodegradation further increased with bioaugmentation. Bioplastic films were found to degrade to a larger extent than PE films. A low degree of PE degradation was observed during the 28 days period, independent of UV weathering. This study

demonstrates the feasibility of a standardised test setup for degradation testing, with the purpose of obtaining insights into the parameters governing biodegradation of plastics in the marine environment.

8.04.P-Th227 Biological Assessment of Pesticide Effects at Swedish Monitoring Sites

Alina Koch¹, Bodil Lindstrom² and Mikaela Gönczi³, (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden, (2)Swedish University of Agricultural Sciences, Sweden, (3)Swedish University of Agricultural Sciences (SLU), Sweden

For sustainable management of agricultural landscapes there is a need to evaluate biological effects of pesticides. In this study, monitoring data from 2010 to 2019 from four national monitoring streams in Sweden were evaluated. Pesticide concentrations in water samples (weekly averages of 100 subsamples) and biological samples, benthic invertebrates and benthic diatoms (yearly samples), were evaluated. Based on these data, and existing toxicity data from the Pesticide Properties Database, biological indicators were calculated to estimate the impacts on aquatic ecosystem. The results show that a relatively diverse community of invertebrates occur in the streams, on average 23-30 species. However, there was a significant decrease of number of species at the two sites in central Sweden between 2010 - 2019 (Mann-Kendall trend test $p < 0.05$). Proportions of deformed valves of diatoms (%) showed for some year's exceedance of the 2% effect level, which indicate effects of heavy metals or pesticides. Calculated eutrophication indexes for both algae and invertebrates showed typical nutrient-rich conditions for all sites. Values for the benthic invertebrate index SPEcies At Risk (SPEAR) ranged between 0 – 0.18 at all sites, which means the amount of sensitive species compared to tolerant species is rather low. The values show greater impact of benthic invertebrates at the four sites compared to other streams in southern Sweden. The Pesticide Toxicity Index (PTI) sums up detected concentrations of pesticides, here up to 120, in surface water and are compared to their toxicity levels. PTI showed higher values for the two sites in the south of Sweden compared to the two sites in central Sweden, indicating larger effects of pesticides. An explanation is that the amount of pesticides used in the south of Sweden is higher, due to e.g. warmer climate and the use of crops with intensive pesticide use. No specific time trends or correlations could be seen for the PTI and SPEAR index. The indexes indicate that the four monitoring sites are affected by nutrients as well as by pesticides. The indirect assessment of biological effects of pesticides using indexes such as proportions of deformed valves of diatoms and SPEAR can help to understand integrated effects over time and quantifying more directly effects on organism communities.

8.04.P-Th228 Biotransformation of Phenylarsenic Chemical Warfare Agents in Marine Environment

Hanna Niemikoski¹, Matti Kjellberg², Raisa Turja³, Noora-Kaisa Rantanen Rantanen², Anna Reunamo⁴, Kari Lehtonen⁴ and Paula Vanninen⁵, (1)Finnish Environment Institute (SYKE), Helsinki, Finland, (2)Finnish Institute for Verification of the Chemical Weapons Convention, Finland, (3)Marine Research Centre, Finnish Environment Institute, SYKE, Helsinki, Finland, (4)Finnish Environment Institute, Finland, (5)VERIFIN, University of Helsinki, Finland

After World War II, extensive dumping operations of chemical weapons (CWs) took place in the Baltic Sea area and the Skagerrak Strait, where the loads of dumped CWs were approximately 50,000 and 170,000 tons, respectively. Abandoned CWs containing toxic chemical warfare agents (CWAs) have raised concern not only for environmental but also safety reasons. Studies have shown that corroded munitions containing toxic CWAs are leaking and therefore causing a risk to the marine environment. Especially phenylarsenic chemicals, such as Adamsite and Clark-related chemicals, are of great interest due to their bioaccumulative potential and toxicity in marine organisms. Phenylarsenic chemicals have already been found in marine biota species living in the vicinity of different dumping areas. The ongoing the WARTOX project (2021-2023) funded by the Academy of Finland investigates the mechanisms of phenylarsenic CWA biotransformation in Baltic Sea sediments and their toxicity. The project aims to characterize the main microbial groups responsible for the formation of biotransformation products in the sediment and to develop targeted chemical analysis methods for the identified compounds, in order to assess the total burden of phenylarsenic CWAs in marine sediment. Previously unreported degradation products of phenylarsenic CWAs, such as sulfur-containing and methylated compounds, have been found in sediment samples collected from the known dumping sites. In the WARTOX project, studies now show that the microbial groups present in the sea sediment are impacting the transformation of CWAs to these novel, sulfur-containing compounds. Similarly, the sediment microbiota may be responsible for the production of methyl-containing derivatives of the dumped CWAs. In the framework of the WARTOX project, the toxicity and sublethal effects of the these novel biotransformation will be assessed, utilizing model aquatic species. The effects of CWA-related phenylarsenic chemicals on marine biota is still poorly understood as well as their environmental behavior is unknown. The information on the bioaccumulation of CWA-related phenylarsenic chemicals, their metabolism, toxicity, and biotransformation products present in the marine environment is essential for enhanced risk assessment related to sea-dumped chemical munitions.

8.04.P-Th229 Can Bacterial Growth Be Used As an Indicator for Biodegradation of Chemicals in a High Throughput Screening Test for Readily Biodegradability?

Aina Charlotte Wennberg¹, Merete Grung² and Adam Lillcrap³, (1)NIVA - Norwegian Institute for Water Research, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)NIVA Norwegian Institute for Water Research, Norway

Standard biodegradation screening tests (BSTs) are laborious and time consuming, thus limiting the number of chemicals that are feasible to test in the laboratory at the same time. Modelling tools, such as BIOWIN for predicting biodegradation, have limited applicability domains. In the current project, we identified a list of 250 chemicals in Norway that should be prioritized for evaluating endocrine disrupting properties and environmental risk assessment. A high throughput screening test that would be applicable for water soluble and non-volatile down the drain substances and that can be adopted to automation is warranted to test the biodegradation potential of many chemicals. Standard BSTs are growth linked biodegradation tests, meaning the chemicals are usually added at a concentration that would result in growth and increase in bacterial biomass. Using a flow cytometer with a plate

reader, bacterial number can be measured for a large set of samples. To allow for high throughput and automation, incubation of environmental inoculum with test chemicals were performed in deep well plates with 1.2 ml sample per well. However, this small volume might make the already stringent BST even more rigorous as the number of bacteria, exposed to the chemical, would be even lower than in standard BSTs. Increasing the cell concentration in the wells are not an option, as there seems to be a saturation limit for growth, meaning that at high cell densities, biodegradation of chemicals is used for respiration only, not growth of biomass. To compensate for low bacterial abundance in the system, methods for enhancing the activity of the microbial community was tested: yeast extract was either added as a co-substrate at a concentration 1 to 100 times lower than test chemical concentration or added to inoculum and incubated for one week to adopt the inoculum to laboratory conditions before adding test chemicals. A set of eight reference compounds were included in the test method development: two readily biodegradable substances aniline and sodium benzoate used in standard BST, four biodegradable compounds with variable biodegradation rates (4-nitrophenol, oxipurinol, trimethoprim, benzotriazol), and two non-degradable compounds (acesulfame and sucralose). Four different inoculum sources were tested: activated sludge from a WWTP, water from an urban river, seawater, and water from laboratory cultures of *Daphnia magna*. Results from this experiment will be presented.

8.04.P-Th230 Cell- and Mathematical-Based Model Describing Synergistic Effects of Aromatic Hydrocarbons and Azoles on the CYP1A Biomarker

Maja Edenius¹, Shirin Fallahi², Anne Farbro³, Torbjorn Lundh⁴ and Malin Celander¹, (1)University of Gothenburg, Sweden, (2)University of Bergen, Norway, (3)Sahlgrenska University Hospital / University of Gothenburg, Sweden, (4)Chalmers University of Technology / University of Gothenburg, Sweden

Up to 140,000 chemicals are currently on the market in Europe and USA and many of these end up in the aquatic environment. Alternative in silico models are needed since it is impossible to experimentally test each potential chemical combination. Mathematical models can help us predict potentially harmful chemical mixtures while minimizing the number of required experiments. Induction of the aryl hydrocarbon receptor (AhR)-cytochrome P450 1A (CYP1A) signaling pathway, which mediates xenobiotic elimination, is commonly used as a biomarker for aromatic hydrocarbon exposure. However, AhR-CYP1A signaling can be affected by other chemicals, such as azoles. Azoles are a broad class of anthropogenic chemicals used as pharmaceuticals and pesticides, which are found in measurable quantities in the aquatic environment. Azoles are also known to inhibit vertebrate CYP enzymes, including CYP1A. We hypothesize that modulation of the AhR-CYP1A pathway by one chemical can affect the metabolism of another chemical that is modified by the pathway, by altering its biological half-life. We have developed a mathematical toxicokinetic model based on experimental data from a fish cell line (PLHC-1) that describes CYP1A and cellular chemical concentrations over time upon exposure to mixtures of the aromatic hydrocarbon, benzo(a)pyrene (BaP) and the azole, clotrimazole (CLO). We have exposed PLHC-1 cells to various combinations of these two chemicals and measured cellular chemical concentrations via GC-MS, CYP1A mRNA expression via qPCR, and CYP1A enzymatic activity via EROD assay at several time points. As expected, BaP and CLO mixtures result in synergistic (more than additive) and prolonged induction of CYP1A mRNA and enzyme activity. Based upon the known signaling pathway we developed a mathematical system of 10 ordinary differential equations to model AhR-mediated induction of CYP1A expression and cellular chemical concentrations. A portion of our experimental data was used to fit and parametrize the model while additional data not used in parametrization was used to validate the model. The model successfully describes the observed synergistic effects in CYP1A expression and enzymatic activity induced by combination CLO and BaP exposure and models cellular chemical concentrations over time. Mathematical models that describe cellular mixture toxicity mechanisms can help better predict mixture toxicity while minimizing the number of needed animal experiments.

8.04.P-Th231 Characterization of Non-Combustion Particulate Emissions From Rail Transport

Gina Bode¹, Karsten Braune², Andreas Schaeffer³, Daniel Fruhwirt⁴ and Sabrina Michael¹, (1)German Centre for Rail Traffic Research at the Federal Railway Authority, Dresden, Germany, (2)German Centre for Rail Traffic Research at the Federal Railway Authority, Germany, (3)Institute Environmental Research, RWTH Aachen University, Aachen, Germany, (4)Graz University of Technology, Austria

Transport-related emissions have been in focus of environmental protection for many years. For a holistic assessment of transport-related particulate emissions all modes of transport have to be considered. Rail transport is known as one of the most environmentally friendly transport systems. However, in addition to combustion-related emissions, abrasion from daily operation as well as infrastructure construction and maintenance measures represent a source of particulate matter. Studies regarding the different source contributions, particle size distribution, particle composition, and morphology of particulate emissions from rail transport have been scarce, making it difficult to assess the hazard potential. Therefore, further investigations are intended to close the gaps of knowledge in the field of non-combustion particulate emissions from rail transport. In a first project, the emission of particulate matter during infrastructure construction and maintenance work was investigated by means of aerosol spectrometry. Additionally, a part of the particulate matter samples was investigated by SEM-EDX to obtain information on chemical composition and morphology of the particles. Mineral components of gravel, as well as parts of elements relevant to railroads, e.g. aluminium, iron and copper from abrasion processes were identified. Therefore, current investigations within the framework of the BMDV Network of Experts, a research program financed by the German Federal Ministry for Digital and Transport (BMDV), focus on emissions from wheel-rail, contact wire and brake abrasion. Particulate matter at different test benches and in the field will be analyzed regarding its particle size, mass distribution and chemical composition. Based on the collected data, dispersion calculations will be carried out and consequences for the environment are highlighted. Moreover, a study on abrasion induced emissions will provide information on the particulate morphology (SEM-EDX) and its fate in the environment. Based on the

overall results, an initial risk assessment can be made, which will allow a significant contribution to closing the knowledge gaps and to gain a holistic understanding of particulate emissions in rail transport.

8.04.P-Th232 Characterizing the Effects of Chronic Conventional Heavy Crude Oil Exposure on the Growth, Development, and Behaviour of Larval Wood Frog (*Lithobates sylvaticus*)

*Adam Scott*¹, *Aidan Guttormson*², *Vince Palace*³, *Lisa Peters*², *Gregg Tomy*⁴, *Caleb Hasler*⁵, *Mark Hanson*² and *Jose Luis Rodriguez Gil*³, (1)University of Manitoba, Winnipeg, Manitoba, Canada, (2)University of Manitoba, Canada, (3)IISD Experimental Lakes Area (IISD-ELA), Canada, (4)Fisheries and Oceans Canada, Canada, (5)University of Winnipeg, Canada

Much like oil transportation pipelines, amphibians are distributed worldwide, spanning a variety of ecosystems. Despite an identified need for additional information, few studies have examined the effects of oil spills on the early life stages of this group. Beginning in 2019, two parallel oil spill studies have been conducted at the International Institute for Sustainable Development Experimental Lakes Area in northwestern Ontario, Canada. The Freshwater Oil Spill Remediation Study (FOReSt) used in-lake enclosures to determine the effectiveness of non-invasive oil spill remediation techniques in different shoreline habitats and the Floating Wetland Treatments to Enhance Remediation (FLoWTER) study examined the efficacy of symbiotic plant-microbe relationships for *in situ* degradation of oil-derived hydrocarbons. In 2021, the effects of *in situ* chronic exposure to conventional heavy crude oil (CHV) (FOReSt study) or a CHV water-accommodated fraction (FLoWTER study) on the biochemistry, growth, development, and behaviour wood frog (*Lithobates sylvaticus*) tadpoles were characterized. Developmental and morphometric measurements were combined with the assessment of bioaccumulation and proteomic techniques to determine the effects of CHV exposure on the tadpoles. Bioaccumulation was quantified using a gas chromatography/tandem mass spectrometer to analyze total polycyclic aromatic compounds in whole body tadpole tissues. Another objective of the FLoWTER project was to characterize the influence of engineered floating wetland (EFW) presence/ absence on wood frog tadpoles. Within the FLoWTER project, weekly behavioural assays were applied to a subset of tadpoles to examine sociality, activity, and predator avoidance behaviours when compared to positive and negative assays. Results from the listed endpoints will be presented. Preliminary findings suggest the presence of a treatment effect on mean Gosner stage in the FLoWTER project. Effects on apical endpoints of oil treatments compared to uniled treatments in the FOReSt project will be discussed. This research will provide much needed data on the toxicological effects of CHV on amphibians which can then be used to inform risk assessment related to the over-land transportation of crude oil and potential impacts of freshwater oil spills on amphibians.

8.04.P-Th233 Chemical Strategy for Sustainability and Crop Protection Products: Untangling Interlinks Across the EU Regulatory Landscape

*Dragan Jevtic*¹, *Doerthe Grebel-Koehler*¹ and *Laurent Oger*², (1)Bayer Crop Science, Germany, (2)CropLife Europe, Belgium

European Union's chemicals regulatory framework is widely acknowledged as one of the most advanced systems in the world, ensuring high level of protection to human health and the environment. It encompasses numerous interdependent regulations covering a broad range of compounds and uses, such as industrial chemicals, plant protection products, biocides, chemicals in food and feed, fertilisers, medicinal and veterinary products, and cosmetics. However, the interlinks between different pieces of legislation may not always be given sufficient consideration – especially in a quickly-evolving regulatory landscape shaped by initiatives balancing state-of-the-art science with bold political vision. One such initiative is European Commission's "Chemicals Strategy for Sustainability" (CSS), intended to "boost innovation for safe and sustainable chemicals, and increase protection of human health and the environment against hazardous chemicals". The CSS publication kicked off a process of unprecedented ambition as it calls for revision of several pieces of legislation beyond core regulation, the launch of numerous non-regulatory initiatives and the engagement of a broad range of stakeholders, and that in a relatively short timeframe. During the discussions taking place throughout 2021 in various expert and political fora it became evident that the overhaul envisioned by the CSS was primarily focused on chemicals managed under REACH Regulation. Chemicals such as plant protection products (PPP) were not given sufficient attention, as the potential impact on sectorial legislation was not properly understood. This work presents an analysis of regulatory interlinks between different pieces of EU legislation, focusing on PPPs. We will show how changes proposed for REACH and CLP regulations (among others) can impact not just the approval of plant protection products in the EU, but also challenge the very foundation of risk-based approaches imbedded into PPP Regulation.

8.04.P-Th234 Chlordecone Uptake in Grasses: Relationship to the Anatomy and Physiology

*Sophie Lorber-Pascal*¹ and *François Laurent*², (1)INRAE, France, (2)Toxalim, INRAE, Toulouse, France

Chlordecone (CLD) is an organochlorine insecticide used to struggle against banana weevil (*Cosmopolites sordidus*) in French West Indies between 1973 and 1992. It is a long-term contaminant of soils and aquatic environment, classified as POP since 2009. Now, it pollutes banana watershed from banana fields to surface and marine waters. Plants growing in contaminated soils lead to human exposure by food, particularly by vegetable consumption. For livestock, the contamination through consumption forage grass-based, for a part. The accumulation of CLD in plants is a passive mechanism. It is highly variable and must depend on their physio-anatomical characteristics. Currently, no remediation method is or can be used on the huge polluted areas. So, the use of plants with efficient CLD extraction capacity could be a process of interest. Here, we had investigated which anatomical or physiological factors are favorable to the CLD uptake and accumulation in plants. Radiolabeled [¹⁴C]-CLD was used to study the CLD uptake and translocation to grass shoots growth in hydroponic conditions. CLD concentrations in wheat shoots were 5 higher than maize ones. As wheat had a poorer water use efficiency than maize (2.9 and 5.7 g.l⁻¹), it efficiently accumulated CLD in ratio of its biomass. In contrast, *Miscanthus giganteus*, with a WUE (6. g.l⁻¹), similar to that of maize, accumulated 6 times less CLD. The apparent TSCF (ratio of CLD absorbed to transpired water volume) is 14 times higher for wheat than for *M. giganteus*. This indicated various retention mechanism in CLD uptake according to plants. In addition to the presence of a rhizome, as in

Miscanthus spe, the anatomy of the roots contributed to this retention. Thus, CLD uptake in wheat roots was easier than in maize roots. The transfer rate through the rhizoderme was 5 times higher in wheat roots (6.8 vs. 1.3 ng/mm².h for maize). In contrast, the accumulated amount was twice as high in these last. That seemed correlate with higher dry matter and lipid contents in maize roots. The higher number of cell layers in these last (8 or 9 in maize and 3 in wheat) contributed to reduced CLD flux. In conclusion, the wheat CLD uptake was more efficient because both its higher rate of transpiration and a weak CLD root retention. These differences were of great interest to select plants for an efficient CLD remediation management. That was also useful to the monitoring of the chemical quality or forage for livestock risk assessment.

8.04.P-Th235 Chronic Effects of Venlafaxine and Its Main Metabolite O-Desmethylvenlafaxine on the Mollusk *Hydrobia ulvae*

Philip Thomassen¹, Tine Engelund² and Henriette Selck³, (1)Institute for natural science and the environment, Roskilde University, Roskilde, Denmark, (2)Roskilde University, Denmark, (3)Roskilde University, Roskilde, Denmark

Venlafaxine (VEN) is a widely used antidepressant with 2643 kg prescribed in Denmark in 2020 alone. Venlafaxine and its main metabolite O-desmethylvenlafaxine (ODV) is released to the environment through the wastewater treatment plants, and recent studies have shown its worldwide distribution in river waters. Little is known about the ecotoxicological effects of VEN and ODV. The study aimed at assessing the environmental impact of sediment-associated VEN and ODV on a common mudsnail, *Hydrobia ulvae*, by examining important physiological and behavioral modalities related to behavioral effects. The deposit-feeding mollusk *H. ulvae* is widely distributed and abundant in Danish fjords and coastal waters. Three experimental setups were used to investigate the chronic effects of sediment-associated VEN and ODV on *H. ulvae*, using sediment concentrations of 0 (i.e., control) 0,01, 1 and 100 µg VEN or ODV /L. We examined: 1) The ability of *H. ulvae* to detect and avoid VEN and ODV contaminated sediment using two groups of snails; taken directly from the laboratory culture or pre-exposed to VEN or ODV for 26 days. 2) Feeding rate of *H. ulvae* before and after a 26 day exposure to VEN or ODV. 3) Growth rate of juvenile *H. ulvae* during a 26 day sediment exposure period to VEN or ODV. The results will be discussed.

8.04.P-Th236 Contamination of Food Through Microplastic From Plastic Cutting Boards

Rana Zeeshan Habib¹, Vijo Poulouse², Rana Al saidi², Ruwaya Al Kendi², Syed Haris Iftekhar², Abdel-Hamid Mourad², Wajeeh Kittaneh² and Thies Thiemann², (1)Biology, United Arab Emirates University, Al Ain, United Arab Emirates, (2)United Arab Emirates University, United Arab Emirates

Plastic cutting boards have been found to be the source of microplastic (MP) contamination in different foods, including beef, goat meat, and chicken as well as fish. In the cutting process of these foods, the boards emit small plastic pieces that either attach to the surface of the food or embed in the food itself. In this research, cut food samples were acquired from butchers, a fish market, and a supermarket chain in the Middle East. The samples were digested in 9.1 w% aq. KOH at 75°C for 10h. The cooled samples were filtered. The MP obtained was weighed and subjected to optical microscopy and infrared spectroscopy. The quantity and size distribution of the particles was determined using Fiji ImageJ software. Differential scanning calorimetry was carried out to understand the thermal behavior of the particles. The mean size of the MP in the raw meat (goat and beef) was found to be 1279.2 ± 835.0 µm. The maximum amount of MP observed in any of the foods was 1.64 ± 0.46 particles/g (goat) meat. Extensive washing of the meat reduced the MP count, but in all cases, residual contamination remained (min. 0.07 ± 0.05 particles/g). Chicken meat and fish contained fewer MP. Washing of the cutting boards with a high-pressure water stream after each cutting process reduces the MP count, but does not ensure that the next cut sample is free of MP. IR spectroscopy showed the MPs to be polythene. Meat containing MP was cooked in a pressure cooker, where MPs in the meat melted and recrystallized. Spent plastic cutting boards were acquired from butchers. From the 3D photo of a typical spent cutting board, it was calculated that 875 g polythene was emitted by the end of its lifetime, where 400 kg of goat meat has been cut. This would mean that one finds 2.2 mg plastic per g of cut goat meat so that on average 50% of the plastic will wash into the drain and either be retained in wastewater treatment plants or will be dispersed in the environment. This makes plastic cutting boards in the Middle East markets another significant contributor to MP in wastewater in certain regions. In addition, plastic cutting boards could be a source of MP in the environment.

8.04.P-Th237 Crude Oil Identification Using Linear Discriminatory Analysis (LDA) of Bicyclic Sesquiterpane (Bicyclane) Profiles in the Adipose Tissue of Exposed Fish

Francis Spilsbury¹, Alan Scarlett², Steven Rowland³, Kliti Grice² and Marthe Monique Gagnon², (1)School of Molecular and Life Sciences, Curtin University, Australia, (2)Curtin University, Australia, (3)University of Plymouth, United Kingdom

Bicyclic sesquiterpanes (bicyclanes) are ubiquitous in crude oils and refined petroleum products, and upon exposure are sequestered in the adipose tissue of exposed fish. In this proof-of-concept study, we demonstrate the application of a linear discriminatory analysis (LDA) model to identify a source oil based on bicyclane biomarkers in adipose tissue extracts of exposed fish. In a laboratory trial, *Lates calcarifer* (barramundi, or Asian sea-bass) were exposed *via* diet (1% w/w) to a heavy fuel oil (n=9) or to Montara (n=9), a medium crude oil from the Australian Northwest Shelf, examples of which have both previously been spilled in the marine environment. An LDA model was then trained using a reference dataset of bicyclane fingerprint ratios of both exposure oils, plus four other NW Shelf crudes, two fuel oils, and eight weathered asphaltites from the Great Australian Bight for comparison. The LDA model correctly identified the respective exposure oils from a test dataset of corresponding bicyclane profiles in adipose tissue extracts of each of the 18 fish fed oil-enriched diets. This work demonstrates the potential of using adipose tissue bicyclane profiles in oil-exposed fish as a forensic identification tool for impact assessment and litigation purposes in an environmental oil spill, of particular use when the source of the spill is unclear.

8.04.P-Th238 Determining the Application of Small Extracellular Vesicles As Biomarkers of Arsenic Induced Urothelial Injury and Carcinogenesis Using a Label Free Quantitative Proteomics Approach

Nicole Washuck¹, Yingxi Li² and Laurie Chan², (1)Biology, University of Ottawa, Ottawa, ON, Canada, (2)University of Ottawa, Canada

Arsenic is a pervasive metalloid that continues to contaminate the water and food sources of millions of people globally. Among the numerous health effects of exposure are urothelial toxicity and potentially cancer. In recent years, small extracellular vesicles (SEVs) have been shown to be vital in intracellular communication and have been used in clinical studies as biomarkers of disease. Understanding the ways in which cells communicate during exposure is imperative and can allow for the detection of minimally invasive biomarkers of toxic responses. This study aims to investigate the SEV response of urothelial cells when exposed to arsenic, including the use of label-free quantitative proteomics to identify the key proteins in SEVs that are involved in early toxic response signalling. SVHUC1 human urothelial cells were exposed to 1, 2 or 5 μM sodium arsenite for 48 hours. SEVs in the culture media were isolated by differential centrifugation and were prepared for mass spectrometry using an optimized filter assisted sample preparation approach. SEV size ranged from 86-130 nm and the total SEVs released were significantly increased in transitional cell carcinoma. SEV origin was confirmed by the positive antibody array identification of several endosomal proteins. A total of 1408 proteins were identified, of which 35 were differentially expressed in arsenic exposure groups and 74 in transitional cell carcinoma. Pathway analysis revealed that those proteins differentially expressed in arsenic exposure groups were responsible for increased cell survival, migration, and invasion and decreased cancer cell death. Similar trends in pathway analysis of arsenic exposed cells and transitional cell carcinoma SEVs suggests potential links between urothelial toxicity and carcinogenesis. Further proteomics of paired cell lysate samples are being analyzed to determine if those proteins differentially expressed in SEVs are comparable to intracellular protein expression. This analysis will help to further elucidate the pathways responsible for arsenic induced urothelial injury and carcinogenesis while identifying novel non-invasive biomarkers of exposure.

8.04.P-Th239 Developing a Comparative Neurotoxicology Understanding of the Chiral Cyanotoxin Anatoxin-a in Two Common Fish Models

Lea Marie Lovin¹, Laura Langan², Sujin Kim², Raegyn Taylor³, Kendall Scarlett², Kevin Chambliss², Saurabh Chatterjee⁴, Thad Scott² and Bryan W. Brooks⁵, (1)Baylor University, (2)Baylor University, United States, (3)United States Department of Agriculture, Agricultural Research Service, United States, (4)University of South Carolina, United States, (5)Environmental Science, Baylor University, Waco, TX

Harmful algal bloom (HAB) toxins present risks to public health and the environment. The cyanotoxin anatoxin-a (antx-a) is a potent neurotoxin observed at the global level. To understand aquatic hazards of anatoxins, we initially conducted meta-analyses using probabilistic hazard assessments, observed diverse exceedances of guideline values, and identified aquatic toxicity data to be lacking, especially in terms of toxin purity, verification of treatment levels, and enantiomer specific and sublethal responses. To help address these gaps, we studied larval fathead minnow and zebrafish behavioral and molecular responses (gene expression, transcriptomics, and proteomics) following exposure to either (\pm) or (+) antx-a at environmentally relevant, analytically verified treatment levels, which were informed by probabilistic exposure distributions. We found duration and distance of fathead minnows swimming at the highest speed was significantly lowered by (\pm) antx-a in all but the lowest treatment level, while the opposite occurred with zebrafish, in which the toxin increased distance, duration, and changes in movement at the highest speed, though not significant. We examined gene expression focusing on genes related to neurotoxicity, oxidative stress, DNA damage, and hepatotoxicity. While there was little change in zebrafish, expression changes related to neurotoxicity and oxidative stress were identified in fathead minnows. This suggests fathead minnows may be more sensitive to this toxin based on these endpoints. We then studied purified (+) antx-a, the only enantiomer naturally produced, and observed high mortality in fathead minnows $>500 \mu\text{g/L}$ and largely refractory, lowered movement in zebrafish for most behavioral endpoints. These observations corroborate our sensitivity findings with (\pm) antx-a and highlights the increased toxicity of the purified enantiomer. We are currently performing gene expression analysis on these samples with an expanded profile based on tandem proteomics experiments. We further aim to develop full data independent proteomics and transcriptomic profiles using 3rd gen nanopore sequencing. Understanding of cyanotoxin effects in aquatic species under environmentally relevant conditions is necessary to support robust assessments and management of algal blooms, including improved risk predictions for HAB events.

8.04.P-Th240 Developing a Persistence Assessment Tool (PAT) to Support Consistency, Transparency and Robustness in Persistence Assessments

Christopher Hughes¹, Emma Pemberton², Megan Griffiths, MSc², Simon Cook², Alan McCullough², Dik Van de Meent³ and John Parsons⁴, (1)Ricardo Energy & Environment, Chester, United Kingdom, (2)Ricardo Energy & Environment, United Kingdom, (3)Association of Retired Environmental Scientists ARES, Netherlands, (4)IBED, University of Amsterdam, Amsterdam, Netherlands

Chemical persistence plays a key role in the determination of environmental exposure making it an important component in risk assessment and regulation. Interest in chemical persistence has increased significantly, highlighted by concerns from per- and polyfluoroalkyl substances (PFAS), (micro)plastic pollution and persistent, mobile and toxic (PMT) substances. Persistence assessment in the regulatory context involves comparing chemical degradation half-lives to set criteria for different environmental compartments (water, sediment and soil). Other information is also relevant for assessments (e.g. screening tests, non-standard experiments, QSARs, field data, etc), and should be considered following a 'weight-of-evidence' (WoE) approach. Implementation challenges remain in persistence assessments, particularly relating to guidance around the evaluation of data quality, and the WoE determination. There are also issues for substances whose properties render them difficult to evaluate using standard methods. This project, sponsored by Concawe, Cosmetics Europe and Cefic-LRI, and launched in February 2022, aims

to develop a Persistence Assessment Tool (PAT) to support the evaluation of persistence under regulatory frameworks such as EU REACH. This software tool will provide clear guidance and structure to evaluate data quality, and a quantitative WoE (qWoE) methodology to process the information input and calculate persistence conclusions. It will be applicable to all substance types and provide specific features for difficult and complex substances. The qWoE methodology will include some flexibility to allow users to adapt assessments to specific regulatory frameworks and other purposes. A further feature will be to incorporate a multimedia fate model to enable the determination of overall persistence. This will allow for potentially important additional environmental fate processes controlling persistence to be taken into account. The aim of the PAT is to provide support to practitioners responsible for undertaking persistence assessments, and to facilitate improved consistency, transparency and robustness in these assessments. During the development of the tool, we are keen to engage with the stakeholder community to seek their input and to maximise engagement. This presentation will provide an overview of the tool under development, the challenges it seeks to address, and information on how interested stakeholders can participate in its development.

8.04.P-Th241 Development of New Biobased Nanocomposites for Food Packaging Applications

Astrid Delorme¹, Tanja Radusin², Petri Myllytie², Vincent Verney³ and Haroutioun Askanian⁴, (1)ICCF - CNRS, France, (2)Norner, Norway, (3)CNRS -ICCF, France, (4)Université Clermont Auvergne, CNRS, SIGMA Clermont, ICCF, F-63000 Clermont-Ferrand, France, France

In this study, we investigate the properties of nanocomposites based on biodegradable PBSA which is food contact grade (complying to EU10/2011). We adopt the approach of mixing LDH fillers into PBSA to improve the overall durability and gas barrier properties of the nanocomposites. The commercially available SORBACID® 911 is our choice of filler due to its low-cost and also because it is listed as an acceptable material in the “Plastic Food Contact Materials” report (Regulation (EU) 10/2011). Moreover, considering that SORBACID® 911 is used on industrial scale as an acid scavenger for PVC materials it pre-sents an appropriate scalability for food packaging applications. The properties of PBSA-LDH based nanocomposites were investigated by rheological, tensile testing, thermogravimetric and optical methods, which demonstrate that the PBSA-LDH combination form compatible polymer composites with good dispersion. The addition of SORBACID® 911 fillers enhanced the gas barrier properties, in particular, the water vapour barrier, rendering the nanocomposites competitors to conventional plastic films used for food packaging [1]. Furthermore, the photo-durability of the PBSA-LDH nanocomposites is examined through accelerated photoaging and compared to natural weathering. The results demonstrate improved resistance to photodegradation and weathering compared to pristine PBSA, and the resistance towards both photoaging and weathering increases with the LDH concentration in the PBSA matrix. With the improved gas barrier properties together with increased durability of PBSA with added SORBACID® 911 we demonstrate a realistic opportunity for transitioning from non-biodegradable to biodegradable food-packaging.

Acknowledgments: The work in this paper is supported by the TERMINUS Project which is funded by the European Union's Horizon 2020 Program, under grant agreement number 814400.

8.04.P-Th242 Development of Pull-Down Assays for More Targeted, Non-Target in Highly Complex Environmental Samples

Garry Codling¹, Ludek Sehnal², Petra Mikusova³, Klara Hilscherova³, John Giesy⁴ and Jana Klanova¹, (1)Masaryk University, Czech Republic, (2)Masaryk University, RECETOX, Czech Republic, (3)Masaryk University, Faculty of Science, RECETOX, Czech Republic, (4)University of Saskatchewan, Canada

The global inventory of identified chemicals is increasing exponentially with databases including millions of natural and synthetic compounds. Chemicals that provide beneficial properties are synthesised industrially and exposure may become ubiquitous. A major challenge in protecting health and the environment is determining which compounds in use and emerging may prove to be a risk.

Effect direct analysis (EDA) first developed over 40 years ago is a tool capable of identifying the level of effect a complex mixture may have for a biological response, but it alone cannot pinpoint all compounds of effect. The development of affordable ultra-high resolution mass spectrometers over the last decade has paved the way for omics style detection but there is a trade off between identifying as much information as possible in a sample and detecting the compounds of relevance. Pull down assays may provide the tool required to filter complex mixtures to specific endpoints.

A pull-down assay uses a binding protein that normally binds specific endogenous compounds but in exposure to xenobiotics that mimic endogenous compounds can potentially also bind these compounds. Here we present the work for development of pull-down assays for Retinoic acid receptor alpha protein (RAR- α).

Proteins were synthesised in house and the extraction protocol optimised through use of known binding compounds followed by the application of the method using biological environmental samples. Extracts were ran on LC-Orbitrap-Fusion in both positive and negative with multiple positive and negative controls applied for quality control and assurance. Processing was performed using multiple free and vendor software's for cross comparison.

With complex bio-assays the pull down was capable of taking a mixture of many thousand features and through application of negative and positive controls the data was reduced to only those compounds that were bound to the protein.

This method opens the way for a more targeted approach to non-target with only the compounds of interest being pulled out from complex matrices. There will still be a need for additional compound detection and identification, but the overall data is far more manageable. The work was supported by the Czech Science Foundation Grant No. 20-04676X, and MSCA 839243.

8.04.P-Th243 Development of Relevance and Reliability Criteria for Hydrocarbon Degradation Half-Lives in Soil and Sediment

David M Brown¹, Christopher Hughes², Louise Camenzuli³, Alberto Martin-Aparicio⁴, Delina Lyon⁴, David Saunders⁵, Neil Wang⁶ and Chesney Swansborough⁷, (1)Ricardo, United Kingdom, (2)Ricardo Energy & Environment, Chester, United Kingdom, (3)ExxonMobil, Belgium, (4)CONCAWE, Belgium, (5)Shell International, Netherlands, (6)TOTAL France, France, (7)Ricardo Energy & Environment, United Kingdom

Under European environmental regulations (REACH, PPP, BPR), a PBT/vPvB assessment is required for most chemicals, taking account of the relevant constituents and transformation/degradation products. Persistence (P/vP) assessment relies on compartment specific degradation half-lives (HL), which must be compared to the criteria laid down under annex XIII of REACH. Definitive biodegradation HL data are typically derived from high tiered OECD degradation simulation tests in surface water, sediment and soil. These tests are technically complex and not applicable to petroleum UVCBs, since the test methods are most appropriate for mono-constituent substances. Difficulties in attaining such demanding P/vP assessment obligations have been recognised by regulators and some flexibility in the P/vP assessment framework exists. For example, according to REACH Annex XIII, a weight-of-evidence (WoE) approach can be used to bring in other non-standard test data to form conclusions on P/vP. Recently, efforts to improve the robustness and transparency in WoE for regulatory decision making have been described, however clear guidance is lacking regarding the assignment of reliability and relevance of data which displays naturally high variability in degradation half-lives. This can lead to useful degradation data being discarded for regulatory purposes because of a lack of certainty on how to assess their relevance. In this work, relevance and reliability criteria were developed based on non-standard test method similarity to OECD 307, OECD 308 test guidelines and concordance with ECHA guidance. A simplified scoring system of “high”, “medium” and “low” was used to assess the relevance and reliability of individual data from a database of non-standard experimental half-lives for hydrocarbons in soil and sediments covering 952 and 1243 datapoints, respectively. This approach permits data to be ‘weighted’ accordingly when drawing conclusions during P/vP assessment. These relevance and reliability criteria may inform testing entities on methods to improve the quality of the testing outcome. It is also useful for curating data to be used in predictive biodegradation models. The database, along with relevance and reliability criteria will be presented. This work is applicable to European regulations and may be extended to other relevant pieces of global legislation.

8.04.P-Th244 Ecotoxicological Effects of Sugarcane Vinasse on the Tropical Insect *Chironomus sancticarloi*

Mayara Felipe¹, Aline Bernegossi², Milena Sousa¹, Juliano Corbi¹ and Marcelo Zaiat², (1)University of São Paulo, Brazil, (2)University of Sao Paulo - USP, Brazil

Vinasse is the main liquid residue generated in the ethanol and sugar production's process. Vinasse is rich in organic matter and nutrients, with acidic pH between 4.0 and 4.5 [1]. The main destination of this residue is the fertirrigation of the sugarcane fields, which is fundamental for reducing the consumption of water and synthetic fertilizers. However, due to the huge volume generated (each liter of ethanol produces 13 L of vinasse), excessive and long-term fertirrigation can cause environmental problems. Anaerobic digestion is one of the most attractive methods for vinasse biodigestion, integrating low operating costs with the possibility of obtaining commercial added value sub-products and energy recovery as biogas in a combined system (acidogenic + methanogenic reactors) [2]. In this context, this study evaluate the effects on the survival of *Chironomus sancticarloi* exposed to vinasse *in natura* (influent) and biodigested vinasse in methanogenic reactor (effluent). The liquid matrix used in the ecotoxicology tests were the influent and the effluent of a lab-scale (2.1L) methanogenic anaerobic structured bed reactor (AnSTBR) treating sugarcane vinasse. The tests were carried out using the methodology adapted from the OECD guideline 235 [3]. Samples of vinasse (Effluent) and vinasse *in natura* (Influent) were diluted in 6 different concentrations: 0.1, 0.4, 1.56, 6.25, 25, 100% (Short-term test) and 5 different concentrations: 0.6, 0.9, 1.35, 2 and 3% (long-term test). For the short-term exposure, the Two-Way ANOVA [4] showed that the dilutions 0.1 and 0.4% were statistically similar to the control (p-value > 0.05) for both matrix. Also, the effluent 1.56% showed to be more toxic than the influent 1.56%, being statistically similar to the effluent 100% (p-value of 0.7792). Regarding the long-term test, only the interaction between the 2% dilution and the influent showed statistical different compared to the control (p-value of 0.008). The results showed that the methanogenic treatment slightly decrease the mortality rate in the short-term and long-term exposure (EC50 of 1.25% (v:v) compared to 1.66% (v:v) and EC50 of compared 1.11% (v:v) to 1.26% (v:v), respectively). However, in both exposure time vinasse showed to be extremely toxic for the *C. sancticarloi* and the reuse of the vinasse showed to be a good alternative to avoid the incorrect discharge in water bodies.

8.04.P-Th245 Effects of Diesel Exhaust Particles on the Health and Survival of the Buff-Tailed Bumblebee *Bombus terrestris* After Acute and Chronic Oral Exposure

Frederic Hüftlein¹, Dimitri Seidenath², Oliver Otti², Heike Feldhaar², Christian Laforsch² and Matthias Schott¹, (1)Animal Ecology I, University of Bayreuth, Bayreuth, Germany, (2)University of Bayreuth, Germany

Biodiversity loss is one of the main concerns in the twenty-first century. Over the last forty years approximately 60 % of the populations of mammal, bird, reptile, and amphibian species went extinct. Environmental pollution is one important driver of this loss. Anthropogenic activity, especially the diesel-powered transportation sector, is a major producer of environmental pollution in the form of micro- and nanoscale diesel exhaust particles (DEP). In addition to DEP, incomplete combustion processes produce polycyclic aromatic hydrocarbons (PAH). These PAHs are the assumed cause of the particles' toxicity. Such particle-based pollution accounts for a substantial part of respiratory diseases in mammals. However, despite of this awareness, we only know

very little of the effects of DEP and PAHs on invertebrates. A large number of wild plants are pollinated by insects, some even predominantly or exclusively by bumblebees. Close to areas with heavy traffic highly active, flying insect pollinators are likely exposed to high amounts of DEP and thus might suffer potential negative effects. Those negative effects could trigger an even greater loss of plant diversity, which pose nutrition, hiding spaces etc. to a lot of organisms. We exposed individuals of the buff-tailed bumblebee *Bombus terrestris* to different concentrations of DEP/ sugar water solution suspensions in acute and chronic oral exposure experiments to investigate dose- dependent effects of DEP on survival and fat body content, as a proxy for an insects' health condition. Acute exposure to DEP showed no effect on survival or fat body content of *B. terrestris*. However, chronic exposure to high doses of DEP lead to a significantly reduced survival of bumblebees by almost 50 % compared to controls. Further, the fat body content of DEP exposed bumblebees was significantly reduced in bumblebees exposed to 0.5 g/l DEP compared to controls. Next to the dietary exposure we investigated the effects of DEP on bumblebees via airstream. For that, we exposed the bumblebees to an airstream with defined particle concentrations and performed electroantennography and scanning electron microscopy after exposure. There was no significant reduction in amplitude intensity in bumblebees exposed to DEP compared to the control. Our results give insights into how accumulation of high concentrations of DEP e.g., near heavily trafficked sites, can influence insect pollinators' health and survival.

8.04.P-Th246 Effects of Eprinomectin on the Reproduction of Earthworms and Springtails *Raphael Souza*¹, *Cleiton Souza*², *Ana Paula Braga*³ and *José Roberto Guimarães*⁴, (1)University of Campinas UNICAMP, Brazil, (2)ASR Analytical & Scientific Research, Brazil, (3)São Paulo State University UNESP, Brazil, (4)UNICAMP University of Campinas, Brazil

Eprinomectin (EPR) is a veterinary drug belonging to the avermectin family and it is commonly used to combat a wide variety of parasites. Large quantities of veterinary drugs are used by rural producers in order to maintain the high productivity of the livestock sector and reduce financial losses caused by different diseases, but they can cause an environmental impact. Approximately 90% of EPR can be excreted in the dung of treated animals and can be found in soil in concentrations ranging from ng/g to ?g/g. So, the objective of this study was analyzing the effects of different concentrations of EPR in a tropical soil on the reproduction of earthworms (*Eisenia Andrei*) and springtails (*Folsomia candida*). For this purpose, soil was contaminated one day prior the experiments with the following concentrations of EPR: C1 = 0.5 ?g/g; C2 = 1.0 ?g/g; C3 = 2.0 ?g/g; C4 = 4.0 ?g/g; C5 = 8.0 ?g/g; C6 = 16.0 ?g/g; C7 = 32.0 ?g/g; C8 = 64.0 ?g/g; and C9 = 128.0 ?g/g (C9 was not carried out in the experiment with earthworms). As the stock solution used to contaminate the soil was prepared with ethanol, a treatment containing soil+ethanol was also performed. A negative control containing uncontaminated soil was also carried out. Experiments were based on ISO 11267 and ISO 17512-1. Ten adult specimens of springtails were placed in glass containers with 30 g of soil for 28 days and then the number of juveniles was counted; ten adult specimens of earthworms were placed in glass containers with 500 g of soil for 28 days and the counting of the number of juveniles occurred 56 days after the beginning of the experiment. According to the statistical analysis, reproduction of springtails was significantly reduced in all concentrations. The exposure of earthworms to the contaminated soil revealed significant decrease in the number of juveniles in concentrations C1, C2, C3, C6, C7 and C8. Decrease in the number of juvenile springtails can be related to the high mortality rate of adults during the exposure, indicating high toxicity to the species. Decrease in the number of juvenile earthworms has been found to other avermectin drugs, such as abamectin, by other researchers in both tropical and temperate climates. So, the results suggest that EPR can affect the reproduction of these two species of soil invertebrates. Financial Support: FAPESP (17/26214-8)

8.04.P-Th247 Effects of Microplastic on the Population Dynamics of a Marine Copepod

*Gert Everaert*¹, *Karel Vlaeminck*², *Michiel Vandegheuchte*³ and *Colin Janssen*⁴, (1)Flanders Marine Institute, Belgium, (2)Ghent University / Arche consulting, Belgium, (3)Flanders Marine Institute VLIZ, Belgium, (4)University of Ghent, Belgium

Microplastic is ubiquitously and persistently present in the marine environment, but knowledge of its population-level effects is limited. In this study, to quantify the potential theoretical population effect of microplastic a two-step approach was followed. First, the impact of microplastic (polyethylene, 0.995 g cm⁻³, diameter 10-45 µm) on the filtration rate of the pelagic copepod *Temora longicornis* was investigated under laboratory conditions. It was found that the filtration rate decreased at increasing microplastic concentrations and followed a concentration-response relationship, but at microplastic concentrations below 100 particles L⁻¹ the filtration rate was not affected. From the concentration-response relationship between the microplastic concentrations and the individual filtration rate a median effect concentration of the individual filtration rate (48h-EC₅₀) of 1956 ± 311 particles L⁻¹ was found. In a second step, the dynamics of a *T. longicornis* population were simulated for realistic environmental conditions, and the effects of microplastics on the population density equilibrium were assessed. The empirical filtration rate data were incorporated in an individual-based model implementation of the dynamic energy budget theory to deduct potential theoretical population level effects. The yearly averaged concentration at which the population equilibrium density would decrease by 50% was 593 ± 376 particles L⁻¹. The theoretical effect concentrations at population level were a fourfold lower than effect concentrations at individual level. However, the theoretical effect concentrations at population level remain three to five orders of magnitude higher than ambient microplastic concentrations. Since the present experiment was short-term laboratory-based and the results were only indirectly validated with field data, the in situ implications of microplastic pollution for zooplankton field populations remains to be further investigated.

8.04.P-Th248 Effects of Plastic on the Freshwater Snail *Biomphalaria Glabrata*

Robin Friedrich, *Nevena Lakic*, *Linda Prähauser*, *Karoline Schweitzer*, *Christoph Olscher*, *Xavier Monforte Vila*, *Rita Leitner* and *Barbara Gepp*, University of Applied Sciences Technikum Wien, Austria

Since the 1950s, plastic has become increasingly important as a material. However, its long life and decomposition into microplastics cause significant environmental pollution. Therefore, students of the Master's programme "Ecotoxicology and

Environmental Management” investigated the effects of conventional (high density polyethylene) and biodegradable plastic bags (based on corn starch) on the reproductive behaviour of the freshwater snail *Biomphalaria glabrata* within one year starting from an open-ended problem-based learning (PBL) case. The application of the 7-step PBL-method allowed the students to design their experiments independently under guidance and with feedback from the lecturers. For the experimental set-up, 6 snails each were placed in jars with tap water, lettuce leaves and cut pieces (approx. 3 x 3 cm, 1 g) of a conventional or biodegradable plastic bag. The treatments were tested in duplicate. The exposure experiments lasted 6 weeks and the reproduction of the snails was observed weekly by their laying behaviour. To test the effect of substances that can leach from plastic bags, pieces of plastic were exposed to tap water for a week before the snails were incubated in the leachate. A new leachate was prepared each week. In addition, the surface of the two types of plastic was examined with a scanning electron microscope (SEM). The exposure experiments showed that *B. glabrata* reacts to the added plastic pieces with increased clutch laying. In particular, snails exposed to conventional plastic reacted with a significant increase in clutches. It was noticeable that the egg clutches were mainly laid on the plastic pieces. However, snails incubated in the plastic bag leachate (without plastic pieces) did not show an increased egg laying behaviour compared to the negative control. The SEM images showed that the conventional plastic bag had a smoother surface than the biodegradable bag. The study showed that the reproduction of the *B. glabrata* is influenced by plastic but it seems that the increased clutch production is not due to leached substances. It is possible that the altered reproductive behaviour in snails exposed to plastic is related to other circumstances such as the surface area and amount of plastic. However, further experiments are needed to better understand the effects of plastic on snails. Financial support from the City of Vienna project PBL in Molecular Life Science (21-06) is gratefully acknowledged.

8.04.P-Th249 Environmental Fate of Venlafaxine and Its Main Metabolite O-Desmethylvenlafaxine

Tine Englund¹, Philip Thomasen² and Henriette Selck³, (1)Roskilde University, Denmark, (2)Institute for natural science and the environment, Roskilde University, Roskilde, Denmark, (3)Roskilde University, Roskilde, Denmark

Venlafaxine is a widely used antidepressant with 2643 kg prescribed in Denmark in 2020 alone. Most wastewater treatment plants (WWTP) are not equipped to remove pharmaceutical compounds, which results in the continuous distribution of active pharmaceutical ingredients to the aquatic environment, including venlafaxine (VEN) and its main metabolite O-desmethylvenlafaxine (ODV). Little is known about the environmental concentrations and fate of VEN and ODV when released into the environment. We conducted: 1) An environmental screening study of the influent-, effluent water and sludge from the local WWTP (Bjergmarken, Roskilde) in addition to water- and sediment samples collected at selected locations from the recipient estuarine ecosystem, Roskilde fjord, Denmark. 2) A study investigating the distribution of VEN and ODV in a laboratory setting, using a water-exposure/sediment system. VEN and ODV was added to the surface water to obtain a concentration of 2 mg/L. The concentrations in water and sediment compartments were sampled continuously during a 28-day period to follow the distribution kinetics between water and sediment compartments. The samples were analyzed with Solid Phase Extraction and QuEChERS extraction procedure followed by gas chromatography coupled with mass spectrometry. 3) An investigation of the environmental fate of VEN and ODV in sediment, under the influence of the sediment dwelling *Hydrobia Ulvae*. This served to elaborate on the complexity of the fate of pharmaceutical compounds within the aquatic environment.

8.04.P-Th250 Environmental Pollutant Monitoring Along Railway Tracks in Germany

Sabrina Michael¹, Gina Elisa Bode², Silvio Klügel³, Thomas Grischek⁴, Majo Karthe⁵ and Markus Zingelmann⁵, (1)German Centre for Rail Traffic Research at the Federal Railway Authority, Dresden, Germany, (2)German Centre for Rail Traffic Research at the Federal Railway Authority, Germany, (3)GEPRO Ingenieurgesellschaft mbH, Germany, (4)University of Applied Sciences Dresden, Germany, (5)Beak Consultants GmbH, Germany

In general, rail transport has a lower release of pollutants in direct comparison with other modes of transport. However, over 180 years of rail operation on today's more than 33,000 km of tracks in Germany have an impact on the environment. In this context, inorganic and organic substance inputs from today's and past rail operations and associated infrastructure maintenance works, for example the vegetation control, treatment of wood sleepers, are of particular importance. The study aims at the characterization of the spectrum of released pollutants and their dispersion in the track and the surrounding environment. The obtained results are important to close knowledge gaps and provide a basis for a comprehensive environmental risk assessment. Five long-term monitoring sites have been established to identify pollutants and characterize their transport behaviour. The investigation program includes the analysis of i. a. heavy metals, herbicides (incl. metabolites), and PAHs in seepage water, ground- and surface water as well as in soil samples. As part of the monitoring site characterizations, the depth-dependent herbicide contamination of all substances used in rail transport since 1985 was determined in different soil horizons and track areas. In addition, the degradation potential in the track and edge areas was also investigated. All sampling and analyses were carried out using standardized methods. The results show a site-specific pollutant distribution, with a clear decrease in pollutants from the centre of the track to its vicinity. Especially after vegetation control, the currently applied herbicides glyphosate, flumioxazine, and flazasulfuron can be detected in the soil and in the leachate. Within the scope of degradation tests, a degradation of the currently applied herbicides was proven at all sites. In addition, other herbicides such as atrazine, bromacil, DCMU (diuron), and ethidimuron were determined in the soil at specific sites. In a direct comparison between in- and outflowing groundwater in the track area, arsenic, iron, and zinc were found, with none of the values exceeding the regulated limits. The study is the first step in a series of investigations aimed at gaining a comprehensive understanding of the potential pollutant emissions in the track area. These studies will contribute significantly to a sustainable development of the transport system.

8.04.P-Th251 European Freshwater Silver Monitoring Data Do Not Suggest a Potential European-Wide Risk

Katrien Arijis¹, Karel Viaene¹, Patrick Van Sprang¹ and Jelle Mertens², (1)ARCHE Consulting, Belgium, (2)EPMF, Bruxelles,

Belgium

European legislations frequently focus on substances that are of potential concern to human or environmental health, like ‘priority substances’ under the Water Framework Directive 2000/60/EC (‘WFD’) that are identified as substances posing a significant risk to or via the aquatic environment. To properly assess the potential risk of a substance, high-quality representative monitoring data should be compared to a safe threshold concentration. In this work, several publicly available monitoring data sets for silver in the freshwater environment are assessed and checked for a potential European-wide risk according to the methodology used by the European Commission. Most of the available silver monitoring data sets contain a large proportion of undetected samples with a reported concentration below the limit of quantification (LOQ) of the analytical technique, leading to considerable uncertainty in the data set. For silver, this LOQ is often at or above the safe threshold concentration and the way undetected samples are treated during the data processing considerably impacts the final conclusion. We demonstrate that for large data sets covering many European countries (and often a wide range of LOQs), the uncertainty in the data set does not allow to make any general conclusions about European-wide risk for silver. However, by examining the data sets in more detail and examining three additional country specific monitoring data sets, we show that silver does not pose a risk to the freshwater environment. We conclude that the available data sets need careful assessment to account for the values that are below the LOQ, and that there is currently no reliable evidence indicating a European-wide risk for silver in the aquatic environment, meaning it should not be selected as priority substance under the WFD.

8.04.P-Th252 Evaluating Brittleness and Fragmentation of Conventional Polymers and Biopolymers Upon Photoaging

Astrid Delorme¹, Luna Valero², Florence Delor Jestin³ and Haroutioun Askanian³, (1)ICCF - CNRS, France, (2)Institut de Chimie de Clermont-Ferrand, Clermont-Ferrand, France, (3)Université Clermont Auvergne, CNRS, SIGMA Clermont, ICCF, F-63000 Clermont-Ferrand, France, France

SEALIVE (Strategies of circular Economy and Advanced bio-based solutions to keep our Lands and seas alIVE from plastics contamination) is a H2020 innovation project, which vision is to reduce plastic waste and contamination on land and in seas by boosting the use of biomaterials and contributing to the circular economy with cohesive bio-plastic strategies. As part of WP7, polymer degradation is investigated in several real service life and end-of-life conditions, in order to assess the life cycle of polymers and to eventually develop international biodegradation and ecotoxicity standards for bioplastics. Particularly, urgent concerns of polymers’ end-of-life are focused on the potential hazards and risks associated with microplastics. A prevailing source of microplastics is the fragmentation of larger plastics or product wear, however studies on the rates of fragmentation of polymers under various conditions are scarce. Photodegradation of polymers leads to structural changes of the polymer backbone, such as oxidation with formation of carbonyl functional groups, chain scission and cross-linking. These transformations at molecular level impact the overall mechanical properties of the plastic and favour embrittlement and fragmentation, leading to the generation of micro- and nano-plastics. Understanding the fragmentation rates and behaviour of photo-aged macroplastic generating secondary microplastics will provide vital information to enable a full risk-assessment of plastics needed for international biodegradation and ecotoxicity standards. Here we present a comparative study between a photoaged conventional polymer, polyethylene (PE), and an emerging biopolymer, polylactic acid (PLA), with a focus on the interrelation between photoaging and brittleness. Changes in morphological and physico-chemical properties of the photoaged polymer films are followed through the use of melt rheology, DSC, FTIR, UV-VIS, SEM and durometry with the aim to identify most relevant polymer properties, such as molecular weight, crystallinity and tensile properties that could explain the brittleness and fragmentation behaviour of aged polymers. In this work, we demonstrate the relationship between the brittleness behaviour of the aged polymers with the crosslinking and chain scission mechanisms which occur during the photoaging. *Acknowledgments* The work in this paper is supported by the SEALIVE Project which is funded by the European Union's Horizon 2020 Program, under grant agreement number 862910.

8.04.P-Th253 Evaluation of Risk of Organophosphorous Flame Retardants in Drinking WATER Sources

Emma Pemberton¹, Chesney Swansborough², Emma Goslan³, Sarah Fane⁴ and Mick Stanger⁴, (1)Ricardo Energy & Environment, UK, (2)Ricardo Energy & Environment, United Kingdom, (3)Cranfield University, United Kingdom, (4)Drinking Water Inspectorate, United Kingdom

Flame retardants are functional additives used in many articles to reduce flammability and prevent fires from starting or spreading. They play an important role in improving the fire safety of articles used in industry and everyday life. Following the restriction and phase out of many polybrominated diphenyl ether (PBDEs) flame retardants because of their hazardous and persistent nature, the use of organophosphorous flame retardants (OPFRs) has increased, OPFRs are not chemically bound within the material and there will be release of OPFRs from articles into the environment through volatilisation, dissolution, and attrition. OPFRs are more water soluble and more mobile than PBDEs with greater potential for long-range transport via waterborne routes. They could be considered as persistent, mobile organic chemicals and may pose a risk to surface, and ground waters including those used as source waters for drinking water supply. There are many reports of the widespread occurrence of OPFRs in the environment, including remote regions far from likely, local sources. Studies have shown that OPFRs could have harmful impacts on human health including neurotoxicity, carcinogenesis, and endocrine disruption activity. Internationally, there is widespread recognition that the replacement of PBDEs with OPFRs may be a case of regrettable substitution. Regulatory authorities are responding with policies that gather data, inform consumers, and limit the use of flame retardants of concern. To understand whether OPFRs are likely to occur in source waters and drinking waters in England and Wales at levels that could present a risk to human health, a desk-based evidence review is being conducted. Evidence has been collated and synthesised to describe (i) which OPFRs are likely to be present in water used for drinking water supply (ii) the range of likely exposure concentrations in raw waters (groundwater and surface water sources) based on reports of occurrence (iii) known uses, sources and pathways of release

that would indicate potentially high sources/concentrations in a catchment and (iv) removal efficiencies of OPFRs through treatment for drinking water supply have been collated and synthesised.

8.04.P-Th254 Evolution of the Electricity Mix in the Italian Context

Benedetta Marmioli¹, Maria Leonor Carvalho² and Pierpaolo Girardi¹, (1)Ricerca sul Sistema Energetico - RSE S.p.A., Italy, (2)Ricerca sul Sistema Energetico - RSE S.p.A., Milano, Italy

“It depends on the energy mix” is a very common output in Life Cycle Assessment studies. However, the electricity datasets many studies rely on are not up to date. In a context like the European one, with mixes evolving rapidly due to energy transition and changing geopolitical context, an old dataset can significantly affect the results. Moreover, studies of cutting-edge technologies might need to consider the change in the energy systems at the time the technology will be available on the market. The current study focuses on the Italian electric system as a case study. An updated and detailed LCA of the electricity mix of the last four years in Italy has been performed. Data from the national Transmission System Operator and statistics from Eurostat along with environmental certificate of the main power plants have been used to perform a LCA of the current mix. The scenarios developed in the framework of the Integrated Climate and Energy Plan and of the Green Deal have been taken as the reference for the evolution of the electricity mix in Italy in 2030, and have been modelled to evaluate the effect of the transition on the mix. In both cases (current and future mixes) the consumption mix has been considered as the national production (without pumped hydro generation) plus the import minus the export. The allocation method cut off has been applied. Plants have been classified per technology and energy source. Each plant type is defined in terms of efficiency and load factors. For future mixes, the technological progress was taken into account through enhanced conversion efficiencies and load factors. Data from the ministry of the economic development, from the Transmission System Operators for Gas have been used to model the geographical origin of oil, gas and carbon, and data from the Energy Service Operator to recreate the mix of biogas and biofuels. The evolution of the electricity mix presents a continuous reduction in the climate change impact in the last four years. All the impact categories show a reduction in the scenarios in 2030 compared to the last current year, except for the resource consumption. A correlation between the level of decarbonization and the increase in resource consumption is detected. If “it depends on the energy mix”, it is important to have an updated and detailed mix available for LCA studies. Knowing in advance the trend of the impacts of our future mixes will help determine the direction of almost every LCA study.

8.04.P-Th255 Experimental Arena Size Influences Larval Zebrafish Photolocomotor Behaviors and Response Thresholds Following Exposure to the Model Neurostimulant Caffeine

Lea Marie Lovin¹, Kendall Scarlett², Abigail Henke², Jaylen Sims² and Bryan W. Brooks³, (1)Baylor University, (2)Baylor University, United States, (3)Environmental Science, Baylor University, Waco, TX

Behavioral experiments with fish and other species are useful, sensitive tools for studying a wide variety of contaminants. However, many behavioral endpoints can also be highly variable, so understanding how experimental parameters influence detection of behavioral changes, including responses to environmental stressors, represents a key issue in comparability and applications of these experimental designs within and among species. Previously multiple sizes of experimental arenas have been used to measure photolocomotor changes with age/size and for diverse endpoints under investigation. However, there remains a need to understand whether behavioral responses are influenced by experimental arena size and if they differ after exposure to a contaminant. Thus, we initially defined baseline swimming profiles of larval zebrafish under light and dark conditions using a ViewPoint ZebraBox across different plate sizes (96, 48, 24, 12, and 6 well). We then performed studies with the common neurostimulant caffeine (0.003 – 112 mg/L) and zebrafish, and analytically verified caffeine treatment levels using liquid chromatography – tandem mass spectrometry. Following caffeine exposure, we observed behavioral responses (i.e. distance travelled, number of discrete movements, and duration of movements at different speed thresholds) using these different observation areas. We found that swimming total distance of naïve fish increased logarithmically with increasing size of the observation area while standard deviation initially increased and then decreased with increasing plate well size. Under light conditions, significant behavioral responses to caffeine were not observed in the smallest wells, but were then more pronounced with larger arena size. Similarly, we observed significant stimulatory responses, including bursting duration, count number and distance traveled, only in the largest arena size, but these effects were not identified in smaller wells. Our results indicate that increasing well size leads to higher movement levels, and performing larval zebrafish larval behavioral assays in smaller observation arenas may not detect or underestimate photolocomotor response thresholds to chemical contaminants. Understanding these changes can improve comparability among experimental designs with different arena sizes and demonstrates the importance of characterizing potentially confounding variables during behavioral assays.

8.04.P-Th256 Exploring Biological Read Across of Endocrine-Mediated Effects Between Birds and Other Vertebrates

Alan Lawrence¹, Helena Crosland¹, Lennart Weltje, Prof. Dr.², Nina Hallmark³ and Sonja Haaf⁴, (1)Cambridge Environmental Assessments, United Kingdom, (2)Ecotoxicology, BASF SE, Germany, (3)Bayer Crop Science, France, (4)ADAMA Deutschland GmbH, Germany

Regulation 1107/2009 states that for approval, pesticide active substances require a consideration of endocrine disrupting (ED) properties for humans and non-target organisms. Currently, environmental safety testing for endocrine properties include tests in mammals, fish and amphibians (OECD, 2018). The available test for avian species is limited to the one generation avian reproduction study (OECD TG 206), which includes only apical endpoints. The US EPA’s avian 2-generation toxicity test in Japanese quail has not been validated by the OECD as it was considered unresponsive for EATS (estrogen, androgen, thyroid and steroidogenesis) modalities. In addition, it is unclear from available guidance whether these studies would be sufficient to draw a conclusion on ED potential in birds. As there are various anatomical and hormonal differences between birds and other vertebrates

(e.g. different body temperatures, the production of cleidoic eggs, production of uric acid to void nitrogenous waste, different sexual differentiation mechanism) it is necessary to understand how responses of birds to endocrine active chemicals compare to better studied vertebrates. There is also the regulatory requirement to avoid unnecessary animal testing. Here we review the evidence for biological extrapolation of endocrine-mediated effects between birds and other vertebrates for which agreed test methods exist (mammals, amphibians and fish). We consider the usefulness of existing methodologies/study guidelines and guidance in the identification and evaluation of potential endocrine-mediated effects in birds. We also briefly compare the hormone systems and ADME (absorption, distribution, metabolism and excretion) processes of birds and other vertebrates. Through a review of published *in vivo* case studies with known ED chemicals targeting the EATS modalities, we compare observed effects in birds with those in other vertebrates. We discuss the question of whether potential ED chemicals for birds are likely to be captured by existing tests on non-avian vertebrates. Our assessment suggests there is a good basis for biological read across between birds and other vertebrate taxa, and also provides some suggestions for future research.

8.04.P-Th257 Exposure to Arsenic From Drinking Groundwater and Methylation Efficiency on the Redox Status of Blood Tissue in Populations of the Colombian Caribbean

Farith Damian Gonzalez¹, Boris Johnson-Restrepo² and Jessica Mercado-Páez³, (1)Bolívar, University of Cartagena, Cartagena de Indias, Colombia, (2)University of Cartagena, Colombia, (3)Universidad de Cartagena, Colombia

Inorganic arsenic (InAs) is considered to be the principal form of arsenic (As) in groundwater. US Environmental protection Agency guideline for arsenic in water is 10 µg/L. Lifetime average daily dose (LADD) is considered an important method for exposure assessment, because the effects of toxicity of InAs may be accelerated with an increase in exposure dosage. Exposure to arsenic leads to increased production of reactive oxygen species (ROS) and other toxic intermediates through its biotransformation, which can subsequently cause oxidative stress and alterations of the cellular system. However, these effects can vary largely among individuals, possibly due to demographic, anthropometric factors, smoking history, lifestyle and genetic factors, increasing the susceptibility to As toxicity. Therefore, this study evaluated the risk of As exposure in humans and the possible effects of the average daily dose and methylation efficiency on the redox status in blood tissue in people exposed from drinking groundwater. Specific surveys on 155 individuals aged between 18 and 81 years old were applied used to collect demographic and anthropometric information of the subjects and their lifestyle. The groundwater and urine samples were analyzed for assessing total As, using HPLC-HG-AFS. Likewise, the exposure and risk of As was assessed by LADD method and the Hazard quotient (HQ) and the methylation efficiency was determined for urinary speciation. Besides, the redox status of blood tissue was determined by enzymatic oxidative stress tests such as Superoxide dismutase (SOD) and Catalase (CAT), as well as with enzymatic oxidative stress tests such as total Glutathione (GSH) status, using the OxiSelect™ kit from Cell Biolabs. In addition, to determine the superoxide ion, the cytochrome C reduction method was used. The effects of the average daily dose of arsenic on the redox status in blood tissue were tested using a multivariate analysis, adjusted by potential confounders. Sixteen groundwater wells from studied municipalities were analyzed. The study population was divided post hoc into two subgroups: a subgroup exposed to arsenic above optimal levels (n=55), with aquifer concentrations of 16 µg/L, and a subgroup exposed to arsenic below optimal levels, with aquifer concentrations of 7.2 µg/L (n=100). The As exposure dose in the subgroup with high exposure was of 0.31 µg/kg-bw/day, generating a risk HQ=1.1. The urinary arsenic species concentrations were 0.80 µg/L for InAs, 0.60 µg/L for MMA^V and 1.2 µg/L for DMA^V. The values of the enzymatic oxidative stress tests; SOD and CAT were higher in individuals from the subgroup with high arsenic exposure (p= 0.03 and p= 0.04 respectively). Besides, were positively correlated with urinary total As metabolite concentrations. Exposure to inorganic As was associated with increased oxidative stress among individuals exposed to arsenic from groundwater. Therefore, SOD and CAT could serve as biomarkers for assessing the effects of As on redox status.

8.04.P-Th258 Foamed Plastic on Shorelines - a Study of Sources and Polymer Composition of Litter From Danish Beaches

Louise Feld¹, Vitor Hugo da Silva² and Jakob Strand², (1)Dept. of Ecoscience, Aarhus Universitet, Denmark, (2)Ecoscience, Aarhus Universitet, Denmark

Foamed plastic contributes importantly to the environmental pollution globally, however, knowledge of the types, sources and composition of this litter pool is limited. The aim of this study was to characterize item types and polymer materials of foamed litter from six Danish reference beaches during 2018-2021. A total of 1962 foamed items were registered during the study, corresponding to 12% of all plastic litter at the beaches. The foamed litter were classified into ten categories, including specific identifiable item types, as well as foamed PS fragments, or pieces of rigid or flexible sponges consisting of other foamed materials. Litter of foamed PS could be recognized with large accuracy by visual assessment, however, only a relatively small proportion of the foamed PS litter were identifiable items such as cups and food containers for take-away, packaging materials or buoys and floats. Hence, PS fragments constituted 31% of the total number of foamed litter and hence, a better source identification of this unidentifiable fraction may be critical to establish effective regulatory measures to reduce littering. Foamed litter of any other types than PS were visually classified into two categories of insulation/wrapping or foam sponges, consisting of rigid foam and flexible foam, respectively. The majority was assumed to origin from land-based sources, e.g. construction and packaging. FTIR spectroscopy was used to determine the polymer distribution of the foamed litter, and PS (44%) and PUR (49%) were identified as the major foamed polymers. In contrast, other polymers such as PE, PP, PVC, PA and EVA were only found in relatively small numbers. PUR comprised 84% of all the rigid foam or flexible sponges. Principal Component Analysis of FTIR spectra of PUR items demonstrated distinct clusters with specific spectra features that were typical for rigid and flexible PUR foams. These differences were associated to chemical fingerprints of the NCO/OH ratio, which are related to the hard-segments (diisocyanates) and soft-segments (polyols) mixed to produce the PUR foam. Finally, we also investigated the use of different

reference spectral libraries for accurate polymer assignment of the PUR litter based on FTIR data and correlation methods. The analysis supported that reference libraries covering several variants of PUR including weathered PUR are important.

8.04.P-Th259 Fractionation and Identification of Target Alkyl Phenols and Naphthenic Acids in Produce Water Discharge
Matteo Ottaviani¹, Neri Bonciani², Karen Feilberg³ and Lars Skjolding⁴, (1)DTU Offshore, Denmark, (2)DTU (Technical University of Denmark), Kongens Lyngby, Denmark, (3)DTU Offshore, DTU (Technical University of Denmark), Lyngby, Denmark, (4)DTU, Denmark

Produced water (PW) is the water co-produced with oil and gas from oil wells and it represents the largest volume waste stream in oil and gas production operations on most offshore platforms. In 2021 there was an estimated 30 million tons of produced water discharged from the Danish continental shelf alone. Current regulation monitor only the dispersed hydrocarbon content on the legal limit of 30 mg/L; this limit does not address the polar species dissolved in the water which are potentially the more environmentally concerning constituents in produced water e.g. Naphthenic acids and Alkyl Phenols. Naphthenic acid comprises a complex mixture of aliphatic, cycloaliphatic and aromatic carboxylic acids that naturally occurs in the oil fraction and from added production chemicals. They act as surfactants and have shown to be toxic to a variety of organisms, especially in aquatic environments. Alkylphenols naturally occurs in crude oil, but they also came from degradation products of alkylphenol ethoxylates (APEOs, a group of non-ionic surfactants) and from the degradation of other production chemicals. Nonylphenols (NP) and Octylphenols (OP) are included in the European Union's list of priority hazardous substances for surface waters. The aim of the study was to isolate fractions of phenols and NAs from samples of produced water from the Danish oil production wells using solid phase extraction. The extracts were measured for target analysis with LC-ESI-MS and the total acidic content of the NAs fraction was determined by Fourier-transform infrared spectroscopy, as a fast and low-cost analysis for identifying functional groups and quantification. Finally, the toxicity of the extracted fractions was assessed using the metabolic activity of bioluminescent bacteria (*Aliivibrio fischeri*) and growth inhibition of algae (*Skeletonema* sp.).

8.04.P-Th260 Gas Chromatography x Cyclic Ion Mobility-Mass Spectrometry: A Novel Platform for the Comprehensive Separation and Discovery of Unknown Per- and Polyfluoroalkyl Substances

Karl Jobst¹, Xiaolei Li¹, Amber Macneil¹, Roshanak Amiri¹, Meera Bissram¹, Mahin Hashemihedeshi¹, Frank Dorman², Sonya Kleywegt³, Andre Simpson⁴ and Myrna Simpson⁵, (1)Memorial University of Newfoundland, Canada, (2)Waters Corporation, United States, (3)Ontario Ministry of Environment, Conservation and Parks, Canada, (4)University of Toronto Scarborough, Canada, (5)University of Toronto, Canada

Per-/polyfluoroalkyl substances (PFASs) have been widely used since the 1940s in industry and everyday household products. They also persist in the environment and bioaccumulate in humans and wildlife. Although PFASs number in the thousands, very few, e.g. perfluorooctanoic acid and perfluoro-octanesulfonic acid (PFOA and PFOS), are subject to regulations aimed at protecting the environment and health. The number of PFASs introduced to the global market has rapidly outpaced research on their environmental impact, and the identities of up to 90% of PFASs in environmental and biological samples are unknown. Gas chromatography hyphenated with cyclic ion mobility (GCxIMS) is a two-dimensional separation technique that promises to accelerate the discovery of unknown PFAS. It can resolve molecules that differ by shape, which can be approximated as a collision cross section (CCS). The cyclic geometry of the mobility cell enables ions to travel successive passes, increasing their arrival time and relative separation. In this contribution, we explore the potential for this novel technique to tackle complex environmental samples and identify unknown persistent organic pollutants (POPs). By modelling the CCS of approximately 20,000 chemical compounds produced in or imported into Canada, we show that most POPs, including PFASs, are characterized by high molecular density, having a relatively compact CCS relative to other industrial chemicals of similar mass. When this filter is applied to GCxIMS data collected from a set of indoor dust samples, POPs, including per- and polyfluoroalkyl substances (PFAS) are revealed. Validation of this approach was performed using a standard reference material (SRM 2585) of indoor dust. We show for the first time that mixed halogenated n-alkanes, ubiquitously used as lubricants and flame retardants, are contaminants of indoor air. The method is also applied to samples collected from industrial emissions in Ontario, Canada.

8.04.P-Th261 Greenhouse Gas Emissions and Sea Level Rise Impact on Coastal Ecosystem Services Within the LCIA Framework

Laura Debarre¹, Manuele Margni¹ and Martin Dorber², (1)CIRAIG - École Polytechnique de Montréal, Canada, (2)Norwegian University of Science and Technology (NTNU), Norway

While providing essential ecosystem services (ES) to people such as food and raw material provision, touristic and cultural opportunities, as well as climate regulation or infrastructures protection, coastal ecosystems are among the most affected natural systems by anthropogenic activities. Greenhouse gas (GHG) emissions lead to temperature increase and – among other effects - to sea level rise (SLR). This poses significant threats to coastal environments; SLR will alter the distribution of coastal assets and habitats and will result in changes in the services they provide to people. ES are barely assessed in life cycle assessment (LCA). To date, the only efforts to model ES impact pathways in the Life Cycle Impact Assessment (LCIA) framework have focused on few terrestrial ES linked to land use such as erosion control, biotic production or water filtration. Potential impact of climate change, acidification or eutrophication – among others - on ES are therefore occulted in LCA impacts profiles, leading to a possible underestimation of the results. This project proposes to address this gap by developing characterization models and factors expressing the potential cost to society resulting from the change of coastal ES supply triggered by climate change and SLR. We firstly propose a novative approach to assess SLR impacts in LCIA by developing characterization factors that assess changes in coastal habitats due to GHG emissions. To this end, we use a recent digital elevation model combined with SLR projections based on different emissions scenarios and a global habitat mapping. This cartography of flooded habitats is then combined with a

mapping table linking habitat type and ecosystem services. Finally, well-known ES monetary valuation tables are used to assess the economic value of the ES supply changes

8.04.P-Th262 Guideline Values for Per- and Polyfluoroalkyl Substances (PFAS) in Soils - a Survey at EU Member State Level

Tobias Frische¹, Arno Märten² and Annegret Biegel-Engler², (1)Federal Environment Agency (UBA), Germany, (2)German Environment Agency (UBA), Germany

Per- and polyfluoroalkyl substances (PFAS) are counting some thousands of chemicals, all of them containing at least one fully fluorinated carbon atom. PFAS have been manufactured for decades for a broad range of technical uses in industrial processes and products, resulting in intentional or non-intentional environmental release. PFAS are highly persistent against abiotic and biotic degradation, and diffuse contamination of even remote areas across the globe by geochemical transport is well-known. Further, accumulation in biota and subsequent food-chain transfer of some PFAS is causing concern regarding long-term adverse effects on human health and wildlife. However, only for a limited number of PFAS extensive toxicological and ecotoxicological studies have been conducted so far, as it is the case for the prominent perfluorooctanoic acid (PFOA) and perfluorooctanoic sulfonic acid (PFOS). Consequently, only a few PFAS have been regulated within the EU or via the Stockholm convention until today. Global diffuse contamination as well as local point contaminations known from a lot of sites across the EU will remain a long-term threat. Contaminations stretching over several kilometres are usually located near the facilities of fluorochemical industry or sites where PFAS are used in production processes or PFAS-containing waste was disposed-off. Soil and groundwater are often severely contaminated in these areas, while smaller scale pollution is typically caused by the use of firefighting foams containing PFAS. In both cases, local authorities have to decide how to deal with the damage, e.g. what remediation or safeguarding measures to take, what land uses are still possible and whether the excavated soil can be reused. Since there are no scientifically derived regulatory values for PFAS-contaminated soils effective at EU level, respective national values have been derived by several Member States. To establish the scientific basis for PFAS soil guideline values under the German Soil Law, we started to gather and review publicly available respective values from several EU member states. The presentation will provide an overview of the results of this exercise. Similarities and differences between national values will be highlighted – from both a regulatory and scientific point of view.

8.04.P-Th263 How Safe Is Nanomaterials to Brain?

Zhiling Guo¹ and Iseult Lynch², (1)School of Geography, Earth & Environmental Science, University of Birmingham, Birmingham, United Kingdom, (2)School of Geography, Earth and Environmental Sciences, University of Birmingham, Birmingham, United Kingdom

Although brain is protected by a tight physiological guardian named blood brain barrier (BBB), deposition of engineered nanomaterials (ENMs) in brain and consequent neurotoxicity has been reported. To date, it is still unclear whether and how ENMs enter the brain by crossing the BBB. Understanding the potential of ENMs to cross the BBB as a function of their physicochemical properties and subsequent behavior, fate, and adverse effect beyond that point is vital for evaluating the neurological effects arising from their unintentional entry into the brain, which is yet to be fully explored. This is not only due to the complex nature of the brain but also the existing analytical limitations for characterization and quantification of NMs in the complex brain environment. Herein, we conducted an interdisciplinary study by using a novel analytical workflow and *in vitro* BBB model, as a complex biological barrier, to determine and quantify the biotransformation of metallic NMs as a function of their physicochemical properties and correlate the influence of the biotransformation to the BBB-penetration ability and transport pathways. We found metallic ENMs transform in the BBB as affected by their shape, size and intrinsic solubility, which in turn modulates their transport form, efficiency and pathways through the BBB, and consequently their neurotoxicity. Very little was transcytosed to the basolateral (brain) side of the BBB model, with significant amounts being recycled back to the apical (bloodstream) side and limited retention in the BBB cells. Paracellular transport was only observed at the higher concentration tested and was associated with membrane damage and NM dissolution. The generated data about biotransformation modulated uptake and transport of NMs through BBB open a new horizon for medical application of NMs, e.g. targetable drug delivery systems for brain diseases and also for biological fate assessment of NMs in brain to support their risk assessment.

8.04.P-Th264 How Useful Can Non-Invasive Sperm Collection in Amphibians Be for In Vitro Toxicology Testing?

Graça Lopes¹, Filipa Santiago², Sónia Coelho³ and Isabel Lopes⁴, (1)Veterinary Clinics, ICBAS - U.PORTO, Porto, Portugal, (2)ICBAS University of Porto, Portugal, (3)Department of Biology & CESAM - University of Aveiro, Portugal, (4)University of Aveiro, Aveiro, Portugal

The decline of Amphibian populations constitutes a critical concern in conservation biology and pollution has been identified as a major driver for such declines. Limited information on the toxicity of chemicals to amphibians exist and most of the available standard toxicity assays for amphibians involve *in vivo* experimentation, which makes difficult their risk assessment considering the increasing amount of chemicals to be tested and the ethical issues involved. An urgent need to develop non-animal assay alternatives for amphibians is warranted, however the replacement of animal testing by *in vitro* methods requires the validation of suitable cell models, preferably obtained using non-lethal/invasive methods. Besides somatic cell-lines, gamete cells may also be considered as an alternative to animal experimentation in risk assessment. In amphibians, such methodology can be very relevant since most anuran amphibian species release gametes directly into the water column for external fertilization, hence both eggs and sperm enter in direct contact with water contaminants. This confers a high ecological relevancy to *in vitro* assays using sperm cells, since effects observed may be related with reproductive success. However, few works have been published on the effects of chemicals on amphibian's sperm cells (25,26), and most involve the sacrifice of males to remove the testes and obtain sperm cells

as testicular macerates or suspensions from sexually mature males. However, anuran spermatozoa can also be collected through hormonal induction, either in spermic urine through abdominal massage or in cloacal fluid through cannulation of the cloaca. This communication presents a review compiling relevant data and describing current knowledge on the use of non-lethal sperm collection in anuran amphibians species and discussing its potential use in the development of in vitro toxicity testing.

8.04.P-Th265 Implementation of a Dual Ionization Source, ESI and APCI, for Determination of Organic Contaminants in Drinking WATER by LC-MS/MS

Ignazio Garaguso, Stefan Edler, Thomas Becker and Derek Mattern, PerkinElmer, Germany

The water directives of the European Union define quality standards of water for human consumption and set forth measures to monitor priority substances that are deemed high risk to humans (1). However, the large number of organic contaminants defined in the chemical parameters to be monitored in water set an analytical challenge. Indeed, the molecules belong to very different chemical compound classes and a reliable separation and sensitive determination by LC-MS/MS would require to use of many different methods separation and detection methods. Here we present our developments of analytical methods to a sensitive determination of organic contaminants in drinking water using a QSight LC-MS/MS system with dual ion source. In particular, we explored the capability of a dual ionisation mode, ESI and APCI, to improve method sensitivity. Initial developments on acrylamide showed a reduction of ion suppression without comprising of sensitivity when using APCI versus ESI ionization. Still permitting a method quantitation limit for acrylamide of 0.01 µg/L. Subsequently, using the compounds chlorate, perchlorate and N,N-dimethylsulfamide (DMS) we implemented a method where the mass spectrometer switches the acquisition between APCI and ESI within the same LC-MS/MS run. Here, first eluting DMS was measured using APCI source, and then the mass spectrometer switches to ESI source to measure both chlorate and perchlorate. The method shows a sensitivity of 0.01 µg/L for all compounds which are well below the parametric values required by EU regulation. References: 1. DIRECTIVE (EU) 2020/2184, available: <https://eur-lex.europa.eu/eli/dir/2020/2184/oj>

8.04.P-Th266 Improved Environmental Impact Assessment of High Salinity Produced Water

Neri Bonciani¹ and Karen Feilberg², (1)DTU (Technical University of Denmark), Kongens Lyngby, Denmark, (2)DTU Offshore, DTU (Technical University of Denmark), Lyngby, Denmark

When crude oil is produced large amounts of water are produced along with the organic petroleum material. This co-produced water (PW) is highly saline and contaminated from contact with crude oil in the formation and the production additives, thus it is heterogeneous and remarkably complex. Considering that this water is being discharged to the sea at most current offshore production sites, reaching the ambition of zero harmful discharge requires stringent produced water management and improved monitoring and toxicology evaluation. This work aims at an initial characterization for improved environmental impact assessment of water production in connection with offshore oil, facing the analytical challenges given by a hypersaline and carbon-rich water sample. This work presents a workflow for complex aqueous samples from oil wells starting with total alkalinity (TA) analysis of samples purified with respect to organic dissolved content and on the analysis of major inorganic anions and specific volatile and semi-volatile organic acids content using liquid ion chromatography (HPIC). The determination of trace elements (As, Cr, Cd, Co, Cu, As, Sb) in produced water has also been targeted using ICP-OES for analyzing non-digested, hot plate digested and microwave digested samples and comparing the results. Matrix matching for blanks, calibration standards and quality checks have been implemented to improve plasma stability, measurements reproducibility and raw data reliability. The same trace elements have been targeted in suspended particulate matter (SPM) of PW via cellulose 0,45 µm filters and using acidic digestion. In addition, due to the complexity of the matrix, for various trace elements, SPE pre-concentration techniques have been also applied and verified in order to minimize the matrix influence on analytical detection. Further characterizations on suspended particulate matter in PW samples have subsequently been carried out through scanning electron microscopy. This presentation includes the initial results of these analyses of actual Danish North Sea produced water as well as discharge point water samples.

8.04.P-Th267 Improving Polymer Identification of Micro- and Mesoplastic Particles Ingested by Seabirds - Potential for Adjustment of Biomolecule Interferences in Fourier-Transform Infrared (FTIR) Spectroscopy

Jakob Strand, Ecoscience, Aarhus Universitet, Denmark

Pre-processing of FTIR spectral data can often be beneficial for the identification of the polymer-based constituents in plastic materials, e.g. by applying baseline correction and smoothing. In some cases, correction of spectral information for matrix effects can also improve the quality for identifying the polymers. In this case, 427 and 227 plastic particles > 1mm ingested by the storm bird Northern fulmar (*Fulmarus glacialis*) from West Greenland and North East Greenland, respectively, was analysed using a diamond ATR-FTIR spectroscopy. Even after wash and drying of particles, many of the spectra did still contain clear signals from also protein-like biomolecules in addition to their typical polymer spectra, because these biomolecules had been sorbed to the plastic. This biomolecule interference had therefore in many cases effects on both the Hit Quality Index (HQI) values and the specific polymer assignments when using spectral reference libraries for identifying the polymers. Manipulating the spectra by adjusting for this matrix effect could therefore improve the confidence in polymer identifications by reducing risks for false positives and false negatives. Other outcomes can be to improve systematic quality criteria for positive polymer assignments and to be able to handle spectral data for many samples more homogeneously in batch analyses and not only assess them one by one. Following steps of pre-processing were included in this study: Smoothing, baseline correction, normalisation, and in the end subtraction with a spectrum previously isolated from gut-fluid exposed plastics in fulmars for reducing the influence of matrix, because of the potential interfering biological protein-like signal. The results of these data treatments showed that 18 % re-assignments of the polymer ID when applying HQI values >0.7 for library matches and a significant increase in HQI-values >0.9

for especially particles consisting of PE (polyethylene) and PP (polypropylene). Only analysing raw un-processed FTIR spectra increased thereby the risk for false polymer assignments. In addition, comparison of spectral reference libraries with or without spectra for important types of environmental weathered plastic materials showed that inclusion of weathered plastic materials in reference libraries also can improve the confidence of polymer assignments of ingested plastic particles from fulmars.

8.04.P-Th268 In Silico and Experimental Screening Platform for Characterizing Environmental Impact of Industry Development in the Arctic - an Overview of the Project EXPECT

Samantha Martins¹, Tania Gomes², Maria T. Hultman³, You Song⁴, Bjørn Henrik Hansen⁵, Anita Evensen⁶ and Knut Erik Tollefsen², (1)Ecotoxicology and Risk Assessment, Norwegian Institute for Water Research, Oslo, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Norwegian Institute for Water Research NIVA, Norway, (4)Norwegian Institute for Water Research (NIVA), Oslo, Norway, (5)SINTEF Ocean, Norway, (6)Akvaplan-niva, Norway

The Arctic environment is facing evident changes such as temperature increase and consequent rapid decline in the sea ice. These conditions will favour the development of industrial activities, e.g., oil and gas exploration, tourism and aquaculture. In order to assess the potential environmental risks from the anticipated industrial development in the Arctic, methods and approaches that elucidate the pollution pathway from the emission to the environment to the display of adverse outcomes in the biota should be developed. EXPECT will develop *in silico*, *in vitro* and *in vivo* approaches for an integrated assessment of impacts of combined Arctic pollution on relevant marine organisms and populations. The experimental outputs will feed into the development of a Source-To-Outcome-Pathway (STOP) to characterise the causal source-exposure-effect-impact relationships for pollutants and their mixtures. The primary objective is to characterise the most relevant Arctic STOPS and use these to perform Cumulative Risk Assessment (CRA) to support sustainable management of existing and future industrial and anthropogenic activity in the Arctic. EXPECT is a 4 years project (started Q3/2021) that includes research groups from Norway (NIVA, Akvaplan-niva and SINTEF), UK (Newcastle University) and USA (Clemson University). Specific work packages include 1) the development of Aggregated Exposure Pathways (AEP) for characterisation of emission sources to external and internal exposure concentrations; 2) the development of Adverse Outcome Pathways (AOP) for the priority toxicity drivers, endpoints and susceptible taxa; 3) hazard assessments of single pollutants and different mixtures; 4) performance and experimental evaluation of a STOP-informed CRA. The outcomes from EXPECT are anticipated to support more mechanistically-informed environmental management, including optimal coastal zone planning and sustainable industrial development. EXPECT is funded by the Research Council of Norway (project # 315969) and supported by NIVA's Computational Toxicology Program (NCTP, www.niva.no/nctp).

8.04.P-Th269 Integrating Hydrothermal Liquefaction in Wastewater Treatment: Impact on Biological Nitrogen Removal

Williane Vieira Macêdo¹, Jennie Spicker Schmidt², Camille van den Langenberg³ and Leendert Vergeynst², (1)Biological and Chemical Engineering, Aarhus Universitet, Denmark, (2)Aarhus Universitet, Denmark, (3)Has Hogeschool, Nederland

Hydrothermal liquefaction (HTL) is a thermochemical conversion technology proposed to replace anaerobic digestion in wastewater treatment plants (WWTP). In order to achieve a net positive energy production as well as nutrient recovery by integrating HTL in WWTPs, investigations on how the wastewater from the HTL process (HTLWW) affect the microbial activity involved in the nitrogen cycle should be addressed. The lack of knowledge on how to treat HTLWW and how to integrate this effluent in the WWTP constitutes a significant obstacle to the industrial scale production of biocrude. In this context, this study investigated the inhibitory effect of HTLWW on the nitrification and denitrification processes and its potential as carbon source for the heterotrophic denitrifiers. In the Nitrification inhibition assays, three different concentrations of the HTLWW were tested 0.05, 0.15, and 0.3% v/v. In the denitrification assays, the inhibition of HTLWW was tested with 0.3% and 1% v/v HTLWW. Denitrification rates of HTLWW, acetate, glucose, starch, and settled influent wastewater from Fredericia WWTP were tested as carbon source. The average nitrification rates over 6 hours of incubation were 0.62 ($\pm 11\%$), 0.48 ($\pm 13\%$), 0.37 ($\pm 24\%$), and 0.19 ($\pm 33\%$) mgN-NH₄⁺·gVSS⁻¹·h⁻¹ for the blank, 0.05, 0.15, 0.3% v/v HTLWW treatments, respectively. The nitrification inhibition relative to the control showed a linear relationship with the HTLWW concentration from which a half-maximal effect concentration (EC₅₀) of 0.21% v/v was estimated. Even though the highest denitrification was obtained for the highest content of HTLWW, there was no significant difference (ANOVA test with $p > 0.05$) between the control and the 1% v/v treatments. The experiments using acetate, glucose and HTLWW yielded the highest nitrate reduction rates of 3.4-4.0 mgN-NO₃⁻·gVSS⁻¹·h⁻¹ and there no significant difference among them ($p > 0.05$). The highest nitrite accumulation was obtained when glucose was used as carbon source. The effect of HTL process water components on nitrification and denitrification have been little explored and our results confirm inhibitory effects that cannot be neglected as 50% nitrification inhibition may be expected when HTL is integrated at a typical WWTP. Relatively high levels (0.3% v/v) of HTLWW showed some (17%) denitrification inhibition, but at the same time proved to be a nearly as good carbon source for denitrification as acetate and glucose.

8.04.P-Th270 Intrinsic Properties of Metallic Contaminants Govern Bioaccumulation Behaviour: An Ex-Situ Comparison of Bulk Metallic, Nanomonometallic and Nanopolymetallic Bioaccumulation in Benthic Isopods

Irene O'Callaghan¹ and Timothy Sullivan², (1)University College Cork, Cork, Ireland, (2)University College Cork, Ireland

The accumulation of metallic contaminants in benthic fauna is well documented, but less is known about the behaviour of emerging nanoscale contaminants. The likelihood of trophic transfer from benthic fauna to higher lifeforms makes elucidating these behaviours vital to our understanding of broader ecological risk and the ultimate fate of contaminants in the environment. This study examines the *ex-situ* uptake and accumulation of analogous bulk (macroscale) and nanoscale metal contaminants in benthic isopods, as well as comparing the accumulation of monometallic and polymetallic compounds. Results show that bulk and nanoscale contaminant accumulation exhibit qualitatively similar behaviour; however, accumulated nanoscale contaminant concentrations were an order of magnitude greater than those of the bulk analogues. This highlights the greater bioavailability of

nanoscale contaminants in the benthic environment. Monometallic and polymetallic compounds showed qualitatively and quantitatively similar accumulation behaviour, despite the inclusion of an additional metallic species in the latter contaminant. Of greater interest, however, is the relative uptake of different metallic species from the polymetallic compounds. The relative accumulation of each species was found to be imbalanced, indicating that the organism preferentially accumulated one ionic component of the compound over the other. Furthermore, this preference was found to correlate with the elemental thiophilicity of the ionic species, indicating a thiol-mediated mechanism of accumulation. These findings improve our understanding of the behaviour and fate of metallic contaminants in the benthic environment. The increased relative ecological risk of nanoscale contaminants is demonstrated, and the influence of thiophilicity on the bioavailability of contaminants is demonstrated at nanoscale for the first time.

8.04.P-Th271 Investigating the Effects of FFP2 Mask Leachates on *Eisenia fetida* and of Microplastic Beads on *Caenorhabditis elegans*

Katharina Wiessner, Thomas Machacek-Link, Saskia Brabänder, Karin Tea, Florian Luksch, Evgeniya Paulis, Stefan Ferlin, Lukas Szemeliker, Lena Oberdorfer, Jasmin Schebesta, Polina Gavrikova and Elisabeth Simboeck, University of Applied Sciences Technikum Wien, Austria

The COVID-19 pandemic has caused an extensive increase of plastic waste. In 2020 over 1.5 million face masks have entered the environment, mostly due to improper disposal. Face masks consist almost entirely of plastic, mainly polypropylene, which is non-biodegradable. Still, over time, depending on weathering conditions, they are disintegrated into smaller particles, microplastic particles, which then can be taken up by soil organisms. Furthermore, plastic can be a vehicle of toxic substances, f.i. in the form of additives that have the potential of leaking out of the masks into the environment. To test the effects of additives in FFP2 masks on the earthworm *E. fetida*, avoidance tests were performed according to the ISO 11268-2 guideline. Adult *E. fetida* were exposed for 48 h to 450 g/L leachate of used FFP2 masks, which was obtained by column percolation according to DIN 19528. Then their avoidance behavior was investigated. As a positive control, 30 g/L sodium chloride was used as an alternative to the teratogenic boric acid. A significantly higher number of specimens was found in the leachate, compared to the negative control. Two FFP2 masks were subjected to a MOSH/MOAH analysis, once leached with n-hexane, once with dH₂O as solvent. This resulted in over 4000 mg/kg for MOSH in n-hexane, dH₂O showed values below 4 mg/kg. Furthermore, two transgenic strains of *C. elegans*, KWN190 (intestinal damage) and CL2166 (oxidative stress) were exposed to fluorescent microplastic beads for 96 h. Then, GFP signaling was investigated under a fluorescence microscope, and viability and brood size were investigated. An uptake of microplastic beads could be observed in all specimens. No clear difference of GFP signals between exposed and negative control was detected. On days 2 and 3, a slight increase in viability and reproduction could be observed. The results of the experiments indicate effects of microplastic and FFP2 mask leachate on the tested organisms. Even though the high MOSH results are of rather little meaning, as the solvent n-hexane does not represent a natural leaching process of masks, it must be noted, that there is a possibility of leaching organic substances out of the FFP2 masks via saliva and by touching the masks. However, further research needs to be done with larger sample sizes and different, more fitting solvents regarding the leachate and more sensitive test organisms.

8.04.P-Th272 Investigating the Impacts and Potential Mitigation Options of a Mixture Assessment Factor (MAF) for Substance Chemical Safety Assessments Under REACH

Christopher Hughes¹, Megan Griffiths, MSc², Emily Butcher², Daniela Jeronimo³ and Rebecca Johansen², (1)Ricardo Energy & Environment, Chester, United Kingdom, (2)Ricardo Energy & Environment, United Kingdom, (3)Toxminds BVBA, Belgium

Environmental risk assessments under EU regulations are generally conducted on a per substance basis. However, in the environment substances may occur in the presence of other substances, and this has led to concern from risks posed by unintentional mixtures of substances. A potential policy measure to mitigate this risk is to apply a generic assessment factor to existing risk assessments of substances to account for unintentional mixtures. This so-called mixture assessment factor (MAF) would therefore increase the conservatism of existing risk assessments in proportion to the magnitude of the MAF. Where a MAF is applied to existing risk assessments, this may lead to the risk assessments no longer demonstrating safe use (risk characterization ratio, RCR > 1). In these cases risk assessments will need to be revised. The MAF is currently proposed to be implemented under the EU REACH regulation for industrial chemicals, as part of the Chemicals Strategy for Sustainability. However, the precise details, such as at what magnitude the MAF will be set, are yet to be decided. In this study, a methodology has been developed for investigating the impacts of, and identifying possible mitigation measures for, a MAF for substances registered under REACH. This methodology has been applied to the environmental components of chemical safety reports (CSRs) of three substances, where a MAF of 10 has been applied. A stepwise approach has been developed, which first identifies those uses for which environmental RCRs are above 1 with the application of the MAF. For these impacted uses, possible mitigation options were explored, including (1) refinements to existing exposure assessment assumptions, (2) data generation, (3) increased risk management measures (RMM), and (4) reduction in amount used. The outcome of the investigations for the three example substances will be presented as case studies. The implications of MAF, further mitigation options, and potential opportunities to improve mixture risk assessment will be further discussed.

8.04.P-Th273 Issues in Cooperation of Science and Industry: How Make Better Use of Our Combined Know-How and Resources All the Way From Life-Cycle Science to Improved Life-Cycle Products and Services in Industry for a More Sustainable World

Martin Baitz¹, Ulrike Bos², Cecilia Makishi-Colodel² and Steffen Schoell³, (1)LCA Data Content, Sphera Solutions GmbH, Leinfelden-Echterdingen, Germany, (2)Sphera Solution GmbH, Germany, (3)sphera solutions GmbH, Germany

There are two Spheres that still do not cooperate optimal: The Sphere Science and the Sphere Industry. The topic is not new. Walter Kloepffer wrote clear words about it in 2001 in „Two planets and one Journal“ and over 10 years later in 2012 22 experienced LCA experts from academia, industry and consulting did refresh the topic in the article „LCA’s theory and practice: Like ebony and ivory living in perfect harmony?“. However, we are still being far away from cooperating well, as we do not use our combined know-how and resources in a best possible way, but waste time to argue our different standpoints. We are losing time that we do not have to save our planet. Neither protectionism of industry nor arrogance of science will lead us forward. Society needs good science and good industry practice, products and services. Best societal benefit is made from good cooperation of both. There are good and bad examples of cooperation among the spheres: e.g. the SETAC Working groups in the 1990s, followed by the SETAC UNEP Life-Cycle-Initiative and the UNEP GLAD / GLAM Initiative and the Product Environmental Footprint as fundamental instrument to steer the European Green Deal. We will discuss in this presentation challenges, hurdles and mistakes, which we learned in the last 25 years and which still are partly being made today in the LCA cooperation of science and industry. We aim to inspire improved understanding and co-working within the different spheres. We will touch on concrete issues, evidence and aspects like data (collection), flow lists, regionalization, unit conversion, data set types, data import-export, data quality, data detail, fundamental different LCA system modelling, mixing of data sets and modelling approaches, documentation and last but not least on the important differentiation of “latest science” and “good practice”. Results and data in “LCA science” reflects a different aim, than “LCA results and data” in industry. Understanding this difference will lead to improved life-cycle cooperation as necessity of a more sustainable future.

8.04.P-Th274 Laboratory Survey on Assessing Vitellogenin in Fish

Natalie Burden¹, Fiona Sewell², Laurent Lagadic³, Yvonne Wolf³, Breanne Holmes³, Lennart Weltje, Prof. Dr.⁴, Edward Salinas⁵, James Wheeler⁶, Grace Panter⁷ and Rebecca Brown⁷, (1)NC3Rs, London, United Kingdom, (2)NC3Rs, United Kingdom, (3)Bayer Crop Science, Germany, (4)Ecotoxicology, BASF SE, Germany, (5)BASF SE, Germany, (6)Corteva Agriscience, Netherlands, (7)wca consulting, United Kingdom

The fish protein vitellogenin (VTG) is an important biomarker for possible endocrine activity of substances acting via oestrogen, androgen, or steroidogenesis pathways. There are, however, concerns regarding the assessment and reporting of this endpoint because it is highly variable as demonstrated by historical control analyses both within and amongst laboratories. Therefore, the possibility for equivocal, false positive and/or negative outcomes is high. Consequences of this may be the requirement for additional fish testing to confirm or refute changes in VTG, and a possibly erroneous identification of endocrine activity. With the aim to gather technical information and understand the reliability of VTG results, a survey was prepared in a collaboration between the UK’s NC3Rs and a working group of industry and consultancy experts. The survey covered a range of aspects including general methodologies for sampling, measuring and interpreting VTG concentrations in different fish species and matrices. The survey was sent to 27 laboratories in August 2021 and was completed by 16 (6 from the UK, 3 from the USA, and 7 from the EU). The main focus of these organisations was testing for regulatory purposes (using fathead minnow (*Pimephales promelas*), zebrafish (*Danio rerio*) or Japanese medaka (*Oryzias latipes*)) although two respondents measured VTG as part of field monitoring using a range of different fish species. The survey results confirmed variability in background VTG concentrations (using the internal historical control datasets of the surveyed labs) associated with different fish batches, or changes in fish husbandry or laboratory practices. These aspects were considered difficult to control. There were also differences related to the general methods for measuring VTG. With a focus on measurement of the VTG protein using enzyme-linked immunosorbent assay (ELISA; the most commonly used method for VTG analysis), differences amongst laboratories will be discussed covering: 1. Sample collection and storage, 2. VTG quantification, 3. Data handling, and 4. The benchmark for data acceptability. The survey highlighted some differences amongst laboratories, which have the potential to impact the VTG results. The survey results provide the basis for further discussion to improve the harmonisation of VTG measurements in fish and an opportunity to reassess the suitability of current acceptability criteria for VTG measurement.

8.04.P-Th275 Launching an Open-Source Global Chemical Inventory

Raoul Wolf¹, Andreas Botnen Smebye², Emma Schymanski³, Eva Fritzell⁴, Hans Peter Arp⁵, Zhanyun Wang⁶ and Sarah Hale⁴, (1)Norwegian Geotechnical Institute (NGI), Oslo, Norway, (2)Norwegian Geotechnical Institute, Norway, (3)University of Luxembourg, Luxembourg, (4)Norwegian Geotechnical Institute (NGI), Norway, (5)NGI, Norway, (6)ETH Zurich, Switzerland

A pioneering effort to index the global chemical inventory, *i.e.*, all chemicals registered on (super-)national economic markets, was first published by Wang *et al.* in 2020.^[1] This ground-breaking work has enabled a greater understanding of the regulatory chemical space and allowed for widescale read across and analyses of the inventories and their chemicals. As part of the H2020 project ZeroPM (<https://zeropm.eu>), a fully reproducible and open-source re-construction of the global chemical inventory will be developed. Re-evaluating and updating previously included and several new inventories, a modern database infrastructure will be established using PostgreSQL as *lingua franca*. The databases will support singular, structurally defined chemicals, *i.e.*, by a unique InChI string, as well as advancing the integration of mixtures, UVCBs, polymers, and moieties. Using InChI strings allows for a robust identification of unique substances, and will allow to establish workflows for, *e.g.*, reproducible SMILES creation using Open Babel and large-scale scanning for potential moieties of interest across all included molecular structures. Wherever possible, cross-references will be made, *e.g.*, from a well-defined mixture to its individual constituents and to their moieties. Individual functionalities for the databases will be implemented within orchestrated Docker containers. The database itself will be downloadable in flat, tabular formats (*e.g.*, as CSV file), and eventually a graphical user interface will be provided for simple access to the database. In addition, application programming interface (API) functionality will be provided to programmatically access the database. The development of the databases will follow FAIR principles, and both the resulting data and code will be shared on the Zenodo community (<https://zenodo.org/communities/zeropm-h2020>) and the GitHub repository

(<https://github.com/ZeroPM-H2020>), respectively, under permissive licenses. The ZeroPM project and its databases will contribute to the European Commission's Chemicals Strategy for Sustainability, and will support open, transparent research projects benefitting both the environment and the general public. ^[1] Wang *et al.*, 2020. *Env. Sci. Technol.* **54**:2575–2584, doi:10.1021/acs.est.9b06379

8.04.P-Th276 Life Cycle Assessment As Affirmation Tool for Faster Uptake of Construction Products Incorporating Waste Materials

Ivana Carevic¹, Matea Flegar², Marijana Serdar², Ivana Banjad Pe?ur² and Nina Štirmer², (1)University of Zagreb Faculty of Civil Engineering, Zagreb, Croatia, (2)University of Zagreb Faculty of Civil Engineering, Croatia

According to Eurostat, the total production of cementitious materials in the EU was estimated to be 163 million tonnes in 2016, corresponding to an estimated turnover of €15.2 billion. Currently, the annual production of cement in Croatia is around 4.4 million tons. At the same time, the global average CO₂ emission per tonne of cement is estimated to be around 0.83 tonnes. Considering the expected rapid population growth and production increase, if no actions are taken by 2050, the production of cementitious materials alone could contribute to 24% of total global CO₂ emissions. There is no other construction material (natural or man-made) that is produced in such high quantity as concrete, therefore a phase-out strategy for cementitious binders in concrete is highly unlikely. In East & south-east Europe (ESEE) countries today, the main cementitious binders used are those with a significant amount of industrial by-products from heavy industry, such as slags from the steel industry and fly ash from coal combustion. However, for these industrial by-products to work, they must have a certain quality and stability in production quantities. Since these criteria cannot be met with regional industry, most industrial by-products are currently imported from countries such as Turkey or China. Such heavy reliance on the import of secondary raw materials poses risks: supply insecurity due to scarcity, regulations and/or geopolitical factors and price volatility of industrial by-products, depending on regulations and market opportunities. Transformation of the construction industry into low-environmental and resource-efficient ones is possible through greater circularity of the different types of waste streams that are still disposed of in landfills. This includes opening new value chains and industrial symbiosis, adapting and redesigning solutions, and creating a framework and standardisation for wider use of construction products incorporating waste materials. LCA presents an important and efficient tool in the affirmation process for faster uptake of these products. This research shows two different LCA examples of different local available wastes used as reactive binders in the construction sector and a comparison of their environmental impact with existing commercial cement. In addition, the greatest challenges and barriers (social and technical) of accepting new materials in the construction sector have been identified through interviews with the key stakeholders.

8.04.P-Th277 Life Cycle Assessment of Na-Ion Batteries With Ti₁Al₁TiC_{1.85} MXene As Negative Electrode: From Laboratory to Industrial Scale

Maria Leonor Carvalho¹, Giulio Mela², Andrea Temporelli², Elisabetta Brivio², Irene Quinzeni², Stefano Marchionna² and Pierpaolo Girardi², (1)Ricerca sul Sistema Energetico - RSE S.p.A., Milano, Italy, (2)Ricerca sul Sistema Energetico - RSE S.p.A., Italy

Energy storage can be the key for the fast decarbonization of the electricity grid and the transportation sector. Nowadays, Lithium-ion batteries (LIBs) are the most used battery chemistry, however, still show critical issues linked to their production, energy consumption, greenhouse gas emissions and rare raw materials use. Thus, it is important to find alternative storage technologies to be used singly or in combination with LIBs. Sodium-ion batteries (SIBs) are promising battery technology and possible successors to LIBs, with good theoretical environmental and electrochemical performance. Particularly, MXenes are promising materials for energy storage applications such as anodes for sodium-ion batteries. SIBs environmental impacts are essential: Life Cycle Assessment (LCA) is a consolidated methodology and is the main assessment approach followed in this study. The LCA is complemented with an economic indicator, the Commodity Life Cycle Costing (CLCC) which quantifies, in economic terms, a product's use of natural resources during its life cycle. When technologies are still under development, the LCA methodology application presents two main criticalities: the lack of data and the effective technology implementation and use in future contexts. It is, therefore, necessary to adopt an approach that allows both to evaluate the impacts of emerging technologies on an industrial scale and consider the system's future evolution. Hence an Ex-ante LCA, using LIBs as a proxy for the transition from laboratory SIBs to industrial scale, has been carried out. In this study, coin cells with Ti₁Al₁TiC_{1.85} MXene as anode material at three different technological grades: laboratory, pilot and industrial are assessed. LCA results allow to compare technological scales and to provide useful information to improve related processes with a view to eco-design. The assessed SIBs result less environmentally friendly than LIBs, an outcome driven by the lower energy density of the SIBs. The CLCC indicator calculated for SIBs batteries is more than seven times higher than that of LIBs, meaning a higher natural resource use or the use of more expensive/scarcer resources. However, if only critical materials are considered, SIBs are characterized by lower values than LIBs. Therefore, EU must encourage research for alternatives to LIBs in the next years, to fulfil its ambitious decarbonization goals.

8.04.P-Th278 Liquid Chromatographic Determination of Per- and Polyfluoroalkyl Substances in Environmental River WATER Samples

Philiswa Nomngongo¹ and Shirley Selahle², (1)University of Johannesburg, Afghanistan, (2)University of Johannesburg, South Africa

Contaminants of emerging concern (CECs) such as per- and polyfluoroalkyl substances (PFAS) have attracted significant interest of researchers, policymakers, and water treatment facilities. This is because PFAS are highly persistent in the environment and tend to be bio-accumulative thus causing adverse effects to terrestrial and aquatic life. Therefore, there is a need for simpler and fast methods for the determination of PFAS in water sources. This work aims at application of dispersive magnetic solid-phase

extraction (DMSPE) for enrichment of PFAS in various surface water samples. Magnetic Fe₃O₄@MIL-101 (Cr) was used as an adsorbent for in MSPE. The concentrations of target analytes in water samples were determined using high performance liquid chromatography-diode array detector and ultra-high performance liquid chromatography-tandem mass spectrometry analysis. The combination of optimized DMSPE with HPLC-DAD and UHPLC-MS/MS provided wide linear range (1-5000 ng/L and 0.05-2000 ng/L, low limits of detection (0.3–0.66 ng/L and 0.011-0.04 ng/L) and limits of quantification (1.0-2.2 ng/L and 0.04-0.12 ng/L). Moreover, acceptable intraday and interday precision based on the relative standard deviation (RSD) lower than 5% were obtained. The developed method showed remarkable practicability for analysis of ultra-trace PFAS in water samples.

8.04.P-Th279 Marine Microbiome Affected by the Discharge of Urban Wastewater Effluent at the Swedish West Coast

Sonja Schaufelberger¹, Alexis Fonseca², Thomas Backhaus³ and Pedro Inostroza⁴, (1)Department of Biological and Environmental Sciences, University of Gothenburg, Göteborg, Sweden, (2)Aarhus Universitet, Denmark, (3)University of Gothenburg, Sweden, (4)Biological and Environmental Sciences, University of Gothenburg, Gothenburg (Sweden), Sweden Marine coastal ecosystems are under increasing anthropogenic pressure. Negative effects due to discharge of nutrients, heavy metals, and organic toxicants from industry, wastewater treatment plants (WWTPs), and/or agriculture not only on macro- and mesofauna, but also microbes are widely recognized. Microbial communities are pivotal players of natural biogeochemical cycles, and thus are vital for the functioning of their ecosystem they inhabit. Hence, any disruption of their ecological functions and/or change in community structure may lead to unwanted disequilibrium. In this study, we used environmental DNA (eDNA) to fill knowledge gaps regarding 1) the biodiversity status of microbial communities, 2) environmental variables driving community structure, and 3) the persistence of sewage-related bacteria in natural environments. Our study site is a fjord system at the Swedish West Coast (Hakefjorden and Havstensfjorden), surrounding the city of Stenungsund, which harbours a variety of industry branches but is chiefly known for being the centre of the Swedish petrochemical industry. Six eDNA samples were collected along the fjords. Additionally, samples from three freshwater inflows were sampled: a WWTP effluent and two streams running through agricultural and urban areas, respectively. Bacterial communities were characterised using 16S rRNA amplicons sequenced on an Illumina platform. State-of-the-art bioinformatic workflows were conducted to obtain amplicon sequence variants (ASVs) and taxonomic assignment (Qiime2 and DADA2). Subsequent downstream analysis was performed using R-packages phyloseq and DESeq2 to assess i.a. α -diversity and differential abundance. Our results showed significantly lower α -diversity in marine microbiomes compared to freshwater ones with about half as many observed ASVs. Interestingly, α -diversity measures were considerably higher at the marine site closest to the WWTP effluent (M5). Conversely, we did not observe α -diversity changes linked to industrial or agricultural freshwater inflows. Communities from marine, freshwater, and WWTP effluent samples were distinct from each other exhibiting a wide range of differentially abundant taxa. Further, environmental variables failed to explain M5 clustering separately from the other marine sites. Overall, we suggest that WWTP may increase the biodiversity in the water column and contribute to shifting the community composition of nearby bacterial communities.

8.04.P-Th280 Modelling the Influence of Climate Change on Contaminant Exposure in Three Key Seabird Species in the European Arctic

Lovise Pedersen Skogeng¹, Igor Eulaers², Pierre Blevin³, Kjetil Sagerup⁴, Jan Ove Bustnes⁵, Geir Gabrielsen², Sabine Eckhardt⁶, Frank Wania⁷, Knut Breivik⁸ and Ingjerd Sunde Krogseth⁹, (1)Environmental Chemistry, NILU - Norwegian Institute for Air Research, Tromsø, Norway, (2)Norwegian Polar Institute, Norway, (3)Akvaplan-niva, Tromsø, Norway, (4)Akvaplan-niva, Norway, (5)Norwegian Institute for Nature Research, Norway, (6)NILU - Norwegian Institute for Air Research, Norway, (7)University of Toronto Scarborough, Toronto, ON, Canada, (8)Norwegian Inst. for Air Research, Kjeller, Norway, (9)Norwegian Institute for Air Research, Tromsø, Norway

The combined impact of climate change and exposure contaminants on Arctic seabirds remains poorly understood. A mechanistic understanding of the link between global persistent organic pollutant (POP) emissions and exposure in seabirds seems vital to advance our knowledge in light of climate projections. The overall objective of this study is to develop and evaluate a bioaccumulation model and utilize it to predict the impact of climate scenarios on the POP exposure in Arctic seabirds. For this purpose, we further developed the Nested Exposure Model (NEM), a dynamic and spatially resolved environmental fate and bioaccumulation model that simulates the link between global organic contaminant emissions and resulting exposure in key Arctic species. Here, NEM is expanded to include three seabird species with contrasting feeding ecology: the pelagic black-legged kittiwake (*Rissa tridactyla*), the omnivorous scavenging glaucous gull (*Larus hyperboreus*) and the benthic-feeding common eider (*Somateria mollissima*). While NEM already accommodates pelagic species that are key prey for the black-legged kittiwake and glaucous gull, the model was expanded to now also include benthic species that are key prey of the common eider. All seabird species were parameterized based on detailed ecological data, including seasonal lipid dynamics, energy needs and reproductive behavior. To evaluate the model, global historical emission inventories and physicochemical properties of polychlorinated biphenyl (PCB-) 153 are used to predict its concentrations in the three seabird species from 1930 – 2050. Predicted concentrations are then compared to empirical time series of PCB-153 concentrations in the study species sampled in Kongsfjorden, Svalbard. An overview of the NEM model framework, parameterization, and preliminary evaluation will be presented. The model will be used to mechanistically understand and predict contaminant exposure in the study seabirds in different future climate scenarios, e.g. changing primary emissions, changes in the physical environment, or changes in dietary preferences or availability. Ultimately, this study will expand our understanding of the impact of climate change on long-range transported contaminants in Arctic seabirds.

8.04.P-Th281 Morphohistological Data of Normal Variation of the Thyroid Glands From Tadpoles in Amphibian Metamorphosis Assays Using Automated Image Analysis by Machine Learned Algorithms

Nils Warfving, Laura Polledo Ruiz, Alex Vitali, Bastian Zingg and Klaus weber, AnaPath Services GmbH, Switzerland

Knowledge of the morphological variation of normal thyroid glands in the corresponding developmental stage of tadpoles is a prerequisite for the assessment of possible induced endocrine effects by the toxicological pathologist. Heterogeneity among thyroid glands from control animals, may be associated with larval stage, breeder, facilities, alimentary conditions, possible solvent effects, etc. Histological sections of thyroid glands stained with haematoxylin and eosin from control tadpoles of 12 studies, n = 301 tadpoles stage¹ 57 to 60) from three test facilities (TF1, TF2, TF3) were evaluated by pathologists and the corresponding whole slide images were analysed using an automated procedure in QuPath: Open source software for digital pathology image analysis². In addition, the high dose group from a study with test-item induced hypertrophy was also analysed using the machine learned algorithms to evaluate the use of this tool to support traditional histologic evaluation. The data obtained include total thyroid gland area, ratio between the follicular epithelium vs. total area, height of the follicular epithelium, total colloid area, and ratio between epithelium and colloid area as well as number of epithelial cells. The results provide a basis for understanding normal variation for specific larval stages, and data revealed differences in thyroid gland morphometry among test facilities. Furthermore, there were minor differences between controls in water and controls in solvents. Thus, thyroid findings need to be carefully interpreted and compared to study stage-matched controls for conclusive results. The methodology was also applied to a study with induced thyroid gland hypertrophy and hyperplasia. Automated image analysis showed marked and significant differences between the control group and high dose for all parameters. It is concluded that image analysis by automated machine learned algorithms enabled objective quantitative data for the thyroid gland and across the complete 2D histological section. Therefore, the image analysis is considered a valuable and accurate tool to support the microscopic evaluation by the pathologist. 1. 1. 8.04.P-Th282 Mosaic-Project Extensive Monitoring of Pesticides and PFAS in 274 WATER Bodies in Southern Germany

Anna-Jorina Wicht, Vanessa Ivenz and Manfred Sengl, Bavarian Environment Agency (LfU), Germany

The Water Framework Directive (WFD) aims at the achievement of a good ecological and chemical status for all surface waters, which is assessed by monitoring of priority substances and certain other pollutants. In 2018 the MOSAIC-project, a six-year monitoring program, started. The project intends to give a broad overview on the pollution status of Bavarian surface waters, with special focus on smaller rivers. Every year surface water samples of 90 different water bodies are analysed monthly or quarterly for a set of 247 parameters (pesticides, perfluoroalkyl substances (PFAS), heavy metals among other compounds) in total reaching approximately 540 water bodies by the end of project. To complete the picture non-target screening technology is used to identify compounds not focused on yet. The results from 274 water bodies analysed in 2018 – 2020 are presented. Temporal trends and spatial differences in substance patterns are statistically evaluated to identify sources and application mixtures. Concentrations are compared to environmental quality standards (EQS) and sampling sites are correlated to the surrounding land use. The data provided may support the differentiation between background levels and hotspot contaminations. 59 of 71 monthly analysed pesticides were detected. However, the majority of samples did not exceed WFD-quality standards (AA-EQS/MAC-EQS). EQS-threshold exceedances were detected for 10 compounds. Sampling sites were selected based on land use and potential point sources in the catchment area. A broad range from rural to agricultural land uses is covered. The data demonstrate spatial trends of pesticides, which can be related to agricultural land use. 10 PFAS were investigated in four samples a year. PFAS are used in a wide range of applications in different mixtures. Application related patterns could therefore help to identify potential sources. Despite the ubiquitous detection of PFOS, patterns in PFAS mixtures were identified. The statistical analysis indicates the differentiation of two main use categories where PFAS are employed: Fire-fighting foams and industrial applications. While many studies and regulatory actions focus on large rivers, this project provides the unique opportunity to gather a comprehensive overview of compounds present in smaller rivers and streams.

8.04.P-Th283 National Environmental Quality Standards Set in Denmark

Janni Magelund Degn Larsen and Pernille Steenkær Munch, Danish EPA, Odense, Denmark

Environmental Quality Standards (EQS) are limit values for substances in the environment set to protect the living organisms in the aquatic environment from possible adverse effects. EQSs are used as tools for assessing the chemical status of waterbodies and to set discharge permits to waterbodies. EQSs set for substances on the Priority Substance List under the European Union's Water Framework Directive (WFD) currently covers 45 substances, cf. directive 2013/39/EU, which have been prioritized for action on a Community level. This directive covers annual average EQS values (AA-EQS) and maximum allowable EQS values (MAC-EQS) for fresh- and marine surface water. And for a few substances the directive covers EQS values for biota, but no EQS values for sediment is covered. The Priority Substance List leaves out substances, which have national relevance for compliance assessments and discharge permits. Thus, in the last couple of years, The Danish EPA has increased the focus on deriving national EQS values for River Basin Specific Pollutants (RBSPs). The focus has primarily been to derive EQS values for sediment in relation to protection of benthic species, in addition to EQS values for biota for the protection of secondary poisoning through the food web, as well as protection of human health from consuming contaminated fisheries products. In the work of setting EQS values for sediment and biota, challenges related to e.g. handling and assessment of available data were encountered. For some RBSPs the amount of reliable data was sufficient to consider and argue for applying a Species Sensitivity Distribution analysis (SSD-analysis) in the derivation of both an EQS value for sediment as well as for biota (secondary poisoning), whereas other RBSPs fulfilled the evidence of e.g. potential to bioaccumulate, which would suggest a derivation of an EQS value for biota, but no reliable and relevant data was available. The list of RBSPs by the Danish EPA covers both organic and inorganic contaminants.

Several EQS dossiers have been finalized and are public available at the agency's webpage. These cover both national relevant substances and substances on the Priority Substance List for which national EQS values for sediment and biota has been set.

8.04.P-Th284 Natural Polyphenolic Extracts As Antioxidants for Biopolymers

Luna Valero¹, Haroutioun Askanian², Astrid Delorme³ and Florence Delor Jestin², (1)Institut de Chimie de Clermont-Ferrand, Clermont-Ferrand, France, (2)Université Clermont Auvergne, CNRS, SIGMA Clermont, ICCF, F-63000 Clermont-Ferrand, France, France, (3)ICCF - CNRS, France

In the plastic field, a major challenge is to substitute synthetic additives with greener chemicals with the intent to develop environmentally friendly materials. The development of natural additives, including stabilizing agents, is increasingly investigated for polymer materials and particularly for biopolymers. All through their lifecycle, polymers are subject to degradation, such as thermo- and photo-degradation, leading to the deterioration of their properties. Stabilizers are used to prevent and/or slow down the degradation kinetics and control the durability of polymers. Recently, bio-sourced antioxidants, such as polyphenols, have demonstrated promising results for the protection of polymers against degradation and aging. This study is a part of the Horizon 2020 project SEALIVE, whose purpose is to reduce plastic waste and environmental pollution of land and seas by developing innovative and sustainable bioplastic strategies contributing to the circular economy. The objective is to elaborate various demonstrators from new bioplastics solutions developed within SEALIVE. This work presents the thermal and photo-stabilization of poly lactic acid (PLA) biopolymer with polyphenol extracts from biomass valorization. As a first step, an initial evaluation of the antioxidant activity of the extracted polyphenols from different vegetal matrices (agri-food by-products, industrial residues, wild plants) has been performed. As a second step, thermal and photo stabilization studies were conducted on PLA formulated with the polyphenols exhibiting high antioxidant activities. The stabilizing efficiency of the extracts was mainly evaluated using rheological analysis to monitor the molecular weight evolution during processing and the exposition to thermal and photo-aging in accelerated conditions. The results demonstrated that different polyphenol extracts successfully delay PLA degradation and constitute very promising natural stabilizers. **Acknowledgments** *The work in this paper is supported by the SEALIVE Project which is funded by the European Union's Horizon 2020 Program, under grant agreement number 862910.*

8.04.P-Th285 Optimization of White-Rot Fungi Mycelial Culture Components for Bioremediation of Pharmaceutical-Derived Pollutants

Bartosz Mateusz Kozka¹, Agata So?nicka², Katerina Makarova², Joanna Giebu?towcz², Marzenna Klimaszewska² and Jadwiga Tur?o², (1)Medical University of Warsaw, Warsaw, Poland, (2)Medical University of Warsaw, Poland

The issue of the presence of pharmaceuticals in the aquatic environment emerged about 15 years ago, but recently more and more data have been collected on their adverse effects on biota. The occurrence of PhACs in the aquatic environment can be caused by improper disposal processes applied by producers or leachate from landfills, farms, nevertheless, wastewater treatment plant (WWTP) effluents contribute the most. Although WWTPs are in general able to remove organic pollutants, the effectiveness of this process varies. Currently, in the treatment of sewage with the activated sludge method, numerous microorganisms are used, mostly bacteria. Nevertheless, these microorganisms are not resistant to many drug contaminants. Moreover, PhACs pollutants accumulating in water environment may also pose a risk to human health. White-rot fungi are promising candidates to solve this problem, because they degrade a wide spectrum of environmental pollutants, including pharmaceuticals, which are not efficiently removed from wastewater by using conventional methods. Numerous studies showed that mycoremediation offers a more effective approach to wastewater treatment. Now, mainly high costs of media ingredients limit the application of mycoremediation on a large scale. We aimed to screen 18 media ingredients, including seven agri-food by-products to select low-cost medium optimal for biomass production for three selected white-rot fungi. The submerged cultures of *Armillaria mellea*, *Phanerochaete chrysosporium* and *Pleurotus ostreatus* were conducted in different media ingredients such as: ammonium salts, corn waste products, molasses, saccharides, sawdust, soy peptone, urea, whey, yeast extract. The reference medium contained glucose, casein peptone, yeast extract and potassium dihydrogen phosphate. Three media variants provided efficient growth, i.e. corn steep liquor, dried distillers grains with solubles and whey. The results could be used in further research towards designing a plan to implement agri-food products for white-rot fungi cultivation in municipal sewage.

8.04.P-Th286 Organophosphate Esters in the Water Column and Surface Microlayer of the Atlantic Ocean

Núria Trilla¹, Naiara Berrojalboz², Jon Iriarte¹, Gemma Casas³, Maria Vila-Costa⁴, Begona Jimenez⁵ and Jordi Dachs¹, (1)IDAEA-CSIC, Spain, (2)Institute of Environmental Assessment and Water Research IDAEA CSIC, Spain, (3)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (4)IDAEA CSIC, Spain, (5)IQOG-CSIC, Spain

Organophosphate esters (OPEs) are synthetic organic chemicals widely used as plasticizers and flame retardants in the industry, in household consumer products and in personal care products. Their range of physicochemical properties is wide, influencing their transport and biogeochemistry in the marine environment. Our goal was to assess the spatial and vertical distribution of OPEs by sampling and analyzing samples taken during a latitudinal transect through the Atlantic Ocean (from latitude 40 °N to 55 °S). Surface seawater was analyzed from 24 sampling stations, while the surface microlayer (SML) and vertical profiles (5-6 different depths from surface to 2000 m depth) were assessed at 9 and 7 stations, respectively. A total of 24 individual OPEs were targeted, among which 13 compounds were found ubiquitous in Atlantic waters (TEP, TiBP, TNBP, TCEP, 1, 2, 3-TCPP, TDCIPP, TPhP, TBEP, EHDP, TEHP, TmCP). Briefly, the surface total concentration for the dominant OPEs ranged between 1.9 and 56.9 ng L⁻¹ (individually TEP: loq to 4.1 ng L⁻¹, TiBP: loq to 5.6 ng L⁻¹, TNBP: loq to 1.5 ng L⁻¹, TCEP: loq to 10.9 ng L⁻¹, TCPP1: 1.2 to 32.8 ng L⁻¹, TCPP2: 0.2 to 19.1 ng L⁻¹, TCPP3: loq to 0.5 ng L⁻¹, TDCIPP: loq to 0.7 ng L⁻¹, TPhP: loq to 1.3 ng L⁻¹, TBEP: loq to 3.1 ng L⁻¹, EHDP: loq to 7 ng L⁻¹, TEHP: loq to 0.3 ng L⁻¹, and TmCP: loq to 0.5 ng L⁻¹). Maximum concentrations were found in tropical waters of the SE Atlantic off-shore Brazil. At the SML, the top 0.1 mm layer at the air-water interface as sampled with a

glass plate, we found higher OPE concentrations when compared to underlying waters by SML enrichment factors ranging between 1.2 to 24. Therefore, OPEs show a tendency to accumulate at the surface of the ocean, as it has been demonstrated for other organic pollutants, with implications for their potential long-range transport through sea-spray aerosol formation. Regarding the vertical profiles, we have found different trends depending on the locations, but generally with maximum concentrations at surface waters, consistent with atmospheric deposition as one of the main inputs. However, a second maximum was often found at deep waters, which suggests that vertical transport by settling particles may lead to the accumulation of OPEs in the deep ocean. The results will be shown in connection with other physical, chemical and biological variables explaining their transport and water column biogeochemistry.

8.04.P-Th287 Persistent, Mobile, and Toxic Substances - Evaluation of Risk to Drinking WATER in England and Wales
Emma Pemberton¹, Christopher Hughes², Chesney Swansborough³, Simon Cook³, Emily Butcher³, Michael John Whelan⁴, Emma Goslan⁵, Todd Gouin⁶, Sarah Bull⁷, Lawrence Segal⁸ and Sarah Fane⁹, (1)Ricardo Energy & Environment, UK, (2)Ricardo Energy & Environment, Chester, United Kingdom, (3)Ricardo Energy & Environment, United Kingdom, (4)University of Leicester, United Kingdom, (5)Cranfield University, United Kingdom, (6)TG Environmental Research, Sharnbrook, United Kingdom, (7)TARA consulting, United Kingdom, (8)Independent Consultant, Spain, (9)Drinking Water Inspectorate, United Kingdom

Substances that are persistent and mobile have a greater potential to pass natural barriers like riverbanks and migrate to groundwater. Such substances also have a greater propensity to breakthrough in standard drinking water treatment because of their physico-chemical properties. Substances with these intrinsic properties, especially when considered in combination with toxicity may pose a risk to human health and the environment through contamination of drinking water sources. In recent years there has been an increasing body of work to explore data criteria for the definition of a hazard class relating to persistent, mobile, and toxic substances with the aim of protecting natural resources that could be used for drinking water supply. In Europe, substances that are persistent (P), mobile (M) and toxic (T) or very persistent (vP) and very mobile (vM) have been proposed as an additional hazard class under REACH and the Classification, Labelling and Packaging regulations. In 2020 the European Commission published its 'Chemicals Strategy for Sustainability Towards a Toxic-free Environment' which commits to the introduction of PMT and vPvM as categories of substances of very high concern. We describe an ongoing project to assess the risk to human health from PMT/vPvM substances through exposure via drinking water. The project focuses on drinking water sources in England and Wales and examines the risks posed by approximately 30 potential PMT substances. Toxicological data has been collated to understand the hazards associated with each substance. Data and intelligence to establish the nature of use and quantities used in England and Wales and evidence on occurrence in environmental waters in England and Wales has also been gathered. Modelled surface water concentrations will be used to generate exposure maps for England and Wales. Exposure predictions for humans via drinking water will be estimated from predicted raw water concentrations after accounting for removal of the compounds of interest by standard and advanced treatment processes, based on their physical chemical properties. A spatially based assessment of risk will be made to identify those substances likely to pose the highest risk to human health through drinking water. Potential risk factors that could be used to inform the development of future targeted risk-based monitoring programmes and identify any high-risk catchments will be identified.

8.04.P-Th288 Prospective Comparison of the Primary and Secondary Production of Nd-Fe-B Magnets
Brenda Miranda Xicotencatl¹, Rene Kleijn² and Sander van Nielsen², (1)Institute of Environmental Sciences, Leiden University, Afghanistan, (2)Institute of Environmental Sciences, Leiden University, Netherlands

Due to the increasing adoption of wind turbines and electric motors for battery-electric mobility, the energy transition requires an increasingly secure supply of permanent rare earth magnets. While the current supply chain of rare earths heavily relies on mining them in China, Nd recycling outside of China is expected to play a prominent role in the future. One of the alternative recycling processes currently under development in the framework of the Horizon 2020 project "SUSMAGPRO" involves the use of hydrogen to retrieve Nd-Fe-B from end-of-life magnets. We performed an LCA resulting in a prospective comparison of the environmental profile of the hydrogen-based recycling alternative and the primary production of permanent magnets, in collaboration with the developers of the recycling technology. This recycling technology currently operates at pilot scale; however, the environmental profile we derived corresponds to an extrapolated scenario of a higher technological maturity. We included, in the product system models, future trends in the energy systems up to 2050. We found that the hydrogen-based recycling of magnets showed a better environmental performance than the primary production at industrial scale in all the impact categories evaluated. One of the key drivers of this difference is the reduced energy demand from reprocessing the alloy instead of chemically reducing the metallic oxide extracted from the ore. The future trends in the energy systems we considered indicate a lower environmental impact of electricity. As a consequence, the environmental burdens of the primary production would decline but the environmental burdens of the secondary production would decline even faster. After discussions with the developers of the recycling process, we also identified environmental hotspots and advised them on how to optimize the technology and the sustainability of the alternative recycling process.

8.04.P-Th289 Read-Across for the Chemical Safety Assessment: Possible Approaches, Challenges and Perspectives
Agnieszka Gajewicz-Skretna¹, Magdalena Piotrowska², Maciej Gromelski² and Ewelina Wyrzykowska², (1)Faculty of Chemistry, University of Gdansk, Gdansk, Poland, (2)University of Gdansk, Poland

The past few decades have seen unprecedented growth in the synthesis of organic and inorganic chemicals. These are then marketed and can be found in the environment. Although the majority of industrial chemicals are designed to be biologically inactive, there are numerous examples of chemicals causing adverse environmental effects years after they've been produced. On

the other hand, with an ever-increasing number of synthetic chemicals being manufactured, it is unrealistic to expect that they will all be subjected to comprehensive and effective risk assessment. The EU REACH legislation, the OECD and US EPA official guidance documents, and 3Rs principle (Replacement, Reduction, Refinement of animal testing) all advocate the necessity of developing comprehensive computational methods (e.g.: read-across methods) that would enable the predictive modeling of both chemical-specific functionalities and their hazard. A shift from conventional animal testing to computer-aided methods is, therefore, an important step towards advancing the environmental risk assessments of chemicals. These tools would also be crucial in establishing *safe-by-design* principles at the early stages of new chemical development. Based on the experience of SONATA-12 project, funded by the Polish National Science Centre (UMO-2016/23/D/NZ7/03973) we will present the current state-of-the-art of the *in silico* methods, with the focus on read-across models. Then, we will demonstrate the examples of read-across models for predicting the acute toxicity of structurally diverse organic chemicals to fish and aquatic invertebrates. Finally, we will discuss a further perspective for the development of computational toxicology.

8.04.P-Th290 RobustNature Excellence Cluster Initiative - Robustness and Resilience of Nature-Society Systems in the Evolving Anthropocene

*Sarah Johann*¹, *Fabian Weichert*², *Frederic Strobl*³, *Carolin Völker*⁴, *Sabrina Schiwy*⁵, *Flurina Schneider*⁶, *Sven Klimpel*⁷, *Ernst H.K. Stelzer*³ and *Henner Hollert*⁸, (1)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (2)Goethe University Frankfurt am Main, Germany, (3)Goethe University Frankfurt am Main, Germany, (4)ISOE - Institute for Social-Ecological Research, Germany, (5)Goethe University Frankfurt am Main, Frankfurt, Germany, (6)ISOE- Institute for Social-Ecological Research, Germany, (7)Goethe University Frankfurt, Germany, (8)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany

Our planet is facing existential challenges such as the decline of biodiversity, climate change and chemical pollution. Though comprehensive research is being conducted to study the individual aspects, especially the interactions and interdependencies of these three areas on a global scale are identified as major challenges for international research in the coming years. The higher-level system functionalities are highly dynamic processes, and their constant changes as well as their robustness and resilience are neither well understood nor quantified. We would like to present the RobustNature Excellence Cluster Initiative, which aims to improve the understanding of robustness and resilience of Nature-Society Systems in the contexts of chemical pollution, biodiversity loss and climate change by means of knowledge-based transformation research. Multiscale approaches from molecules to ecosystems in the three research areas Water, Organismic Interactions and Systemic Risks are used to identify markers for multiple stressors and their specific effects. Furthermore, economic and societal impacts are investigated and strategies to manage and avoid the risks stemming from imbalanced nature-society systems are developed. We believe that such a holistic approach needs to combine interdisciplinary expertise from biology, geosciences, environmental sciences, social sciences, law, economics, and medicine to cover ecological, economical, and social perspectives. Thus, the RobustNature consortium, a large collection of various departments from Goethe University Frankfurt am Main (Germany) as core institution as well as international partners from academia and industry invites researchers for collaboration, expert dialogues, and scientific exchange. RobustNature is an initiative to establish a cluster of excellence with a long-term perspective, which we believe is crucial to tackle the challenges of our modern society. As an innovative method to successfully implement the research questions and to strengthen interdisciplinary collaborations, several SynergyFund projects have been initiated in RobustNature. In a first phase, 11 joint projects are successfully established. Projects are characterized by the funding of scientists in early career stages, by the participation of many working groups and (inter)national external partners.

8.04.P-Th291 Role of Dissociation Kinetics in Determining Platinum and Palladium Toxicity to a GREEN Alga and Their Accumulation

*Julien Michaud-Valcourt*¹, *Severine Le Faucheur*², *Jelle Mertens*³ and *Claude Fortin*¹, (1)INRS - Centre Eau Terre Environnement, Canada, (2)Université de Pau et des Pays de l'Adour, France, (3)EPMF, Bruxelles, Belgium

Ever since the introduction of platinum (Pt) and palladium (Pd) in automotive catalysts, the motor vehicle exhaust has become the primary source of emission of those metals in the environment. Although initially believed to be inert, several studies have recently demonstrated their mobility. Once mobilized, they are likely to reach aquatic ecosystems, where both Pt and Pd complexes will undergo speciation changes. The kinetic process can be predicted by the water exchange rate which, for many transition metals, is in the order of 10^{-7} to 10^{-10} s⁻¹. For Pt and Pd, the rate constants are orders of magnitude higher (around 10^3 s⁻¹), which means that speciation changes may take place over a relatively long-time scale. In this project, we examined the accumulation and toxicity of Pd and Pt using the green alga *Pseudokirchneriella subcapitata* as a function of their initial forms (i.e. as amine or chloride complexes) and potential re-speciation during the exposure experiments. The microalgae were exposed for 96 h in a modified USEPA medium containing either the chloride or amine complex of Pt(II) or Pd(II). We hypothesized that, if these metals quickly reach thermodynamic equilibrium, they should mainly re-speciate into hydroxo-complexes and exert similar toxicity irrespective of the initial form. Similar growth inhibition thresholds (EC50s) and levels of Pd accumulation were observed for both complexes. However, tests with chloro-Pt showed higher toxicity than with amine-Pt. Surprisingly, similar accumulation levels of Pt were observed, indicating a disconnect between accumulation and effects. These results thus suggest that the changes in Pd speciation occur within a time frame short enough to provide similar toxicity to the green alga while Pt speciation occurs slowly and toxicity differs based on the initial speciation. Changes in metal speciation over time for all complexes tested was further investigated by UV-visible absorbance to get insight on the time scale of these changes. Changes in spectrophotometric spectra were observed within hours for chloro-complexes of Pt but not for amine-complexes, suggesting a higher stability of amine-Pt complexes. Our work shows that the initial form of Pt(II) used in toxicity tests needs to be considered

and that thermodynamic equilibrium cannot be assumed to be reached over the exposure time. On the other hand, the toxicity of Pd(II) is likely governed by the resulting chemical speciation at equilibrium.

8.04.P-Th292 Species Sensitivity Distribution in Ground Beetle Communities Inhabiting Oilseed Rape Fields Towards Three Insecticides

*Danuta Anna Frydryszak*¹, *Agnieszka Bednarska*² and *Ryszard Laskowski*³, (1)Jagiellonian University, Kraków, Poland, (2)Polish Academy of Sciences, Poland, (3)Jagiellonian University, Poland

The ever increasing pesticide use in agriculture is considered one of the most important causes of insect decline worldwide. Among non-target invertebrates particularly endangered by pesticide sprays are ground beetles – an important group of Ecosystem Service Providers (ESPs) in agro-ecosystems, acting as natural enemies of crop pests. To understand how pesticides may affect ecosystem services provided by carabids it is crucial to assess effects of exposure not only at the individual level, but also for whole communities. The objective of our study was, thus, to assess the distribution of sensitivity in ground beetle communities inhabiting oilseed rape fields towards three insecticides: lambda-cyhalothrin, acetamiprid and chlorpyrifos. Using a vial test, in which an active ingredient dissolved in acetone is distributed evenly inside a glass vial, we first assessed acute toxicity of each insecticide to 7-14 species. The median lethal doses (LD₅₀) for each active ingredient, estimated using probit analysis, were used to establish Species Sensitivity Distribution (SSD) curves by fitting cumulative distribution functions to the species-specific 48h-LD₅₀ data. The SSD curves were further used to estimate the Potentially Affected Fraction (PAF) of species at doses of the active ingredients recommended for field use and to derive Hazardous Dose for 5% species (HD₅). PAFs of species at one recommended field dose were ca. 75% for acetamiprid and almost 100 % for lambda-cyhalothrin and chlorpyrifos. The estimated HD₅ values for acetamiprid, lambda-cyhalothrin and chlorpyrifos constituted 0.047 (95% confidence interval (CI): 0.016 ? 0.155), 0.006 (95% CI: 0.002 ? 0.020) and 0.002 (95% CI: 0.001 ? 0.004) of their recommended field doses, respectively. Although the threat to ground beetle communities in oilseed rape crops was the lowest in case of acetamiprid and the highest for chlorpyrifos, the dose of acetamiprid approx. 20 times lower than the recommended dose is already dangerous for beetle communities. Our results also revealed a high level of variability of the sensitivity in the set of species tested, with *Bembidion lampros* being one of the most sensitive species to all insecticides. This study was supported by the European Union's Horizon 2020 research and innovation programme, under grant agreement no. 773554 (EcoStack)

8.04.P-Th293 Structural and Functional Changes in the Wheat Rhizosphere Bacterial Community Upon Copper Nanomaterials Application to Soil

*Sara Cristiana Lopes Peixoto*¹, *Rui Morgado*², *Diogo Filipe Nunes Cardoso*³, *Marija Prodana*², *Catarina Correia de Lemos Malheiro*⁴, *Susana Loureiro*⁵ and *Isabel Henriques*⁶, (1)Biology, University of Aveiro, Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)CESAM & University of Aveiro, Portugal, (4)Department of Biology, University of Aveiro, Portugal, (5)Universidade de Aveiro, Portugal, (6)University of Coimbra, Portugal

The application of (nano)pesticides in agriculture might lead to the exposure of rhizosphere to copper-based nanomaterials, possibly affecting several bacterial-mediated processes. Thus, we investigated the effects of copper-based compounds [Kocide®3000, nCu(OH)₂, nCuO and Cu(OH)₂-i (as an ionic control), at 50 mg kg⁻¹ soil] on the function and structure of rhizosphere bacterial communities from *Triticum aestivum* L., using indoor mesocosms which included other soil organisms: *Eisenia andrei* (ten individuals), *Porcellionides pruinosus* (ten individuals), and *Tenebrio molitor* (ten individuals), during 28 days of exposure. The soil located outside the rhizosphere, i.e., bulk soil, was analyzed for comparison purposes. Overall, the structure and function of the rhizosphere bacterial community were affected by copper exposure, mainly at day 14. At this exposure time, enzymatic activity related to the nitrogen, phosphorous, and sulfur cycles significantly decreased in copper-treated rhizosphere soil when compared with control rhizosphere soil. At the structural level, a reduction of alpha-diversity was observed in nCu(OH)₂-treated rhizosphere soils, at day 28. Additionally, the structure and function of bulk soil bacterial community were affected by copper, but only at day 28, suggesting a stimulation of copper dissolution by the root exudates. In general, the ionic Cu(OH)₂-i exerted a similar impact compared to the nano-formulations. Concerning nanomaterials, nCu(OH)₂ (structure) and nCuO (enzymatic activity) presented a stronger effect on the rhizosphere bacterial community. Thus, this work highlights the relevance to study the rhizosphere soil to assess the impact of copper-based nanomaterials in terrestrial compartment. Further studies should clarify the role of exudates as a driver of the rhizosphere microbiome and as a determinant of copper dissolution in soil.

8.04.P-Th294 Sub-Lethal Exposure to Teflubenzuron Leads to Disrupted Feeding Rates in *Daphnia magna*

*Juris Tunens, MSc*¹, *Simon Schmid*², *Villem Aruoja*³, *Knut Erik Tollefsen*⁴ and *Margit Heinlaan*⁵, (1)Environmental Toxicology, National Institute of Chemical Physics and Biophysics, Tallinn, Estonia, (2)NIVA - Norwegian Institute for Water Research, Oslo, Norway, (3)Laboratory of Environmental Toxicology, National Institute of Chemical Physics and Biophysics, Tallinn, Estonia, (4)NIVA - Norwegian Institute for Water Research, Norway, (5)National Institute of Chemical Physics and Biophysics, Estonia

Benzoylureas are chitin synthesis inhibitors (CSIs) used as larvicides in agriculture, aquaculture and pest control. The wide use of CSIs leads to increased exposures to non-target organisms in surrounding aquatic ecosystems. However, the effects of CSIs are poorly studied on non-target organisms like filter feeding cladocerans. Physiological endpoints, such as feeding activity are expected to be sensitive indicators of CSI effects, due to possible changes in the functionality of the chitin containing peritrophic membrane (PM) in the midgut. As the standard acute toxicity tests require the absence of food during exposure, there is a need for data describing molecular level responses in environmentally representative scenarios. The aim of the study is to quantify the sub-lethal effects to the integrity of PM due to reduced chitin synthesis and the subsequent effect on feeding rate and growth of *D. magna*. To test the hypothesis that at sub-lethal levels of CSI exposure, the toxic effects are primarily expressed as disruption of

PM integrity and consequential reduction in feeding, *Daphnia magna* juveniles (4-5 days old) were exposed to sub-lethal concentrations of teflubenzuron (0,005-2 µg/L) for 48 to 72 h to evaluate its effect on the feeding behavior, expression of chitin synthase 2 (*CHS2*) in midgut and the chitin content of PM. Feeding behavior was assessed as clearance rate (CR) of algae *Chlamydomonas reinhardtii* every 12 h measuring the cell count in flow cytometer, *CHS2* expression was measured by qPCR using non-specific *CHS* and targeted *CHS2* primers, chitin content in the PM was quantified with colorimetric analysis after wet digestion in KOH and chitinase. Only the highest teflubenzuron concentration showed consistently lower CRs (30-60% of control) over the entire duration of exposure. The dynamic changes of CRs in lower concentration exposures were attributed to the toxicity mitigating effect of food and bioavailability of teflubenzuron as the CR recovery showed a dose-dependent effect toward the end of exposure. The changes in PM chitin content and the expression of *CHS2* in gut epithelia according to the suspected mode of action of benzoylureas are presented. This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No. 859891 and was supported by NIVA's Computational Toxicology Program (NCTP, www.niva.no/nctp).

8.04.P-Th295 The Brigid Project: Bridging the Gap Between Microplastics and Human Health

Camilla Catarci Carteny¹, Neslihan Aygun Kocabas², Michel Cassart³, Robert Ellis-Hutchings⁴, Markus Gahleitner⁵, Jens C. Otte⁶, Mark Pemberton⁷, Aaron Redman⁸ and Erik Rushton⁹, (1)Plastics Europe AISBL, Belgium, (2)Total, Belgium, (3)Plastics Europe, Belgium, (4)The Dow Chemical Company, United States, (5)Borealis Polymers Oy, Austria, (6)BASF SE, Germany, (7)Systox Ltd, United Kingdom, (8)Exxon Mobil Biomedical Sciences, Inc., United States, (9)LyondellBasell, Netherlands

While plastics application provides benefits that contribute to a safe and sustainable society, widespread plastic pollution has been recorded in many ecosystems on Earth. This has been associated with measurable microplastic (MP) presence across the globe, leading to unintentional biota and human exposure. Currently, there is no clear consensus from scientists and regulatory bodies over MP adverse health effects. However, large knowledge gaps still exist within this research topic, which need to be urgently addressed with high-quality scientific data. Moreover, previous studies often employ experimental conditions relying on unrealistic exposure scenarios, including testing higher concentrations, or narrow size distributions, and using virgin MPs. In this context, Plastics Europe, the pan-European plastics manufacturer trade association, is launching a large-scale five-year scientific research project: **Brigid**. Brigid aims to assess the potential risks to human health from MP exposure via ingestion (one of the major hypothesized routes of human exposure, together with inhalation). To deliver relevant results, Brigid focuses on secondary MPs of polyethylene (both linear low density & low/high density), polypropylene, polystyrene, polyvinyl chloride, polycarbonate, and polyamide-6, which are representative of higher production volume polymers currently produced.

The initial planned project work and communication activities include: i) creation and characterisation of secondary MPs through milling in relevant size ranges. Some of the MPs will also be labelled to help with exposure studies; ii) quantification of potential MP human internal exposure through ingestion, with *in vitro* and *in vivo* data to support an advanced exposure assessments with *in silico* PBPK model; iii) in-depth MP hazard characterisation using an integrated approach, starting with *in vitro* human cell models, as well as innovative *ex vivo* testing on organoids, and *in vivo* testing with animal models; iv) development of a hybrid Risk Assessment framework by combining *in vivo*-based and *in vitro* assessment approaches; v) active stakeholder dialogues with different interest groups to facilitate open and transparent communication of results to support informed policymaking. Further, Brigid works closely with other industry-funded projects to develop a coordinated global MP research program addressing identified data gaps: the ICCA Microplastics Advanced Research and Innovation Initiative (MARII).

8.04.P-Th296 The Early Environmental Safety Approach

Marc-Sven Roell, Sebastian Schmidt, Tobias Pamminer, and Thorsten Leicher, Bayer Crop Science, Germany

Chemical plant protection products are crucial to meet growing agricultural demands in the 21st century. However, novel plant protection products (PPP) need to meet rigorous societal and regulatory standards. The optimal balance between a high efficacy to lower application rates and a minimal environmental footprint, (e.g. off target toxicity in pollinators & persistence in the environment), challenges the development of novel molecules. To cope with this challenge, rapid and reliable screening of environmental profiles of novel PPP candidates, combined with tailored *in silico* solutions, is already needed in early developmental phases to identify and prioritize candidates with a high success rate. Within early Environmental Safety (eEnSa), we develop integrated automated high-throughput environmental screening assays for a wide range of safety dimensions ranging from classic hazard assessment to advanced soil persistent screening and bioaccumulation modeling. These capabilities will enable to rapidly identify and consequently focus on developing the next generation of only the most environmentally compatible PPPs with a high probability of societal and regulatory acceptance. This integrated eEnSa approach will ultimately enable to select compounds with improved favorable environmental safety profiles and re-shape the selection and optimization of promising novel chemical starting points to develop the next generation of more sustainable plant protection solutions. This poster presentation will introduce the concept and application of the eEnSa strategy and aims to serve as a starting point to facilitate a discussion with the wider SETAC community about the challenges and opportunities of shaping the next generation of plant protection products.

8.04.P-Th297 The Potential of Emerging Bio-Based Products to Reduce Environmental Impacts [Under Review]

Emma Zuiderveen¹, Koen Kuipers², Carla Caldeira¹, Steef Hanssen³, Mitchell van der Hulst², Melinda de Jonge³, Anestis Vlysidis⁴, Rosalie van Zelm⁵, Serenella Sala¹ and Mark Huijbregts⁵, (1)European Commission - Joint Research Centre, Italy, (2)Environmental Science, Radboud University, Nijmegen, Netherlands, (3)Radboud University Nijmegen, Netherlands, (4)EC JRC, Italy, (5)Radboud University, Netherlands

Moving from a fossil-based to a bio-based economy is considered an important strategy to mitigate climate change. However, to

ensure that bio-based products will contribute to a more sustainable economy, environmental assessments at early developmental stages are needed. Prospective Life Cycle Assessment may support the evaluation of emerging bio-based products and unveil possible trade-offs. We reviewed 112 papers and retrieved data related to the environmental impacts of 86 emerging bio-based products. To compare the results, a data curation was needed, namely harmonizing system boundaries, functional unit, end-of-life treatment and biogenic carbon accounting across all prospective life cycle assessments. We find that the greenhouse gas (GHG) footprints of emerging bio-based products are on average 47% lower (95% confidence interval (CI): 38, 54%) compared to their fossil alternatives. Grouped in product categories, biorefinery products show the highest predicted GHG reduction with 73% (95% CI: 50, 85%). Non-renewable energy demand is also reduced with 30% (95% CI: -58, 8%), however, emerging bio-based products have on average 32% (95% CI: -29, 143%) and 359% (95% CI: 109, 906%) higher acidification and eutrophication impacts compared to their fossil-based alternatives. Most emerging bio-based products can thus make an important contribution to reaching GHG emission reduction targets, but tradeoffs with other environmental impacts should not be overlooked.

8.04.P-Th298 Towards Environmentally Relevant Biodegradation Kinetics for Chemicals Emitted From Offshore Oil Platforms

Mette Møller¹, Heidi Birch², Karina Sjøholm¹ and Philipp Mayer³, (1)DTU (Technical University of Denmark), Denmark, (2)DTU Environment, Lyngby, Denmark, (3)DTU Environment, Denmark

Persistency of chemicals emitted to the environment is commonly evaluated using data from standardized laboratory biodegradation tests. The conditions of these tests can vary greatly from the real environmental conditions. Research is needed to bridge the knowledge gap between the biodegradation kinetics predicted from standardized laboratory tests and the actual environmental biodegradation kinetics. Produced water from offshore oil and gas production is continuously discharged to the sea in high volumes. Produced water from a platform in the North Sea is used as a case study in this research. The aims are to (1) develop an approach to improve environmental relevance of biodegradation kinetic testing and (2) investigate the effect of dilution of produced water in seawater on biodegradation kinetics. Produced water (emitted chemicals) is combined with seawater (native degrader microorganisms) in a novel biodegradation test. A series of parallel experiments at different dilution levels will run for 60 days, testing at environmentally relevant concentrations and at the sampling temperature of the seawater. During the experiments, biotic (seawater) and abiotic (ultrapure water) test systems will be analyzed using SPME coupled to GCMS, to obtain relative substrate depletion. This data is then used for biodegradation kinetics estimations. The experiments will run in April and May 2022 and preliminary results will be presented. Methods for environmentally relevant biodegradation kinetics testing of emitted chemicals can improve the site-specific risk assessment and give information on chemicals of concern when aiming at a reduced pollution society.

8.04.P-Th299 Toxic Reference Substances for Soil Organism Studies Performed According to OECD and ISO Guidelines: Are There More Safe Alternatives?

Ulrich Menke, Dr., Bayer Crop Science, Germany

To ensure environmental safety in the process of registration of agrochemicals, or to investigate the toxicity of contaminated soils, surrogate soil organisms are tested according to OECD (Organization for Economic Co-operation and Development) or ISO (International Organization of Standardization) guidelines. As an integral part of the validity criteria in each OECD/ISO guideline, testing of a toxic reference substance (positive control) should provide assurance that test conditions and sensitivity of test organism strains used in the specific laboratory or of species observed in the field are adequate. The effects observed with the reference substances should fall into a given range to indicate that the lab test strain or the field species show an appropriate sensitivity. We reviewed the safety, availability, and effect characteristics of the currently suggested toxic reference substances used for soil organism testing. The toxic reference substances suggested in the OECD/ISO guidelines for the surrogate soil organisms *Eisenia fetida/andrei*, *Folsomia candida* and *Hypoaspis aculeifer* are older pesticides (carbendazim, dimethoate, phenmedipham), biocides (chloracetamide) or basic chemicals (boric acid). We compared these substances regarding their worker safety, availability, and effect characteristics in laboratory tests. Based on European Chemicals Agency (ECHA) data, apart from phenmedipham, all suggested substances (especially boric acid) are labelled as highly toxic being either reprotoxic, carcinogenic, mutagenic, and/or volatile. They should, if possible, be substituted in new guideline versions. It becomes increasingly difficult to order the older pesticides since due to their toxicity and environmental profile they are no longer registered in many countries. We present our own studies with *H. aculeifer* comparing the effects (toxicity and dose response curve) of dimethoate, boric acid, and two potential reference substances chlorpyrifos-methyl and copper chloride (CuCl_2). CuCl_2 appears as a suitable alternative for *H. aculeifer*. Laboratory tests from literature performed with CuCl_2 showed also for *F. candida* and *E. fetida/andrei* good dose-responses in reproduction tests. We conclude that CuCl_2 would be a promising candidate for a substitute of the current reference substances since it exhibits low toxicity to humans, is cheap, is readily commercially available (as basic chemical) and its dose response curves appear suitable.

8.04.P-Th300 Until We Know Better, Suggestion of Mixture Allocation Factors (MAFs) Based on Human Blood Exposure

Josefin Engelhardt¹ and Jana Weiss², (1)Department of Environmental Science (ACES), Stockholm University, Stockholm, Sweden, (2)Stockholm University, ACES, Sweden

In the Anthropocene, all living organisms are exposed to multiple anthropogenic organic contaminants (OCs) at once. The combined chemical mixture effect is currently unknown. Different public health issues, such as autoimmune diseases and reproductive disorders can only be genetically explained by a third of the incidences. Other reasons potentially influencing the incidences are viral infections, stress and chemical exposure. When performing a risk assessment (RA) of an OC entering the market today, there is no consideration for unintentional mixtures, even though REACH is underpinned by the precautionary

principle (PP). Furthermore, when a mixture of OCs is assessed the lack of comparable toxicity data is evident. This study offers a guidance on how to address unintentional chemical mixture exposure when sufficient data is not available for a RA. In a recent project, an in-house database (Human Blood Database, HBDB) was created, and used for an exposure assessment for the Swedish general population. Human biomonitoring guidance values (HBM-GVs) were used for the RA. Only a first-tier mixture RA could be made since the reference values available had different critical endpoints. Also, only 9 HBM-GVs could be found for the OCs found in blood of the Swedish population. According to HBDB, 440 OCs have been reported in human blood world-wide. In this guidance, we include all potential OCs in the exposure assessment, which could be considered a worst-case scenario as some OCs might not constitute a risk. Using different time ranges of sample analysis, and different choice of model drivers, six scenarios were constructed. They were created to estimate the range of mixture allocation factors (MAFs) that could be used when assessing the risk of individual chemicals. The scenarios are presented with all their limitations as transparently as possible to highlight the uncertainties. Only OCs in blood were considered, no urine contaminants and no inorganic contaminants. The MAFs derived for each scenario ranged between 15-200. Since little is known regarding the risk associated to complex mixtures, the PP should be applied. Adding a MAF of 200 during risk assessment of new OCs entering the market would theoretically protect the general population from public health diseases. The MAF should be subject to review when new scientific information becomes available, encouraging testing and innovation.

8.04.P-Th301 Wastewater-Based Epidemiology Monitoring of Drug Use and Chemical Exposure During COVID-19 in Athens, Greece, Utilising Wide-Scope Lc-Hrms & LC-MS/MS Target Screening Analysis

Eleni Aleiferi, Aikaterini Galani, Aglaia Gkogkou, Aikaterini Kontou, Maria-Christina Nika, Nikiforos Alygizakis and Nikolaos Thomaidis, National and Kapodistrian University of Athens, Greece

Wastewater-based epidemiology monitoring of drug use and chemical exposure during COVID-19 in Athens, Greece, utilising wide-scope LC-HRMS & LC-MS/MS target screening analysis Aleiferi E., Galani A., Gkogkou A., Kontou A., Nika M.C., Alygizakis N., and Thomaidis N.S.*Laboratory of Analytical Chemistry, Department of Chemistry, School of Natural Sciences, National and Kapodistrian University of Athens, Panepistimiopolis, Zografou, Greece* Corresponding Author After the outbreak of **COVID-19** pandemic, countries around the world proceeded with the implementation of restrictive measures as key strategies for coping with the pandemic transmission. Strict containment measures such as extensive quarantine during the COVID-19 pandemic, in combination with the psychological pressure that the pandemic itself might have inflicted in the general population, may have affected **mental health, human lifestyle and behaviour**. As a result, changes in patterns of drug and chemicals use might have occurred. These changes can be monitored by the utilisation of the emerging field of **wastewater-based epidemiology** (WBE). The continuously growing field of WBE aims at observing potential consumption and use trends of chemicals in community levels via the determination of biomarkers such as pharmaceuticals, illicit drugs, antipsychotic drugs, surfactants, biocides, personal care products and other chemicals through the analysis of influent wastewater samples. The focal scope of this study was the reflection of potential pattern changes in chemical exposure and drug use in Attica, Greece during the COVID-19 pandemic after the second wave. For this purpose influent wastewater samples were collected on a daily basis and analysed from January 2021 onwards. A total of four or five pooled samples per month were prepared for each week of the pandemic. A generic sample preparation and a wide-scope LC-ESI-QTOF-MS analytical method, in both positive and negative polarities was employed, for the determination of > 2000 chemicals from various category classes. In addition, a LC-MS/MS method was applied for a total of 180 substances, due to its great sensitivity for specific analytes of interest. The detected analyte concentrations were back-calculated using daily flow rates for the investigation of potential load and consumption trends. The drugs and chemicals' use reflected pattern changes during the studied months. Some of the results may be linked with the pandemic and its effects on the population of Attica.

8.04.P-Th302 What Makes a Sustainable Chemical Product? Case Study of Supporting Domino's Ink and Printing Solutions With LCA

Sam Hinton¹, Emily Dawson¹ and Josie Harries², (1)Ricardo Energy & Environment, United Kingdom, (2)Domino Printing Sciences, United Kingdom

1. Challenge Domino is a global printing solutions provider, supporting clients with printers and inks across industries such as food & drink, life sciences and personal care. Domino's clients and its end consumers are increasingly sustainability focused and are asking Domino to evidence the sustainability credentials of its products. As a result, Domino needs a way to robustly quantify the sustainability impact of its products, from its printers to the different chemical compositions of its ink choices – this is where life cycle assessment (LCA) can help. 2. Solution Domino appointed Ricardo Energy & Environment to develop a LCA tool that could model its printers using different ink types under a specified user-defined scenario. The tool enables Domino to assess the environmental impacts of its products for a specific customer from cradle to grave. It can analyse one specific printer; 10 ink formulations; various use scenarios and 21 environmental indicators, from global warming potential to water use to ozone formation and many more. 3. Outcome The LCA tool is a differentiator in the market and sets Domino apart from other printing companies as a sustainable company who take environmental impacts seriously. The LCA enables Domino to talk to its clients about the sustainability impacts associated with a specific customer's specific operation, accounting for geography, print runs, ink composition and more. The tool has demonstrated the importance of thinking beyond carbon, as solutions that yield the lowest global warming potential were found to result in the highest impact in other environmental indicators. Domino now has a tool to assess the wider environmental issues, helping to target improvements in areas that will have the greatest sustainability impact and avoid improving one impact criteria to the detriment of another.

8.04.P-Th303 Where Are the Microplastics? The Abundance and Distribution of Microplastics in the Waters and Organisms of the River Thames, UK

Stephanie Andrews¹, Ceri Lewis² and Tamara Galloway³, (1)University of Exeter, Exeter, United Kingdom, (2)Biosciences, University of Exeter, Exeter, United Kingdom, (3)University of Exeter, United Kingdom

Microplastic contamination of the global environment is a growing issue of great concern. Freshwater systems, specifically rivers, are key in the transportation of terrestrially derived microplastics into the marine environment and it is crucial to understand the abundance, distribution and biological effects of microplastics within river systems. The River Thames is the second largest river in the UK and has multiple anthropogenic stressors and pathways of microplastic contamination along its trajectory. This study aims to determine the distribution and abundance of microplastics in the surface waters and benthic organisms of the River Thames. It explores how location and proximity to points of contamination can affect dispersal of microplastics and how feeding mode might influence the ingestion of microplastics in benthic dwelling organisms. Water samples were collected from the river in May 2019 along with benthic invertebrates from three sites with points of potential contamination. Initial findings reveal a high abundance of microplastics which increases along the trajectory of the river (1.05 mp/m³ at the furthest upstream sampling site increasing to 5.72 mp/m³ at the lowest downstream sampling site). Points of suspected contamination to the river influenced the distribution of microplastics along the trajectory. In all sites sampled, fragments and fibres were the most dominant particle shape. In benthic invertebrates, filter feeders ingested the highest abundance of fibres whilst grazers ingested the highest abundance of fragments. The abundance of particles ingested by invertebrates varied across study sites showing differing levels of contamination. The presence of microplastics in a range of benthic taxa aligned with differences in dominant particle shapes in species with distinct feeding modes indicates widespread contamination with potential ecological impact of microplastics in freshwater species of the River Thames.

8.04.P-Th304 Differential Impact of Brominated and Organophosphate Flame Retardant POPs on Gene Expression in Monocyte-Macrophage Differentiation Models

Leila Khani¹, Leonardo Martins², Maciej Studzian² and Lukasz Pulaski², (1)Laboratory of Transcriptional Regulation, Institute of Medical Biology PAS, Institute of Medical Biology PAS, Lodz, Poland, (2)Laboratory of Transcriptional Regulation, Institute of Medical Biology PAS, Lodz, Poland

Several groups of flame retardant chemicals have recently been classified as persistent organic pollutants (POPs), while others are under close ecotoxicological scrutiny. Immunotoxicity and immunomodulation are two of their modes of deleterious action that are insufficiently comprehensively studied. Signalling pathways and gene expression patterns during immune cell differentiation are the most vulnerable site of deleterious xenobiotic action. We have verified the impact of flame retardants from different chemical groups (brominated ethers, brominated phenols, organophosphates and chlorinated organophosphates) on a cellular model of the human monocyte-macrophage differentiation axis which is crucial for effective innate immunity. We applied three cell lines which differ in advancement of the differentiation process (HL-60, THP-1 and MonoMac6) as well as their pharmacologically stimulated macrophage-like derivatives. We measured the effect of flame retardant exposure at environmentally relevant concentrations on levels of gene expression of crucial differentiation markers, immune activity effectors and important signalling pathway elements. Our results point to two main conclusions: a higher vulnerability of less differentiated cells (myeloid precursors and monocytes) to immunomodulatory action of POPs, and a pronounced difference in modes and effects of action of model brominated flame retardants (BDEs, HBCD, TBBPA) from organophosphate ones (TPhP, TCEP).

8.04.P-Th306 Accounting for Individual Environmental Conditions in Assessing Pollution Exposure of a Long-Lived Top Predator Population (P)

Peter Vermeiren¹, Andreas Focks², Cynthia Munoz³ and Sandrine Charles⁴, (1)Faculty of Science, Radboud University, Nijmegen, Netherlands, (2)University of Osnabrück, Germany, (3)Radboud University, Netherlands, (4)University Lyon 1, Villeurbanne, France

Environmental stressors originating from both natural (e.g. food availability) and anthropogenic (e.g. synthetic pollutants) sources may have strong influence over extended periods on long-lived species. Consequently, environmental management needs to account for the cumulative long-term effects of multiple stressors on such species. Additionally, when population sizes are reduced with individuals exposed to multiple stressors, the behavior of individuals becomes relatively more important in determining population-level outcomes, these later being more relevant in terms of conservation actions for such species. We developed an individual based toxicokinetic (IBM-TK) model for American alligators as a case study of a long-lived top predator exposed to organochlorine pesticides. The model simulates internal chemical accumulation over the lifetime of individuals, accounting for dietary uptake, growth dilution and maternal transfer processes. The model furthermore considers the between-individual variability in pollution exposure, growth and reproduction directly stemming from food availability in these highly territorial species. Environmental conditions in lakes occupied by alligator populations (such as air and water temperature as well as food web composition) are also considered. Meanwhile, lifecycle development of alligators was modelled using a dynamic energy budget, calibrated against sparse data on growth during early life stages, nest productivity, and age at reproduction. At last, prior knowledge regarding parameter values were phylogenetically derived from related crocodile species in order to feed the Bayesian inference process leading to the parameter estimates of the whole model. Long-lived top predator populations play an important role in the structure and functioning of ecosystems. With this research we aim to contribute towards quantitative mechanistic understanding of the interactions of such species with environmental pollutants present in their natural environments.

8.04.P-Th307 Chemometers: An Integrative Tool for Studying Chemicals in Biota and Surrounding Abiotic Media (P)

Elisa Rojo-Nieto¹, Eva Barbara Reiter², Theo Wernicke¹ and Annika Jahnke³, (1)Helmholtz Centre for Environmental Research

GmbH - UFZ, Germany, (2)Helmholtz-Zentrum für Umweltforschung GmbH - UFZ, Leipzig, Germany, (3)Helmholtz Centre for Environmental Research - UFZ GmbH, Germany

Chemometers are a common and well-defined polymer reference phase for passive equilibrium sampling of a large range of organic pollutants in different matrices like biota, sediment and water. By bringing the chemometer into direct contact with the sample, the chemicals partition between the sample and the polymer until a thermodynamic equilibrium is established. As the chemometers are defined as a common reference phase, the chemical concentrations in the chemometers at equilibrium can be directly compared between different biotic and abiotic compartments and organisms of different trophic levels. This approach has opened a new analytical window for determining the chemical activity of pollutants, which is one of the main drivers for partitioning, biouptake and toxicity. It allows to express the data on a common basis, as the equilibrium partitioning concentrations in the silicone, circumventing normalization, and the extracts of the chemometers can both be submitted to chemical analysis and/or to bioanalytical profiling. The chemometers have proven to be a relevant tool to evaluate chemical pollutants in biota, and we are currently applying them in diverse applications, amongst others to study (I) the thermodynamics of bioaccumulation in aquatic environments using multimedia sampling in a remote Swedish lake, (II) the internal exposure in marine mammal tissues from the German North and Baltic Sea coasts, and (III) passive sampling in the abiotic compartments sediment and water from German rivers with different patterns and levels of pollution as a proxy for chemical concentrations in biota. This presentation will give an overview of our related activities and applications of chemometers aimed at characterizing the complex environmental exposure by mixtures of pollutants at high trophic levels using a common reference phase. An outlook will cover future plans for applications to describe the lifelong exposure to mixtures of pollutants, the so-called exposome, of top predators.
