3.10.T-16 Additives, Plasticizers, and Small Microplastics (< 100 Mm) in Seawater: A Comparison of Three Sampling Methods

Fabiana Corami¹, Beatrice Rosso², Silvia Spinello², Elena Gregoris¹, Gabriella Caruso³, Andrea Gambaro² and Carlo Barbante³, (1)Institute of Polar Sciences, CNR-ISP, Italy, (2)Ca' Foscari University of Venice, Italy, (3)Institute of Polar Science-National Research Council (ISP-CNR), Italy

Microplastics (MPs) are ubiquitous, persistent emerging pollutants that have been observed in every environment and in different animal species (from invertebrates to mammals). MPs are part of the micro-litter, together with additives, plasticizers, natural fibers, non-plastic synthetic fibers such as rayon (APFs). The main concern is that invertebrates can ingest all these particles according to the size of their mouthparts, and filter-feeders can collect these particles together with the seston. In particular, all the particles smaller than 100 μm are actively ingested or filtered; hence, these particles can enter the trophic web, where they can be bioaccumulated and biomagnified. Besides, due to their size, these particles can be transferred from the gastrointestinal tract to other organs or other tissues, such as muscle tissue. Therefore, they can pose a health threat to humans who use them as a food source. There are currently no standardized and harmonized methods for the sampling, pretreatment, contamination control, and analysis of SMPs and APFs (< 100 μm), which are often overlooked in marine environments. Consequently, a lack of knowledge regards the abundance and chemical characterization of these particles in the seawater and their pathways and fate. Awareness-raising projects and citizen science help spread scientific knowledge and raise the consciousness of more people about crucial environmental issues such as microplastic pollution. SEA Plastics [7] has organized a cruise expedition in the Tyrrhenian Sea and has offered to collect samples to investigate SMPs and APFs. Seawater samples were collected at two sites in South Italy during the 2021 expedition. Three different sampling systems were employed: manta net, plankton net, and Niskin bottles. Samples were

filtered on-site and stored at 4 °C till the arrival at the laboratory of CNR-ISP. An elutriation method was developed to retrieve all the particles collected. A pretreatment method previously developed was performed. All the operations were performed in a plastic-free Clean Room Iso 7. SMPs and APFs were quantified and simultaneously identified via Micro-FTIR. Pyrolysis-gas chromatography was employed as an inter-calibration technique to confirm the identification of specific polymers. The first results show differences among the samples collected with different sampling devices.

3.10.T-17 Effects of Microplastics on Aquatic Community in Freshwater Microcosm

Jenna Molaro¹, Christopher Peterson¹ and Tham Hoang², (1)Loyola University Chicago, United States, (2)Auburn University, United States

Microplastics are emerging as a profound scientific and public concern given their abilities to serve as a substrate for growth of microorganisms, to sorb organic pollutants which easily leach into organisms after ingestion, and to travel through and between ecosystems proliferating the entire planet. Research has indicated that microplastics affect living organisms including zooplankton, fish, and several others but has not yet determined their effect on freshwater phytoplankton. This study aims to fill this knowledge gap since phytoplankton are the foundation of the food web in many aquatic ecosystems and invaluable primary producers. Specifically, this study investigates the influence of algal colonization atop the surfaces of microplastics in freshwater microcosms on the following: microplastic deposition rate, phytoplankton community structure, primary productivity, and nutrient availability. Sediment and water were collected from a local pond and added to 9 90-gallon aquaria at Loyola University Chicago to initiate the microcosm systems. After five months of growth and stabilization, microplastics were added in low concentration—for an environmentally relevant comparison—and in high concentration to determine the effects of plastic particles on fully established phytoplankton communities. The addition of plastics initiated the treatment phase. Three aquaria with no addition of microplastics were used as control microcosms for comparison. Additionally, three abiotic aquaria were set up with filtered water to serve as a comparison for microplastic deposition rate with no influence of phytoplankton. Over the course of the treatment phase, monitoring of microplastic deposition, phytoplankton colonization on microplastics, primary productivity, chlorophyll a absorbance, nutrient concentrations, phytoplankton community structure and density, as well as water quality characteristics were conducted. Repeated-measures ANOVA for change in criteria over time and treatments will be used to analyze the significance of any change in the analyzed criteria that takes place after microplastics are added. Non-metric multidimensional scaling will be used to examine changes in phytoplankton communities. A preliminary study revealed that microplastics cause an overall increase in phytoplankton density. Detailed results will be presented at the conference in May.

3.10.T-18 Root System Response of Three Agricultural Crops to Microplastic Type and Concentration

Deqa Farow¹, Rebecca Chloe Lebel¹ and Cameron Proctor², (1)University of Windsor, Windsor, ON, Canada, (2)University of Windsor, Canada

Microplastics are introduced to agricultural fields through several pathways, including the application of biosolids as a nutrient source. Crops grown in soils with biosolids alter their rooting strategy to uptake the additional nutrients, and alter a number of important traits related to nutrient uptake at the root-system and root segment level, such as the root length density. The attraction of roots to biosolids may increase root exposure to microplastics, especially as smaller microplastics are liable to travel into the rhizosphere and potentially accumulate against the external surface through root water transport and uptake. Surface accumulation may interfere with the uptake of necessary resources from soil, or hinder the excretion of extracellular solutes that are a key element of root foraging strategies and trophic interactions with soil organisms. However, there are a paucity of studies that have investigated how roots respond to soil microplastics and whether root development, architecture, and lifespan are influenced by certain microplastic types and concentrations. Whether roots sense and avoid microplastic alterations to soil properties (e.g., excretion of toxins) remains a considerable knowledge gap. Through a dose-response study, the treatment effects of biosolid microplastics on the root systems of wheat, soybeans, alfalfa were investigated in soil spiked with two plastics at two concentrations 2,000 particles/kg per soil dry weight which reflects ~4 biosolid applications and 15,000 particles/kg per soil dry weight which represents biosolid concentration levels. A control and treatment of direct biosolid application were also included for a total of six treatments. Using the rhizobox approach, plants were grown from seed in a controlled greenhouse. To assess root stress responses, rhizoboxes were scanned weekly over 10 weeks to trace the development of individual roots. Unlike previous studies that assessed microplastic impact at the root system scale the focus of this investigation is higher order roots, as these fine roots are most sensitive to soil properties and their traits align with water, carbon and nutrient cycling processes. Baseline soil microplastic analysis was conducted pre and post planting to determine whether microplastic concentrations were altered by the growing root system. Microplastics in rhizosphere soil were characterized and compared to control soil in terms of the size, shape, type and number of microplastics.

3.10.T-19 Water-Soluble Polymers As New Possible Emerging Concern: Toxicity Evaluation of Polyvinyl Alcohol

Stefano Magni¹, Lara Nigro², Camilla Della Torre², Marco Ortenzi², Daniela Maggioni² and Andrea Binelli², (1)Biosciences, University of Milan, Milan, Italy, (2)University of Milan, Italy

Water-soluble polymers (WSPs) represent a new environmental concern, due to their huge use in many industrial products as detergents, pharmaceuticals, single-use and personal care products. However, no information about the impact of these substances on ecosystems are available. For this reason, the aim of the present study was the evaluation of toxicity induced by a common WSP: the polyvinyl alcohol (PVA). We selected two PVA materials, represented by a PVA powder standard and PVA bag, used as bait container for fishing. Firstly, we characterized the hydrolysis degree as well as the eventual presence of additives in the PVA bag through the Fourier Transform Infrared Spectroscopy (FT-IR) and Nuclear Magnetic Resonance (NMR), respectively. Then, we assessed the chronic toxicity of different concentrations of these materials, solubilized in water, on two different

biological models, represented by the crustacean *D. magna* (exposure of 14 days in semi-static conditions) and the embryos of the teleost *Danio rerio* (exposure from 0 to 120 hours post fertilization - hpf). We evaluated the effects at a high level of biological organization (organism) through the monitoring of the behavioral alterations of exposed specimens, as well as the assessment of the neuro-enzymes monoamine oxidase (MAO) activity. From the chemical point of view, we observed a hydrolysis degree of 85% in the PVA bag, as well as the presence of some additives. Regarding the ecotoxicological evaluation, the exposed specimens of the two species did not show any significant behavioral effects. In the same manner, despite the increasing in the biological trend of MAO, no significant alterations were obtained. However, considering the wide plethora of WSPs, other investigations are necessary to clarify and characterize their ecotoxicological impact.

3.10 Microplastics in the environment: Behaviour, transport, fate, risks, and alternatives to conventional plastics (Virtual Only)

3.1.V-01 Accumulation of Small Microplastics (<100 Mm) and Additives in Gills and Gastrointestinal Tracts of Freshwater Bivalves *Anodonta cygnea*

*Giulia Cesarini*¹, *Fabiana Corami*², *Beatrice Rosso*³ and *Massimiliano Scalici*⁴, (1)Sciences, University of Roma Tre, Rome, Italy, (2)Institute of Polar Sciences, CNR-ISP, Italy, (3)Ca' Foscari University of Venice, Italy, (4)Roma Tre University, Italy

The increasing production of plastics and the limitless applications, combined with poor management of waste, generated the widespread global presence of this material in all ecosystems. In particular, freshwaters are very threatened and impacted by microplastics, despite being less studied than marine environments. To fill this knowledge gap, molluscs could be employed to investigate the plastic pollution being filter feeders. Molluscs can uptake microplastics via filtration of seston by gills; these particles (generally < 100 µm, small microplastics, SMPs) can be transferred to the gastrointestinal tract (GIT) and be accumulated in their body. To study accumulation of SMPs, five specimens of the freshwater bivalve, *Anodonta cygnea* Linnaeus, 1758 were bought; then they were exposed in cages in three rivers located in the Lazio Region (Italy), River Marta, River Aniene, River Sacco, to different environmental conditions for short range (one month) and for long range (three months) exposure. After the environmental exposure (i.e., short range and long range exposure), specimens were dissected in laboratory. The gills and the GITs were removed and analyzed separately to evaluate the possible uptake and ingestion of SMPs. The pre-treatment of gills and GITs was performed in a plastic-free clean room ISO 7 (CNR-ISP). All the steps of the pre-treatment procedure allowed to not further denature SMPs and additives, so as to avoid over- and under-estimation of the particles and for an optimal polymeric identification. After chemical digestion, the slurred samples were filtered on alumin oxide filter membranes (0.2 µm, 47 mm diameter) and the analysis for the quantification and simultaneous polymer identification were performed via Micro-FTIR. The polymers most found were nylon, widely used in clothing, fishing and agriculture fabrics, and olefin, used in carpeting, ropes, and vehicle interiors due to its resistance to staining, mildew, abrasion, and sunlight. Several plastic additives such as Varox DCP-40C, a vulcanizing additive, N-(2-ethoxyphenyl)-N(2-ethylphenyl)-ethanediamide, a stabilizing plasticizer, and poly(N-methyl acrylamide), a thermoresponsive additive, were found in the samples. The preliminary results highlight an environmental pollution by SMPs using freshwater bivalves as sentinel organisms.

3.1.V-02 Assessing the Role of Polyethylene Microplastics As a Vector for Organic Pollutants in Soil: Ecotoxicological and Molecular Approaches

*Carmen Fajardo*¹, *Carmen Martin*², *Mar Nande*³, *Sebastian Sanchez-Fortun*³, *Gerardo Mengs*⁴, *Gonzalo Costa*⁵ and *Margarita Martin-Fernandez*⁶, (1)Universidad de Alcalá, Madrid, (Spain), Spain, (2)Biotechnology-Plant Biology, Universidad Politécnica de Madrid, Madrid, Spain, (3)University Complutense of Madrid, Spain, (4)Ecotoxilab S.L., Spain, (5)Universidad Complutense Madrid, Spain, (6)UCM, Spain

Microplastics (MPs), pharmaceuticals and pesticides are emerging pollutants with proposed negative impacts on the environment. Rising interest in investigations of MPs is likely related to their potential to accumulate in agricultural systems as the base of the food chain. In this study, the ecological stress of MP contamination, alone or associated with other environmental pollutants, on soil was evaluated. We applied an integrated approach using classic bioassays and molecular methods to evaluate the impact associated with a mixture of three types of polyethylene (PE) microbeads, and their interactions with organic pollutants (OCs), including ibuprofen (IB), sertraline (STR), amoxicillin (AMX) and simazine (SZ), on different soil organisms. PE-MPs exhibited different abilities for the adsorption of each tested OC. Standard soil was artificially contaminated with OCs and MPs (alone or combined with OCs) and incubated for 30 days. The presence in soil of MPs, or MPs and OCs (MIX), did not produce any effect on *Caenorhabditis elegans* endpoint growth, reproduction, or survival. Inhibition of leaf growth in *Zea mays* was detected, but this negative effect declined over time, while the inhibition of root growth increased, especially when OCs (32 %) or MIX (47 %) were added. Moreover, the expression of the antioxidant genes *CAT 1*, *SOD-1A* and *GST 1* on plants was affected by the treatments studied. The addition of MPs or MIX affected the soil bacterial phylogenetic profile, which selectively enriched specific members of the bacterial community (particularly *Proteobacteria*). The predicted functional profiles of MP/MIX samples indicated a potential impact on the carbon and nitrogen cycle within the soil environment. Our results indicate that MPs and their capability to act as pollutant carriers affect soil biota. The synergistic effects of both types of elements are particularly relevant for plants. Considering that the maintenance of healthy ecosystems relies largely on the key role of plant and microbe interactions, particular attention may be paid to agricultural systems as the base of the food chain. Therefore, further studies should be carried out with different types of MPs to establish their respective interactions with organic compounds, their bioavailability and how long it takes for leaching of these organic pollutants into different organisms and/or ecosystems.

3.1.V-03 Assessment of Eleven Phthalate Acid Esters in Mediterranean Edible Fish Species in Relation to Microplastic Ingestion

Margherita Concato¹, **Matteo Baini**², **Matteo Galli**², **Dario Giani**², **Cristina Panti**³ and **Maria Cristina Fossi**², (1)Department of Physical, Earth and Environmental Sciences, University of Siena, Siena, Italy, (2)University of Siena, Italy, (3)Department of Physical Sciences, Earth and Environment, Cristina Panti, Siena, Italy

The relationship between the presence of microplastics and plasticizers level in the environment and marine organisms is a new area of research under development. Phthalate acid esters (PAEs) are chemicals widely used as plasticizers to improve the properties of plastic materials. It has been shown that they can be easily released into the environment and reach all environmental compartments. PAEs are considered a class of pollutants that cause significant damage to the environment, wildlife, and humans. However, few studies have assessed the presence of phthalates in commercially important fish species. This study aimed to evaluate and compare the levels of PAEs in the muscles of edible fishes, from the North-Western Mediterranean Sea, in relation to microplastics ingestion. Microplastics ingestion was evaluated in *Boops boops*, *Engraulis encrasicolus*, *Mullus surmuletus*, *Sardina pilchardus*, collected in areas affected by different anthropic pressure of the North-Western Mediterranean Sea. The abundance of 11 PAEs (Dimethyl phthalate, Diethyl phthalate, Diallyl phthalate, Dipropyl phthalate, Diisobutyl phthalate, Dibutyl phthalate, Benzyl butyl phthalate, Dicyclohexyl phthalate, Bis(2-ethylhexyl) phthalate, Di-n-octyl phthalate, Diisononyl phthalate) were investigated in a sub-sample of each species, properly selected in order to compare contaminants loads among organisms with and without microplastics, for a total of 104 specimens (30 *B. boops*, 30 *E. encrasicolus*, 16 *M. surmuletus*, 28 *S. pilchardus*). Results show that all the PAEs investigated were detected in an appreciable amount in the 4 species. The PAEs compositions were different in each species, the most founded were Diisobutyl phthalate, Dibutyl phthalate, Bis (2-ethylhexyl) phthalate. Specimens of *B. boops* had the highest levels of PAEs. No differences in the abundance and composition of PAEs were observed in relation to microplastics ingestion. However, distinctions were highlighted for specimens belonging to species and from specific areas affected by different microplastics impacts.

3.1.V-04 Assessment of Microplastics in Indus River System, Pakistan

Mehboob Maryem, *Ecole des Ponts ParisTech, Champ-sur-marne, France*

Indus River apart of being one of the longest rivers of Asia is also the main source of freshwater supply in Pakistan. The following research focused on the quantification and characterization of microplastics in this river system with primary focus on selected glaciated and freshwater lakes including: Batura lake, Borith lake, Naltar lakes, Attabad lake, Khalti lake, Passu lake and Upper kachura lake. The preliminary results reveal the occurrence of plastic particles in all glaciated and freshwater lakes. The presence of fibres in microscopy indicates the impact of tourism and anthropogenic activities in the surrounding, however, the presence of microplastic content could indicate both the anthropogenic and atmospheric origin of contamination. The fibre content in the glaciated lakes was found to range from 2 fibres/Kg to 180 fibres/Kg of dried sediments, whereas for surface water the fibres ranged up to 27 fibre/L of surface water. Although the comparing of the results from different lakes does not suggest a specific trend or reason of occurrence, however, the sites more laden with anthropogenic activities were found to be more fibre laden. From the microplastic analysis (referring to the specificity of studied lakes), the mainly occurring microplastics were polypropylene (PP) and polyethylene (PE) accompanied by polystyrene (PS), Poly vinyl chloride (PVC) and **Polyethylene terephthalate (PET)** at various sites.

3.1.V-05 Cladophora Spp. Could Interact With MPs Particles?

Stefania Marcheggiani¹, **Filippo Chiudioni**², **Camilla Puccinelli**³ and **Laura Mancini**², (1)Italian Institute of Health ISS, Italy, (2)Istituto Superiore di Sanità, Italy, (3)Istituto Superiore di Sanità, Rome, Italy

Macrophytes can trap microplastics (MPs) in surface water ecosystems, mainly working as a net through roots and filament. In a previous study, presented at Seatac 2020, we studied the environmental fate of these new contaminants, finding in macrophytes sample an MPs concentration higher than in other matrices analyzed (water and sediment). The study was performed in two watercourses in the natural area of Farfa river and in a highly impacted site, located in the urban area of Rome, Almone river. In the current study, we investigate, in vitro, the interaction between MPs, pellet, foam and fragment, and a filamentous alga (*Cladophora* spp.) both sampled and isolated in the laboratory from raw environmental samples (water, sediment and plants). *Cladophora* and MPs were placed in a multiwell plate, with filtered river water as a growth medium, at 18-20 °C with a 16h light and 8h dark photoperiod. In each multiwell, two wells were dedicated to negative controls (without MPs), two wells with low concentration and the last two as high concentration of MPs. Comparing the control sample with the treated ones, preliminary results show that *Cladophora* growth is not significantly influenced by the concentration of MPs. Moreover, this alga's remarkable capability to adhere and trap the MPs particles, functioning as traps during an algal bloom. Further analyzes are underway to detect any cellular interactions between this algae and MPs.

3.1.V-06 Comparison of Three Sampling Methods for Microplastic in Rivers

Gudrun Obersteiner¹, **Johannes Mayerhofer**², **Sabine Lenz**², **Gabor Bodos**³ and **Dusan Milovanovic**⁴, (1)BOKU, Institute of Waste Management, Austria, (2)BOKU University of Natural Resources and Life Sciences, Austria, (3)WESSLING Hungary Ltd., Hungary, (4)University of Novi Sad Faculty of Technical Sciences, Serbia

Despite many studies and different estimates on microplastic occurrences in rivers, microplastic analysis is still a young field of research with many challenges. However, one of the main difficulties lies not least in a reliable representative and thus comparable sampling. Above all, the isolation of microplastic particles from the sample matrix of environmental samples before detection is challenging. In river samples, there are comparatively few microplastic particles in a heterogeneous and complex matrix of organic and inorganic bycatch of different grain sizes, which have to be separated and analysed by means of different

preparation steps. Currently, there is no standard method used to sample microplastics from riverine systems. The presented study therefore focusses on different sampling methods for microplastics in rivers and shows empirical data from sampling in the Danube comparing three different sampling techniques and their possible influence on subsequent sample preparation and evaluation. In the Tid(y)Up project, different microplastic sampling methods were compared for the first time at 8 different sampling sites (in Austria, Hungary, Serbia, Romania and Bulgaria) along the Danube and Tisza. A further developed net method, taking into account the depth variance and spatial distribution over the transverse profile (Liedermann et al. 2018), the so-called cascade pumping method (higher resolution for small particle sizes) and a sedimentation box (temporal component through measurement over 2 weeks) were used. The focus of these measurements was on the practicability of these established measurement techniques in terms of implementation, user-friendliness, susceptibility to errors, personnel requirements, etc. depending on the fluvial framework conditions as well as subsequent following requirements for sample preparation. The methods show different advantages and disadvantages in their application. However, it seems essential that each method involves different sample preparation steps. The challenge in sample preparation lies primarily in isolating the plastic particles from all other unwanted (in)organic residues without altering or even destroying the MP particles in any way. Harmonised protocols or standardised approaches for quality assurance and quality control in the sampling and evaluation of microplastics have to be developed.

3.1.V-07 Following the Fate of Microplastics: Why Are Wastewater Treatment Plants Two-Edged Swords?

Lara Dronjak¹, Nora Exposito Lorenzo², Joaquim Rovira², Jordi Sierra¹, Karin Florencio³, Beatriz Corzo³ and Marta Schuhmacher⁴, (1)Universitat Rovira i Virgili, Spain, (2)University Rovira i Virgili, Spain, (3)Sorigue, Spain, (4)Rovira i Virgili University, Spain

Microplastic (MP) pollution is ubiquitous in the environment presenting a global problem of both scientists and general public. One of the major pathways of microplastics entering the natural environments are through wastewater treatment plants (WWTPs). Once microplastics reach natural environment, they are posing treat to aquatic ecosystems and public health. Still to date, there are no strict regulations regarding its monitoring and waste management. The aim of this study is to investigate concentration, morphology and composition of microplastics in different treatment units of WWTP. Sampling included different points of WWTP in the water line and sludge. Pre-treatment of the samples consist of the advanced Fenton oxidation, alkaline and enzymatic digestion, in order to remove organic matter. A density separation was applied using zinc chloride solution. Once the particles were isolated, their morphology and size were studied using a stereoscopic and optical microscope. Spectroscopic techniques such as ATR-FTIR and micro-FTIR were used for the analysis of the polymer's composition. Results showed that removal efficiency of WWTP is high and exceed 99%. Most abundant morphology is fibers that are coming from synthetic materials during washing processes. The most abundant polymers are: PE, PP, PVC, PE-PP copolymer, polyethylene-ethyl-acrylate copolymer, and for fibers: polyester, polyamide and cellulose. Considering the amount of wastewater treated annually (12,892,235 m³/year) and the average number of microplastics removed per litter for both sampling periods (710 MPs/L), it can be concluded how much microplastics are avoided from being emitted into the environment through direct water discharge (9,147,685 MPs/year). Removed MPs will accumulate in the sludge that is used in agricultural purpose although it should be managed as waste properly, avoiding transition of microplastic pollutants to terrestrial ecosystems adding to the number of MPs that will inevitably end up in receiving water bodies through this route (3,744,549 MPs/year).

3.1.V-08 Long- Term Impacts of Microplastics From Disposable Medical Masks on Terrestrial Invertebrates

Anita Jemec¹, Andraz Dolar², Ana Nagode³, Damjana Drobne⁴, Luka Škrlep⁵, Andrijana Sever Škapin⁵ and Cornelis A.M. van Gestel⁶, (1)University of Ljubljana, Biotechnical Fac., Slovenia, (2)Biology, Biotechnical faculty, Ljubljana, Slovenia, (3)University of Ljubljana, Biotechnical Faculty, Slovenia, (4)University of Ljubljana, Slovenia, (5)Slovenian National Building and Civil Engineering Institute, Slovenia, (6)Vrije Universiteit Amsterdam, Netherlands

The global coronavirus pandemic crisis has increased the consumption of disposable medical masks, which may represent an important source of microplastics in the environment. The aim of this study was to investigate microplastics from polypropylene medical masks. Three layers of the masks were separately milled and characterised. Each of the inner frontal, middle filtering, and outer layers yielded different types of microplastics: fibres were obtained from the inner and outer layer, but irregular fragments from the middle layer. The particle diameters according to laser diffraction analysis were 45.1 ±21.5 µm, 55.6 ±28.5 µm and 42.0 ±17.8 µm for inner, middle and outer layer, respectively. The chemical composition of plastics-associated chemicals varied between the different layers. The inner layer contained more chemicals related to antimicrobial function and flavouring, the other two layers also contained antioxidants, plasticisers, cross-linking agents, antistatic agents, lubricants, and non-ionic surfactants. We investigated the effects of long-term exposure to these microplastics in soil on the woodlice *Porcellio scaber*, mealworms *Tenebrio molitor* and enchytraeids *Enchytraeus crypticus*. The immune response of woodlice after 7 and 21 days, energy-related traits (electron system activity, lipids, carbohydrates, proteins) of mealworms, and reproduction of enchytraeids after 21 days exposure were evaluated. None of the three microplastic types affected the survival of the invertebrates, but other physiological changes were observed. Woodlice responded by induction of immune response, which was more pronounced after 7 days at the highest concentration tested (1.5%; w/w), but most of the parameters returned to normal levels after 21 days. In general, no significant shifts in energy allocation were observed in mealworms, but some of the parameters were changed sporadically. Lipids were only increased at 0.06% and 0.5% of inner layer particles, protein content was increased at 0.5% of middle layer particles, but electron system activity was increased at 0.5% and 1.5% of outer layer microplastics. Carbohydrates levels were not changed. No effects on the reproduction of enchytraeids were observed. We could not find a clear difference in effects between the microplastics from the three layers despite their different shape and organic chemicals composition. We conclude that organisms respond to the presence of microplastics in soil, but changes are not adverse.

3.1.V-09 Micro- and Macroplastic Concentrations in the WATER Column and Sediment of Belgian Sea Ports and Estuaries

Jan Bouwens¹, Maaïke Vercauteren², Colin Janssen³, Bert Teunckens⁴, Stefan Van Damme⁴, Ana I Catarino⁵, Prof. Jana Asselman⁶ and Gert Everaert⁵, (1)Research, Flanders Marine Institute, VLIZ, Oostende, Belgium, (2)Ghent University, Ghent, Belgium, (3)University of Ghent, Belgium, (4)Universiteit Antwerpen, Belgium, (5)Flanders Marine Institute, Belgium, (6)Ghent University, Belgium

Society is surrounded by a wide range of plastic objects, ranging from everyday items to complex products and machines. During production, use and waste management, there is a potential emission of plastics of all sizes (micro – macro) to various environmental compartments. This includes emissions to the environmental compartments such as air, soil, freshwater and the aquatic environments. Plastic particles and filaments are known to settle in riverine sediments, and/or to flow downstream and eventually reach the marine environment. Until now, there is however little information about the three-dimensional distribution of plastic in water bodies, including the influence of abiotic conditions in plastic debris fate. Within the PLUXIN project, one of the objectives is to map and quantify plastic waste accumulation zones and the plastic flux from Flemish estuaries and ports to the southern North Sea. More than 130 microplastic (100 µm – 5 mm) and 260 macroplastic samples have been collected in the water column and sediment at 20 sampling locations in the port of Nieuwpoort (Yser estuary), port of Ostend, port of Antwerp, North Sea Port and the Scheldt estuary in Belgium. The sampling strategy included three types of campaigns to account for spatial and temporal variation in the concentrations of plastics in different environmental compartments. We performed: (1) seasonal multi-day campaigns; (2) 13h tidal cycle measurements; and (3) bimonthly spot sampling campaigns. We report on in situ observations of micro- and macroplastic, including their horizontal and vertical distribution in the water column and their presence in the sediment at predefined locations. In addition to location-specific concentrations, the polymer types and size-frequency distributions of the simultaneously sampled micro- and macroplastics are determined.

3.1.V-10 Microplastic Contamination in Flanders: Identification of Sources, Pathways and Mitigation Strategies

Maaïke Vercauteren¹, Ilias Semmouri¹, Emmanuel Van Acker², Emmy Pequeur³, Leen Van Esch⁴, Inge Uljee⁴, Prof. Jana Asselman³ and Colin Janssen⁵, (1)Ghent University, Ghent, Belgium, (2)Ghent University Laboratory of Environmental Toxicology and Aquatic Ecology, Belgium, (3)Ghent University, Belgium, (4)Vlaamse Instelling voor Technologisch Onderzoek NV VITO, Belgium, (5)University of Ghent, Belgium

Plastic industry is a booming business but unfortunately, part of the produced plastics end up in the environment. Once in the environment, the plastic will fragment into small particles, called microplastics (MP, smaller than 5 mm). Despite large (inter)national research efforts, many questions remain unanswered, especially at a local or regional scale. Therefore, the aim of the current study was to explore the MP pollution in the freshwater environment in Flanders. This research processed and analysed 210 samples collected from eight different matrices distributed in the geographic region Flanders (Belgium). Plastics were identified using Fourier-transform infrared spectroscopy. It was evident that MP are omnipresent in the freshwater ecosystems of Flanders. One litre of surface water contained 0.48 MP particles (ranging between 0 and 4.8 MP per litre). The sediment of the waterways contained on average 2,990 MP particles per kg of dry weight sediment (ranging between 610 and 9,558 MP per kg). The risk of adverse effects of MP pollution for the Flemish waterways are low to negligible. The current research quantified the MP present in domestic waste water as one of the sources of MP pollution. Per litre of domestic waste water, 0.96 to 39.8 microplastic particles were found. In 83% of the households, the domestic waste water is being transported to an active waste water treatment plant (WWTP), which are able to remove 97.5% of the MP before discharged in the waterway. Another source of MP contamination in the environment are the microscopic rubber tire wear particles that are formed due to the friction between the tires and the road. Based on the run-off samples, an estimated emission of 10.8 mg tire wear particles per driven km was calculated. The emissions of both above mentioned sources were extrapolated to whole Flanders region area. From the yearly MP pollution in the domestic waste water, 623 kg of MP particles will end up in the aquatic environment. The highest losses originate from the households that are not connected to a WWTP. The yearly net emission of tire wear particles in Flanders is estimated to be 245,926 kg, a remarkably higher emission compared to the estimated MP emission from domestic waste water. In conclusion, this research was able to demonstrate that MP are ubiquitous in the Flemish environment, but this data offers some clear perspectives on mitigation measures to reduce MP emission to the freshwater ecosystem.

3.1.V-11 Microplastic Distribution in Seagrass Sediments From a Tropical Atoll, Belize

Alice A. Horton¹, Freya Radford², Stacey Felgate¹, Anna Lichtschlag¹, James Hunt¹ and Claire Evans¹, (1)National Oceanography Centre, United Kingdom, (2)University of Southampton, United Kingdom

Microplastics (MPs) are widespread, but the key factors affecting their fate and distribution remain to be fully elucidated. One of the factors that is believed to significantly influence microplastic transport and sequestration is the presence of aquatic plants, including seagrasses, which reduce the velocity of water flows leading to sediment deposition. For this study, we collected sediment samples from seagrass meadows on the Turneffe Atoll, Belize, with replicate samples taken from four sites representing a range of anthropogenic and hydrodynamic influences. Each sample was collected within a quadrat, in which % seagrass cover was estimated using drone imagery. It was hypothesised that: a) microplastic concentrations would vary between sites due to broadly different anthropogenic influences and hydrodynamics (affecting site energetics), with high energy sites containing fewer MPs due to less deposition of particles overall, b) increased seagrass cover would lead to higher concentrations of MPs in the underlying sediments, and c) smaller-grained sediments (and thus lower energy environments) would be associated with higher local concentrations of MPs. Samples were processed using an oil separation method to separate MPs from inorganic particles, followed by H₂O₂ digestion to remove organic material. Samples were analysed using 25 µm resolution µFTIR and spectral maps processed using siMPle software. Sediment grain size was measured for each sample. Contrary to hypothesised, microplastic

concentrations did not vary significantly between sites, nor did seagrass cover influence concentrations. Concentrations within samples were highly variable, even within sites, suggesting that the conditions affecting microplastic accumulation can be highly localised, and highlighting the importance of replication within sites for MPs studies in this location, and in general. Sediment grain size was significantly correlated with microplastic concentration but in the opposite way to expected, with a higher proportion of larger grained sediment related to a higher concentration of MPs. This suggests that MPs are deposited more readily in higher hydrodynamically energetic environments compared to lower energy environments and thus cannot be considered as sediment analogues. This unexpected behaviour may be related to variable particle density as a result of polymer type, or wider biological interactions such as biofouling and aggregation.

3.1.V-12 Microplastic Pollution in Drinking WATER in Flanders

Maaike Vercauteren¹, Ilias Semmouri¹, Emmanuel Van Acker², Emmy Pequeur³, Prof. Jana Asselman³ and Colin Janssen⁴, (1)Ghent University, Ghent, Belgium, (2)Ghent University Laboratory of Environmental Toxicology and Aquatic Ecology, Belgium, (3)Ghent University, Belgium, (4)University of Ghent, Belgium

Recent studies described the occurrence of microplastics in nearly all environmental aquatic matrices. As expected, microplastics have also entered the food chain and can be ingested by humans via food and beverages such as salt, beer, drinking water and fruits. The purpose of this study was the identification of microplastics in large volumes of tap water that were derived from the purification of ground water, surface water or purified wastewater effluents in a densely populated region in western Europe, i.e. Flanders (Belgium). The samples were collected across Flanders at two different places in the supply chain: (1) purified water from drinking water treatment plants and (2) drinking water from conventional household taps. To identify potential microplastics, Fourier transform infrared microscopy was performed which enabled the identification of microplastic particles down to a size of 25 µm. A rescaling of the concentrations, based on a published method, was performed to enable the calculation of the microplastic concentration in the default microplastic range (1µm-5000µm). An average of 0.02 ± 0.03 microplastics (>25µm) per liter (ranging between 0 and 0.06 microplastics per liter) was found in the samples taken in the water production centers. In three different water treatment plants – Essen, Egenhove and Gavers – no microplastic particles were found. Polypropylene is most commonly found polymer type after purification of the source water. Relating microplastic concentrations to the origin of the water (surface water, ground water and purified waste water), we observed that drinking water produced from groundwater did not contain microplastics in our samples. The drinking water from waste water effluents contains on average more microplastics (0.05 ± 0.02 MP/L) than that from surface water (0.02 ± 0.02 MP/L). However there is no significant difference in microplastic contamination according to the source of the water (p = 0.08). More data should be collected to confirm these results. It is not (yet) possible to assess potential risks of microplastics ingestion for human health as no epidemiological or other relevant studies on the effects of ingested microplastics have been published. More research is necessary to calculate a Derived No Effect Level (DNEL) for risk assessment of microplastic intake for human health.

3.1.V-13 Polyethylene Microplastics Induce Neurotoxicity in Terrestrial Snail but There Are No Effect on Behavior

Tae-yang Lee, Sang A Kim and Prof. Youn-Joo An, Konkuk University, Korea, South

Microplastic pollution has been rising in soil ecosystem. This study confirmed the effect of ingesting polyethylene microplastics in giant African snail (*Achatina fulica*). We fed microplastics with food to snails every two days for seven weeks. We observed that how much time spent snails looking for food. After exposure we sampled cerebral ganglion and measured acetylcholinesterase activity (AChE activity). We found that ingest of microplastic could decrease the AChE activity of snail which is the biomarker of neurotoxicity. But compared with previous study, behavioral disorder did not appear. This study found that continuous intake of microplastic cause neurotoxicity on snail in terrestrial ecosystem. *Acknowledgement- This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT and future planning(2020R1A2B5B02001734).*

3.1.V-14 Surfactant Agents in Micro- and Nanoplastic Research: Friend or Foe?

Maaike Vercauteren¹, Colin Janssen² and Prof. Jana Asselman³, (1)Ghent University, Ghent, Belgium, (2)University of Ghent, Belgium, (3)Ghent University, Belgium

As microplastics are posing a challenging problem for the environment, there is an increasing need for relevant studies (both in terms of exposure and effects) on the effects on humans and (aquatic) animals. Within this context, the availability of standard reference micro- and nanoplastic particles is recognized. Small micro- and nanoplastics in various shapes and size can be produced by cryomilling, however, a main challenge appears to be linked to the hydrophobicity of the plastics resulting in insoluble plastic particles. Surfactant agents such as Triton X-100 are often used to reduce hydrophobicity and thus increase solubility of the plastics. Nonetheless, these surfactants could in their turn affect cells or organisms during experimental exposure causing unreliable results. The goal of this study was to identify and recommend surfactant agents to be used to prepare test solutions of micro- and nanoplastics reference materials for exposure studies. The performance of the surfactants was studied by analysing the capability of reducing the hydrophobicity and the toxicity of the surfactants. The latter was tested on human colorectal adenocarcinoma (Caco-2) cells and alveolar cells (BEAS-2B), the two most important intake pathways of micro- and nanoplastics. To understand the possible toxic effects of surfactants on the (physiology of the) cells, four different assays were used to determine the mitochondrial activity, total protein count, cell viability, and reactive oxygen species (ROS)-production. Tests were initiated by seeding cells at 20,000 cells/well in a multiwell plate and grown for 24 hours. Subsequently, the cells were exposed to a concentration range of surfactant ranging from 1 x 10⁻⁶ mg/ml to a maximum 5 mg/ml. After a 48 hour exposure period, the four previously mentioned assays were performed. The results clearly indicate surfactant-specific effects on the cells, and Triton X-100 shows the highest cytotoxicity.

3.1.V-15 Whereabouts of Microplastics and Their Flux Towards the Marine Environment

Maaike Vercauteren¹, Jan Bouwens², Erik Toorman³, Gert Everaert⁴, Prof. Jana Asselman⁵ and Colin Janssen⁶, (1)Ghent University, Ghent, Belgium, (2)Flanders Marine Institute VLIZ, Belgium, (3)KULeuven, Belgium, (4)Flanders Marine Institute, Belgium, (5)Ghent University, Belgium, (6)University of Ghent, Belgium

Plastics are globally dispersed and reported at increasing concentrations in marine ecosystems. Due to their persistence in aquatic environments the global plastic litter problem will last for decennia. Hence, plastic detection methods and plastic remediation measures are urgently needed and may become obligatory in the near future. A first prerequisite to take effective plastic remediation measures is to know where and when action should be taken. However, to date there is a critical knowledge gap about the whereabouts of plastics and their flux towards the marine environment. Part of the PLUXIN project aims to close this knowledge gap by using numerical modelling to gain insight into the fate and transport of plastic debris across environmental compartments (www.pluxin.be). The model is calibrated and validated using field sampling and experimental data. More than 130 microplastic (100 μ m – 5 mm) samples have been collected at 20 sampling locations in port of Nieuwpoort (River Yser), port of Ostend, port of Antwerp, North Sea Ports and the river Scheldt in Belgium. Information on microplastic concentrations in the field was combined with settling experiments to study the behavior of microplastics in the water column by determining their vertical flux as a function of polymer type, shape, size, degree of biofouling, and weathering. A depth-averaged, two-dimensional-horizontal coupled Eulerian particle transport model for the Scheldt Estuary and Belgian Coast was set up using open-source TELEMAC software. Based on the preliminary results accumulation hotspots were pinpointed and the total flux from rivers and harbors towards the marine environment can be quantified.

3.1.V-16 Microplastics and the Water Industry: Studying Source, Transfer and Fate Within the Microplastic Cycle

Thilakshani Atugoda¹, Richard Brazier², Ceri Lewis³, Mark Hodson⁴, Tony Griffiths⁵, Oliver Raud⁵ and Bob Barnes⁶, (1)Department of Geography, University of Exeter, Exeter, United Kingdom, (2)University of Exeter, United Kingdom, (3)Biosciences, University of Exeter, Exeter, United Kingdom, (4)University of York, United Kingdom, (5)South West Water, United Kingdom, (6)Environment Agency, United Kingdom

Biosolids are recovered as a by-product from sewage treatment works and, in the UK, are typically used as a fertilizer and means of returning organic matter to agricultural land. Application of biosolids is potentially a major source of microplastics in soils as the biosolids can retain over 90% of the microplastics present in the wastewater entering a sewage works. This study will assess the presence of microplastics in sewage sludge produced by sewage treatment plants in the south west of England. Microplastics will be extracted from the sludge by density separation using saturated ZnCl₂ followed by peroxide digestion of organic matter and filtration. Microplastics will be retained on the filter paper. The size, shape and colour of the microplastics will be determined using stereomicroscope observations; Fourier Transform Infrared Spectroscopy will be used to identify the polymer types present. The same approach will be used for soil samples obtained from agricultural soils where biosolids have been applied. Soil from agricultural land that has not had biosolid applications, but which has similar land use history and similar chemical, physical and landscape scale properties will be used as controls for identifying non-sludge derived microplastics. Site selection will be based on data gathered from farmers and data records held by the sewage treatment plant. This project will also investigate the potential risks of microplastics to soil inhabiting invertebrates, alteration of soil properties due to the accumulation of microplastics and whether microplastics are likely to be retained in the soil or transferred into aquatic systems via runoff from agricultural land contributing to diffuse pollution downstream.

3.10 Microplastics in the environment: Behaviour, transport, fate, risks, and alternatives to conventional plastics (Poster)

3.10.P-We061 The Occurrence of Waterborne Pathogens Colonizing Different MPs Polymers

Neusa Figueiredo¹, Bernardo Gerónimo¹, Filipa Bessa² and Marta Martins³, (1)MARE - Marine and Environmental Sciences Centre, Portugal, (2)University of Coimbra, MARE - Marine and Environmental Sciences Centre, Portugal, (3)MARE Marine and Environmental Sciences Centre, Portugal

Microplastics (< 5 mm, henceforth designated as MPs) have been shown to serve as a new habitat for microbial community, by forming the so-called “plastisphere”. The colonization of MP surface by biofilm-forming bacteria is a coin of double face since this biofilm can contain human and animal pathogens (e.g., the genus *Vibrio*) and hydrocarbon-degrading bacteria, which can potentially influence the fragmentation and degradation of plastic waste. It has been shown that this community differs from the community in the surrounding waters and plastic polymer types. Thus, this study aims to disclose the microbial communities forming the plastisphere in different types of microplastics. To accomplish this, the microbial community was isolated from two impacted aquatic systems and incubated with 1-2 mm MP particles of 5 different plastic polymers (polypropylene (PP), polystyrene (PS), expanded polystyrene (EPS), polyethylene terephthalate (PET) and polyethylene (PE)). After 1, 3, and 7 days of incubation at room temperature with a low-speed shake (100 rpm), MP samples were collected for: (a) DNA extraction and quantification; (b) extracellular polymeric substances detection and quantification; (c) 16S rRNA amplification (PCR and metabarcoding with 16SV1V3 and 16SV3V5 primers). After 30 days of incubation, MPs particles were collected for analysis by FTIR spectrum. The results showed the existence of DNA and extracellular polymeric substances associated with all five MPs particles assessed. The highest amount of DNA quantified was found in the PET particles while the PP category showed higher polymeric substances formation. Concerning the microbial community composition, a diverse community composed of *Vibrio* sp., *Pseudomonas* sp., *Catenococcus*, and *Shigella* sp., was found, with *Vibrio* sp. showing higher occurrence. Some pathogenic species showed high similarity with the amplified sequence, including *V. campbelli*, *V. parahaemolyticus*, *V. fortis*, *V. ichthyenteri*, *V. pelagius*, and *S. dysenteriae*. Higher diversity was found for PS particles. The FTIR spectrums showed some differences

compared with the MPs control. Thus, this study strengthens the impact of MPs particles, including those from different polymers on aquatic systems by acting as a vector for aquatic life exposure to pathogens.

3.10.P-We062 Biodegradation Test Methods to Assess Microplastic Materials: A Multi Compartment Study Using Polyester-Based Materials

Glauco Battagliarin¹, Stefano Lazzari¹, Eynat Biedermann¹, Katharina Schlegel¹, Chong Becker¹, Andreas Künkel¹, Christian Lott², Miriam Weber² and Andreas Eich², (1)BASF SE, Germany, (2)HYDRA Marine Sciences GmbH, Germany

The ECHA restriction proposal on intentionally added microplastic exempts biodegradable microplastic materials from bans, labelling and reporting. To determine the biodegradability of microplastic materials, a tiered approach has been proposed by ECHA based on OECD testing guidelines and ISO standard methods. In these tests different inoculum sources can be used such as sludge from sewage treatment plants, soil, marine water and/or sediment. One of the key questions is if these test methods can be considered equivalent, since a systematic evaluation is still missing. In this study we investigated the biodegradation of a polyester blend applying different test methods that are included in the ECHA microplastic restriction proposal. To validate the environmental relevance of these methods, in parallel, field studies have been performed on macroscopic samples of the same material. In addition, kinetic modelling of the results was performed to better understand relevant parameters affecting biodegradation. Our results show a positive correlation between lab and field studies, demonstrating the environmental relevance of the ISO methods developed in the recent years for the testing of biodegradable materials. Furthermore, the data presented in this work show that the investigated material can be biodegrade in all different environmental compartments to the same extent as the positive control. Finally, the developed model gives valuable insights into the understanding of the biodegradation mechanisms.

3.10.P-We063 A Full Year of Atmospheric Microplastic Monitoring in a Remote High-Altitude Catchment Area in the Pyrenees, Southwestern France

Oskar Hagelskjær¹, Gaël Le Roux², Jeroen Sonke³ and Laure Gandois², (1)ENSAT Toulouse, EcoLab, France, (2)Laboratoire écologie fonctionnelle et environnement, Université de Toulouse, CNRS, Toulouse, France, France, (3)OMP-GET Toulouse, France

Atmospheric deposition of microplastics to mountainous areas has been demonstrated by Allen et al., 2019. This study aims at pursuing these investigations, with a focus on seasonality, deposition form (wet versus dry deposition), as well as the altitude effect on atmospheric deposition of microplastics. In addition, Microplastic distribution and quantity will be intercompared with trace element content to help determine whether some trace elements act as proxies for specific synthetic polymer types. From 26/11-2019 to 07/10-2021 rainwater as well as dry atmospheric deposition have been collected on a monthly basis, from an automated rainwater/dry deposition collector. The collector was placed in a natural mountainous area in the Pyrenees in Bernadouze, France at an altitude of 1425 meters. A total of 24 rainwater and 24 dry deposition samples were prepared for automated Raman microscope analysis. Samples synchronously collected in the state of Andorra, at similar conditions, will later be compared to these findings. From each sample 1000 ml of rainwater was filtrated unto 0.45 µm Millipore Teflon filters, and the content transferred into vials with 30% H₂O₂ for the degradation of biogenic material. After 7 days of digestion at 50°C the content was once again filtrated unto 0.45 Millipore Teflon filters and transferred into a 1.6 g/cm³ ZnCl₂ (Zinc Chloride) solution. Here the heavy fraction i.e. lithic fragments, was gradually sorted out by repeatedly shaking, settling and flushing the contents of a glass decanter. After separation, the light floating fraction was filtrated unto 1 µm, 10x10 mm pure silicon membrane filters and thoroughly rinsed with milli-Q deionized water. The silicon filters were analyzed using the automatic scan function of the Horiba Soleil Raman microscope. The instrument is capable of measuring particles down to 1 µm; a critical feature when analyzing atmospheric particles. Results have yet to be procured but will be ready in May 2022.

3.10.P-We064 Exploring the Potential of Raman Microspectroscopy for the Analysis of Microbial Degradation of Microplastics

Kara Müller¹, Julian Weng², Natalia Ivleva³ and Martin Elsner³, (1)Institute of Hydrochemistry - Technical University of Munich, Germany, (2)Technical University of Munich, TUM, Germany, (3)Technical University of Munich, Germany

Biodegradation of microplastics in the aquatic environment is not studied sufficiently to predict the fate of microplastics – synthetic polymer particles in the size range 1 µm – 1 mm. Mainly indirect methods like mass loss of the polymer or changed polymer properties have been investigated, which give information about microbial colonization and enzymatic depolymerization. Alternatively, CO₂ formation during microbial utilization of hydrolysis products is commonly monitored. However, the most direct line of evidence - biomass formation out of plastics - has only once been investigated by Zumstein et al.: carbon from synthetic polymers in soils was traced into microbial biomass using stable isotopes and nanoscale secondary ion mass spectrometry (NanoSIMS). In this work, Raman microspectroscopy (RM) will be applied with the aim to directly monitor the uptake of isotope labels from the polymers into the biomass on a single cell level in a non-invasive way: application in water samples can enable to directly detect phenotypical heterogeneity within the microbial community. While NanoSIMS has excellent lateral resolution, RM persuades with easy sample preparation, non-destructiveness, water insensitivity and structural information, which offer to trace isotope labels into different cell compartments. For a first study, the bacteria *Sphingomonas koreensis*, which were isolated from an environmental aquatic sample, were chosen due to their potential to biodegrade Poly(lactic acid) (PLA) particles. *S. koreensis* cells contain carotenoids in various cell compartments, which can be used for resonance Raman due to their chromophoric system. This way, Raman spectra can be obtained in only 1 s with a laser power of 1 mW at the sample. Quantitative ¹³C labeling of carotenoids was previously shown by the group of Huang. Since isotopically labeled polymers are very expensive or not commercially available, a reverse labeling approach will also be tested by initially labeling cells with ¹³C-

glucose. The resulting red-shift can be linearly assigned to the according ^{13}C -content of the substrate. For the first experiments PLA, the most common biodegradable plastic, is chosen as single carbon source. While this procedure will be used as cheap method to indicate whether single bacteria cells are able to metabolize a specific polymer by shifting the label bands back to the initial wavenumber, a direct labeling approach will be required for environmental samples. Therefore, D- and ^{13}C -labeled polymers will be used in a following direct labeling approach.

3.10.P-We065 Determination of Microplastics in Moss Using Thermal Extraction- Desorption Gas Chromatography Mass Spectrometry Ted-Gc-Ms

Mike Wenzel¹, Katharina Hellmann², Matin Funck¹, Carmen Wolf³, Christine Kube⁴, Winfried Schröder⁵, Stefan Nickel⁶, Annekatriin Dreyer⁷, Barbara Völksen⁸, Jürgen Schram⁹, Torsten Schmidt² and Jochen Tuerk¹, (1)Institute of Energy and Environmental Technology e.V. (IUTA), Germany, (2)University of Duisburg-Essen, Germany, (3)Institute of Energy and Environmental Technology e.V. - IUTA, Germany, (4)Institute of Energy and Environmental Technology e.V. - IUTA, Germany, (5)University of Vechta, Germany, (6)Planwerk, Unterdorfstraße 3, 63667 Nidda, Germany, Germany, (7)ANECO, Germany, (8)Planwerk, Germany, (9)Hochschule Niederrhein, Germany

The use of mosses as biomonitor for several atmospheric pollutants like heavy metals and persistent organic pollutants is well established in the literature. To investigate whether moss can also be used as biomonitor for atmospheric microplastics deposition, a method for quantifying microplastics in moss using thermal extraction - desorption gas chromatography mass spectrometry (TED-GC-MS) was developed. Within the sample preparation a homogenization of the young plant parts and an oxidative digestion using the Fenton reaction to reduce the matrix followed by a filtration step was performed. For validation six different polymers, polyethylene (PE), polystyrene (PS), polyamide (PA), polypropylene (PP), Polyethylene-terephthalate (PET), Styrene-butadiene-rubber (SBR) were added to 1 g (dw) moss samples (*Pseudoscleropodium purum*) and recovery rates were determined. The calculated recovery rates ranged between 84 and 93% with a standard deviation between 4 and 9%. After validation, environmental moss samples from different sampling sites in Germany (Lower Saxony, North Rhine-Westphalia, Rhineland-Palatinate, Baden-Württemberg) were analyzed. Microplastics could be identified and quantified in all environmental moss samples. This method will be applied in a pilot study as part of the German Moss Survey 2020/2021 supported by the German Environment Agency (UBA, Research code 3720632010) to quantify microplastics in environmental moss samples from further 20 sampling sites.

3.10.P-We066 Microplastics in Total Atmospheric Fallout: Monitoring in Peri-Urban and Agricultural Sites

Max Beaurepaire¹, Rachid Dris², Bruno Tassin² and johnny gasperi¹, (1)LEESU, France, (2)Univ Paris Est Creteil, France
Microplastic (MP) pollution has been the source of an increasing scientific interest since the beginning of the century. While MPs have been described in virtually environment, some environments remain less studied and less understood than others. In particular, the occurrence of microplastics in the atmospheric compartment has only been studied for a few years. This work presents the result of three total atmospheric fallout monitoring campaigns conducted in two different sites in the Paris region. Total atmospheric fallout was collected using passive sampler for 4 to 6 month for the different studies. Samples underwent a density separation followed by a chemical treatment, before they were analysed using an automated μFTIR mapping analysis using a Nicolet iN10 by Thermo Scientific. MPs could be identified down to a size of 25 μm , cutoff point determined by the μFTIR detectors. Preliminary showed deposition rates of a few dozen MP/m²/d. In the case of two fully analysed samples from site A in 2021, deposition rates reached 9.5 and 48.9 MP/m²/d. Other samples currently await μFTIR analysis. These results were compared to earlier studies conducted in the Greater Paris region.

3.10.P-We067 Caddisfly Larvae As a Novel Biological Source of Microplastics in Freshwater Systems

Katey Valentine¹, Alistair Boxall², Richard Cross³ and Gina Woodmancy², (1)Environment Department, University of York, United Kingdom, (2)University of York, United Kingdom, (3)UK Centre for Ecology & Hydrology, United Kingdom

Plastic pollution is ubiquitous in freshwater environments globally, with many invertebrates known to interact with both micro- and macroplastics. Caddisfly larvae (order Trichoptera) utilize material from their environment to build portable cases, and previous studies have found that some species incorporate microplastics into their cases alongside typically used materials such as sand and rocks. Other caddisfly species use flexible material, such leaves, to build their case, which they first fragment to the correct size with their mandibles. This study explored the ability of *Agrypnia pagetana* larvae to fragment and utilize flexible plastic film to build portable cases and observed whether their interaction with plastic could be a source of biological microplastic creation. Larvae were removed from their original cases and incubated with 6x3.4mm pieces of microbially-conditioned polylactic acid (PLA) film and oak leaf. One treatment (T1) was given just enough material to build a new case (13 plastic, 13 leaf), whilst a second treatment (T2) was given enough plastic and enough leaf to build a case out of only one material (26 plastic, 26 leaf). After six days, the amount of leaf and plastic used in cases was analysed; exposure water was filtered to 0.2 μm and imaged under a microscope to quantify the presence of microplastic fragments and FTIR was used to confirm the polymer identify of observed fragments. All larvae had constructed new cases after six days. In T1, all twelve larvae incorporated PLA into their new case. In T2, eleven of the twelve larvae had incorporated PLA into their case, despite nine of these larvae still having unused leaf material remaining in the jar. Plastic fragmentation was evident, with 53% of PLA pieces in T1 and 43% of PLA pieces in T2 being fragmented. PLA microfragments were found in exposure water from both treatments, with up to 924 microfragments (45 - 928 μm) created by just one larvae over six days. This study found that *A. pagetana* larvae fragmented and used PLA film to build new cases - which led to microplastic release to the surrounding water. Plastic was incorporated into cases even when natural material was replete, indicating the likelihood of this behaviour to occur in natural habitats. These findings demonstrate the need

to consider the role of biological fragmentation in plastic degradation and should be considered when developing models to predict the fate and behaviour of microplastics in the environment.

3.10.P-We068 Release of Micro- and NanoPlastics From Single-Use and Reusable Facemasks

Yuyue Huang¹ and **Elvis Genbo Xu**², (1)University of Southern Denmark, Denmark, (2)University of Southern Denmark, Odense, Denmark

Release of micro- and nanoplastics from single-use and reusable facemasks Yuyue Huang (presenter), Elvis Genbo Xu Department of Biology, University of Southern Denmark, Odense 5230, Denmark Presentation type: **Poster** Face masks helped prevent the spread of coronavirus and mass masking is recommended by almost all health groups and countries to control the COVID-19 pandemic. The massive production, use, and inappropriate disposal of plastic face masks result in new concerns of the plastic problem. The single-use masks ended in the natural environments may fragment into micro- and nanoplastics (MNPs) that are known hazardous to environmental organisms. Some new reusable face masks, therefore, are made and recommended but they may also release MNPs during sterilization and washing. In this study, we investigated the release of MNPs from both single-use and reusable face masks under both environmental aqueous and sedimentary conditions, as well as during sterilization, hand, and machine washing procedures. The efficiency and recovery of different MNP extraction/separation methods were also compared, including chemical digestion (acids, alkalis, and Fenton's reagent), enzymatic digestion (Proteinase-K and cellulose), density floatation (NaCl, ZnCl₂, and NaI), centrifugation, and sequential filtrations. This study provides important data on face masks as a new MNP source and it is urgent to recognize this environmental threat, particularly under the circumstance of facing new challenges of the coronavirus variants. **Key words:** microplastics; disposals masks; sediments; soils

3.10.P-We069 Release of Microplastics From a Newly Developed Bio-Based Composite After Ultraviolet Irradiation

Zhiyue Niu¹, **Ana I Catarino**², **Maelenn Le Gall**³, **Marco Curto**⁴, **Elke Demeyer**⁵, **Hom Dhakal**⁴, **Peter Davies**³ and **Gert Everaert**², (1)Research, VLIZ, Oostende, Belgium, (2)Flanders Marine Institute, Belgium, (3)IFREMER, France, (4)University of Portsmouth, United Kingdom, (5)Centexbel, Belgium

The dependence on petroleum-based polymers such as polypropylene (PP) has led to a series of environmental issues, including the persistence of microplastic (MP), i.e. plastic particles smaller than 5 mm in diameter, in the global ocean. Polymers made from a natural-sourced feedstock, like polylactic acid (PLA), known as bio-based polymers, are seen as more sustainable alternatives. However, our knowledge remains limited about their degradation and fate in the marine environment. Studies have provided evidence of the release of MP from larger debris under Ultraviolet (UV) radiation in laboratory conditions. However, the most direct and quantitative evidence of MP formation, i.e. observation, identification and enumeration of MPs formed after UV radiation, is limited. Indeed, only a few studies have assessed the disintegration of bio-based polymers and their capacity to form MPs. As part of the Interreg 2 Seas Mers Zeeën project SeaBioComp (seabiocomp.eu), we aim to compare, quantify and characterise the MP formation of a newly developed bio-based composite (i.e. bio-based polymers integrated with synthetic or natural fibres) and a reference petroleum-based polymer during their degradation under UV radiation. To do so, we exposed 3D printed cylinders (d=h=1cm) of self-reinforced PLA (SR-PLA) and PP respectively, immersed in natural seawater, to accelerated UV radiation for up to 1368h, simulating about 18 months of natural solar exposure in central Europe. Dark controls (i.e. sealed from the UV) were incubated in the same conditions also for 1,368h. To identify, characterise and quantify the formed MPs, we used a combination of fluorescent microscopy, infrared technology (FT-IR) and image analysis. We found that 1,368h UV exposure accelerated the MP formation of PP samples but not SR-PLA samples, suggesting that the newly developed bio-based composite SR-PLA is more resistant to releasing MPs than the reference petroleum-based polymer. We anticipate that our results will contribute to assessing the sustainability of future bio-based polymers and composites applications and to supporting a transition process to more sustainable plastic materials.

3.10.P-We070 Response to Microplastic Exposure: An Exploration Into the Sea Urchin Immune Cell Proteome

Carola Murano¹, **Simona Nonnis**², **Gabriella Tedeschi**², **Ilaria Corsi**³ and **Anna Palumbo**⁴, (1)Biology and Evolution of marine organisms, Stazione Zoologica Anton Dohrn, Napoli, Italy, (2)University of Milano, Italy, (3)University of Siena, Italy, (4)Stazione Zoologica Anton Dohrn Naples, Italy

Nowadays, it is undeniable that marine organisms are interacting with plastic debris with serious consequences on organism and population health mostly based on size lower than 5 mm defined as microplastics (MPs). Despite the growing attention on MPs pollution, there are still several scientific issues to be addressed in understanding MPs toxicity especially related to the molecular mechanisms and the cellular processes that are activated in response to MPs exposure. Translating this knowledge-gap on the biological impacts of MPs on one of the key species of the Mediterranean Sea, the *Paracentrotus lividus*, this study aims to explore for the first time the sea urchin immune cells profile combined to their proteome upon *in vivo* exposure to different concentration of polystyrene-microplastics (micro-PS). In detail, adult specimens of the sea urchin *P. lividus* were exposed to different concentration of fluorescent micro-PS (45 µm) (0, 10, 50, 1000, 10⁴ particles/L) for 72h. Already after 24h of micro-PS exposure, immune cells showed a significant increase at highest concentration tested (10⁴ particles/L), while the low micro-PS concentrations tested (10 and 50 particles/L) reported no significant differences. Moreover, coelomocytes showed an increase in both intracellular reactive oxygen and nitrogen species levels (ROS and RNS) at 24h and 48h, compared to the control. In the case of the RNS, the increase is maintained after 72h of exposure also to 10 and 1000 particles/L. Proteomics analysis revealed the presence of 2060 control group proteins. By comparing these proteins to the total proteins found in the treatments, 69 unique proteins were identified for 10 part/L, 75 for 50 part/L, 93 for 1000 part/L and 82 for 10⁴ part/L. Among these unique proteins, only the 8% of proteins (n=13) are shared by all four concentration tested simultaneously and mostly involved in cytoskeletal organization, intracellular membrane trafficking as well as protein metabolism. Overall, these findings provide new insights in

understanding the mode of action of MPs in the sea urchin immune cells at the molecular and cellular level. The combination of “-omics” approaches and ecophysiological techniques affords a more holistic understanding of the potential impacts of microplastics providing new perspectives for environmental risk assessment purposes.

3.10.P-We071 Finding the Culprit. Point-Source Tracking of Microplastic Concentrations in a Sewer Network

Lucian Lucian Iordachescu¹, Konstantinos Papacharalampos¹, Lauriane Barritaud², Valérie Ingrand³, Marie-Pierre Denieul⁴, Emmanuel Plessis⁵, Veronique Julien⁵, Gilles Baratto⁵ and Jes Vollertsen¹, (1)Aalborg University, Denmark, (2)VEOLIA Recherche et Innovation (VERI), France, (3)VEOLIA Recherche et Innovation, France, (4)VEOLIA Environnement Recherche et Innovation, France, (5)Veolia Eau, France

1. Introduction Plastic has spread rapidly after its discovery and has become essential to human life. While plastic production has increased, plastic waste management lagged behind, causing an accumulation of plastic debris in the environment. Some of the plastic enters the environment as small particles < 5 mm, defined as microplastics (MP). Urban areas have been identified as a prominent source of MP release to the environment. Stormwater, wastewater and combined sewer overflows can be major sources of MP. In developed countries, wastewater from households, institutions, and industries is usually collected by sewer systems, then gets treated at wastewater treatment plants. However, 48% of global wastewater produced is released to the environment untreated. Our focus is to investigate the distribution of MP in wastewater produced from the different activities before entering the wastewater treatment plants. In the current study, we analyzed wastewater coming from several domains in Toulon, France. **2. Materials and methods** The wastewater samples were taken with an autosampler over 24 hours from manholes receiving sewage from the different activities as mentioned previously. The samples underwent extensive treatment using SDS, H₂O₂, three types of enzymes, and density separation before analysis. Subsequently, the concentrated samples were analyzed with a state-of-the-art FPA- μ FTIR instrument in transmission mode, where MPs were quantified in terms of particle number and mass, polymer composition, size distribution in the size range 10 – 500 μ m. This technology was combined with an automated analysis of the vast amounts of data that such analysis produces. **3. Results and discussion** The results show that industrial laundry facilities release considerably more MP than the rest of the investigated areas. The second and third largest concentrations were found at Car garage and Domestic. The distribution of the polymer types in each sampling spot was also investigated. More than 80% of the MPs in the wastewater originating from the laundry facility were identified as Polyester. **4. Conclusion** In this study, we showed significant differences between different types of wastewaters in a sewer network, a knowledge that is important when assessing MP pollution and designing protective measures.

3.10.P-We072 Microplastics in a Highway Stormwater Retention Pond

Nanna Klemmensen¹, Fan Liu², Jeanette Lykkemark³, Emma Drastrup³, Helena Hjørringgaard³ and Jes Vollertsen³, (1)Thomasmanns vej 23, Aalborg University, Denmark, (2)Department of Build, Aalborg University, Denmark, (3)Aalborg University, Denmark

It is known that different pollutants accumulate in stormwater retention ponds, including microplastics (MP). When investigating MP in such retention ponds car tyre rubber is often overlooked, even though there is a big potential for accumulation of these, especially if the stormwater retention ponds are located next to highways, large roads, or urban areas. This also results in insufficient knowledge regarding the accumulation of rubbers in these ponds. This study aims to quantify the mass of car tyre rubber in a stormwater retention pond using pyrolysis-GC/MS. Here the rubber content in the sediments are investigated at different depths namely, 0-3 cm and 3-6 cm. The objective is to increase the knowledge on the fate of car tyre rubber in such pond. In total 6 locations were sampled in a highway stormwater retention pond located at Låsby in Denmark using sediment corers. For each location two samples were collected one from the top layer (0-3 cm) and one from the middle layer (3-6 cm), ending up with a total of 12 sediment samples. To extract the rubber, each sample went through extensive sample preparation, including processes such as oxidation, density separation, and enzymatic treatment. After sample preparation the mass of rubber was quantified using pyrolysis-GC/MS with 4-vinylcyclohexene as the indicator product. Rubber was detected at all 6 sample locations in both the top and middle layer of the sediments. The concentrations were however varying. Both the lowest and highest concentration of rubber was measured in the top layer of the sediment, which indicates significant variance in the rubber concentration. This is also valid when comparing the top and middle layer as concentration between 35 μ g/g and 1084 μ g/g and 81 μ g/g and 997 μ g/g were measured in the top and middle layer, respectively. Even though there was substantial variation in the distribution of rubber in the stormwater retention pond, the levels were generally quite high, i.e. up to 0.1% of the sediment dry weight was constituted of car tyre rubber.

3.10.P-We073 Exposure of Microplastics at Levels Relevant for Human Health: Acute and Chronic Cytotoxicity and Cellular Localization of Polystyrene Microparticles in Four Human Cell Lines

Miao Peng¹, Maaike Vercauteren², Charlotte Grootaert¹, Andreja Rajkovic¹, Colin Janssen³ and Prof. Jana Asselman¹, (1)Ghent University, Belgium, (2)Ghent University, Ghent, Belgium, (3)University of Ghent, Belgium

The ubiquity of microplastics (MPs) in the environment raises concerns on human health through potential exposure via air pollution, the food chain and drinking water. However, little is known about the effects of MPs on human health at realistic exposure levels. Herein, the chronic and acute effects of MPs at human realistic exposure levels on four types of human cell lines derived from colon (Caco-2), liver (HepG2) and lung (A549 and BEAS-2B) were investigated. The undifferentiated and differentiated cells involved the most representative exposure routes (inhalation, ingestion, and physiological transport through the liver by the portal vein) were exposed to 2- μ m fluorescent polystyrene (PS) microspheres (10³-10⁸ particles/L) for 48 h and 12 d. The measurements of flow cytometry and laser confocal microscopy showed that PS could be internalized in cell membrane and even in the nuclei. PS did not cause any significant toxic impacts on mitochondrial membrane potential and cell viability, but

induced reactive oxygen species production in undifferentiated A549 and Caco-2 cells upon short exposure, and differentiated A549 cells upon short and chronic exposure. The adenocarcinoma A549 cells from the lung seems to be more sensitive to PS exposure than normal bronchial BEAS-2B cells. Differentiated cells show a higher tolerance to PS than undifferentiated cells under the same exposure conditions. This research is a first step towards more relevant exposure studies to assess risks associated with ingestion, inhalation and internal transport of MPs in the human body.

3.10.P-We074 Retention of Microplastics and Tire Wear Particles in Stormwater Retention Ponds

Lasse Rasmussen¹, Fan Liu¹, Nanna Klemmensen² and Jes Vollertsen¹, (1)Aalborg University, Denmark, (2)Thomas Manns vej 23, Aalborg University, Denmark

Stormwater runoff from roads and urban areas can contain a multitude of different pollutants. Stormwater detention ponds are used to mitigate the possible detrimental effect these might cause when released to the environment. However, their effects with regards to emerging pollutants such as microplastics and tire wear particles are not so well-understood. The objective of this study was to investigate the retention efficiency for microplastics and tire wear particles in stormwater retention ponds. To this end sediment and effluent samples from four different Danish stormwater retention ponds were analyzed. The sediment samples were collected as pooled sample from several locations in each pond, while the effluent samples were collected by filtration during three separate sampling campaigns using a specialized filtration system capable of collecting particulates down to 10 µm. This way between 2.4 – 3.2 m³ were sampled at each site. Prior to analysis the samples were subjected to a multi-step sample preparation consisting of oxidation, enzymatic digestion, and density separation with sodium polytungstate solution at 1.9 g/cm³ in an effort to remove organics and minerals while preserving polymers. Then triplicate subsamples were analyzed by FPA-FTIR imaging (Focal Plane Array-based Fourier Transform Infrared spectroscopy) and processed using siMPLE, a software developed for automated detection of microplastic. Subsequently, other subsamples were analyzed by Pyrolysis GC-MS (Gas Chromatography Mass Spectrometry) for identification of tire wear particles. Microplastics were found in all samples and more than 16,000 MP particles had their size, polymeric composition and mass measured. Across all ponds the average retention efficiency in terms of mass for MP were 83 %. Tire wear particles were identified in all sediments but in only one of the effluent samples, which gave an average retention efficiency of 95 % across all ponds. These results indicate how stormwater retention ponds can act as a sink for microplastic and tire wear particles and mitigate the spreading from urban areas.

3.10.P-We075 Temporal Fluctuations in Microplastic Concentrations Downstream From Sewage Treatment Works: A High-Resolution Study

Anna Tuulikki Kukkola¹, Uwe Schneidewind¹, Holly Nel¹, Lee Haverson², Iseult Lynch³ and Stefan Krause¹, (1)University of Birmingham, United Kingdom, (2)University of Birmingham, School of Geography, Earth and Environmental Sciences, United Kingdom, (3)School of Geography, Earth and Environmental Sciences, University of Birmingham, Birmingham, United Kingdom

Microplastics (< 5mm) have been recovered from all environmental compartments, from deep-sea to the Arctic. It is hypothesized that wastewater treatment plants (WWTP) and sewage treatment works (STW) act as point sources for microplastics in freshwater systems. Some recent literature has estimated that discharge from German WWTPs contains up to 7 ? 10¹² microplastics (in size range of 10 and 5000 µm) annually (Schmidt et al., 2020) However, these calculations often are based on snap-shot sampling (i.e., single or limited time points) that may not account for potential changes in release patterns that may have large fluctuations in a course of a single day. There is limited understanding on whether microplastic abundance fluctuates in the course of a single day, or whether they stay broadly the same. This study aims to assess the validity of snapshot sampling and evaluate typical variability of microplastic abundance in a river system with known point source. To address this question, a four-day high-frequency sampling campaign was carried out downstream from a medium-sized Barston STW, located near Birmingham, UK. Sampling comprised two weekdays (Tuesday and Wednesday, 15th & 16th June 2021) and two weekend days (Saturday and Sunday 19th & 20th June 2021). Each day, 50 L surface water samples were collected in triplicates at one-hour intervals covering a twelve-hour period on each sampling day. Flow velocity was obtained using a Sensa-RC2 (Aqua Data Services Ltd) electromagnetic velocity meter water velocity meter, to aid in discharge and mass-flux calculations. Samples (lower size limit 64 µm) underwent organic matter digestion using wet peroxide oxidation with Fe²⁺(aq), and were subsequently stained with Nile Red (5µg mL⁻¹) in deionized water. Fluorescence microscopy in combination with Raman spectroscopy was applied to identify and quantify microplastics shape, size and polymer type. Initial results suggest relatively low hourly and daily variability in the overall concentration of microplastics in surface water despite significant changes in river height (~30 cm) and discharge (0.55 m³ s⁻¹ to 2.13 m³ s⁻¹) that were linked to effluent releases over the day. Future work will compare polymer composition and any possible fluctuations observed, and integrate the intensive 4-day sampling into a longer-term monthly sampling over a 1 year period. Schmidt, C., Kumar, R., Yang, S. and Büttner, O., 2020. Microplastic particle emission from wastewater treatment plant effluents into river networks in Germany: Loads, spatial patterns of concentrations and potential toxicity. *Science of The Total Environment*, 737: 139544.

3.10.P-We076 Effects of Microplastics Containing Additives on Blue Mussel (*Mytilus edulis*): Study of the Ageing and the Sorption of PAHs As Influencing Factors

Romarie Moncrieffe¹, Binbin Cai¹, Maria Masry², Stéphanie Rossignol², Laurence Poirier³, Samuel Bertrand¹, Pascal Wong-Wah-Chung⁴ and Aurore Zalouk-Vergnoux⁵, (1)Université de Nantes, France, (2)Aix-Marseille Université, France, (3)Nantes Université, France, (4)Université Aix Marseille, France, (5)Université de Nantes, France

The effects of microplastics at environmental levels have yet to be fully examined taking into account the factors of ageing and sorption of some ubiquitous environmental contaminants, such as polycyclic aromatic hydrocarbons (PAHs). Current hypotheses indicate that microplastics which have been degraded by ultra-violet (UV) radiation and/or sorbing PAHs could have a greater

impact on the organism, for example by the transfer of additional contaminants to the organism. This study aimed to assess the influence of these factors on the sentinel species, *Mytilus edulis*, combining biochemical marker analyses and a lipidomic approach. The microplastics used in the experiment were polyethylene microplastic beads (MP). Then, some of them were irradiated for 1000 h in an accelerated ageing chamber (AMP). To simulate PAH sorption, raw microplastics and irradiated microplastics were added to a solution of 4 PAHs (MP-PAH and AMP-PAH respectively). The contamination of tanks was done with the 4 types of microplastics at 10 µg/L, with a treatment without contamination (Control). Fifteen individuals were exposed for 8 days in 15-L tanks filled with artificial seawater per treatment and in triplicates. The potential of microplastics to induce neurotoxicity was determined by Acetylcholinesterase (AChE) measures. Superoxide dismutase (SOD), catalase (CAT), and glutathion S-transferase (GST) served to monitor oxidative stress. These biomarkers were measured on gills, digestive gland and mantle after dissection. Acid Phosphatase (AcP) was used as biomarkers for immunotoxicity and measured in hemolymph. Finally, lipidomic analyses were performed using flow injection analysis coupled to high resolution mass spectrometry (FIA-HRMS) on lipid extracts of digestive glands. All the experiments were performed from 5 individuals per tank, *i.e.* 15 par condition. The combination of artificial ageing and sorption of PAH factors for microplastic exposures showed effects on the blue mussel after 8 days of exposure at environmental doses (10 µg/L) with the detection of oxidative stress and neurotoxicity which were organ dependent. The mantle, not usually analyzed in ecotoxicological studies, seemed to be an interesting organ to monitor the biochemical effects of microplastics. None marked influence of either the ageing or the PAH sorption was highlighted through the lipidomics. Biochemical and lipidomic approaches are complementary tools in the environmental risk assessment.

3.10.P-We077 Influence of Microplastics on Rates of Potential Nitrification and Denitrification in Floating Treatment Wetland Systems

Meredith Keleigh Sutton¹, Daniel Miller², Tiffany Messer³ and Shannon Bartelt-Hunt⁴, (1)University of Nebraska Lincoln, United States, (2)USDA-ARS Agroecosystem Management Research Unit, United States, (3)University of Kentucky, United States, (4)University of Nebraska - Lincoln, United States

Microplastics, plastic particles smaller than 5 mm, are a contaminant of emerging concern due to their potential for detrimental environmental and human health effects and persistence in the environment. Documented in an increasing array of environments, microplastics are commonly found in sources that traditionally contain high levels of other contaminants, such as urban and agricultural runoff. Floating treatment wetlands are a method of remediation for nutrient pollutants, especially nitrates and phosphates. As microplastics are also found in similar sources as those contributing to nutrient pollution, and microplastics have been shown to impact nitrogen transformation processes in wastewater treatment plants, microplastic pollution may impact similar processes in remediation efforts such as floating treatment wetlands. To evaluate the potential impact microplastics may have on nitrogen transformation in these environments, root samples from an established floating treatment wetland were collected and used to inoculate microcosms to study nitrification and denitrification processes. Microplastic treatments included polyethylene and polystyrene microspheres at two diameters (30 µm and 200 µm) for three concentrations (10 mg/L, 100 mg/L, and 1000 mg/L). Nitrification microcosms were observed in aerobic conditions over a 24 hour period and denitrification microcosms flushed with nitrogen gas to encourage anoxic conditions were monitored over a week. Nitrate and nitrite production/consumption was analyzed using a microplate method to calculate potential nitrification and denitrification rates. A preliminary potential denitrification experiment using 1-4 µm polyethylene microbeads found there was not a significant difference in potential denitrification rate between microplastic concentrations (10 mg/L and 100 mg/L) nor between the added microplastic treatment and root controls. Preliminary results from nitrification microcosms show similar results where the addition of microplastics do not impact potential nitrification rates. Further research to observe the impacts of weathering and chemical additives would give a better understanding on how microplastics in the environments may interact with microorganisms and influence nitrogen transformation in the system.

3.10.P-We078 Plastic Content and Additive Distribution in Wastewater Treatment Plant Effluent in Oslo (Norway)

Ian John Allan¹, Alfhild Kringstad², Elena Martinez-Frances² and Laura Rohler², (1)Norwegian Institute for Water Research, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway

Microplastics have been the subject of increasing focus over the last decade since they have been found in virtually all waters and oceans around the globe. While rivers are assumed to be a major contributor of microplastic pollution to the marine environment, treated and untreated wastewater effluents and stormwaters are expected to be a significant emission source of not only microplastic particles but also of the less studied nano-size plastic to freshwaters. Chemical additives are generally added to plastics during production to enhance certain properties, e.g. flexibility, flame retardancy, or lifetime. The leaching capability of additives such as plasticisers, flame retardants, UV stabilisers or residual curing agents is dependent on the type of plastic and the chemical agent itself. The release of chemical additives to and fate in the environment is linked to the fate of plastic (emission, particle size or breakdown). It also remains totally unclear whether microplastics release to the environment currently provides an unaccounted-for pathway for the release of chemical additives to the aquatic environment. The objective of this study was to assess the distribution of selected additives (flame retardants, plasticisers and UV filters) in wastewater effluents in Oslo (Norway). Suspended particulate matter was sampled from the effluent using continuous flow centrifugation. The plastic content was measured with pyrolysis GC/MS while different extraction and sample cleanup procedures were applied to extract additives. Total additive concentrations were obtained with Soxhlet extraction while silicone rubber extractions were applied to estimate the easily desorbable additive concentrations. Other sample treatment options tested included KOH and H₂O₂ treatment prior to Soxhlet extraction. Freely dissolved additive concentrations were obtained by passive sampling in situ in the effluent itself. Results of this work include estimates of plastic content of the effluent and of the distribution of selected additives in the suspended matter of the effluent.

3.10.P-We079 Early Stages of Biofilm Formation on Bio-Based Microplastics in a Reservoir

Nhung Nguyen¹, Marlita Marlita², Yehia El-Temsah¹, Pavel Hrabák¹, Jakub Riha¹ and Alena Sevcu¹, (1)Technical University of Liberec, Czech Republic, (2)Technical University of Liberec, Liberec, Czech Republic

Bio-based plastics, produced from renewable biomass sources, are currently increasing in products and applications, including high-density polyethylene (HDPE), polylactic acid (PLA), and poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV). However, their biodegradability and environmental fate are not fully understood, especially microplastics. Therefore, we performed an *in-situ* study in a freshwater reservoir in the winter season. Three pristine microplastics materials (HDPE, PLA and PHBV) were separately placed into cellulose dialysis bags and anchored in a cage in the inflow part of the reservoir. Initial stage of biofilm formation on plastics was investigated using 16S rRNA sequencing to identify rare and more abundant bacterial taxa (> 5% of total biomass) were distinguished. After two months, bacterial and algal abundance on plastics increased in the order of PHBV > HDPE > PLA, while fungal abundance was highest on HDPE > PHBV > PLA. The biofilm composition showed that dominant bacterial populations were irrespective of plastic types, while rare taxa were significantly diverse. The dominant taxa belonging to *Caulobacteraceae/Asticcacaulis*, *Cellvibrinaceae/Cellvibrio*, and unclassified *Oxalobacteraceae* were unchanged on all plastics during the study. Within the rare families, *Bacteriovoracaceae*, *Crocinitomicaceae*, *Oxalobacteraceae*, *Sphingobacteriaceae* increased on all plastics after 2 months. Overall, rare taxa specific to each plastic type were uncultured bacteria on HDPE, *Cytophagaceae* on PLA, and *Sphingobacteriaceae* on PHBV.

3.10.P-We080 Fate of Microplastics in Background Headwater Lake Catchments, Ontario, Canada, Using a Microplastic Particle Balance Approach

Brittany Welsh¹, Julian Aherne² and Andrew Paterson³, (1)Trent University, Peterborough, ON, Canada, (2)Trent University, Canada, (3)Ontario Ministry of the Environment, Conservation and Parks, Canada

Microplastics are pervasive contaminants of concern, but the fate of microplastic pollution in headwater lakes, especially in background regions, remains relatively unknown. Few studies have quantified or synthesized the inputs, outputs, and pathways of microplastics to lakes at the watershed or catchment level. In this study, the flux of microplastics (MP) were quantified over a 12-month period for three background headwater lake catchments in Muskoka-Haliburton, Ontario, Canada. A microplastic particle balance approach was used, incorporating inputs from atmospheric deposition and inflows against outflows and sedimentation to lakes. Lake samples were collected 1-metre below the surface from each of the three study lakes and stream samples were collected from 17 gauged inflows and outflows as grab samples from the point of controlled discharge. Duplicate sediment cores were collected from the deepest point of the lake and deposition samples were collected from 3 stations using bulk precipitation collectors. The results showed that atmospheric deposition had the highest daily microplastic flux rate (3.84–8.04 MP/m²/day), between 1.5 and 4 times greater than the flux of microplastics in the inflow streams (2.14–2.34 MP/m²/day). This suggests that the atmosphere is the dominant source of microplastics to lakes in background regions, accounting for all of the inflowing microplastics to the study sites. Of the microplastics deposited on the catchment from the atmosphere, 41–73% were retained in the terrestrial area. Furthermore, a large fraction of the microplastics in the inflow streams were retained in the lakes (30–45%). This suggests that lakes are a reservoir for microplastics; in the current study the residence time for microplastics ranged from 3.15 to 7.70 years. Fibres were the dominant shape identified in atmospheric deposition, stream water and lake water; however, in lake sediment, there was a higher proportion of fragments. For all sample media, polyethylene terephthalate (20%) was the dominant polymer identified followed by polypropylene (18%) and polyamide (14%).

3.10.P-We081 Detection of Plastics in Soil - Prevalence, Origins and Effects

Ulrike Braun¹, Gunnar Bachem¹, Ulrike Braun², Maria Kittner³, Korinna Altmann³, Jana Meierdierks⁴, Peter Grathwohl⁵, Carina Lackmann⁶, Antonio Šimič⁷, Mirna Velki⁸ and Henner Hollert⁹, (1)German Federal Environment Agency (UBA), Germany, (2)BAM Federal Institute for Materials Research and Testing, Germany, (3)Federal Institute for Materials Research and Testing (BAM), Germany, (4)Eberhard Karls Universität Tübingen, Germany, (5)Uni Tübingen, Germany, (6)Goethe-Universität Frankfurt, Germany, (7)Josip Juraj Strossmayer University of Osijek, Croatia, (8)Josip Juraj Strossmayer University in Osijek, Department of Biology, Croatia, (9)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany

Soil acts as a final sink for pollutants. Microplastics from different sources such as plastic mulching, littering, compost, sewage sludge, sedimentary deposition, and tyre abrasion are expected to be found in soil. However, representative and comprehensive information is missing on the sources, transport, and fate. Therefore, a reliable analysis method for microplastics in soils needs to be developed. [1]The work presented here describes the development of a procedure for microplastics analysis in soil. A representative sampling based on the on-site conditions and a sample preparation method were established including a drying step, the separation of microplastic particles > 1 mm, and a density separation for particles < 1 mm. The detection of the large microplastic particles (> 1 mm) was conducted with Attenuated Total Reflection - Fourier Transform Infrared Spectroscopy (ATR-FTIR), while Thermal Extraction Desorption - Gas Chromatography / Mass Spectrometry (TED-GC/MS) [2] was applied for particles < 1 mm, gaining information on the type of polymer and mass fraction. Based on the established method, 14 environmental soil samples with different exposure to microplastics from agriculture, industrial sites, roads, and floods were investigated. High contents of small microplastic particles (< 1 mm) were discovered in the soil samples exposed to plastic mulching, fertilization with sewage sludge or compost (0 – 115 mg/kg). On average, microplastic contents detected in soil samples taken from a construction site and an inner-city lake were higher (13 – 238 mg/kg). As expected, microplastic contents in soil sampled in proximity to roads was more pronounced in the upper soil layers. In contrast, very remote sampling sites, believed to be uncontaminated, did not lead to the detection of microplastics by TED-GC/MS. In a proof of concept experiment several *in vivo* and *in vitro* ecotoxicological tests were applied to evaluate the effect of microplastics (tyre abrasion, polystyrene containing

hexabromocyclododecane) in natural soils. In summary, while no effects of the examined probes could be detected on higher levels of biological organization after exposures to earthworm *E. andrei*, significant changes in several oxidative stress related biomarkers were observed. [1] Moßler, Julia N., et al. *Environmental science & technology* 54.4 (2020): 2078-2090. [2] Dümichen, Erik, et al. *Journal of Chromatography A* 1592 (2019): 133-142.

3.10.P-We082 Transfer of Microplastics From Aquatic to Terrestrial Environments

Samuel Daughenbaugh¹, Martin Berg², Christine Custer³ and Tham Hoang⁴, (1)Loyola University Chicago, School of Environmental Sustainability, United States, (2)Loyola University of Chicago, United States, (3)U.S. Geological Survey, United States, (4)Auburn University, United States

Microplastics are important emerging contaminants in marine, aquatic, and terrestrial environments. As microplastic pollution increases, it is important to understand their occurrence, fate, and transport in these environments. While the trophic transfer of microplastics within ecosystems has been studied, we lack empirical evidence of the trophic transfer of microplastics across ecosystems. This study aims to characterize a pathway of microplastic movement from aquatic to terrestrial ecosystems, using *Tachycineta bicolor* (i.e., tree swallows) as a model. Here, we analyze samples of water, sediment, insects, and lower digestive tracts of *T. bicolor* nestlings for microplastics from three locations along the St. Louis River in Minnesota and three locations in Wisconsin. In each state, we examined urban, suburban, and rural sites. Modified versions of the NOAA Marine Debris Program's Laboratory Methods for the Analysis of Microplastics in the Marine Environment were applied to remove as much organic material from the water and sediment samples as possible to better detect plastic particles without significantly altering them. Plastic polymers were identified with Fourier-Transform Infrared Spectroscopy (FTIR). Overall, the results show that microplastics were present in the lower GI tracts of in nestling tree swallows, water, and aquatic insects. Although the concentrations were not significantly different across the six sites, tree swallows collected from urban sites appeared to have higher number of microplastics in their GI tracts than tree swallows from rural sites. Interestingly, concentrations of microplastics in tree swallows are strongly correlated with microplastic concentrations in aquatic insects-Odonatans but not Dipterans. These results suggest that Odonata could be the main food source for nestling tree swallow and carried microplastics to the birds- a mechanism of microplastic transfer back to terrestrial ecosystem from aquatic ecosystem. To our knowledge, this scientific evidence for microplastics transfer across ecosystems was observed for the first time.

3.10.P-We083 Evidence for Very High Microplastic Contamination in Amphibian Breeding Pools and First Data Indicating the Potential for Harmful Effects on Wild Tadpoles (Common Toad, *Bufo bufo*)

Chloe Houseman¹, Jeanette Rotchell² and Frances Orton³, (1)School of Health and Life Sciences, The University of the West of Scotland, Glasgow, United Kingdom, (2)University of Hull, United Kingdom, (3)Health and Life Sciences, UWS, Glasgow, United Kingdom

Microplastics (MP) have been widely reported in surface water, sediment and biota sampled from aquatic environments. However, relatively few data exist on MP contamination of small freshwaters (SFWs) such as ponds, puddles and ditches, which are likely to harbour high levels due to their low volumes combined with probable high exposure levels. Amphibians are one of the most common vertebrates to inhabit SFWs and are undergoing catastrophic decline globally. We investigated MP pollution of SFWs and common toads (*Bufo bufo*) under different land use characterisations. Water and sediment samples were collected from reference (R: $n = 3$), urban (U: $n = 3$) and agricultural (A: $n = 3$) ponds at 4 timepoints in the Spring (15th March - 9th June). Where found (1 x R, 1 x U, 2 x A), 20 tadpoles were collected *per site* on visits 3 and 4. The levels of MPs found across all site characterisations ranged between 0–30 items/L⁻¹ in water and 12–1484 items/kg⁻¹ in sediments, exceeding levels found in coastal environments globally (~ 0.002 items/L⁻¹, ~ 60 items/kg⁻¹). MP abundance, shape and size did not differ between site characterisations, but some differences in polymer type were observed. For example, styrene-butadiene rubber ($n = 1$ particles) was only found in urban sediments, whereas polyvinyl chloride ($n = 2$), ethylene-vinyl acetate ($n = 2$), and epoxy ($n = 1$) were only found in reference and agricultural surface waters. Tadpoles also contained MPs ranging between 0 – 163 items/g tissue⁻¹ (0 – 19 items/individual⁻¹) that were 10 - 100-fold higher than previously reported for other freshwater vertebrates. The vast majority of MPs were found in the gut (81.26 %, $n = 464$) compared to the liver (8.06 %, $n = 46$), brain (2.8 %, $n = 16$) and carcass (7.88 %, $n = 45$), suggesting dietary uptake. This is the first study to report MPs in the brain of a wild vertebrate. Across all sites, a significant negative correlation ($p < 0.01^{**}$) was found between tadpole MP abundance and weight ($R^2 = 0.1135$), total length ($R^2 = 0.1587$) and snout-vent length ($R^2 = 0.1805$), suggesting that MPs may be negatively impacting wild tadpole health. These results provide important insights into the extent of MP pollution in SFWs, which currently do not form part of routine water quality monitoring, as well as potential links between MP ingestion and health-endpoints in wild amphibians for the first time.

3.10.P-We084 Occurrence and Ecological Risks of Microplastics in the Amazon River

Andreu Rico², Theresa Schell¹, Marco Vighi¹, Andreu Rico², Gabriel Silva de Souza Nunes³, Rhaul de Oliveira⁴, Andrea Waichman⁵, Cecilie Singdahl-Larsen⁶, Rachel Hurley⁷ and Luca Nizzetto⁸, (1)IMDEA Water Institute, Spain, (2)IMDEA Water Institute/University of Valencia, Spain, (3)Federal University of Pernambuco, Brazil, (4)State University of Campinas, Brazil, (5)Federal University of the Amazon, Brazil, (6)Norwegian Institute for Water Research (NIVA), Norway, (7)Nowegian Institute for water research, Norway, (8)Norwegian Institute for Water Research NIVA, Norway

The main objective of this study was to characterize the contribution of large cities of the Brazilian Amazon to MP exposure in the Amazon river; to characterize their particle size, shape, and polymer distribution; as well as to assess their risks for freshwater organisms. For this, we analyzed the MP content of 40 water samples collected along a longitudinal gradient of more than 1500 km, which included urban streams and areas of the Amazon River with relatively low anthropogenic impact. MPs were found in all samples, with concentrations varying from 5 MPs/m³ to 74550 MPs/m³. Overall, the total concentration of MPs was higher in

surface waters close to urban areas: streams near the city of Manaus had the highest, followed by those close to Belém, Macapá and Santarém, respectively. MP pollution was dominated by particles >300 µm, where fibres of polyester and fragments of polypropylene, polyethylene, and polystyrene were most abundant. The measured MP concentrations were compared with available threshold concentrations for aquatic organisms (PNECs). MP concentrations were lower than the available PNECs in 93% of the samples. However, three samples taken near Manaus had concentrations above at least one of the available PNECs. This study shows that MPs are ubiquitous contaminants in Amazonian surface waters and that the release of untreated urban wastewaters clearly contributes to increased exposure levels. Our risk assessment shows that ecological impacts may be expected in pollution hotspots near densely populated areas, such as the city of Manaus, which has very limited wastewater treatment. Further work includes the calculation of MP emission by the different urban areas, the total MP loads into the ocean, as well as the refinement of risk calculations with species sensitivity distributions.

3.10.P-We085 Lateral Distribution of Surface-Floating (Micro) Plastic Particles in the North Pacific Ocean

Robby Rynek¹, Stephan Wagner², Annika Jahnke³ and Thorsten Reemtsma⁴, (1)Helmholtz-Centre for Environmental Research - UFZ, Germany, (2)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (3)Helmholtz Centre for Environmental Research - UFZ GmbH, Germany, (4)Helmholtz Centre for Environmental Research, Germany

The mass of globally produced plastic is constantly increasing and nearly reached 370 million tons in 2019. Among other factors, insufficient waste management systems and littering lead to the pollution of the marine environment with plastic particles. In the environment, plastic particles are affected by mechanical, photochemical and biological processes which lead to their weathering and the formation of even smaller particles. Assuming a business as usual scenario, the mass of plastic in the oceans continues to increase and will reach more than 250 million tons by 2025. In the oceans, it accumulates in specific regions due to the influence of ocean currents and winds. One of the biggest known accumulation zones is the so-called Great Pacific Garbage Patch between California and Hawaii. The aim of this study is to determine the lateral distribution of plastic particles floating at the sea surface in the Pacific Ocean. Therefore 10 samples were collected during cruise SO268/3 of the German research vessel SONNE between Vancouver and Singapore from May to July 2019 using a Neuston catamaran with a mesh size of 330 µm. Plastic particles >500 µm were submitted to sieving and enzymatic digestion and afterwards analyzed by ATR-FT-IR spectroscopy. Smaller particles were analyzed by FT-IR imaging in transmission mode after deposition on Anodic filters. Here we present our results for the distribution of surface-floating plastic particles >330 µm. We found plastic particles at every sampling station with concentrations that were extrapolated to 10.000 to 173.000 particles per km². Furthermore we were able to identify two regions with highly elevated concentrations of floating plastic particles – the North Pacific Subtropical Gyre and an area belonging to the Papahānaumokuākea Marine National Monument. These results are consistent with litter survey and modeling data.

3.10.P-We086 Chemical Additives in Weathered Microplastic in the Marine Environment - Occurrence and Risk

Patrik Fauser¹, Linyan Zhu¹, Katrin Vorkamp², Hans Sanderson¹, André Bøgevik³ and Sophie Jensen⁴, (1)Aarhus Universitet, Denmark, (2)Aarhus University, Denmark, (3)Nofima AS, Norway, (4)Matis, Iceland

A Nordic project identified and measured residues of chemical additives in two plastic materials made from the commonly used polymer types polyurethane (PUR) and polyvinyl chloride (PVC). Measurements were performed in applied (new) plastic, and in plastic exposed to weathering for four months in the marine environment. To simulate some degree of weathering the plastic was granulated into particles in micro-meter size (microplastic) (250 µm – 710 µm), and exposed in water-permeable bags in the Samnangerfjord near Bergen from June to October 2020. A suspect list of known and new chemical additives was constructed for PUR and PVC. Targeted chemical analysis with GC-Orbitrap was performed for identification of the suspect chemicals in the plastic particles before and after weathering. For the identified chemicals, GC-MS analysis was performed for quantification. Four plasticizers were detected in PUR, and three in PVC, before and after weathering: Dibutyl adipate, N-butylbenzenesulphonamide, dibutyl phthalate, and di-2-ethylhexyl phthalate (DEHP). Maximum concentrations were 1587 ng/g plastic before weathering, and 946 µg/g plastic after weathering. Two detected additives were a heat stabilizer (triphenyl phosphite) and an antioxidant (octadecyl 3-(3,5-di-tert-butyl-4-hydroxyphenyl)propionate), identified both in PUR and PVC before and after weathering. Measured concentrations were used to calculate PECs for the pelagic environment (copepods and cod), and for secondary poisoning of fulmar. PNECs and risk quotients (RQ=PEC/PNEC) were derived. Additionally, non-target screening with GC-Orbitrap was done to identify chemicals with certain structures found in the NIST library and MassBank database. Proper filters were applied to further identify phthalates, polyaromatic hydrocarbons (PAHs), chlorinated or brominated compounds, and aromatic nitro compounds, which can be considered as representatives of plasticizers, impurities in PVC, flame retardants, and biocides, respectively. Sixteen chemicals were identified with non-target screening. A PAH identified in PVC both before and after weathering, i.e. 2,6-Diisopropylnaphthalene, used as plant growth retardant and agrochemical, is classified as very toxic to aquatic life with long lasting effects. A chlorinated compound identified in PUR both before and after weathering, i.e. 2-Propanol, 1-chloro-, phosphate (3:1), used as flame retardant, is classified as suspected of damaging fertility or the unborn child.

3.10.P-We087 Effect of Polyethylene Microplastic (MPs) and Adsorbed Organic Pollutants on Zea mays L.: Physiological and Transcriptomic Analysis

Carmen Martín¹, Michela Pirreda², Carmen Fajardo³, Gonzalo Costa⁴, Gerardo Mengs⁵, Sebastian Sanchez-Fortun⁶, Mar Nande⁶ and Margarita Martín-Fernandez⁷, (1)Biotechnology-Plant Biology, Universidad Politécnica de Madrid, Madrid, Spain, (2)Universidad Politécnica de Madrid, Spain, (3)Universidad de Alcalá, Madrid, Spain, (4)Universidad Complutense de Madrid, Spain, (5)Ecotoxilab S.L., Spain, (6)University Complutense of Madrid, Spain, (7)Universidad Complutense Madrid, Spain

Research on the environmental impact of plastics, especially on the effect of microplastics (MPs), has become a priority issue in

recent years, mainly in terrestrial ecosystems where there is a lack of studies. This work aims to assess the impact of three types of polyethylene MPs: white microbeads (W), blue microbeads (B) and fluorescent blue microbeads (FB), and their interactions with a mix of organic pollutants containing: ibuprofen (IB), sertraline (STR), amoxicillin (AMX) and simazine (SZ), on *Z. mays* L. plantlets developed under *in vitro* conditions. Murashige and Skoog (MS) plant culture media were prepared including one of each type of MPs, alone or combined with the organic pollutant mixture (MIX). Seeds of *Z. mays* were subjected to sterilization and sown in culture tubes. Seeds were incubated at 25 °C with a 16 h photoperiod and photosynthetic photon flux density (PPFD) of 50 $\mu\text{mol m}^{-2} \text{s}^{-1}$ from cool white fluorescent tubes. Ten seeds were sown per treatment, and a control without MPs or MIX was included in the analysis. After 2 weeks, germination and development were evaluated, and samples of root and leaf tissue were collected. The effect of the different treatments on the physiological characters of *Z. mays* plantlets was analysed through development parameters (root and leaf length), chlorophyll content, and oxidative stress level (ROS and RNS). In order to determine the molecular basis of the MPs and MPs-MIX complexes effects on maize development, a RNA-seq analysis was performed. The effect of the three MPs types on the maize plants development were significantly different, being the W microbeads the ones that caused the greatest inhibition in both root and leaf. Inhibition in root length was only detected when W MPs were combined with the MIX pollutants. Likewise, this last treatment supposed a significant difference in the chlorophyll content compared to the other MPs and MPs-MIX treatments. The three treatments in which MIX pollutants were adsorbed to MPs resulted in a significant increase of free radicals, compared to the control, in root samples, although this response was not observed in leaf samples. The negative effect of W microbeads also was detected in the transcriptomic analysis. Differences in gene expression were detected in the treatment with W MPs (without pollutants) when compared to the control treatment.

3.10.P-We088 New Environmental Monitoring Program; Microplastics in Norwegian Coastal Areas, Rivers, Lakes and Air (Mikronor)

Inger Lise Nerland Brate¹, **Rachel Hurley**², **Maria T. Hultman**³, **Elisabeth Røland**⁴, **Nina Buenaventura**⁵, **Cecilie Singdahl-Larsen**⁴, **Bert Van Bavel**⁴, **Dorte Herzke**⁶ and **Amy Lusher**⁴, (1)NIVA - Norwegian Institute for Water Research, Norway, (2)Norwegian Institute for water research, Norway, (3)Norwegian Institute for Water Research, Oslo, Norway, (4)Norwegian Institute for Water Research (NIVA), Norway, (5)NIVA Norwegian Institute for Water Research, Norway, (6)Environmental Chemistry, NILU - Norwegian Institute for Air Research, Tromsø, Norway

Norwegian Institute for Water Research (NIVA) have, on behalf of the Norwegian Environment Agency (NEA), started Norway's first microplastic (MP) monitoring program, together with Norwegian Institute for Air Research (NILU). The program, *Microplastics in Norwegian coastal areas, rivers, lakes and air (Mikronor)*, started sampling of different matrices in 2021 and will continue until 2024. Despite the continued challenges with MP assessments, including those on processing and analysis, there is a need to commence monitoring in order to address significant knowledge gaps. The primary aim is to provide information on levels and types of MPs in aquatic environments as well as in air. *Mikronor* will explore variations in MP concentrations between geographical areas and sample types, as well as possible sources. The project will gain important knowledge for MP monitoring and contribute towards national and international requirements, such as for the EU and OSPAR. *Mikronor* have received samples from a broad geographical span from large parts of the Norwegian environment (coastal sites, open marine waters, lakes and air) through pre-existing national monitoring programs that cover a range of different water bodies. The following matrices have been sampled in 2021: water samples collected using vertical plankton nets (~150 litres; 200 μm), subsurface seawater using a FerryBox system linked to the seawater intake of the cruise ship Color Fantasy (~5000 litres; 100, 200 and 500 μm meshes), high-volume surface pumps (1000 litres; 200 μm and 50 μm), urban runoff (~2 litres; 50 μm), effluents from wastewater treatment plants (~70 litres; 20 μm) and riverine water from one urban river (1000 litres; 200 μm and 50 μm). Soft bottom sediments samples (~600 ml; 50 μm) corresponding to the water sampling sites have also been collected, as well as biota: namely, marine mussels (Blue mussel, *Mytilus edulis*; 50 μm), freshwater mussels (duck mussels, *Anodonta anatina*; 50 μm) and different marine polychaetes (e.g. family Nephtys and Terebellidae; 50 μm). Both deposition and active air samples were collected for atmospheric MPs. The analysis of water samples will be conducted through a combination of scanning micro-fourier-transform infrared spectroscopy (μFTIR) and pyrolysis GC-MS, whilst the air samples will be analysed with a combination of RAMAN spectroscopy and pyrolysis GC-MS. Preliminary results and insights into the activities of the monitoring programme will be presented.

3.10.P-We089 Influence of Polyethylene Microplastics on Acute Toxicity of Tebuconazole on Different Earthworms

Antonia Weltmeyer¹, **Isaac Heimbach**², **Mara Eppert**² and **Martina Roß-Nickoll**², (1)Institute for Environmental Research, RWTH Aachen, Aachen, Germany, (2)RWTH Aachen University, Institute for Environmental Research, Germany

Microplastic (MP) and pesticides are coexisting contaminants in agricultural soils nowadays. Deriving from degradation of introduced materials such as mulch films or secondary MP input through e.g. wind drift and sewage sludge application, microplastic is ubiquitous in soils of the agrarian landscape. As well as pesticides, MP can accumulate in the soil due to long degradation times and interact with pesticides. In this study we investigated the effects in the presence of microplastic on the toxicity of pesticides in worm species. However, since the standard worm in ecotoxicological testing, *Eisenia fetida*, is less ecologically relevant for agricultural toxicity assessment due to its natural habitat, we also included the species *Lumbricus terrestris*. The pesticide chosen for this study is the fungicide Folicur® (a.i. Tebuconazole), which is mainly used in rappt cultivation. The microplastic was derived from black polyethylene mulch film with a size range of 50 to 1000 μm and an application concentration of 150 mg/kg dw soil as not affecting, but realistic scenario. Investigation of MP influence was conducted in the acute toxicity test according to OECD 207 with *E.* and in the cast production test with advanced concentration range to test mortality with *L. terrestris*. The toxicity of Tebuconazole was determined with a LC50 of 112 mg/kg dw for *E. fetida* and 12 mg/kg dw for *L. terrestris*. For both tests the presence of MP lowered the acute toxicity of Tebuconazole, though not

significantly. The LC50 values in presence of MP were 121 mg/kg dw for *E. fetida* and 15 mg/kg dw for *L. terrestris*. We found significantly different pesticide toxicities on both species with *L. terrestris* being about 10 times more sensitive. We conclude that the influence of MP at the chosen concentrations of MP is low, but predictable and might be enhanced by higher concentrations of MP in soil. However, also the opposite effect was found in other studies with aggravated toxicity at MP co-exposition. Even though, MP might in this case have influence on the toxicity of Tebuconazole, the question remains, if effects like the Trojan-Horse-effect might lead to a higher selective toxicity long-term. Furthermore, the high difference in both worm species LC50 values opens the question how reasonable the testing with *E. fetida* for agricultural assessment is.

3.10.P-We090 The Impacts of Microplastics From Conventional and Biodegradable Mulching Films on Earthworm *Eisenia andrei*

Salla Kristiina Selonen¹, Raisa Turja², Minna Sepponen³, Ansa Palojärvi⁴ and Liisa Maunuksela⁵, (1)Suomen ympäristökeskus, Finland, (2)Marine Research Centre, Finnish Environment Institute, SYKE, Helsinki, Finland, (3)Finnish Environment Institute (SYKE), Finland, (4)Natural Resources Institute Finland (Luke), Finland, (5)Finnish Food Authority, Helsinki, Finland

Mulching films are widely used in agriculture and horticulture to facilitate cultivation and to reduce the need of irrigation and the use of plant protection products. However, these plastic films can be prone to fragmentation when exposed to UV radiation and various physical strains in the field, and thus can act as sources of microplastics in the soil. As alternatives to conventional plastics, biodegradable plastics have been developed. In contrast to conventional mulching films, biodegradable mulching films are intended to be incorporated into the soil after use. However, in subarctic, cold climates decomposition can be slow and the material may accumulate in soil due to frequent use of biodegradable mulching films. Despite the release of particles of conventional and biodegradable plastics in agricultural soils due to use of mulching films, their potential impacts on soil biota are still poorly known. In this study, we investigated the effects of mulching film particles (< 1 mm) on earthworm survival, growth, reproduction and biochemical biomarkers. The earthworms were exposed to three different microplastic types: one conventional and two biodegradable plastics in concentrations of 0.1% and 1%. The experiments were performed twice: immediately after mixing the microplastics in the soil and approximately two months after the addition of the microplastics. In this presentation, the results of the experiments will be shown. This study is part of the project "Microplastics in agricultural soil – Sources, effects and reduction (MicaAgri)" funded by the Ministry of Agriculture and Forestry of Finland, from the Makera Fund.

3.10.P-We091 Interaction of Unicellular Green Alga *Chlamydomonas Reindhardtii* With Biocompostable Plastic Bags

Marlita Marlita¹, Alena Sevcu² and Nhung Nguyen², (1)Technical University of Liberec, Liberec, Czech Republic, (2)Technical University of Liberec, Czech Republic

A growing concern about fossil-based plastics pollution rises the fast growth of bio-based plastics as its alternative. The bio-based plastics derived from renewable biological sources, are believed to be more environmentally friendly. However, their biodegradation and fate in the environment are not fully understood. Here, we studied the initial phase of plastic biodegradation, which was an attachment of freshwater microalga, *Chlamydomonas reinhardtii* on three types of starch-based plastic bags with the main component of polyethylene terephthalate (PET), PET-C made from corn starch, PET- WPC made from wheat, potato and corn starch, and PET-CB made from cornstarch and beetroot. Algal growth rate, biofilm formation, and changes in plastic properties were evaluated. The plastic pieces (0.75 x 0.75 cm²) were added into the algal culture and incubated at laboratory temperature and low light density. The algal culture was then monitored by measurement of optical density at OD 680 nm and the biofilm formation on the plastics was observed under an epifluorescence microscope. The changes of plastic properties were analyzed by a scanning electron microscope (SEM) for morphology and a confocal microscope (CM) for surface roughness. After the first week, algal cells were already attached on the plastic surface forming colonies and biofilm. The highest cell density was found in samples with PET-WPC from wheat and potato starch following by PET-C and PET-CB from corn starch. In the second week, the SEM results showed a biodegradation signal by changes of plastic morphology compared to the pristine plastics. Moreover, plastic debris was detected in the supernatant. The experiment is continuing to obtain a complete picture of biointeraction of *C. reinhardtii* with plastics.

3.10.P-We092 Small microplastics(<100 Mm), Additives, and Plasticizers in Freshwater Filter Feeders: First Evidence of Ingestion in Black Flies

Fabiana Corami¹, Beatrice Rosso², Simone Ciadamidaro³ and Valentina Iannilli⁴, (1)Institute of Polar Sciences, CNR-ISP, Italy, (2)Ca' Foscari University of Venice, Italy, (3)ENEA CR Saluggia, Italy, (4)ENEA CR Casaccia, Italy

Microplastic contamination has been an emerging issue in the last decade, and much data was produced to assess the distribution in environmental matrices. This contamination is more important as it is transferred to the food web and involves the biota. Along the food chain, the microplastic particles, in particular, the smallest (SMPs), and other contaminants present inside or adsorbed on, can be transferred throughout the trophic web. The current knowledge about the impacts of these pollutants on freshwater organisms is significantly incipient compared to marine organisms. Because of their relevant ecologic role, macroinvertebrates are commonly used in biomonitoring to assess freshwater's ecological conditions (European Water Framework Directive 2000/60/EC). Black flies (Diptera, Simuliidae) larvae are freshwater filter feeders; their special brush-like mouthpart collects tiny organisms and organic matter out of the water that flows through it, acting as a sieve or filter. They can also ingest microplastics when they get trapped in their mouthparts. They have a key role in watercourses ecology, making the filtered matter available for other invertebrates, amphibians, and fishes that feed on them. In this study, we analyze the MP uptake in 2 black flies species, *Simulium equinum* e *Simulium ornatum*, collected in Central Italy, to discuss the potential employment of this taxon as an indicator of microplastic pollution in freshwaters. The specimens were identified before the pretreatment. After chemical digestion to dissolve organic matter and purification, the samples were filtered on aluminum oxide filter membranes (0.2 µm, 47 mm

diameter). The analysis for the quantification and simultaneous polymer identification were performed via Micro-FTIR. Additives and plasticizers were also detected. The abundance of SMPs and additives in the studied species was relevant; this is the first report of SMPs intake on these organisms, to the best of our knowledge. These results are important to understand the mechanisms of plastic interaction with biota and identify the organisms to be used as bioindicators of plastic contamination.

3.10.P-We093 Microplastics in the Gastrointestinal Tracts of a Freshwater Chub (*Squalius vardarensis*) From an Eastern Mediterranean River

Angeliki Maria Koi¹, Nicholas Koutsikos¹, Georgios Karris², Catherine Tsangaris³, Elias Dimitriou¹ and Olga-Ioanna Kalantzi⁴, (1)Hellenic Centre for Marine Research, Institute of Marine Biological Resources & Inland Waters (HCMR), Greece, (2)Ionian University, Greece, (3)Hellenic Centre for Marine Research, Greece, (4)Environment, University of the Aegean, Mytilene, Greece

Microplastic particles have been observed in the marine environment all over the world for three decades now, however, microplastics in freshwater ecosystems have attracted less attention until recently. Studies on microplastic pollution in inland waters typically concern lentic ecosystems, while research in lotic ecosystems is scarce. Our study area, Pinios River basin, can be described as a typical medium-sized European Mediterranean river; located in one of the most intensely cultivated agricultural area and densely inhabited regions in Greece. In total, 45 individuals from a native chub species (*Squalius vardarensis*) were used to assess the microplastic ingestion from the river. The results indicated high occurrence and abundance of microplastics (58 items) in the fish gastrointestinal tracts; almost two thirds of specimens (62.2%) contained microplastics. The average number of microplastics per specimen was 1.29 ± 0.2 (SE). Mean dimension length range of microplastics was $0.64 \mu\text{m} \pm 0.05$ (SE). The dominant type of the detected microplastics was fibers (66%), while fragments had a smaller contribution (34%) to the total amount of the ingested items. The most common colors of microplastics were blue and transparent (26% and 22%, respectively) followed by black and green (both with 19%). The major polymer types identified by FT-IR analysis were: 40% polyethylene (PE), 36% polyvinyl alcohol (PVA) and 21% polypropylene (PP); reflecting the fragmentation of larger litter from local sources, such as plastic sheets or plastic bags and pouches from industrial packaging or agrochemical products, and household goods. Surface runoff of the environment, via motorways and road network, could also be one more contributing factor to the reported microplastics. Our results suggest that microplastic pollution is well established in Pinios, along with other significant threats that the river is facing (e.g. groundwater over-exploitation, soil erosion, hydromorphological alterations, deforestation etc.) and could further augment through intensive anthropogenic activities such as extensive agrochemical use, semi-industrial activities and domestic sewage wastes from large cities in the area. Nevertheless, more research is needed to assess the microplastic contamination throughout the river basin, especially in reaches which are adjacent to large areas with mixed land use types, and whether the microplastic ingestion is dependent on fish species traits, and/or on plastic types.

3.10.P-We094 In Vitro and In Vivo Toxicity of Biobased & Biodegradable Polymers on Rainbow Trout Cell Lines and Juvenile Perch

Azora König¹, EL Joachim Sturve² and Bethanie Carney Almroth³, (1)University of Gothenburg, Sweden, Gothenburg, Sweden, (2)University of Gothenburg, Sweden, (3)Goteborg University, Sweden

This study investigates the acute and chronic toxicity of biobased and biodegradable microplastics in freshwater fish species using in vivo and in vitro test systems. Our studies differentiate between polymer microparticles and the chemicals inherent to these materials. We used the microplastic particles in a size range of 90 – 150 μm , chemical extracts of larger particles and non-polymer natural Kaolin control particles. The toxicity of Polylactic acid (PLA) microplastic particles was assessed in juvenile perch (*Perca fluviatilis*) in a 6 months chronic food-exposure study, using several endpoints, life cycle parameters (growth, weight gain), metabolism, general stress response and behavior (locomotion, schooling and predator response). The cytotoxicity of chemicals associated with biobased and biodegradable microplastic polymers (PLA, PBS, PBAT, PBSA, P3HB and PLimC) was tested using chemical extracts on rainbow trout (*Oncorhynchus mykiss*) gill and liver cell lines. Cytotoxicity was studied on different cell viability and metabolic endpoints, such as lysosomal membrane stability, proliferation and enzymatic activities. Additionally, oxidative stress, gene expression and cell migration were investigated on the rainbow trout cells. Results of different measured endpoints indicate a cytotoxicity of the polymer P3HB on rainbow trout cell lines. The chronic exposure of juvenile perch to PLA particles had effects on growth and weight gain, as well as the Gonadosomatic index (GSI), compared to the control and natural particles (Kaolin) exposed fish. PLA-fed male perch showed a tendency to sexually mature faster than the other groups. This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 860720 (LimnoPlast ITN).

3.10.P-We095 Microplastic and Potential Harmful Trace Elements (PHTE) As Co-Pollution in Wild Brown Trout (*Salmo trutta*) in High Mountain Rivers

Henar Margenat¹, Gaël Le Roux², Oskar Hagelskjær³, Laure Gandois², Anna Vila Gispert⁴, Delfina Cornejo⁵, Michael Butler-Margalef⁶, Helena Guasch⁵ and Sophia V. Hansson⁶, (1)Laboratoire écologie fonctionnelle et environnement, France, (2)Laboratoire écologie fonctionnelle et environnement, Université de Toulouse, CNRS, Toulouse, France, France, (3)ENSAT Toulouse, EcoLab, France, (4)GRECO, Institute of Aquatic Ecology, Universitat de Girona, Girona, Spain, Spain, (5)Centre d'Estudis Avançats de Blanes, CSIC, Blanes, Spain, Spain, (6)CNRS, CASTANET TOLOSAN Cedex, France

Over the last few years, plastic has been defined as a new emerging pollutant found in every habitat across the globe. The fragmentation of large items of plastic litter into small particles is the main source of microplastics in natural environments. These tiny plastic particles can be easily transported, reaching all habitats, even the most pristine. Microplastics are an issue of great concern due to their size since they can interact between different ecosystem compartments and easily be incorporated into the trophic chain. Furthermore, due to their recalcitrant nature, microplastics interact with other contaminants present in the

environment, such as trace metals. Still, little is known about the mechanisms driving these interactions and the consequences that this co-pollution might pose to the biota and ecosystem function, and as such this study, therefore, focuses on assessing and determining the pollutants (i.e., microplastics and trace metals) present in (relatively) pristine mountain areas, where the presence of microplastics is mainly derived from atmospheric deposition. First, this study aims to determine whether there is any correlation between the presence of microplastics and trace metals in different compartments of the river ecosystem. Second, we also aim to determine the likely effects of these two groups of pollutants on river biota. Because our study sites are subjected to different impacts (current and historical), we also aim to determine the possible sources of microplastics and trace metals. For this purpose, we analyse microplastics and trace metals present in river trout (*Salmo trutta*) and other ecosystem compartments (e.g., biofilm) in the Pyrenees. The mercury concentrations up to 500+ $\mu\text{g kg}^{-1}$ w.w. measured in trouts, occasionally even exceeding EU guidelines of maximum threshold values, are clearly associated with a bioaccumulation phenomenon as demonstrated by the correlation between size, $\delta^{15}\text{N}$ signatures and mercury concentrations. On the contrary, microplastic concentrations identified by Nile Red fluorescence and FTIR, as well as other trace metals, are not associated with bioaccumulation mechanisms but rather with specific characteristics of the habitats. Finally, we will assess the risk this co-pollution may pose for other components of the trophic chain, including humans.

3.10.P-We096 Microplastics in Seafood From the Coastal Areas of Semarang, Java, Indonesia

Inneke Hantoro¹, Ansje Löh², Frank G.A.J. Van Belleghem³, Budi Widianarko¹ and Ad Ragas⁴, (1)Soegijapranata Catholic University, Indonesia, (2)Open University, Netherlands, (3)Department of Environmental Sciences, Open Universiteit, Heerlen, Netherlands, (4)Environmental Science, Radboud University, Nijmegen, Netherlands

Indonesia is considered to be the world's second largest contributor to the amount of plastic waste in our oceans. However, there is little data on the abundance of microplastics in the Indonesian marine environment. This is particularly true for microplastics in seafood, which is widely consumed in Indonesia. The objective of this study was to determine the contamination levels and properties of microplastics in commercial seafood from the coastal region of Semarang, a densely populated city on the Indonesian island of Java. Three types of seafood were collected: milkfish (*Chanos chanos*), blood cockle (*Anadara granosa*), and green mussel (*Perna viridis*). Microplastics were found in almost all seafood samples (97 -100%). The highest abundance was observed in green mussels (70.7 ± 48.0 particles/individual), followed by blood cockles (18.3 ± 7.3 particles/individual) and milkfish (5.9 ± 4.3 particles/individual). The seafood samples were dominated by fragments, with the exception of milkfish, which was dominated by fiber-shaped particles. Beads and pellets were discovered as well. Microplastics in the size range of 50 - 100 μm were mainly found in bivalve samples, while particles in the size range of 100 - 1000 μm were mainly found in milkfish. Polymers of various types were discovered in the seafood samples. The composition of microplastics in milkfish was dominated by rubber, cellulose, styrene copolymers, and polyamide. In blood cockles, the top three plastic polymers were cellulose, polyamide, and polyethylene, while in green mussels, rubber, cellulose, and styrene copolymers were the top three. In parallel with the sampling of seafood, the occurrence of microplastics in sediments and water was examined and it was found that the occurrence of microplastics was higher in the vicinity of residential areas. These results confirm that microplastics contaminate our environment and our daily diet, so further research into the potential health risks from ingestion of microplastics is urgently needed.

3.10.P-We097 Temporal Variability of Microplastic and Anthropogenic Particles Uptake by Four Commercial Species From Arcachon Bay (North East Atlantic , France)

Charlotte Lefebvre¹, Bettie Cormier², Florane Le Bihanic², Gabriel Rampazzo Magalhães², Bénédicte Morin², Sophie Lecomte³ and Jérôme Cachot², (1)Environnements et Paléoenvironnements Océaniques et Continentaux, F-33600 Pessac, France, (2)University of Bordeaux, France, (3)Centre National de la Recherche Scientifique, France

Microplastics (MP) overrun every marine compartments of the world. Their small size ($< 5\text{mm}$) make them easily ingestible by a wide range of organisms. In this study, MP uptake at several seasons was described in four commercial marine species from the Arcachon Bay: wild Pacific oysters (*Crassostrea gigas*), common sea bass (*Dicentrarchus labrax*), common sole (*Solea solea*) and sea spider crab (*Maja brachydactyla*). In total, 304 individuals were analysed in the framework of the whole study. After a chemical digestion of digestive tracts (fish and spider crab) or soft tissues (oyster), a visual sorting was made under a binocular to extract highly suspected MP-like items from 26 μm (oyster) or 50 μm (fish and spider crab) to 5 mm. Then, a chemical identification was performed by infrared spectroscopy. After visual sorting, particles were recovered in all species at each sampling time. Maximal concentration was found for sea bass in January (6.80 ± 9.19 item.ind⁻¹). Items were mainly cellulosic in sea basses and soles (at least 78%) while similar proportions between cellulosic and plastic items were found in spider crabs (around 36%). In all species, fiber-shaped items were overwhelming (at least 78%). Cellulosic fibers pollution in marine environments is likely to stem from abrasion of fabrics. Focusing on MP (i.e. cellulose excluded), concentrations tended to be more shlgly higer in spider crabs (from 0.53 ± 1.06 MP.ind⁻¹ to 1.40 ± 2.41 MP.ind⁻¹) compared to sole's MP uptake (from 0 MP.ind⁻¹ to 0.62 ± 0.46 MP.ind⁻¹). MP concentration for sea bass range from 0.27 ± 0.59 MP.ind⁻¹ to 0.33 ± 0.65 MP.ind⁻¹. Polyethylene (PE) and polyester (Pes) were mainly identified in fish species (at least 23% for Pes and 25% for PE) while polyamide was predominant in spider crab (28%). Ecological traits such as feeding behaviour or trophic level may explain these differences as already suggested in the literature. These preliminary results will be completed by wild oysters analysis and inferential statistics to check at quantitative (i.e. concentration) and qualitative (i.e shape, color and polymer type) temporal variability. Moreover, data on MP contamination of sea surface, water column and sediments will help in understanding these results and may give insights on the transfer pathways from abiotic to biotic compartments.

3.10.P-We098 Microplastics in Polychaeta and Sediments From Offshore and Coastal Areas in Norway

Mari Engvig Løseth¹, Bianca Petzold², Maren Tjønneland³, Desiree Maloney³, Arne Pettersen³, Hans Peter Arp⁴ and Øyvind Fjukmoen⁵, (1)Environmental Chemistry, Norwegian Geotechnical Institute, Oslo, Norway, (2)Hochschule Fresenius, University of Applied Sciences, Norway, (3)Norwegian Geotechnical Institute, Norway, (4)NGI, Norway, (5)DNV, Norway

The global concern about microplastics (MP) has grown considerably since their first detection in the marine environment and wildlife. Ocean sediments may constitute the ultimate sink for MPs, both for denser plastics such as nylon, polyethylene terephthalate (PET) and polyvinylchloride (PVC) and for low-density polyolefins (e.g. PE and PP) which may aggregate and increase density over time due to biofouling. Still, little is known about the concentrations and impacts of MPs in benthic ecosystems. A previous study has seen potential bioaccumulation of microplastics in tube-dwelling polychaeta when compared to MP concentrations in their surrounding sediments. These polychaetes burrow in sediments and embed their tubes with particles from their surroundings, thus potentially also MPs. These results indicated that the feeding behaviour and life cycle of polychaetes could have an important influence on the transport, distribution and food-chain dynamics of microplastics in sediments. The present study aims to investigate potential differences in MP levels and quantify MP in sediments and polychaeta from offshore and coastal areas in Norway. The study also aims to investigate potential differences in MP levels in tube-dwelling and deposit feeding polychaeta without tubes. A total of 9 sediments samples (0-1 cm) and 24 polychaeta samples, both tube-dwelling and deposit feeding, were collected from offshore and coastal areas in Norway between 2017 and 2020. The offshore samples were collected on the Norwegian Continental Shelf and in the Barents Sea, while inshore samples were collected at Ålfjord, Lindesnes, Nordgulfjord and Oslofjord. Offshore sediments were sampled at remote locations or adjacent to oil platforms, which constitutes a probable local source of microplastics other than aquaculture and shipping in these areas. The inshore sediments are most likely more affected by anthropogenic sources of microplastics such as emissions from waste-water, various industry, aquaculture and boat traffic. Analyses of MPs > 45µm in sediments and polychaeta were performed using density separation with ZnCl₂:CaCl₂ solution (? ? 1.52 g/cm³), and chemical digestion using a twostep procedure with NaOH:thiourea:urea to dissolve cellulosic material and further chemical oxidation with NaOH and H₂O₂. Finally, the samples are analysed using µFT-IR which will be performed during December 2021. Funding was provided by the Norwegian Retailers' Environment Fund.

3.10.P-We099 The Effect of Ageing on the Behavior of Poly(Lactic Acid) Particles As a Potential Vector for the Transport of Metals in the Presence of Natural Organic Matter

Ricardo Henrique De Paula Pedroza¹, Calin David², Pablo Lodeiro², Carlos Rey-Castro² and Josep Galceran³, (1)University of Lleida, Spain, (2)University of Lleida and Agrotecnio, Spain, (3)Chemistry, Universitat de Lleida, Lleida, Spain

Plastic production presents an exponential growth over the years since their commercial development. Unfortunately, only a small portion of this plastic is recycled when discarded, while most of it is released directly into the natural environment where it can persist for several years until its complete degradation. To overcome this issue, there is a new trend on the development of bio-based polymers, which are eco-friendly and biodegradable, to replace conventional petroleum-based plastic products. The presence of microplastics (MPs, fragments < 5 mm in diameter) in the environment is of great concern due to their adsorption/desorption capacity toward chemical substances such as organic compounds and metals. Here we present a physicochemical study on the adsorption/desorption of metals to commercial poly(lactic acid) microspheres (PLA) that is considered a biodegradable plastic. The pristine and aged PLA were characterized through FTIR, Raman, SEM, and N₂ BET isotherms, as a function of the duration of different degradation treatments. We obtained kinetic and equilibrium information on the binding of metals by pristine and aged PLA in aqueous media considering the effect of variables such as pH, ionic strength, and the presence of natural organic matter. These results represent a preliminary study to assess the risks of using biodegradable plastic products and provide the key factors that should be considered concerning potential hazard environmental effects. *Acknowledgments* – The authors thank the support from the European Union's H2020 research and innovation programme under Marie Skłodowska-Curie grant agreement No 801586, and Grants PID2019-107033GB-C21 and PID2020-117910GB-C21 funded by MCIN/AEI/10.13039/501100011033. 3.10.P-We100 Eco-Corona Formation on Plastic: Effect of Plastic Type and Aging

Roman Schefer¹, Antonius Armanious², Michael Sander² and Denise M Mitrano³, (1)ETH Zürich, Zürich, Switzerland, (2)ETH Zurich, Switzerland, (3)Environmental Systems Science, ETH Zurich, Zurich, Switzerland

Concerns about the adverse environmental impacts of nano- and microplastic are continuously increasing, yet the understanding of plastic fate in freshwater environments is still limited. Plastic chemistry, size, shape, density as well as the freshwater composition all influence plastic particle fate. Aging of plastics, either by photochemical weathering or by adsorption of (bio)macromolecules which leads to formation of an ecocorona, can further change the physicochemical properties of plastics. However, the impact(s) of photochemical weathering on the physicochemical properties of plastic, and how this impacts subsequent adsorption of (bio)macromolecules and eco-corona formation, is often neglected. Here we conducted systematic studies on adsorption of a selection of ubiquitous (bio)macromolecules (humic & fulvic acids) to a set of the most environmentally prevalent polymer types (polyethylene, polypropylene, polyethylene terephthalate & polystyrene) in their pristine and photochemically weathered forms. Using Quartz Crystal Microbalance with Dissipation (QCM-D) allowed for determination of changes in mass of adlayers on the sensor surface. We spin coated various polymers onto the QCM-D sensor surface followed by passing solutions of (bio)macromolecules dissolved in synthetic freshwater over the polymer coated quartz crystals to monitor adsorption over time, as measured by changes in the resonance frequency of the piezo crystal. The extent of ecocorona formation on pristine plastics was compared to plastic films which underwent photochemical weathering. Both pristine and UV aged plastic films were characterized before ecocorona formation by contact angle measurements (changes in polarity and charge), Fourier

Transfer Infrared spectroscopy (chemical changes) and Atomic Force Microscopy (changes in physical surface roughness). Photochemical weathering of the pristine polymer results in decreased adsorption of (bio)macromolecules in synthetic freshwater which is expected due to the increased surface polarity and more negatively charged surface. This information will help to understand the rate and extent of ecocorona formation for dissolved organic matter on different pristine and photochemically weathered plastics. Ultimately, this will allow us to produce more realistically aged materials to be used in further experiments on fate of plastics.

3.10.P-We101 Effects of Microplastic and Fine Particulate Organic Matter (FPOM) on Aquatic Invertebrates - Putting Microplastic Effects Into Perspective

Tobias Schmitt, Dipl. Bio.¹, Christopher Rensing², Sandra Ritz³, Elvira Lafuente⁴, Katja Räsänen⁵, Brendan Mckie⁶ and Mirco Bundschuh⁷, (1)University of Koblenz-Landau, iES Landau, Institute for Environmental Sciences, Germany, (2)Fujian Agriculture and Forestry University, China, (3)Institute of Molecular Biology, Germany, (4)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (5)Eawag, Switzerland, (6)Swedish University of Agricultural Science, Sweden, (7)Institute for Environmental Sciences University of Koblenz-Landau, Germany

The growing demand for products containing plastics has led to an increasing release of plastic waste into the environment. Plastic residues enter the hydrological cycle and gradually break down into tiny particles (< 5 mm), so called microplastics (MP). Freshwater systems have been recognized as a major pathway carrying over 2 million metric tons of plastic into the world's oceans every year. These lotic ecosystems are receiving significant amounts of plastic litter either during surface run-off events or via sewage and domestic wastewater treatment plants. Besides a permanently growing awareness of potential effects posed by MP on aquatic biota, knowledge on effects towards leaf-shredding freshwater organisms and its impact on microbial litter decomposition, as a catalyst for ecosystem functioning, is still scarce. To assess the effects of MP on the physiological performance of shredders and on microbially mediated leaf litter decomposition, we performed three 28-day-bioassays using the freshwater isopod *Asellus aquaticus* and three particles, polystyrene (PS), polymethyl methacrylate (PMMA), and fine particulate organic matter (FPOM). As a natural particle, FPOM was chosen to put potential effects into perspective. *A. aquaticus* is considered as both a grazing and shredding macroinvertebrate that nourishes of aquatic hyphomycetes (AH) on the leaf's surface, as well as on the actual leaf itself. AH are crucial for the microbially mediated leaf decomposition and the palatability of the leaves to aquatic detritivores. Each experiment was split in two parts, each part with one control and five treatment groups (n=10) with final particle concentrations of 0.18, 1.8, 18, 180, 1800 particles per milliliter. During the first part, 5 individuals of *A. aquaticus* from a laboratory-owned culture and sets of 30 pre-weighed and pre-conditioned leaf discs were added to the microcosms to assess the effects on the physiological fitness of the isopods. To monitor the microbially mediated leaf litter decomposition, the second part with 10 additional replicates per treatment, was set up without any isopods but with an adjusted number of 18 leaf discs per replicate. This study represents an important linkage between the effects on organisms and the impact on the longitudinal nutrient transport within streams and rivers through the effects on the microbial community on the leaf's surface as a part of the detritivore system and as a food source for shredders. Preliminary results showed that particles did not impact the survival of *A. aquaticus* however, PS significantly decreased the feeding rate. To get a more comprehensive overview on the impact of different concentrations of MP, further analysis will be performed to evaluate (i) the effects on the physiological performance of *A. aquaticus*, (ii) the impact on their gut microbiome, as well as (iii) to assess further effects on the microbially mediated leaf litter decomposition and on fungi and bacteria density.

3.10.P-We102 Co-Exposure With an Invasive Seaweed Exudate Increases Toxicity of Polyamide Microplastics to the Marine Mussel *Mytilus galloprovincialis*

Filipa Rodrigues¹, Hugo Vieira¹, Diana Campos¹, Sílvia Pires¹, Andreia Rodrigues², Ana Silva³, Amadeu Soares⁴, Jacinta Oliveira¹ and Maria Donas-Bôto Bordalo¹, (1)University of Aveiro, Portugal, (2)Italian National Research Council, Portugal, (3)Campus Universitário de Santiago, Portugal, (4)Universidade de Aveiro, Portugal

Marine environments face ongoing multiple pressures. For instance, invasive species are considered a major threat to marine biodiversity. The red seaweed *Asparagopsis armata* is considered a highly invasive species, which is known to exude a myriad of secondary metabolites as a defence mechanism that may have detrimental effects on native organisms. Microplastic pollution is also an issue of growing concern, especially for marine biota. Polyamide microplastics (PA-MP) are a group of polymeric debris commonly detected in marine environments deriving from fisheries activities. A major risk associated with these ubiquitous pollutants is their bioavailability to marine organisms, potentially affecting filter-feeders such as the mussel *Mytilus galloprovincialis*. This species is abundant and widespread in the Iberian coast with a major ecological and commercial value, being largely produced and consumed by local populations. *M. galloprovincialis* not only is known to ingest and accumulate microplastics, it is also known to be negatively affected by *A. armata* exudate. However, joint exposure of these co-occurring stressors has not yet been addressed. Thus, the aim was to assess the potential impacts of PA-MP exposure (1 mg/L) in *M. galloprovincialis* alone and combined with *A. armata* exudate (2%). For this purpose, byssus production as well as biochemical responses associated with oxidative stress and damage (in the gills), energy metabolism and production (in the muscle) were measured. Byssus number declined in mussels exposed to PA-MP either in the presence or absence of the exudate, with a lower number of byssus / mussel being found in the combined treatment. Decreased investment on byssus production is in accordance with the changes observed at the sub-cellular level and high energetic requirements to deal with oxidative stress. Oxidative damage at the protein level reflected the depletion in antioxidant capacity under combined stress. Increased ETS (Electron Transport System) activity and consequent increment of aerobic energy production was observed in mussels exposed to PA-MP treatments. This was accompanied by a depletion of CEA (Cellular Energy Allocation) activity representing a decrease in the energy budget especially when PA-MP were combined with the exudate. Overall, results reveal more severe effects of PA-MP on

M. galloprovincialis in the presence of *A. armata* exudate, suggesting that combination of these stressors may pose a threat to the marine biota.

3.10.P-We103 The Adsorption on Microplastics Reduces Phototoxicity of Titanium Dioxide Nanoparticles

Gabriela Kalcikova¹, Rajdeep Roy², Barbara Klun³, Ula Rozman⁴, Gregor Marolt³, Tina Skalar³, Alexander Feckler⁵ and Mirco Bundschuh⁶, (1)University of Ljubljana, Slovenia, (2)Institute for Environmental Sciences; University of Koblenz-Landau, Germany, (3)University of Ljubljana, Faculty of Chemistry and Chemical Technology, Slovenia, (4)Faculty of Chemistry and Chemical Technology, University of Ljubljana, Ljubljana, Slovenia, (5)University Koblenz-Landau, Germany, (6)Institute for Environmental Sciences University of Koblenz-Landau, Germany

Over the last decades, the ecotoxicological effects of microplastics and nanoparticles have been intensively studied. Researchers have focused on the individual effects of these pollutants, although they can occur simultaneously in the environment, as both are commonly used in cosmetic products. In this context, the aim of this study was to evaluate the interactions and ecotoxicity of polyethylene microplastics (MPs), used as abrasives in cosmetic products, and titanium dioxide nanoparticles (nTiO₂), commonly used as UV filters in sunscreens. First, the interactions between MPs and nTiO₂ were investigated and the results showed that nTiO₂ is rapidly adsorbed on MPs (72% in 9 hours), which is most likely explained by chemisorption. Scanning electron microscopy and element mapping showed a uniform distribution of nTiO₂ on the surface of MPs. The interaction between nTiO₂ and MPs was strong and limited the desorption of nTiO₂ into the surrounding media. In the second part of the study, the ecotoxicity of MPs, nTiO₂ and MPs loaded with nTiO₂ was investigated for *Daphnia magna* (largely following the OECD 202 guideline) under visible light and ambient UV light. MPs, nTiO₂ nor MPs loaded with nTiO₂ did not affect *Daphnia* when the experiment was performed under visible light, but the presence of UV light (24 h) resulted in increased inhibition in all treatments. Under UV light, 100% of *Daphnia* were immobilized at all concentrations of nTiO₂, while the inhibition caused by the combination of UV light and MPs loaded with the same amount of nTiO₂ was approximately 30% lower and more comparable to the results obtained for MPs only. The plausible explanation is that nTiO₂ produced reactive oxygen species (ROS) under UV light throughout the entire volume of the test vessel, while nTiO₂ adsorbed on MPs produced ROS only locally near the surface of MPs limiting their contact with *Daphnia* that were located at the bottom of the test vessel. These results suggest that MPs and nTiO₂ may interact with each other and influence their ecotoxicological profile.

3.10.P-We104 Microplastics As Vector for Pollutants in Soils - Influence of Polyethylene Microplastics on the Bioaccumulation of Ivermectin in *Eisenia fetida*

Johannes Junck¹, Angela Flachsbarth² and Rolf-Alexander Düring², (1)Department of Soil Science and Soil Conservation, Institute of Soil Science and Soil Conservation, Giessen, Germany, (2)Justus Liebig University Giessen, Germany

The ubiquitous occurrence of microplastics is increasingly recognized as a global concern. Microplastics, which can consist of many different polymers, enter the food chain. However, research has so far focused primarily on aquatic ecosystems. Knowledge regarding the impact of microplastics on soil organisms such as earthworms (lumbricids) is still limited. Especially concerning soil fertility and the food chain, it is controversially discussed whether microplastics serve as a vector for pollutants and thus influence the accumulation of certain lipophilic compounds. In this study the very hydrophobic antiparasitic agent ivermectin, which is applied extensively in veterinary medicine worldwide and enters the soil via animal excretions, is used. To examine the influence of low-density polyethylene (LDPE) microplastics on the accumulation of ivermectin in earthworms, a bioaccumulation experiment with *Eisenia fetida* was carried out according to OECD Guideline 317. For this purpose, the earthworms were kept in artificial soil for a period of 21 days. The soil was spiked with ivermectin at a concentration of 0.5 mg kg⁻¹ and 0.3% (w/w) LDPE (particle size 200-500 µm) was added. Soil and earthworm samples were collected at specific intervals and analyzed via high performance liquid chromatography using fluorescence detection (HPLC-FLD) after derivatization. Furthermore, the gut content of *Eisenia fetida* was also collected and analyzed. Bioaccumulation factors (BAFs) were then calculated and the uptake kinetics were modeled. The results were compared with a control (without LDPE). Finally, to obtain visual evidence for microplastic ingestion by *Eisenia fetida* a method was developed to examine the gut contents using Nile red staining with a fluorescence microscope. The first preliminary results of this study will be the subject of the current poster.

3.10.P-We105 Is the Ingestion of Microplastics Related to Feeding Habits and Trophic Levels in Fish Species? A Novel Approach Based on Stable Isotopes Analysis

Dario Giani¹, Matteo Baini¹, Cristina Andolina², Cristina Panti³, Salvatrice Vizzini² and Maria Cristina Fossi¹, (1)University of Siena, Italy, (2)University of Palermo, Italy, (3)Department of Physical Sciences, Earth and Environment, Cristina Panti, Siena, Italy

The Mediterranean Sea is a crucial biodiversity hotspot and has been defined as one of the most affected areas by plastic pollution worldwide. This study aims to assess the impact of microplastics on 253 individuals from 8 fish species (*B. boops*, *E. encrasicolus*, *M. merluccius*, *M. poutassou*, *M. barbatus*, *S. pilchardus*, *S. scombrus* e *T. trachurus*) sampled in the Ligurian Sea (Northwestern Mediterranean Sea). The focus of the study was to investigate how factors such as habitat, trophic level and feeding habits may influence or be related to the microplastics ingestion. To define the trophic niches and trophic levels of each specimen, analysis of the stable isotopes of ¹³C and ¹⁵N in the muscle of all sampled specimens were carried out. In all eight species analyzed, ingestion of plastics was confirmed and a total of 139 plastic particles were isolated. The species with the highest microplastic occurrence (%) was *B. boops* where 37% of individuals had ingested microplastics, followed by *S. pilchardus* (35%). *M. merluccius* was the least impacted with 8.3% of individuals with microplastics in their GI tracts. The microplastics detected and characterized were mainly polyethylene (67%), followed by polypropylene (20%) and polystyrene (9%). No significant correlation between microplastic occurrence and trophic level, isotopic niche width (SEAc), trophic diversity (CD) and nitrogen

range (NR) was observed. A significant positive correlation between microplastics occurrence and increasing diversity of basal sources used (Carbon range) was found. Planktivorous species such as sardine and bogue show the highest occurrence of MPs and the greater diversity of basal resources used. Moreover, a significant negative correlation between the number of ingested items per individual and the trophic level was observed. This relationship could be explained by the different feeding habits of the 8 analyzed species; at lower trophic levels we have planktivorous/pelagic species (anchovies, sardines, bogue) while the benthic predator species have higher trophic levels (i.e. red mullet, hake). This also agrees with the wider trophic niche (SEAc) exploited by benthic species. Overall, an influence of trophic niche descriptors on the occurrence of microplastics ingestion was not observed, but it seems that at the increase of the diversity of basal carbon sources used, the occurrence of plastic ingestion raises significantly.

3.10.P-We106 The Combined Presence of Microplastics and Hg Affects Hg-Resistant Fungal-Community Activities?

Laura Silva¹, Neusa Figueiredo¹, Paula Ramos², Vasco Branco³, Cristina Carvalho³ and Marta Martins⁴, (1)MARE - Marine and Environmental Sciences Centre, Portugal, (2)Centro de Investigação em Agronomia, Alimentos, Ambiente e Paisagem, Portugal, (3)Research Institute for Medicines (iMed.Ulisboa), Faculty of Pharmacy, Universidade de Lisboa, Lisboa, Portugal, Portugal, (4)MARE Marine and Environmental Sciences Centre, Portugal

Estuaries are heavily impacted by anthropogenic contamination, serving as reservoirs of various pollutants such as heavy metals (e.g., mercury (Hg) and microplastics (MP, $\varnothing < 5\text{mm}$)). These pollutants can affect water quality and cause toxic effects in aquatic organisms. Mercury, a trace heavy metal, is characterized as neurotoxic, persistent, and bio-accumulative in the food chain. In systems contaminated by Hg, microorganisms are responsible for reducing Hg, contributing to its natural detoxification. However, the effects of the presence of MP in this process are still unknown. The growing concern of micro-plastics is not only the chemical additives in their constitution that can be released, but also their ability to act as vectors of other contaminants, namely Hg, and microbial community biofilm, the so-called “plastisphere”. Therefore, the following questions arise A) Does the presence of microplastics and Hg affect Hg-resistant fungal-community and activities? To answer this above-mentioned question, the fungal community was isolated from a Hg-contaminated area of the Tagus estuary (Barreiro), and the most resistant strains were selected to assess the effect of the presence of polystyrene MP (PS) (40 mg/L) on fungi activity in a Hg-containing medium. After 1, 5 days, and 10 days of incubation of Hg-resistant strains with PS MPs and Hg (1ppm), the following factors were analyzed: A) Hg detoxification capacity and B) acute toxicity associated with the leached (Microtox bioassay). Furthermore, the isolates were identified through the amplification ITS. The results showed that: (i) fungal strains isolated from the Tagus Estuary exhibit high Hg-resistance (MIC range 37.5 – 50.0 ppm), (ii) Hg concentration in the medium were reduced via fungal activity (65-93% of the control), (iV) however, the presence of MPs increased the toxicity associated to the leached. Thus, we can conclude that MPs interfere with fungal activity in a Hg-contaminated aquatic system by increasing the toxicity associated.

3.10.P-We107 Individual- to Population-Level Effects of Smoked and Non-Smoked Cigarette Filters in the Deposit Feeding Polychaete *Capitella teleta*

Monica Hamann Sandgaard¹, Sara Nicoline Grønlund², Kristian Syberg², Eva Riisgaard², Christian Rishøj² and Annette Palmqvist³, (1)Department of Science and Environment, Roskilde University, Roskilde, Denmark, (2)Roskilde University, Denmark, (3)Dept. of Science and Environment, Roskilde University, Roskilde, Denmark

Cigarette filters (CFs) are the most dominant item in litter clean up surveys. In the environment CFs deteriorate into smaller fibres and leach an array of chemicals trapped in the filter. Thus, CFs may pose an environmental risk due to the release of plastic fibres and associated chemicals. It is recognised that CFs may affect both pelagic and benthic organisms, but little information is available on their long-term effects at higher levels of biological organization. The aim of the present study was to assess the effects of smoked CFs (SCFs) and non-smoked CFs (NCFs) on individual life-history traits and extrapolate these to possible effects at higher biological organization (i.e., populations). The benthic polychaete *Capitella teleta* was exposed to sediment-spiked granule of SCFs and NCFs at an environmentally realistic concentration (0.1 mg fibre g⁻¹ dw sed) and a 100-fold higher (10 mg fibre g⁻¹ dw sed) concentration. The experiment was divided in a juvenile and an adult exposure phase. In the juvenile exposure 10 larvae (5 days old) was exposed and monitored weekly for survival and time to sexual maturity. Once worms reached sexual maturity a male and a female were paired (adult experiment) and monitored every other day. The endpoints included somatic growth as well as survival, time to first reproduction, time between reproductive events and reproductive output. Overall, juvenile survival decreased with time in all treatments. After three weeks of exposure juvenile survival was significantly lower for worms exposed to SCF at high concentration compared with the control. Similarly, the presence of SCFs in the sediment affected the number of surviving worms that reached sexual maturity within three weeks of exposure when comparing with control. High concentration of SCFs significantly affected number of worms reaching sexual maturity, whereas a borderline significant effect was detected at low concentration. Overall, none of the tested endpoints in the current experiment was significantly affected by the presence of NCFs in the sediment. The initial results of the current experiment indicate that chemicals associated with the smoked filters are causing the effects rather than the cellulose acetate fibers from the filters in itself. Ultimately, measured life-history traits are to be incorporated in a simple demographic model to project changes in population growth rate in order to assess potential effects of exposure to CFs on population level.

3.10.P-We108 The Effect of Leachates From a Ultraviolet Weathered Bio-Based Composite on Marine Diatom Growth

Zhiyue Niu¹, Ana I Catarino², Maelenn Le Gall³, Marco Curto⁴, Elke Demeyer⁵, Michiel Vandegheuchte⁶, Hom Dhakal⁴, Peter Davies³ and Gert Everaert², (1)Research, VLIZ, Oostende, Belgium, (2)Flanders Marine Institute, Belgium, (3)IFREMER, France, (4)University of Portsmouth, United Kingdom, (5)Centexbel, Belgium, (6)Ghent University, Belgium

Polymers made from a natural-sourced feedstock, like polylactic acid (PLA), known as bio-based polymers, are seen as more

sustainable alternatives to petroleum-based polymers, with lower carbon and environmental footprint. However, concerns are emerging on whether these bio-based polymers have a lower ecological impact than petroleum-based polymers. In the marine environment, plastic additives can be released, i.e. can leach, from plastic to the surrounding seawater and organism. Studies have demonstrated the negative effects of leachates from several petroleum-based polymers on marine organisms, however, to date, few studies have assessed the potential effect of leachates from bio-based polymers. As part of the Interreg 2 Seas Mers Zeeën project SeaBioComp (seabiocomp.eu), we aim to assess the effect of leachates from a newly developed bio-based composite (i.e. bio-based polymers integrated with synthetic or natural fibres) on the growth of a marine diatom; and explore whether the effect is enhanced or diminished by UV radiation. To do so, we exposed the marine diatom *Phaeodactylum tricorutum* to a dilution series of leachates from pristine and weathered self-reinforced (SR-) PLA, following the ISO 10253:2016 protocol. To obtain weathered plastic, SR-PLA sheets flakes were subjected UV radiation, simulating up to 18 months of natural solar exposure. Our results indicate that neither leachates from pristine SR-PLA nor from UV-weathered SR-PLA had an effect on the growth of *P. tricorutum*, and UV radiation had no effect on the toxicity of SR-PLA leachates. In addition, we determined the EC₅₀ (i.e. half maximal effective concentration) to algal growth of two potential leached compounds, which were 1.86 ± 0.06 mg/L for dodecan-1-ol and 341 ± 30 mg/L for di-lactide. We anticipate that our results will contribute to assessing the ecological impacts of bio-based polymers and composites which may be more sustainable alternatives to petroleum-based polymers.

3.10.P-We109 Mapping of Occurrence of Microplastics in the Sediments of a Stormwater Pond

Marziye Molazadeh¹, Fan Liu², Laura Simon-Sanchez³ and Jes Vollertsen⁴, (1)Build Environment, Aalborg University, Denmark, (2)Department of Build, Aalborg University, Denmark, (3)Institute of Environmental Science and Technology (ICTA-UAB), Universitat Autònoma de Barcelona, 08193 Cerdanyola del Vallès, Barcelona, Spain, Spain, (4)Aalborg University, Denmark

In the modern world, dependency on plastic polymers for extensive commercial, industrial, medicinal and municipal applications is inevitable. Stormwater, wastewater and combined sewer overflows are commonly considered significant potential sources of Microplastics (MPs), discharging to waterbodies in urban areas. In this study we investigate the spatial distribution of MPs in the sediments of an inland stormwater pond located in the city of Aarhus, Denmark. To examine if MPs are evenly distributed in terms of location, size and polymer composition and the driving factors on these spatial patterns, thirteen sediment samples were collected. Briefly, samples underwent physical and chemical treatments including preoxidation, Sodium Dodecyl Sulfate (SDS) treatment, enzymatic treatment and density separation. Samples were sieved through a 500 µm mesh. Microplastics below 500 µm were identified and quantified by microscopy coupled to a Fourier Transform Infrared microscope (µFTIR with Focal Plane Array). Considering both number and mass, the average MP concentration was $44'396.86$ item kg⁻¹ and $11,839.98$ µg Kg⁻¹. There was no systematic variation of neither number nor mass concentration in the pond. Although samples were taken from different locations, small-sized low dense Polypropylene particles were the most abundant MP type in the majority of the sampled sites. Therefore, it can be concluded that deposition of MPs in the pond's sediments did not follow any pattern corresponding to their size and type. In the other word, MP distribution in the sediments was not size and type (density) selective. The fact that lighter-than-water-polymers were the most abundant types, and that there was no systematic relationship between position in the pond, concentration, and composition of MPs indicates that the transport mechanism of MPs from the water to the sediments was not simple sedimentation, but that the deposition was governed by some other mechanism. This study contributes to gain knowledge of the processes and mechanism which drives transport of mp in shallow water systems.

3.10.P-We323 Microplastics in the Rhizosphere: Consequences on Root Exudation and Microbial Communities

Rebecca Chloe Lebel¹, Deqa Farow¹ and Cameron Proctor², (1)University of Windsor, Windsor, ON, Canada, (2)University of Windsor, Canada

Important agricultural crops are able to establish symbiosis with the microbial community in agricultural soils, forming mutually beneficial exchanges of photosynthates for nutrients that are otherwise inaccessible to the plant. These root-soil-microbial interactions are honed over millions of years of evolution and predicated on naturally occurring soil properties which can be altered by microplastics. Plastic particles from biosolids added to soil as a nutrient source are potentially ecotoxic and may interfere with normal root functioning through several mechanisms, including deleteriously affect soil properties, blocking signaling molecules, absorb soil organic matter important for roots and soil microbes, and may release toxins that exert a selective pressure against the microbial community. To investigate biosolid microplastic effects on the root-soil-microbial interactions of three crops (corn, soybean, alfalfa) ranging in their association with root-symbionts (fungal partnership only, fungal partnership with N fixing bacteria, alternative fungal partnership and N fixing bacteria) crops will be grown in agricultural soils amended with artificially created microplastics that reflect reported biosolid microplastic properties (i.e. size, quantity, type, surface morphology), yet are free of other potentially toxic substances that are variably found in biosolids and could be confounding variables. The presence of microplastics in the rhizosphere is envisioned to disrupt root-soil-microbial interactions will can be quantified via rot exudate analysis of rhizosphere soil and soil microbial community functional profiling. As roots alter the physicochemical properties of the adjacent soil through root exudation to increase nutrient availability, stabilize of toxic metals, and protect against pathogens using anti-microbials [5] it is plausible microplastics may induce similar stresses and thus alter the magnitude and composition of low-weight molecules transferring from roots into the soil. Exudation can suppress microbial metabolism pathways and thereby alter their utilization pattern of soil carbon [6] quantifiable by the MicroResp method which monitors the evolution of carbon dioxide from microbial respiration in soil amended with various C sources.

3.10 Microplastics in the environment: Behaviour, transport, fate, risks, and alternatives to conventional plastics (Part V)

3.10.T-22 Do Microplastics and Pharmaceuticals Interactively Affect Mussels? An Insight Into Uptake, Tissue Distribution and Metabolomic Profiles

*Jose Maria Castano-Ortiz*¹, *María García-Pimentel*², *Victor León*², *Juan Campillo*², *Frederique Courant*³, *Elena Gomez*⁴, *Lúcia Santos*¹, *Damià Barceló*¹ and *Sara Rodriguez-Mozaz*¹, (1)Catalan Institute for Water Research (ICRA), Spain, (2)Instituto Espanol de Oceanografía (IEO-CSIC), Spain, (3)Université de Montpellier - UMR 5569 Hydrosociences, France, (4)Université de Montpellier, Hydrosociences Montpellier UMR 5569, France

Mussels are suitable model organisms in ecotoxicology studies of pharmaceutically active substances (PhACs). Antidepressants and lipid regulators constitute good examples of relatively bioaccumulative PhAC classes ($\log K_{ow} > 3$), which co-occur in the aquatic environment with other contaminants of emerging concern, such as microplastics (MPs). MPs can adsorb pollutants on their surface, impacting their bioavailability and associated effects. In this study, we aimed to evaluate the interactive effects of polyethylene MPs and selected PhACs through a comprehensive assessment of PhAC bioconcentration, tissue distribution and depuration. In addition, a non-targeted analysis approach (LC-HRMS) is implemented to explore alterations in metabolic signatures and metabolism of PhACs by mussels. A bioassay was designed using Mediterranean mussels (*Mytilus galloprovincialis*) exposed to polyethylene MPs 4-6 μm (PE), the antidepressant citalopram (CP), the lipid regulator bezafibrate (BZ), and the corresponding PE-PhAC mixtures, besides a control without contaminants (CT). Mussels were sampled twice during exposure (10 and 21 days) and after a depuration period of seven days, extracting hemolymph, digestive gland and whole tissue samples. Elevated concentrations of citalopram were found in mussels at 21 d (mean: 729 ng/g dw), which surpassed bezafibrate by three orders of magnitude (2 ng/g dw). Accordingly, moderate bioconcentration factors (BCFs) were reported for the antidepressant, in the range of a previous study, and regardless of PE-MP presence (1279 – 1535 L/kg). Partition from seawater to mussel hemolymph (P_{HW}) was also higher for citalopram than bezafibrate. In this context, PE-MPs seemed to delay the internalization of citalopram, with diminished whole body levels in co-exposed mussels after 10 days ($p < 0.05$). In addition, an enhanced excretion of the parent drug in MP-unexposed mussels, as observed in depuration seawater, may indicate interactive effects on drug biotransformation and excretion. Future work will provide insights into affected molecular pathways, as well as possible impacts on the metabolism of PhACs.

3.10.T-23 The Leaching of Phthalates From Polyvinyl Chloride Microplastics Into Aqueous Environments

*Charlotte Henkel*¹, *Thorsten Huffer*¹ and *Thilo Hofmann*², (1)University of Vienna, Vienna, Austria, (2)University of Vienna, Austria

Excellent material properties and raising demand have led to an increasing production of plastics from 50 Mt in 1976 to 348 Mt in 2017. Polyvinyl chloride (PVC), the third most used polymer in the European Union PVC contains the highest amounts of additives amongst the most widely used polymers, especially phthalic acid esters (phthalates). Additives can transfer to the surrounding environment within the lifespan of the plastics. Leaching of phthalates from plastics changes the mechanical properties of the plastics and results in embrittlement and fragmentation of larger plastic pieces to microplastics. Phthalates like bis(2-ethylhexyl) phthalate (DEHP) pose a risk to the environment due to their endocrine disrupting effect. For the environmental risk assessment and modelling of the fluxes of plastics and its associated additives in-depth knowledge of leaching kinetics of additives from (micro-) plastics into aqueous environments is required. The release of additives and non-additives from microplastics is controlled by internal and external diffusion, i.e., intraparticle diffusion (IPD) and aqueous boundary layer diffusion (ABLD), respectively. The diffusion process of some organic contaminants like polycyclic aromatic hydrocarbons (PAHs) and polybrominated hydrocarbons (PBCs) from microplastics to aqueous systems has been identified. Yet data on leaching kinetics of phthalates to the aqueous environment are not available. In this work, we used an infinite sink method using activated carbon powder to investigate the leaching of phthalates from PVC microplastics into aqueous environments. Batch leaching experiments were conducted over a time span of 120 days with six different microplastics containing ~23% to ~38% of bis(2-ethylhexyl) phthalate (DEHP), diisononyl phthalate (DINP) or dioctyl terephthalate (DOTP). Thereby, time dependent leaching curves for each phthalate could be obtained. These leaching curves were evaluated using models for IPD and ABLD. The aqueous boundary layer diffusion model could well match the experimental data and could be identified as the governing diffusion process. Elucidating the governing diffusion process allowed us to calculate specific desorption times (e.g., desorption half-lives) of phthalates in aqueous environments. Our findings contribute to better understand the fate and behaviour of microplastics and phthalates in the aqueous environment.

3.10.T-24 Microplastics and Microalgae As Vectors for Chlorpyrifos and Mercury Toxicity in the Marine Copepod *Acartia tonsa*

*Estefanía Pereira Pinto M.S.*¹, *Estefanía Paredes Rosendo*¹ and *Juan Bellas*², (1)University of Vigo, Spain, (2)IEO, Spain

Plastic pollution has become a world-wide concern that can potentially threaten the stability of aquatic communities. While it remains unclear whether microplastics (MPs) introduced in the marine systems may or may not be toxic on their own, these particles have the capacity to interact with ubiquitous environmental contaminants, potentially acting as a vector of toxicants to marine organisms. The purpose of this study was to test this hypothesis using the calanoid copepod *Acartia tonsa* and two toxicants, a metal: mercury (Hg) and a hydrophobic organic compound: the organophosphate insecticide chlorpyrifos (CPF), and as model polyethylene MPs: high-density polyethylene (MPP-635XF) and oxidized high density polyethylene (Aquatex 325). The individual effects of Hg, and their combined effects with polyethylene MPs, on the survival, fecundity, feeding and egg viability of *A. tonsa*, were determined. Furthermore, this study aimed to compare the role of MPs and natural organic particles (microalgae, MA, *Rhodomonas lens*) as vectors of Hg and CPF toxicity. *A. tonsa* individuals were exposed to oxidized polyethylene MPs (0.25, 0.5, 1, 2 and 4 mg/L), to Hg (0.01, 0.1, 1, 10 $\mu\text{g/L}$) and to the combination of Hg and MPs (0.5-8 $\mu\text{g/L}$ of Hg + 0.25-4 mg/L of oxidized MPs). No significant effects were observed after exposure to oxidized MPs, but significant toxicity was found after

exposure to Hg on survival (LC50 = 3.55 µg/L), egg production (EC50 = 2.31 µg/L), hatching (EC50 = 3.88 µg/L) and recruitment rate (EC50 = 2.64 µg/L). However, the presence of MPs decreased the toxicity of Hg obtaining LC50/EC50 values of 6.67, 5.44, 4.03 and 2.49 µg/L, for survival, egg production, hatching and recruitment rate, respectively. On the other hand, the obtained results showed similar toxicity of Hg and CPF in copepods exposed to loaded MPs and MA, indicating that MP are vectors of CPF and Hg to the same extent than MA.

3.10.T-25 Biofouling Causes Tolerance of *D. Magna* to Microplastic Stress

Georgiana Amariei¹, Roberto Rosal², Francisca Fernandez-Pinas³ and Albert Koelmans⁴, (1)Aarhus Universitet, Denmark, (2)University of Alcalá, Spain, (3)Universidad Autónoma de Madrid, Spain, (4)Wageningen University, Netherlands

Ingestion of microplastic (MP) cause detrimental effects on organisms by diluting the nutritional value of food, but can also be beneficial if nutritious biofilms are present on the MP surface. This renders the question: is ingestion of MP harmful or beneficial and can the net effect of the two mechanisms be quantified? In this work, we quantified these harmful and beneficial effects on *Daphnia magna* (*D. magna*), using dose-response tests with clean and biofouled MP respectively, and determined the trade-off between these counteracting effects. For this end, polyethylene fragments were aged in natural water samples with different composition and organic load, namely river downstream and upstream a wastewater treatment plant (WWTP), and the effluent and influent from the same plant. The results of toxicity evaluation indicated that the environmental biofouling caused tolerance to MP exposure on *D. Magna* immobilization. The usual dose-response curve was observed for pristine MP. Pristine MP also showed higher immobilization of *D. magna* than biofouled particles. We found that the negative effects of MP can be compensated by the positive effects of biofouling layers as a food source. The survival rate of *D. magna* could be attributed to the amount of the resulting biofilm (carbon content) formed on MP. The highest survival rate was observed for MP biofouled in WWTP influent for 21 days, which had the higher content of biofilm. We successfully developed a theoretical modelling approach which simulates population growth by incorporating dose-effect relationships for ingestion of MP and ingestion of food, with part of the food being biofilm from biofouled MP. The model was applied for both pristine and biofouled MP. The applicability and accuracy of the model was tested by comparing model predicted profiles with experimental data ($R^2=0.868-0.991$). We also plotted isoclines for zero population growth, separating MP concentration and food concentration combinations that support *D. Magna* population growth from the combinations that jeopardize population growth due to ingestion of MP. These results contradict previous studies were only pristine MP were used and demonstrate that the ruling paradigm of unambiguously adverse MP effects is not ecologically justifiable.

3.10 Microplastics in the environment: Behaviour, transport, fate, risks, and alternatives to conventional plastics (Part VI)

3.10.T-26 Influence of Microplastics and Freshwater Snow Heteroaggregation on Particle Settling Rates in Freshwater

Francesco Parrella¹, Stefano Brizzolaro², Markus Holzner³ and Denise M Mitrano⁴, (1)ETH Zurich, Zürich, Switzerland, (2)ETH Zurich, Switzerland, (3)Swiss Federal Research Institute WSL, Switzerland, (4)Environmental Systems Science, ETH Zurich, Zurich, Switzerland

To date, many studies have focused on the detection and quantification of microplastics (MPs) in natural waters, but only a few have been conducted to systematically understand the processes which drive MPs fate and transport in freshwater ecosystems. This includes hetero-aggregation with suspended natural colloids and small biota, and how these interactions affect distribution and transport in freshwater (e.g. settling dynamics). Freshwater snow (FWS), a mixture of algae and natural particles, is responsible for most of the flux of organic matter from the water surface to the sediment and can potentially act as a vector for MPs through the water column. Here we systematically analysed the settling rates of particles of different densities and morphologies in a plexiglass column, illuminated by a laser to track particles with a stereoscopic camera system. Image sequences were acquired and analysed with a tracking software to determine settling rates of the particles in three test systems: 1) MPs of various composition, size and morphology, 2) FWS and 3) MPs-FWS heteroaggregates. For each experimental set, our setup allowed the tracking of up to 2×10^4 particles, which ensured statistical convergence of the results. FWS was created by mixing freshwater algae (*Asterionella*, *Mycrocystis*, *Kirchneriella*) on a roller table to simulate the formation of natural flocks over time. Our goal was to assess if the settling rates changed when plastic and FWS were aggregated together, compared to their settling dynamics individually. While data analysis is still ongoing, we hypothesize that MPs size, shape and extent of incorporation into FWS will be important variables in the settling dynamics of the materials. Through this work, we demonstrate the utility of our experimental approach (camera setup, laser and the tracking software) for the analysis of particle settling dynamics – which has been validated with spherical particles of different sizes and densities according to Stokes law. Collectively, we provide further insights on the settling rates of MPs which can be used as input values for future fate models in freshwater systems, as well as an indication as to how the presence of MPs can impact the biogeochemical cycles through altering FWS settling in freshwater.

3.10.T-27 Science to Solutions: From Characterising to Tackling Microplastic Pollution in the Galapagos Islands and the Wider Eastern Pacific

Ceri Lewis¹, Jen Jones², Adam Porter³, Juan Pablo Munoz Perez⁴ and Tamara Galloway⁵, (1)Biosciences, University of Exeter, Exeter, United Kingdom, (2)Galapagos Conservation Trust, United Kingdom, (3)Biosciences, University of Exeter, Exeter, United Kingdom, (4)Universidad San Francisco de Quito, Ecuador, (5)University of Exeter, United Kingdom

Plastic leakage from the Eastern Pacific rim countries of Ecuador and Peru is captured by the South Pacific Subtropical Gyre, transporting it towards the open ocean, where it pollutes oceanic islands such as Galápagos, famous for its unique biodiversity and a global conservation priority. Here we report on our collaborative programme working to first quantify the widespread plastic contamination of the Galapagos marine ecosystem and then to develop both local and regional monitoring and management plans

with regional stakeholders with the aim of reducing plastic input and wildlife impacts for this iconic archipelago. A two-year field sampling campaign focussing on the island of San Cristobal was undertaken, sampling the sea surface, benthic sediments, beaches and representative invertebrate biota for microplastics in combination with beach macroplastic surveys. Our data reveals widespread microplastic contamination of San Cristobal of both benthic sediments (6.7–86.7 particles·kg⁻¹) and surface seawater (0.04–0.89 particles·m⁻³), with elevated concentrations in the harbour suggesting some local input. Microplastics were present in all seven marine invertebrate species examined, found in 52% of individuals (n = 123). Highest beach plastic accumulation was on the eastern coast indicating major input of plastic waste to Galapagos from the Humboldt Current. A systematic priority scoring analysis identified the most vulnerable vertebrates as pinnipeds, seabirds, turtles, and sharks due to risk of entanglement and ingestion. Finally, we developed citizen science projects to provide ongoing time series data and recommend a monitoring and management framework for marine plastic pollution in remote oceanic islands, supporting the strategic efforts of the Galapagos National Park Directorate.

3.10.T-28 The Shapes of Microplastics

Fan Liu¹, Lasse Rasmussen², Nanna Klemmensen³, Alvise Vianello², Guohan Zhao², Rasmus Nielsen² and Jes Vollertsen², (1)Department of Build, Aalborg University, Denmark, (2)Aalborg University, Denmark, (3)Thomas manns vej 23, Aalborg University, Denmark

Microplastics (MP) are ubiquitous and potentially pose risks to organisms. The environmental fate of MP is not only associated with its density and size, but also the shapes. Common shapes for MP are ‘*fiber*’, ‘*fragment*’, ‘*film*’, etc.. Some of them require determination of the thickness (the third dimension), which is feasible for MP above 300 µm using optical microscopy. The majority of MP are smaller sized, their identification relies on hyperspectral imaging, but this only analyses particle’s 2D projection. This means that some of the current shape categories are unsuitable for the most environmentally abundant MP. This study aims to derive a set of 2D shape categories for MP identified by hyperspectral imaging. The proposal is based on practical experiences of experts who work closely with MP analysis using this technique. The shapes were then used as references to evaluate the shape of 11,402 environmental MP (identified by FPA-µFTIR imaging), aiming to investigate patterns of MP shapes in the environment. We asked 5 experts to give input on 1) what are the often-seen pixelated MP shapes? 2) which 2D geometries can represent the pixelated shapes? Then we proposed 9 categories: *fiber*, *rod*, *ellipse*, *ovoid*, *sphere*, *quadrilateral*, *triangle*, *free-form*, and *unidentifiable*. These categories were used to evaluate the shape of the 11,042 MP extracted from indoor air, wastewater influent, effluent, sludge, stormwater, sediments, and marine water. The evaluation was conducted individually by the experts, and the degree of distinguishability of the shapes was also assessed. The most abundant shape was *ellipse* (19.1%), and the least was *fiber* (2.3%). But *fiber* was the most distinguishable shape, while *ellipse* was the least. Freshwater MP were differentiated from that of air and marine water regarding particle shape, and the differentiation on particle size showed a clear phase-based pattern: MP from solid-phase samples had the largest size, indoor air MP had the smallest. Hyperspectral imaged MP need suitable 2D geometries for shape categorization. These shapes must be relevant to the natural MP shapes, but also feasible for manual assessment. The proposed shapes are not meant to serve as the universal MP shapes categories. Nevertheless, they give a clear picture of the distribution of MP shapes in the environment. We finally suggest that MP shape should be considered in environmental mapping studies to enhance the applicability of such data for environmental impact assessment.

3.10.T-29 Environmental Safety of Second and Third Generation Bioplastics in the Context of the Circular Economy

Paul Benjamin Boisseaux¹, Peter Hopkinson², Alysia Garmulewicz³, Zoe Powell⁴, Charlene Smith⁴ and Tamara Galloway⁵, (1)Exeter University, UK, (2)University of Exeter, UK, (3)University of Santiago de Chile, Chile, (4)Materiom, UK, (5)University of Exeter, United Kingdom

Biodegradable plastics designed using organic materials other than crude oil are often suggested as sustainable solutions for tackling end-of-life plastic waste, but little is known of their ecotoxicity to aquatic species. Here, we investigated the ecotoxicity of four second (2G) and third generation (3G) plastics (i.e. those using organic by-products, residuals, or waste feedstock (2G), in our case pork, fish or shellfish waste, or algae (3G) feedstock), toward the freshwater zooplankton *Daphnia magna*. In acute toxicity tests (48h), survival was impacted only at high concentrations (g/L range), similar in range to salinity-induced toxicity. All tested bioplastics decreased exposure media pH suggesting the potential to induce acidification stress. Algae-based bioplastics induced hormetic responses under chronic exposure (21d), enhancing most biological traits compared to controls (reproduction rate, body length, width, apical spine, protein concentration) from 0.06 to 0.5 g/L. Phenol-oxidase activity, indicative of immune function, was also enhanced at the lowest concentrations (62 and 125 mg/L). These suggested health benefits were hypothesised to be due to assimilation of carbon derived from the seaweed-based bioplastic as food. Also, the seaweed-bioplastics showed a complete compost disintegration and a readily biodegradation in freshwater, suggesting a low environmental persistence. In conclusion, the tested bioplastic showed promising environmental safety, classified as ‘not harmful’ under current global regulations; further studies are needed to better understand their longer term ecological and multi-generational effects.

3.11 One Health next generation wastewater management and reuse: the role of non-target and retrospective analysis, bioassays, and wastewater surveillance (Part I)

3.11.T-01 Integrating Panel Studies, Survey Data and Wastewater Based Epidemiology for Illicit Drug Use Monitoring; the Amsterdam CASE

Thomas L ter Laak¹, Erik Emke², Annemieke Benschop³, Ton Nabben³ and Frederic Magnus Been⁴, (1)KWR, Netherlands, (2)KWR Watercycle Research Institute, Netherlands, (3)Amsterdam University of Applied Sciences, Netherlands, (4)KWR Watercycle Research Institute, Netherlands

Drug consumption estimates are of relevance because of public health effects and associated criminal activities. Here we illustrate the combined use of Wastewater Based Epidemiology (WBE) of drug residues to estimate drug *use* and panel studies and survey data to reveal information from and on *users*. We present the triangulation of ten years of monitoring Amsterdam's cocaine, amphetamine, methamphetamine and MDMA *use* and *user* data. WBE revealed significantly higher consumption during weekends of MDMA (+41%) and cocaine (+26%). This observation corresponded to qualitative information from panel studies for MDMA, cocaine use setting. Furthermore a significant increase in *per capita* consumption of all stimulants was observed between 2011 and 2019, this was not reflected in the panel and survey data. However, the observed decrease in use during the COVID-19 pandemic 2020-2021 did corresponded to the obtained information from users. These different types of studies that reveal different information enable to connect observed trends in total drug consumption to behavior of users and the social context in which the use takes place.

3.11.T-02 The Role of Wastewater-Based Epidemiology As a Complementary Information Source During the COVID-19 Pandemic in Belgium

Tim Boogaerts¹, Maarten Quireyns², Bram Pussig³, Hans De Loof², Bert Aertgeerts³, Adrian Covaci² and Alexander Van Nuijs², (1)University of Antwerp, Toxicological Center, Belgium, (2)University of Antwerp, Belgium, (3)Academic Center for General Practice, KU Leuven, Belgium

Wastewater-based epidemiology (WBE) is a complementary approach to monitor substance use in the general population. The aims of this study were to: (i) evaluate intra- and inter-year temporal changes in stimulant and alcohol use during the first wave of the COVID-19 pandemic (14th of March 2020 till September 2020); and (ii) measure the effect of the COVID-19 restrictions on substance use. Daily 24-h composite influent wastewater samples were collected from the beginning of September 2019 until the end of September 2020 in four wastewater treatment plants corresponding to four Belgian cities (i.e. Antwerp, Boom, Brussels and Leuven). Human metabolic excretion products of amphetamine, cocaine (i.e. benzoylecgonine), ethanol (i.e. ethyl sulphate), 3,4-methylenedioxymethamphetamine, and methamphetamine were measured in these samples using a validated method based on liquid chromatography coupled to tandem mass spectrometry. Measured concentrations (ng/L) of human biomarkers were converted to per capita mass loads (mg/day/1000 inhabitants) by multiplying with the daily flow rate and dividing by the catchment population. The temporal fluctuation in population size was accounted for through the inclusion of mobile phone data as a dynamic population proxy. Day-to-day temporal changes during the COVID-19 pandemic were assessed, and the effects of the COVID-19 interventions on alcohol consumption were investigated. In most of the investigated locations, stimulant use remained stable or even increased in 2020 compared to 2019. Consumption of stimulants did not change, or was even higher, in the full lockdown period compared to the exit strategy and relaxations period. Similar to stimulant use, the consumption of alcohol did not significantly decrease during the lockdown period compared to the pre-lockdown period (starting from September 2019 till March 2020). However, in contrast to illicit drugs, alcohol use increased during the relaxation period after re-opening of the catering industry and increasing the allowed number of contacts per household. The present study shows the potential of WBE to rapidly assess the impact of COVID-19 interventions on alcohol and illicit drug consumption in Belgium. This study also indicates that WBE could be employed as a complementary data source to fill in current knowledge gaps linked to lifestyle behavior during the COVID-19 pandemic.

3.11.T-03 Determination of Phthalate Monoesters in Wastewater As an Indication of Human Exposures

Fiona Regan¹, Jenny Lawler², Catherine Allen² and Anthony Staines², (1)DCU Water Institute, Dublin City University, Ireland, (2)Dublin City University, Ireland

Phthalates are synthetic organic chemicals commonly used as plasticisers in PVC and additives in personal care products. Over 213 million kilograms of phthalates are produced each year with end uses including food packaging, flooring, paints, tubing and medical devices. (EPA 2006). Due to the ubiquitous nature of phthalates in the environment they are considered emerging pollutants. As a result, their toxicity has been thoroughly investigated leading to their classification as endocrine disruptors; having effects on male reproductive health, children's neurodevelopment, obesity and cancer. High molecular weight phthalates have been investigated less frequently but may have the same effects on health. The majority of studies on phthalates focus on environmental presence of phthalate di-esters or biological presence of phthalate mono-esters. The ability to monitor both is beneficial to examining the life-cycle of these compounds and how pervasively they persist in biological systems. Exposures to phthalate di-esters were estimated from the mono-ester metabolite concentrations in influent using flow rates, population served and correction factors for phthalate metabolism. Levels were found to be between 0.32 to 277.25 µg/inhabitant/day. This paper demonstrates the development of an analytical method for the determination of phthalate metabolites in urban wastewater to demonstrate likely human exposure levels in the environment.

3.11.T-04 Occurrence and Fate of Pharmaceuticals and Personal Care Products in Crops Irrigated With Reclaimed Water

Gerard Quintana¹, Adria Sunyer Caldu² and Silvia Diaz-Cruz³, (1)IDAEA CSIC Barcelona, Barcelona, Spain, (2)IDAEA, CID-CSIC, Spain, (3)QA, IDAEA-CSIC, Barcelona, Spain

Wastewater reuse for agricultural irrigation has increased worldwide in the recent years due to water scarcity and climate change. However, wastewater treatment plants (WWTPs) do not have the capacity to completely remove emerging contaminants, such as pharmaceuticals and personal care products (PPCPs), and thus they are still present in these irrigation waters. Therefore, the possibility that these compounds can be uptaken by the crops intended for human consumption is real. The occurrence of 56 PPCPs in three types of crops, namely tomatoes, lettuces, and carrots, as well as in soil and irrigation water, was evaluated. WWTPs secondary effluent water and reclaimed water produced by the effluent infiltration through reactive barriers of a managed aquifer recharge (rbMAR) were tested for irrigation. Besides water quality, the effects of soil composition and irrigation system

on the PPCPs crops uptake were also investigated. The extraction of the target compounds from the different crops and soils was carried out by a QuEChERS-based (Quick, Easy, Cheap, Effective, Rugged and Safe) method, while the water analyses were performed by on-line solid-phase extraction coupled to high performance liquid chromatography and tandem-mass spectrometry (on-line SPE-HPLC-MS/MS). The results showed that the best combination of variables to lower the plants and fruits uptake of PPCPs was to irrigate with the reclaimed water, in soil with high content in clay. The irrigation system appeared to have low influence on the PPCPs uptake. A significant and differential bioaccumulation was observed with a total load of the selected PPCPs up to 1248.53 ng/g dw, 1691.76 ng/g dw and 7786.63 ng/g dw in the lettuces, tomatoes and carrots, respectively. These findings have significant implications for the reuse of wastewater in agriculture intended for human consumption. Contamination control in source and more efficient wastewater treatments are needed for a safe use of reclaimed water in agriculture in compliance with current water reuse regulation Acknowledgements: The authors are grateful to the Spanish Ministry of Science and Innovation (Project ROUSSEAU CTM2017-89767-C3-1-R and Project CEX2018-000794-S), Project RESTORA (ACA 210/18/00040) and Consorci d'Aigües Costa Brava Girona (CACBGi) for the unlimited access to the facility and treated and reclaimed water supply for irrigation, and to BEKOLut®, for the provision of the QuEChERS kits.

3.11.T-05 Soil Self-Cleaning Capacity: Removal of Persistent and Mobile Organic Compounds During Sub-Surface Irrigation With Sewage Effluent

Dominique Mon-Coeur Narain-Ford¹, Annemarie van Wezel², Rick Helmus³, Stefan Dekker⁴ and Ruud Bartholomeus⁵, (1)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands, (2)University of Amsterdam/IBED Institute, Amsterdam, Netherlands, (3)University of Amsterdam/Institute for Biodiversity and Ecosystem Dynamics (IBED), Netherlands, (4)Copernicus Institute of Sustainable Development - Utrecht University, Netherlands, (5)KWR Water Research Institute, Netherlands

While significant attention has been paid to the more arid regions of the world, temperate climates also suffer from seasonal droughts. The pressure on the availability of freshwater will continue to increase due to climate change, which will enhance prolonged dry periods. Hence, it is crucial that alternative freshwater resources such as sewage treatment plant (STP) effluent are explored. When using sub-surface irrigation for agriculture as method of supply, the quality of STP effluent may improve due to the soil passage and related biodegradation processes. Nonetheless, the extent to which the dispersion of the mixture of contaminants of emerging concern (CoECs) is diminished in sub-surface irrigation systems is not yet fully understood. Consequently, the aim of this study is to identify and quantify CoECs from a real-scale cropland that is directly irrigated with STP effluent using sub-surface irrigation. We also aim to elucidate the fate of CoECs during soil passage and relate this to CoECs physicochemical properties. The selected area of study is the only Dutch cropland intentionally and directly irrigated with municipal effluent. In total 133 water samples taken from the rhizosphere and groundwater up to 12 meters were analyzed with a maXis 4G quadrupole time-of-flight high-resolution mass spectrometer equipped with an electrospray ionisation source (ESI-Q-TOF) to achieve MS detection. This study is complemented by more than a hundred targets that represent a variety of chemical structures and uses. The logD (pH=7.4) ranged from -2.77 (acesulfame) to 5.69 (flufenoxuron). The persistency (half-life) diverges from 0.4 days (Propanil) to 1194 days (2,6-Dichlorobenzamide/BAM). To correct for dilution by rainwater and groundwater, concentrations in the rhizosphere-and groundwater samples were corrected based on the effluent tracer saccharin. The targets were separated into four groups representing the four combination of low and high persistency (P) and mobility (M). Our results show that the fate of CoECs is highly dependent on their physicochemical properties and external factors of the SSI system. After the extremely dry year of 2018 the sub-surface irrigation system needs more time to recover, which can be correlated to the low amount of precipitation in the winter of 2018-2019 and resulting low dilution.

3.11 One Health next generation wastewater management and reuse: the role of non-target and retrospective analysis, bioassays, and wastewater surveillance (Part II)

3.11.T-06 Operational Application of Invertebrate Behaviour Videotracking for Online and Real-Time Wastewater Surveillance

George Ruck¹, arnaud chaumot², Olivier Geffard³, Jean-Baptiste Aubin⁴, Jean-Luc Bertrand-Krajewski⁵, Alexandre DECAMPS⁶, Didier Neuzeret⁷, Kassandra Montalbano⁶, Maxime Dauphin⁶, Laura Garnero³ and Hervé Quéau⁸, (1)INRAE Centre de Lyon-Grenoble Auvergne-Rhône-Alpes, France, (2)Irstea, France, (3)INRAE Lyon, France, (4)INSA de Lyon, France, (5)INSA LYON, France, (6)ViewPoint, France, (7)ViewPoint Behavior Technology, France, (8)INRAE, France

As availability of water resources decreases, the apparition of new contaminants of concern (CEC) identified in water networks continues to increase. Current wastewater monitoring in treatment plants relies on interval based grab sampling measurements for a select few chemicals or for punctual effluent toxicity assessment using a restricted choice of bio-assays. As this strategy is known to omit at large portion of micro-pollutants and contaminants of emerging concern (CECs), innovative approaches to wastewater management are essential to both avoid potentially detrimental impact of largely unknown CEC discharge in aquatic ecosystems and improve efficiency of urban water re-use. To better characterise micro-pollutant fate in wastewater treatment plants, we proposed a bio-innovative approach based on the video-tracking of locomotor behaviour of bio-indicator invertebrates (the crustacean *Gammarus*, the gastropod *Radix*, and the annelid *Erpobdella*), in an on-line wastewater multi-species monitoring device: ToxMate. For testing, certain CECs were selected according to French research and ground reports for both laboratory and WWTP testing (as the ToxMate apparatus is already present in French WWTPs). Our results illustrate the specific sensitivity of the bio-activity signal to the micro-pollutant discharge, as well as reporting results and feedback from real-case long-term monitoring sites which uncover moments of micropollutant linked water quality degradation. Finally, undergoing laboratory research on the definition of multi-species behavioural fingerprints to discriminate causes for CEC discharge is presented. The

success of this initial testing immediately showed the potential of such bio-innovation to better encompass contaminant discharge without sensitivity to environmental confounding factors. Continuous surveillance identifies critical moments that could be missed with current grab sampling techniques. These moments may help adapt wastewater management strategy in real-time. Thus, the potential is not only limited to the improvement of aquatic environmental quality through wastewater management, but could also provide concrete indicators of the suitability of urban water re-use.

3.11.T-07 Combined Chemical and Effect-Based Analysis for a Robust and Efficient Assessment of (Advanced) Wastewater Treatment

Sebastian Buchinger¹, Shima Ghorban², Irene König³, Marcus Lukas⁴, Bertram Kuch² and Georg Reifferscheid¹, (1)Federal Institute of Hydrology, Germany, (2)University of Stuttgart, Germany, (3)Federal Institute, Germany, (4)German Environment Agency (UBA), Germany

Anthropogenic pollutants discharged into the aquatic environment via wastewater can cause negative effects on aquatic ecosystems despite very low concentrations. Therefore, there is a demand for advanced wastewater treatment technologies such as ozonation and/or the use of activated carbon but as well efficient methods to evaluate the removal of contaminants of emerging concern. Especially for the regulatory wastewater monitoring and operators of wastewater treatment plants, there is a need to monitor the success of the advanced wastewater treatment, not least because this is associated with significant investments and higher operational costs. In addition to the chemical analysis, effect-based methods are highly relevant to investigate the overall toxicity of treated wastewater, because they cover all substances contributing to an observed effect. Besides classic bioassays such as the Yeast Estrogen Screen or the Ames-Test to detect mutagenic effects a variety of methods was recently developed to combine chromatographic separation of compounds by thin-layer chromatography (TLC) with an effect-based detection directly on the surface of the thin-layer plate. To develop a robust and efficient approach to assess the success of (advanced) wastewater treatment by a combination of complementary chemical and effect-based parameters a systematic sampling of wastewater was performed along with the wastewater treatment processes including advanced treatment technologies. The samples were characterized using classic bulk parameters such as DOC, SAK, TNb and enriched by solid-phase extraction. The extracts were directed to a comprehensive chemical target monitoring and an effect-based assessment including mutagenic, genotoxic, hormonal and cytotoxic effects. Furthermore, a battery of planar bioassays - performed in a direct combination with thin-layer chromatography - was applied. The findings demonstrate that effect-based in-vitro methods are valuable complementary tools to chemical analysis since they detect existing, unwanted effects rather than compounds and thus directly indicate the quality of the treated wastewater. Especially bioassays in combination with thin-layer chromatography are robust and sufficiently sensitive to detect for example trace amounts of estrogenic compounds such as EE2 in the low pg/l-range.

3.11.T-08 Non-Target Screening of Pharmaceuticals Transformation Products in Urban Wastewater and Evaluation of Their Fate in Constructed Wetlands. a Retrospective Analysis

Dorde Tadic¹, Andres Sauvetre² and Serge Chiron³, (1)University of Montpellier, Montpellier, France, (2)IMT Mines Alès, France, (3)University of Montpellier, France

The path of the contaminant from its discharge in the environment to the complete degradation to inorganic salts, water and carbon dioxide is rather long and complex. Although the state of knowledge on this subject is still insufficient, it has been demonstrated that some transformation products (TPs) may be as harmful as their parent compounds, in addition, they may be much more harmful in an environmental situation, where they occur in mixtures. In this study, two sampling techniques, passive and grab sampling, were compared for qualitative analysis of pharmaceutical TPs in urban WW effluents. Results demonstrated better suitability of passive sampling mainly due to the better quality of MS² spectrum. The non-target screening revealed the occurrence of 13 TPs in secondary treated effluents (i.e., tramadol N-oxide, N,O-didesmethyltramadol, amisulpride N-oxide, O-desmethylvenlafaxine N-oxide, O-desmethylvenlafaxine, N-desmethylvenlafaxine, venlafaxine N-oxide, gabapentin lactam, O-desmethyltramadol, clarithromycin N-oxide, hydroxycarithromycin, hydroxycarbazepine, and carbamazepine-10,11-epoxide). Retrospective analysis of the previously acquired data by high-resolution mass spectrometry was used to reveal the fate of these compounds during the treatment in constructed wetlands. Among identified compounds, N-oxides and carbamazepine-10,11-epoxide appeared to be the most recalcitrant, alongside amisulpride, gabapentin, and carbamazepine. The results obtained offer insight into the fate of pharmaceutical TPs and may serve as a guideline for the prioritization of contaminants TPs based on their persistence during the treatment and assist in the design of treatment systems.

3.11.T-10 Evaluation of Innovative/Alternative Septic Systems for the Removal of Contaminants of Emerging Concern

Susan T. Glassmeyer¹, George Heufelder², Brian Baumgaertel², Paul Bradley³, Maura Donohue⁴, Laura Erban⁴, Edward Furlong³, Timothy Gleason⁴, Dawn King⁴, Dana Kolpin³, Rachael Lane³, Denis LeBlanc³, Elizabeth Medlock-Kakaley⁴, Timothy McCobb³, Marc Mills⁴, Mallikarjuna Nadagouda⁴, Sheree Pagsuyoin⁵, Jorge Santo Domingo⁴, Kelly Smalling⁶, Daniel Tettenhorst⁴ and Daniel Tush³, (1)U.S. Environmental Protection Agency, Cincinnati, OH, (2)Massachusetts Alternative Septic System Test Center, United States, (3)U.S. Geological Survey, United States, (4)U.S. Environmental Protection Agency, United States, (5)University of Massachusetts, Lowell, United States, (6)U.S. Geological Survey

Groundwater is susceptible to elevated nitrogen concentration and co-pollutants from a variety of sources, including onsite wastewater treatment systems. For example, conventional onsite septic systems can release high levels of both nutrients (e.g., nitrogen and phosphorus) and contaminants of emerging concern (CECs) to groundwater and, in turn, into nearby receiving surface waters. In some areas, centralized wastewater treatment is not practically possible due to cost, lack of political will, or

physical limitations; as such, septic systems should no longer be considered a temporary measure in advance of sewers but rather a permanent part of residential wastewater treatment infrastructure. Some coastal communities have been evaluating the removal of conventional septic systems and the installation of innovative/alternative (I/A) septic systems to reduce nutrient loads. Communities can select from various proprietary and non-proprietary I/A systems, each with its specific benefits and limitations. Enhanced I/A systems that include a lignocellulosic carbon source have been demonstrated to efficiently remove nitrogen from effluent along with some CECs. The removal of CECs during I/A treatment may be a co-benefit of installing these systems for residential wastewater treatment. Conversely, if some critical CECs are not removed (or only minimally removed) by the I/A treatment, communities may choose to opt for sewers instead of installing I/A septic systems. This project examines the removal from effluent of over 280 chemical and microbial CECs by conventional and I/A septic systems. Two conventional treatments were sampled: 1) a standard pipe-in-stone trench with 1.3 m of vadose zone, and 2) a drip disposal system where the septic tank wastewater disposal is in the active bio-zone (root zone) underneath the turf with percolate collected at a 0.6-m depth. Effluent was collected from 4 points in 3 different I/A systems: 1) a saturated wood layer system; 2) a denitrifying system with an aeration chamber and denitrification chamber; and a second denitrifying system with collection points after both the 3) nitrifying bed, and 4) wood chip bioreactor. This study will fill a critical information gap about the influence and/or mitigatory effect I/A systems have on ground and surface water quality as a diffuse source of CEC pollution. In addition, it will provide important contributions to the growing body of literature on the performance of I/A septic systems.

3.11 One Health next generation wastewater management and reuse: the role of non-target and retrospective analysis, bioassays, and wastewater surveillance (Virtual Only)

3.11.V-01 Evaluation of Comprehensive Quality Control Pipeline for Wastewater Surveillance of SARS-CoV-2

Yuwei Xie¹, Jonathan Challis², Femi Oloye², Paul Jones², Mohsen Asadi², Kerry McPhedran², Markus Brinkmann² and John Giesy², (1)Toxicology Center, University of Saskatchewan, Saskatoon, SK, Canada, (2)University of Saskatchewan, Canada

Wastewater-based epidemiology (WBE) has been widely applied to track outbreaks of coronavirus disease 2019 (COVID-19). Viral load in wastewater is a promising community indicator of outbreaking magnitude. However, there are no standardized protocols for quantifying viral load in wastewater, especially for population normalization. Wastewater is complex and dynamic, which can impact the efficiency of viral enrichment, RNA extraction, and RT-qPCR. Additionally, community population is dynamics due to major events, which should be considered for long-term longitudinal surveillance. Here, a comprehensive quality control pipeline was proposed and evaluated to quantify the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) RNA and key Variants of Concern (VOCs) in wastewater at Saskatoon, Canada. Internal and external spiking controls were applied to estimate recovery ratio and extraction efficiency. Wastewater parameters (daily inflow rate and ammonia) and population indicators (pepper mild mottle virus, acesulfame K and creatinine) were used to normalize viral load. Normalization methods were evaluated against the daily numbers of new cases of COVID-19 of the sewershed. Viral load was positively correlated with daily new cases reported in the sewershed. WBS had a lead time of approximately 7-day, which indicated surges in the number of cases of COVID-19 and revealed the major circulating VOCs with a and d driving the third and fourth wave, respectively. Adjustment with recovery ratio and extraction efficiency improved the correlation between viral load and daily, new cases. Acesulfame K performed better than pepper mild mottle virus, creatinine, and ammonia for population normalization. Normalization to acesulfame K improved the trend of viral load of the second wave during the Christmas and New Year holidays. Hence, the whole process controls to characterize recovery ratios and extraction efficiencies, and population normalization with Acesulfame K is essential for precise WBE programs supporting decision-making in public health.

3.11.V-02 Integrated Approach on Irrigation Management Using Non-Conventional WATER Resources Through Multidisciplinary Strategies for Risk Reductions

Francisco pedrero Salcedo¹ and Juan José Alarcón Cabañero², (1)IRRIGATION, CEBAS-CSIC, Spain, (2)CEBAS-CSIC, Spain

Agriculture faces the challenge to produce more food to feed a growing population. The world population is expected to grow by 2.3 billion people by 2050, which will require extending the land equipped for irrigation by some 32 million hectares to guarantee raising overall food production by some 70%, since the per capita food consumption is also increasing. Under these circumstances, water withdrawals for irrigation to cope with the increasing food demands should grow by 11% for 2050. This intensifying water scarcity scenario represents a threat to the long-term role of irrigated agriculture in global food security, which cannot meet current or future demands for irrigation by relying solely on conventional water sources. New solutions are required to maintain or enhance sustainable agricultural production, including new or alternative water resources and water conservation strategies. In this context, an interesting technological approach is to increase the use of nonconventional water resources to guarantee long-term food security and socioeconomic stability. Although reclaimed water is commonly and successfully used in many countries, water reuse faces numerous barriers. Therefore, for the preservation of profitable intensive agriculture that respects the environment, are needed innovative agricultural projects incorporating state of the art technologies in water reuse with multidisciplinary studies. Sustainability of agriculture irrigated with low quality water will require a comprehensive approach to soil, water, and crop management consisting of site- and situation-specific preventive measures and management strategies. The objective of this work is to show a multidisciplinary approach on water reuse projects in agriculture through an integrated methodology, generating novel strategies based on the three new concepts on water reuse: “fit for purpose” (water quality should be adapted to the type of crops and irrigation techniques), “multiple barrier” (water quality for specific uses should result from a stepwise approach, cascade treatment technologies should allow for sequential quality upgrade according to changing requirements) and “risk-based approach” (water quality should be evaluated through the definition and assessment of risk levels that are appropriate for the specific use).

3.11 One Health next generation wastewater management and reuse: the role of non-target and retrospective analysis, bioassays, and wastewater surveillance (Poster)

3.11.P-Tu153 Wastewater Surveillance Supports COVID-19 Clinical Findings Across Epidemic Waves in South Africa

Renee Street¹, Angela Mathee², Suranie Horn³, Tarylee Reddy², Johan Louw², Christo Muller² and Rabia Johnson², (1)South African Medical Research Council, Durban, South Africa, (2)South African Medical Research Council, South Africa, (3)North-West University, Cape Town, South Africa

Wastewater surveillance of non-infectious SARS-CoV-2 RNA fragments can provide an early warning for detecting COVID-19 cases in the community, detect variants, assess trends and track hotspots. This may in turn provide a cost-effective, rapid and reliable source of information on the spread of SARS-CoV-2 in communities. More than 18 months into the pandemic, South Africa has experienced three district COVID-19 waves with over 85 000 COVID-19 related deaths. Late November 2021, an increase of cases has been noted marking the start of the imminent fourth wave. The aim of this study was to describe and compare the difference in SARS-CoV-2 RNA levels in wastewater between 2 regions in the Western Cape (South Africa) during the second COVID-19 wave which coincided with the December 2020 holiday period. Both the Breede Valley and Theewaterskloof municipalities have four wastewater treatment plants (WWTPs) each. Wastewater influent samples were collected weekly from each of the eight WWTPs over a 12-week period. The total RNA was extracted with Qiagen RNeasy® PowerSoil® Kits and the SARS-CoV-2 RNA copy numbers were determined using quantitative Real-Time Polymerase Chain Reaction Analysis (qRT-PCR). The results showed that the SARS-CoV-2 viral loads from both catchments/municipalities followed the same trend as the clinical cases reported for the Western Cape province during the festive season. The two catchments are both located approximately 100 km inland from the coastal city of Cape Town, which is a popular holiday destination. The Breede Valley catchment is located on the national main road that stretches from Cape Town, across South Africa, through Bloemfontein and Johannesburg, and ends at the Zimbabwe border. Interestingly, higher SARS-CoV-2 RNA levels were quantified at the end of the second wave (4 January 2021) from Breede Valley compared to Theewaterskloof, potentially because this marks a peak travel period with people returning home. Wastewater surveillance of SARS-CoV-2 RNA proved to accurately reflect the clinical surveillance of COVID-19 infections in the Western Cape. In addition, the tool can be applied to retrospectively track the movements of people and advise on regulations for future outbreaks.

3.11.P-Tu154 Monitoring COVID-19 Through Wastewater-Based Epidemiology: Method Development, Disease Surveillance and Modelling in the South West UK

Kishore Kumar Jagadeesan¹, James Alexander Boxall-Clasby¹, Richard Standerwick², Ruth Barden², Marjorie Gibbon¹, Julian Faraway¹, Pedro Estrela¹, Theresa Smith¹, Edward Feil¹ and Barbara Kasprzyk-Hordern¹, (1)University of Bath, United Kingdom, (2)Wessex Water, United Kingdom

Infectious disease outbreaks are a growing threat, as both the frequency and global impact of disease outbreaks are increasing. This is particularly exemplified by the COVID-19 pandemic, and urbanisation, population growth and rapid mass movement make such global disease outbreaks increasingly likely. Against such a background, improvements to disease outbreak monitoring are vital. This work proposes to address this challenge through the use of wastewater-based epidemiology (WBE). WBE is a field of research that treats wastewater as a fingerprint of a community's health. The quantification of nucleic acids in a single wastewater sample can help bring about an understanding of public health in a cheap and non-invasive way: indeed, it is estimated that the health of 27% of the global population could be monitored globally by analysing samples from just 105,600 wastewater treatment plants (WWTPs). To make best use of WBE, methodologies for the quantification of analytical targets must be fully characterised. To this end a study was carried out in the South West of the UK to develop a methodology for sample preparation and analysis of wastewater from 4 different WWTPs for the routine quantification of SARS-CoV-2 RNA, each with different catchment populations and industrial contribution proportions. Long-term surveillance of wastewater from these sites was carried out, enabling comparison with public health case data and the construction of a mathematical model. The impacts of sample composition, storage, pasteurisation and clarification upon SARS-CoV-2 RNA quantification were all assessed, as were the various efficacies of different concentration and extraction methodologies. Additionally, the precision and range of the methodology were assessed and inherent variabilities of the method were characterised, and the impact of sampling frequency upon disease outbreak modelling was also assessed. The findings from this study can be applied to the future development of a wastewater-based early-warning system for disease outbreak detection and/or surveillance. This work shows that, when fully characterised and understood, WBE can be a powerful tool for public health monitoring. In the hands of public health officials, WBE promises to enable timely and well informed decisions for the surveillance and control of disease outbreaks.

3.11.P-Tu155 Wastewater-Based Epidemiology in Valencia City (Spain): 8 Years of Drugs of Abuse Monitoring

Julian Campo¹, Dyana Vitale², Lucía Herrera³, Daniele Sadutto², Yolanda Pico² and Vasiliki Soursova⁴, (1)CIDE-CSIC, Spain, (2)University of Valencia, Spain, (3)Environmental and Food Safety Research Group of the University of Valencia (SAMA-UV), Spain, (4)University of Valencia, MONCADA, Spain

Wastewater treatment plants (WWTPs) can provide the ideal matrices to monitor quickly and efficiently spatial and temporal differences in the consumption or exposure to chemical substances or pathogens in a population by measuring certain compounds. This technique is known as wastewater-based epidemiology (WBE). In addition, given the high stability of certain compounds, through the WWTPs' effluents they can reach the surface and underground waters, impacting negatively the ecosystem. Our study focused on the analysis of six drugs of abuse and metabolites in the entrance of three WWTPs located in Valencia city (Spain). The sampling was carried out by collecting 24-hour daily composite influent samples for seven consecutive days from 2014 to 2021. Amphetamine (AMP), benzoylcegonine (BECG), cocaine (COC), methamphetamine (MAMP), 3,4-

Methylenedioxymethamphetamine (MDMA) and 11-nor-9-carboxy-D9-tetrahydrocannabinol (THC-COOH) were extracted by solid phase extraction (SPE) and detected by liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS). Drugs were found in all samples analysed. Mean concentration values measured were high for cocaine compounds, BECG (1939.39 + 115.92 ng L⁻¹), COC (875.18 + 64.75 ng L⁻¹), followed by the cannabinoid THC-COOH (346.85 + 34.56 ng L⁻¹), and amphetamine type stimulants AMP (75.53 + 5.78 ng L⁻¹), MAMP (10.08 + 0.70 ng L⁻¹), MDMA (44.91 + 3.21 ng L⁻¹). A general significant increase in concentrations was noted in the weekend's samples but different trends were observed between years. Similar concentrations were also observed between WWTPs. The results of this study provided updated information about the consumption of these substances in the city of Valencia. They also highlight the importance of annual monitoring of the elimination efficiency of these compounds in WWTPs in order to decrease their environmental impact on the different ecosystems. Acknowledgements This work has been supported by Grant RTI2018-097158-B-C31 funded by MCIN/AEI/10.13039/501100011033 and "ERDF A way of making Europe".

3.11.P-Tu156 Spread of Antibiotic Resistance and Pharmaceuticals in Blackwater Reuse: From Source to Recipient Environment

Foon Yin Lai¹, Meritxell Gros², Windi Muziasari³, Annika Nordin¹, Foon Yin Lai¹, Karin Wiberg², Lutz Ahrens² and Svante Bertil Rehnstam⁴, (1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)Swedish University of Agricultural Sciences, Sweden, (3)Resistomap oy, Finland, (4)Lennart Hjelm's vag 9, Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden

Reuse of domestic wastewater is of growing global interest and is a key part of the transition to a circular economy. As source-separated wastewater fractions, blackwater is a concentrated solution of human excreta and flush water from households, and thus is beneficial to nutrient recovery. Blackwater reuse in agriculture offers a promising solution to reducing the dependence on chemical fertilisers. However, the potential environmental impacts due to blackwater reuse are not yet fully understood. The aim of this study was to evaluate the dissemination of antibiotic resistance and other pharmaceuticals in an agricultural field with blackwater reuse as biofertiliser. Soil and nearby surface water samples were collected before and after blackwater application at increasing time intervals (up to 35 days). Blackwater treated with urea, for hygienisation, and samples from the recipient environment were analysed for pharmaceuticals including antibiotics, as well as antibiotic resistance genes (ARGs). More than half (57%) of the target pharmaceuticals were quantified in the blackwater with a concentration range of 23-154 000 ng/L. Compared the urea-treated blackwater stored for one year with that for four year, there was a reduction in the concentration of several antibiotics by an order of magnitude, except for ofloxacin. The rest of the studied pharmaceuticals remained similar in their levels over time. Although their detection frequency was lower in the recipient environment, a few antibiotics were persistent in the nearby water streams over time, especially ofloxacin and enrofloxacin. Similar results were also observed for other pharmaceuticals, such as carbamazepine and ibuprofen. Enrofloxacin was the only antibiotic that could be quantified in the soil samples over time. Interestingly, an increase in the relative abundances of antibiotic resistance genes was observed for blackwater after four-year storage compared to one-year storage. In the soil recipient, there was a general decrease in the number of resistance genes detected over time. However, for the clinically relevant ARGs, the relative abundances in the soil increased over time. Their occurrence in soil remained even after one year of blackwater application. Overall, our results showed a potential spread of antibiotic resistance and other pharmaceuticals via blackwater reuse, and also the need for better treatment strategies to remove antibiotic residues and other pharmaceuticals in blackwater.

3.11.P-Tu157 Prevalence of Antibiotics and Antibiotic-Resistance Genes in Dutch Urban Wastewater - a Case Study

Daniel Joao da Silva Tavares Duarte¹, Caterina Zillien², Martine Kox³, Rik Oldenkamp⁴, Bas van der Zaan³, Erwin Roex⁵ and Ad Ragas⁶, (1)Department of Environmental Science, Radboud University, Nijmegen, Netherlands, (2)Radboud University, Nederland, (3)DELTA RES, Netherlands, (4)Radboud University Nijmegen, Netherlands, (5)Dutch Ministry of Defense, Netherlands, (6)Environmental Science, Radboud University, Nijmegen, Netherlands

The spread of antibiotic resistance genes (ARGs) is increasing globally and putting pressure on the long-term effectiveness of antibiotics. Antibiotics are critical pharmaceuticals widely used in human health care for controlling bacterial infections. ARGs and antibiotic residues are often emitted indirectly to the environment via wastewater treatment plants (WWTP). Therefore, WWTPs are a steady source of antibiotics and ARG pollution. Considering the substantial technological and economical hurdles of increasing the removal efficiency of these pollutants, it is of interest to evaluate upstream emissions within the wastewater collection system to help devise alternative reduction strategies. In the present study, sewage samples from the city of Nijmegen (The Netherlands) were collected between Sep'2019 and Sep'2020 at 10 locations representing a variety of urban settings, i.e. hospital, elderly home, student complex, city centre, industrial park, residential area, rainwater pit and WWTP. In total, 23 antibiotics, 5 ARGs and 1 mobile genetic element were quantified and analysed. Site-specific profiles of antibiotic selective pressure and ARG were generated. Preliminary results show that the aggregated selective potential of antibiotics in wastewater positively correlates with the prevalence of ARGs. Furthermore, the city hospital, student residence and residential area constitute the main contributors to antibiotic and ARG emission in the sewage catchment.

3.11.P-Tu158 Identification of Toxic Drivers in Water Using Effect-Directed Analysis

Sofia Lindblad¹, Johan Lundqvist², Karin Wiberg² and Lutz Ahrens², (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden, (2)Swedish University of Agricultural Sciences, Sweden

Anthropogenic organic micropollutants in the aquatic environment have shown to cause toxic effects (Rosenmai *et al.*, 2018; Lundqvist *et al.*, 2019) and has been recognized as an emerging cause for concern. Surface water contains complex mixtures of tens of thousands of organic micropollutants (Schwarzenbach *et al.*, 2006), challenging complete chemical characterization. There

is therefore a lack of knowledge on the toxic potential of organic micropollutants in water. One approach to identify organic micropollutants that drive toxicity is effect-directed analysis (EDA) (Brack, 2003). In EDA, fractionation of the sample is combined with bioassays and high resolution mass spectrometry (HRMS) analysis. Bioassays utilize cell based *in vitro* tests, which enables detection of the total bioactivity of an extract (Niss *et al.*, 2018), also taking unknown compounds and possible mixture effects into consideration. When the bioassay is conducted after fractionation of a water sample, identification efforts can be directed towards compounds that show bioactivity, and therefore are potentially toxic. The EDA approach thus saves both time and resources, and holds great promise for research as well as environmental monitoring. Unknown, toxic organic micropollutants in drinking water are of special concern. Since many drinking water contaminants are unknown or not well investigated, they are not covered by regulations and pose a potential threat to human health (Nilsen *et al.*, 2019). Studies have shown that only 0.1 % of the bioactivity observed in environmental water samples could be attributed to known, analyzed chemicals, for specific toxicity pathways (Neale *et al.*, 2017; Escher *et al.*, 2013). The unexplained bioactivity could either be attributed to unknown compounds or to mixture effects. By continuous improvement of analytical methods (Menger *et al.*, 2020; Gago-Ferrero *et al.*, 2018) more compounds – as well as mixture effects – can be identified, leading to a safer environment. In this project, a methodology will be developed and utilized, aiming to expand current knowledge on toxic drivers in water and mixture effects of organic micropollutants in the aquatic environment. Special focus will be directed at stormwater, wastewater treatment plants and landfills – which are important origins of pollutants in drinking water source areas (Rehrl *et al.*, 2020; Golovko *et al.*, 2021).

3.11.P-Tu159 The Relevance of the Fate of CECs in Sewers - Results From a Meta-Analysis on CEC Half-Lives in Wastewater and Sewers

Caterina Zillien¹, Leo Posthuma², Erwin Roex³ and Ad Ragas¹, (1)Radboud University, Nederland, (2)RIVM, Netherlands, (3)Dutch Ministry of Defense, Netherlands

Many chemicals of emerging concern (CECs) enter the environment via different pathways and put pressure on the quality of our resources - particularly water. While large amounts of empirical data on exposure and effects of CECs are currently being gathered, the immense number and variety of CECs used in society and industry calls for a more efficient and systematic approach to tackle this issue. Estimating the emission of CECs to the environment based on production and usage data requires modelling the chain of processes that take place between the production and use of a CEC and its release into the environment. Within this modelling chain, the fate of CECs in sewer systems is one aspect that has received relatively little attention leading to scarce and fragmented information on in-sewer fate of CECs. Therefore, we compiled information on sewer systems, in-sewer fate processes and existing modelling efforts. We concluded that biotransformation likely plays an important role in the fate of CECs upon passage through the sewer system. However, to model biotransformation we currently rely heavily on empirical half-life data. Consequently, we conducted a meta-analysis and collected half-lives (DT50s) of CECs in wastewater from various experimental set-ups including OECD 314A, bioreactor tests, pilot and field studies. The resulting dataset contains 277 DT50s associated with 96 unique compounds. 120 DT50s are shorter than 12 hours, and thus relevant for urban sewer catchments. The majority of entries (>83%) were reported for bioreactor tests, while only few entries were reported for pilot and field studies (10% and 7% respectively). Using the created dataset, we explored the relationships between DT50s and compound properties as well as between DT50s and experimental settings. Hereto, we performed correlation tests, principal component analysis and hierarchical clustering. However, except for some weak, yet significant, correlations between aerobic bioreactor DT50s and wastewater temperature ($R = 0.29, p < 0.05$), DT50s and area-to-volume ratio of biofilm ($-0.25, p < 0.05$), and geomean DT50 and $\log K_d$ ($R = -0.46, p < 0.05$), no meaningful patterns were found. With this poster presentation, we would like to present our data, methods and (partially inconclusive) results to open up a discussion on data quality, methodology and potential alternative approaches regarding both, experimental data as well as data analysis.

3.11.P-Tu160 Phosphorous in Wastewater: Speciation and Recovery With Polymer Inclusion Membranes

Enriqueta Antico, Alba Bosch, Victoria Salvado and Claudia Fontas, University of Girona, Spain

Phosphorus (P) is a natural element considered an essential nutrient for its importance in the growth of living organisms. P can be found in waters in different chemical species, inorganic or organic, and different phases (dissolved, colloidal and particulate). In the dissolved phase, orthophosphate and condensed phosphates are the predominant species. The presence of phosphate at high concentration cause eutrophication in surface water bodies, and consequently a severe reduction in water quality [1]. The influent of wastewater treatment plants may contain around 4-15 mg L⁻¹ total P, coming mainly from urban leachates and anaerobic digested sewage sludge. Run-off from agriculture and pasture, where phosphate fertilizers are used, can also contribute to P loadings. Therefore, to maintain water quality, the removal of P is an important priority. P determination is commonly carried out by spectrophotometric methods (molybdenum blue method, PO₄³⁻), ion chromatography (PO₄³⁻) or using atomic emission techniques (P total). The determination of P organic species or colloidal P requires the use of more specific techniques and expert personnel [2]. Moreover, the recovery of P from wastewater has a great interest from both the economical point of view and sustainability. In this work, we present polymer inclusion membranes (PIMs) for P speciation and recovery. PIMs are a type of functionalized membranes synthesized in the laboratory and composed by two main components: a polymer and a carrier [3]. The polymer constitutes the skeleton of the membrane and in this work we have used cellulose triacetate (CTA). The ionic liquid Aliquat 336 (trioctylmethylammonium chloride) acts as the carrier for the ion exchange of anionic P species. The PIM is placed between the source phase (wastewater containing P) and a receiving phase containing NaCl solution, where P species are preconcentrated for detection or recovery. We have evaluated the speciation capacity of the PIM system by measuring different

inorganic P species and organic soluble species like adenosine 5'-triphosphate (ATP) and adenosine 3:5'-cyclic monophosphate (AMP). P recovery has been achieved by using a PIM mounted in a cell (spiral-wound) where the two phases were recirculated. **Acknowledgements** This work has been supported by the Ministerio de Ciencia, Innovación y Universidades (MCIU) through project PID2019-107033GB-C22 / AEI / 10.13039/501100011033 **References** [1] Guignard et al. *Frontiers in Ecology and Evolution*, vol 5, 2017. [2] Worsfold et al. *Analytica Chimica Acta* 624 (2008) 37-58- [3] Almeida et al. *Journal of Membrane Science* 415–416 (2012) 9–23.

3.11.P-Tu161 Going Into Circles: A Combinatory Approach to Investigate the Risks of Micropollutants and Their Transformation Products in Water Reuse Systems

Jan Christof Specker¹, Antonia Praetorius², Nora Sutton³ and Annemarie van Wezel⁴, (1)Department of Freshwater and Marine Ecology, University of Amsterdam, Amsterdam, Netherlands, (2)University of Amsterdam/IBED Institute, Netherlands, (3)Wageningen University, Netherlands, (4)University of Amsterdam/IBED Institute, Amsterdam, Netherlands

To maintain water security, availability, and quality, alternative water sources (AWS) offer great potential to make future water systems more resilient. AWS include, for example, rainwater, greywater, surface water, cooling water, or treated wastewater. However, water reuse only offers a real possibility if the associated risks for human and environmental health are thoroughly understood. Concerns for water reuse may arise as AWS are potentially contaminated with micropollutants (MPs) and their transformation products (TPs). Especially wastewater contains a broad range of MPs and TPs that are insufficiently removed or generated during treatment processes. However, for water reuse, the current legislative risk assessment and existing guidelines are insufficient. A clear focus by these guidelines was put on microbial safety to lower the risks of water reuse. Moreover, the current risk assessment pays little attention to TPs. Additionally, the risks for most MPs and TPs are only insufficiently known and have yet to be critically examined and assessed. By a combination of high-resolution mass spectrometry (HRMS) and effect-based monitoring (EBM), it is aimed to evaluate the fate and toxicity of MPs and TPs in various water reuse schemes. Target, suspect, and non-target HRMS screening will facilitate a comprehensive investigation of the chemicals present in reused water. To determine which water reuse schemes pose environmental or human health risks, EBM can help to elucidate harmful water samples and account for chemical mixture effects. To assess the potential of water reuse, different AWS, and different reuse schemes, we will present a schematization of water reuse which allows the definition of fit-for-purpose quality parameters. The schematization is based on the AWS, the applied treatment techniques, either advanced or nature-based, the reuse purpose, and associated protection goals. We present different potential case studies in the Netherlands within this schematization. Potential case studies include, for example, intentional recharge of groundwater through the infiltration of surface water, advanced treatment of treated wastewater that is discharged into the IJsselmeer, an important source for drinking water production in the Netherlands, or reuse of water for irrigation of green infrastructure.

3.11.P-Tu162 A General Framework to Address the Impacts of Salinity Variations, Including Emission-Related Positive Effects

Alba Roibás-Rozas¹, Montserrat Nunez², Anuska Mosquera¹ and Almudena Hospido³, (1)Universidade de Santiago de Compostela, Spain, (2)IRTA, Spain, (3)CRETUS (Cross-Research in Environmental Technologies), Universidade de Santiago de Compostela, Spain

Salinity is changing in aquatic systems due to anthropogenic activities and climate change. These impacts can be even more uncertain in transitional waters. Although there are studies on the effects of salinity variations on individual species, little is known about the effects on overall ecosystems. The few works that do address this topic have considered these impacts using ecotoxicity models. But these models state that an increase in the concentration of a pollutant generates an increase in the impacts. However, the impact of salinity is also linked to concentration decreases. Moreover, salt is not a pollutant, but an essential element, so a critical improvement of these methodologies is necessary. Impacts linked to chemical releases are measured using the characterization factors (CFs). They consider the principal cause-effect chains – thus, fate and effect factors. CFs addressing impacts on ecosystem quality have units of potentially disappeared fraction of species (PDF)·m³·time/kg. The Fate Factor is expressed in units of time, and the Effect Factor is expressed as PDF·m³/kg. Here, the classic models used to define the effect factor are expanded to include effects linked to a decrease in the concentration of the substance, acknowledging the specific features of salinity. The proposed approach is based on the premise that the species in an ecosystem have an optimal range of salinity for living at which no impact occurs (i.e., PDF = 0), and that detrimental effects will be observed if it varies below or above it. Then, negative effects will occur if salinity increases above the optimal range or decreases below it. Moreover, positive impacts will occur for increments in the salt concentration for environmental concentrations below the optimal, and vice versa. Then, after defining the optimal salt concentration range, there are two EFs: EF_{LOW} and EF_{HIGH}, both in PDF·m³/kg. This research work addresses for the first time the potential effects on the environment derived from a decrease in the concentration of essential substances, where the effects of an emission can also generate positive impacts. Moreover, it is expected that the framework can also be applied to model environmental impacts of other essential substances in life cycle assessment, such as metals and macronutrients. According to the obtained results, salinity cannot be modelled using classic ecotoxic models (which address the issue considering salt as a pollutant). Therefore, the present study opens a new pathway to model how essential substances are modeled in the environment.

3.11.P-Tu163 Site-Specific Organic Contaminants Characterization of a Reclaimed WATER Irrigation System Through a High Resolution Mass Spectrometry-Based Non-Target Screening

Manuel Garcia Garcia-Vara¹, Cristina Postigo² and Miren López de Alda³, (1)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (2)IDAEA, CID-CSIC, Spain, (3)Institute of Environmental Assessment and Water Research

(IDAEA CSIC), Spain

The unbalanced use of water between territories due to an unsustainable agricultural system forces, in some regions, the irrigation of crops and/or aquifer recharge with reclaimed water. The European legislation in these cases demands an extra treatment of this water after conventional wastewater treatment prior to its use. Despite the treatment efforts, this irrigation system may lead to the accumulation of pollutants in soils and plants. In contrast to the current monitoring techniques that only cover a limited number of targeted organic contaminants, high-resolution mass spectrometry-based non-target screening (NTS) permits to characterize these waters on a more holistic way and, thus, identify the most relevant pollutants in each case based on their occurrence and ecotoxicity. The Baix Llobregat Agrarian Park is an agricultural area partially irrigated with reclaimed water. In this study, a prioritization of the most relevant site-specific organic contaminants was performed. For this purpose, samples were taken from the water regeneration plant and from different points of the irrigation channels, during summer and winter. To avoid the loss of compounds during pre-treatment, the samples were lyophilised, re-dissolved in ethyl acetate and methanol, centrifuged, concentrated under nitrogen, reconstituted in the initial chromatographic conditions and, finally, filtrated. Analyses were performed with liquid chromatography coupled to high-resolution mass spectrometry using a Q-Exactive Orbitrap (Thermo Scientific) system. Both data dependent and independent acquisition modes were used. Then, the post-processing of data was carried out with the NORMAN software *Digital Sample Freezing Platform* and a NTS workflow to identify features and categorize each identified compound into the different levels of confidence, using the results obtained then for identification of the site-specific priority contaminants and evaluation of the treatment plan performance. Acknowledges: This work was supported by the European Commission (Project MAGO, PRIMA number 2022), by the Spanish Ministry of Science and Innovation (Project CEX2018-000794-S), and by the Generalitat de Catalunya (2017 SGR 01404).

3.11.P-Tu164 Chemical and Biological Assessment of WATER Treatment Using Novel Led-Based UV Reactors

Ludek Blaha¹, Michal Bittner², Jutta Eggers³, Tim Schwarzenberger³, Kumiko Oguma⁴, Jaroslav Lev⁵ and Lucie Baborska⁵, (1)RECETOX, Masaryk University, Faculty of Science, Brno, Czech Republic, (2)Masaryk University, RECETOX, Czech Republic, (3)TZW: DVGW (German Water Centre), Germany, (4)University of Tokyo, Japan, (5)ASIO TECH s.r.o., Czech Republic

In the present research we investigate the applicability of highly innovative and sustainable technology (UV LED system) for chemical-free and efficient treatment of drinking water and wastewater. The efficiency and performance are compared also with other conventional treatments. The study focused on the assessment of installations of UV LED systems at end users in urban and rural areas in Japan (disinfection of community drinking water supply systems) and in the Czech Republic (final cleaning steps of urban waste waters). The samples of water were collected (and if relevant pre-concentrated using Solid Phase Extraction), and then assessed using a series of chemical and biological assays prior- and after-treatment. The endpoints included routine water quality parameters (such as turbidity, conductivity, N and P levels etc.), microbiological quality (total microbial activity, *E. coli*, *Pseudomonas* sp. etc), analyses of toxic metals (by ICP-MS), polar contaminants such as residual pharmaceuticals (15 analytes measured by LC-MSMS), bioassay for total estrogenicity (reporter gene assay) and ecotoxicological assays with algae, *Daphnia* and others. Preliminary data indicate that UV LED systems installed in the field are durable for extended periods of time and are efficient in removing of both microorganisms and trace pollutants. The unique direct comparisons with other treatment technologies are available thanks to parallel installations of both novel and standard approaches. [Acknowledgement – Supported by the EIG CONCERT-Japan programme via the international project “Innovative UV-LED applications to drinking water and wastewater treatment systems for sustainable water management in future communities (InLEDapp)” and by the Czech Ministry of Industry and Trade project No. CZ.01.1.02/0.0/0.0/19_262/0020109]

3.11.P-Tu165 Investigation of the Toxic Effects of Constituents in Textile Wastewater From WET Processing Using Effect-Based Methods

Nicole Jennifer Goede¹, Mira Große², Dhivakar Govindarajan³, Sarah Crawford², Viktoria Urban⁴, Sajid Hussain⁵, Indumathi Nambi⁶, Sabrina Schivy⁷ and Henner Hollert⁸, (1)Goethe University Frankfurt am Main, Germany, (2)Goethe University Frankfurt am Main, Germany, (3)IIT Madras, India, (4)IBACON GmbH, Germany, (5)Tamilnadu Water Investment (TWIC), India, (6)Indian Institute of Technology Madras, India, (7)Goethe University Frankfurt am Main, Frankfurt, Germany, (8)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany

Wastewater from the textile industry, especially wet processing, is one of the main factors for surface water pollution, especially in the central producing countries such as India. In India, the assessment of textile wastewater is currently limited to analysing physicochemical parameters such as pH, biochemical oxygen demand (BOD) and chemical oxygen demand (COD). However, the effects of chemical mixtures resulting from the complexity of textile effluents cannot be detected in conventional toxicity assessments but can lead to adverse effects such as acute toxicity, mutagenicity, and endocrine activity in organisms. In addition, the textile wastewater from India often shows high salinity, which leads to salinization of freshwater. If untreated or incompletely treated wastewater enters the environment, it can have serious consequences for the aquatic organisms and the ecosystem. Therefore, further test systems are needed to properly assess the complex mixture of components contained in textile effluents. In this context, effect-based methods (EBMs) are useful to detect the mode of action of chemicals. For this reason, one of the “EfectroH2O” project's goals is to establish EBMs in the form of a test battery that meets the specific requirements for the comprehensive analysis of textile wastewater (e.g., high salinity and complex chemical mixture). Samples of the dyes and the composition and concentration of salts in the wastewater were obtained from the textile industry MS/Rohini, Erode in Tamil Nadu in India. The acute toxicity of known components, including the salt concentration recorded at the textile dyeing plant MS Rohini, was investigated using established model organisms of different trophic levels. Among others, the bioassay battery included the fish embryo acute toxicity test (FET DIN EN ISO 15088) with the established freshwater model organism *Danio rerio* to

determine the acute sublethal toxicity of the salts in mixtures and singly. Additionally, *Daphnia magna* were used in the acute immobilization test (DIN 38 412 EN / ISO 6341) in combination with the algae growth inhibition test (DIN EN ISO 8692:2012). The project aims to reduce the toxicological impact on the environment by improving industrial process water treatment and additionally reducing water consumption in water-scarce regions such as India.

3.11.P-Tu166 Effect-Based Methods As Tool to Assess the Toxicity of Textile Wastewater

Mira Goßen¹, Nicole Jennifer Goede², Dhivakar Govindarajan³, Sarah Crawford⁴, Viktoria Urban⁵, Sajid Hussain⁶, Indumathi Nambi⁷, Sabrina Schivy⁸ and Henner Hollert⁹, (1)Department for Evolutionary Ecology and Environmental Toxicology, Goethe University, Germany, (2)Goethe University Frankfurt am Main, Germany, (3)IIT Madras, India, (4)Goethe University Frankfurt am Main, Germany, (5)IBACON GmbH, Germany, (6)Tamilnadu Water Investment (TWIC), India, (7)Indian Institute of Technology Madras, India, (8)Goethe University Frankfurt am Main, Frankfurt, Germany, (9)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany

During wet processing in textile production, which includes the dyeing of textiles, thousands of chemicals are applied, some of which are highly toxic. Alone the used dyes contain several toxic and stable compounds. If these get into the water system, for example due to the discharge of untreated or inadequately treated wastewater into rivers, this has serious implications for human and environmental health, as can currently be observed in major producing countries such as India. However, the impacts of industrial wastewater on organisms and the environment are difficult to assess because of the complex composition and mixture of chemicals present. The interactions of chemicals can lead to the formation of degradation products, resulting in more toxic compounds than the parent compound. Chemical analysis cannot fully detect the complexity of substances, which making it difficult to identify the drivers of toxicity. In addition, the high salt concentration in textile wastewater can lead to salinization of rivers, which can have an additional negative impact on the inhabiting freshwater organisms. A realistic risk assessment requires the use of holistic and impact-oriented methods. Therefore, within the German- India project, 'efectroH₂O', the adaption of effect-based methods to address the complexity of textile wastewater are investigated. Within the project two main approaches were followed. The first approach aims at the challenge of identifying suitable bioassays that can be used specifically for highly saline industrial wastewater. For this purpose, the species sensitivity of different model organisms was determined by exposing them to a specific salt composition. The composition of the salts is based on the original data of a dye factory in India (Ms/Rohini, Tamil Nadu). Within the second approach, wastewater samples from this dye factory were taken and fractionated by solid phase extraction so that the organic pollutants could be investigated without the influence of the salts using standardized bioassays. The acute toxicity on different trophic levels (algae, daphnia, fish) and specific endpoints like mutagenic, neurotoxic, or endocrine potential are investigated. In addition to the ecotoxicological investigation, chemical analyses of the wastewater sample was performed. By combining effect-based methods and chemical analysis, toxic drivers in textile wastewater can be detected and regulated.

3.12 Organic micropollutants in urban waters - occurrence, transformation, and treatment (Part I)

3.12.T-01 Predicted No-Effect Concentration (PNEC) - Based Design for Removal of Pharmaceuticals in Wastewater Treatment Plant

Vaidotas Kisielius¹, Suman Khare², Jørgen Skaarup³ and Kai Bester⁴, (1)Environmental Science, Aarhus Universitet, Denmark, (2)Aarhus Universitet, Denmark, (3)Hillerød Forsyning, Denmark, (4)Environmental Science, Aarhus University, Denmark

In Denmark there are no regulatory demands for municipal WWTPs to remove pharmaceuticals. However, the polluter (e.g., an industrial unit) carries the environmentally related responsibility. A local hospital in northern Zealand (Hillerød), which will be replaced by a big regional hospital in 2025, discharges wastewater to a nearby WWTP (HCR Syd). The WWTP discharges the cleaned effluent to an environmentally vulnerable freshwater system, leading to strict effluent requirements. Moreover, the dilution factor of the effluent in the receiving water body is nearly zero. As a result, the utility is negotiating to take over the responsibility and is discussing design and target values with the local authority to reach the concentrations of active pharmaceutical ingredients (API) in the effluent down to the values of predicted no-effect concentration (PNEC). Based on recommendations from "Clear Waters from Pharmaceuticals" (CWPharma) guideline for advanced API removal "GoA3.4: Optimization and control of advanced treatment" (2020), pilot processes in the WWTP were tested treating the effluent with ozonation and granular activated carbon (GAC). Three treatment variations were applied: i) different ozone dosages, ii) GAC filtration, and iii) ozonation followed by the GAC filtration. Over 50 PNEC-referenced medicine-related compounds were measured with an LC-MS/MS, compared with the baseline effluent concentrations and with the latest PNEC values. Though GAC is spontaneously able to achieve all targets, extended use resulted in exceedance of some target values (e.g., for clarithromycin, venlafaxine. Ozonation effectively reduced most of the compounds but did not reach certain target values (e.g., for bicalutamide, oxazepam) even with 1 mg-O₃/mg-DOC. Besides, it alone can lead to formation and discharge of unfavorable by-products. The combination of both technologies reached effluent concentrations complying to all target values. However, in this project we also argue that PNEC values for certain compounds are set, lacking reliable toxicity data and comprise huge uncertainties. Adoption of more precise national or case-specific API targets would assist technology assimilation and benefit the environment. However, the ozone GAC combination seems to achieve all required removal for the target compounds.

3.12.T-02 Sartans and Sartan Metabolisation in Wastewater Treatment

Rui Li¹, Chuanzhou Liang¹ and Kai Bester², (1)Aarhus Universitet, Denmark, (2)Environmental Science, Aarhus University, Denmark

Sartans such as Losartan, Valsartan, Irbesartan are angiotensin II receptor blockers (blood pressure regulators). As they have become quite popular, their concentrations in wastewater are considerable (10 ng/L-2 µg/L). In this contribution we describe for the first time removal and metabolisation in a full scale activated sludge wastewater treatment plant in comparison to metabolisation in a biofilm reactor. The situation in the activated sludge plant is somewhat complex as several metabolites also originate from human metabolism meaning they were present in the raw wastewater. However, removal of Losartan, Valsartan and Irbesartan in the CAS WWTP were around 90, 90, and 40% respectively. 14 transformation products were characterized by high resolution mass spectrometry and structural formulas are verified by true standards or suggested based on product ion spectra analysed with high resolution mass spectrometry from samples originating from experiments in the biofilm reactor. The respective metabolites are also found in the activated sludge treatment plant, especially Losartan acid, Losartan carboxylic acid and Losartan TP453. Other metabolites Losartan TP 335, and Irbesartan TP447 stem to a high extend from human metabolism and are rather removed 40 and 90%, respectively than formed in the CAS-WWTP.

3.12.T-03 Use of Wood Pellets and Cork in Biofilters for the Simultaneous Removal of Nitrates and Pesticides From Groundwater

Monica Escola Casas¹, Miriam Guivernau², Marc Viñas², Belén Fernández², Carme Biel² and Víctor Matamoros³, (1)Environmental Chemistry, Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Barcelona, Spain, (2)Institute of Agrifood Research and Technology - IRTA, Spain, (3)Institute for Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain

About 13 and 7% of groundwater in Europe exceeds, respectively, the permitted levels of nitrates (50 mg NO₃⁻ L⁻¹) or pesticides (0.1 µg L⁻¹). Rapid Sand Filtration can remove nitrates via denitrification when oxygen is limited. For this process, microorganisms require organic carbon as an electron donor, which can be added by using natural and synthetic biopolymers in the Rapid Sand Filtration packing-material. Thus, we assessed the usage of wood pellets and cork as packing materials under water-saturated and -unsaturated conditions for the attenuation of nitrates and pesticides from groundwater. Biofilters were fed with groundwater spiked with nitrate (200 mg L⁻¹) and pesticides (5 µg L⁻¹) at an HLR of 95 mm d⁻¹. Nitrate, pesticides (atrazine, bromacil, diuron, and mecoprop) and their transformation products were monitored for >400 days. Microbial composition of the biofilter material was also characterized. In cork biofilters, nitrate attenuation decreased with time, reaching almost no attenuation. This indicates that organic-carbon release ceased, hindering denitrification. In the saturated wood-pellet biofilter, denitrification increased over time, reaching 99% removal. This could be due to the continuous release of organic matter from wood pellets and to the adaptation of microbial communities. Regarding pesticides, >99% of mecoprop was removed in all configurations but transformation products were detected in all biofilters except for the unsaturated wood-pellet one. Diuron degradation was >75% in all biofilters and no transformation products were seen. Atrazine was better removed in wood-pellet biofilters (68-96%) than in cork biofilters (31-38%). However, both unsaturated biofilters (cork and wood pellet) produced dealkylated atrazine. Finally, less than 20% of bromacil was removed in all biofilters but the unsaturated cork biofilter, which achieved >60% attenuation. Still, there, we measured a high intensity of a transformation product corresponding to bromacil oxidation, which questioned the applicability this configuration to remove bromacil. Microbial characterization suggests that higher diversity is linked to material composition and thus better biofilter performance. Both wood-pellet biofilters had a high relative abundance of Basidiomycota, which comprise white-rot fungi, known degraders of chlorinated compounds. Therefore, the use of wood pellet as a biofiltration material is effective to treat nitrates and pesticides from groundwater.

3.12.T-04 Removal of Urban Stormwater Runoff Organic Contaminants by Cost-Effective Reactive Media

Marc Teixido¹, Francesc Labad Roig², Laura Scheiber³, Sandra Perez⁴ and Enric Vázquez⁵, (1)Spanish National Research Council (CSIC), Barcelona, Spain, (2)CSIC - Spanish National Research Council, Spain, (3)IDAEA-CISC, Spain, (4)IDAEA-CSIC, Spain, (5)Institute of Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain

Growing populations, urbanization sprawl, and climate change poses a challenge on traditional cities' drinking water supplies. Stormwater harvesting schemes could replenish over-drafted groundwater resources, augmenting urban water supplies. However, urban stormwater runoff carries a myriad of dissolved contaminants (e.g., organics, metals, nutrients), which impair receiving water bodies. Moreover, some organic contaminants of urban origin —particularly persistent, mobile, and toxic substances (PMTs), like pesticides, plasticizers, flame retardants, etc.— may not be adequately removed by conventional infiltration treatments (e.g., blue-green infrastructures). Therefore, it is of the utmost importance to fully understand their fate, transport, and effect, while designing novel or upgrading conventional treatment systems. Pyrogenic carbonaceous materials (e.g., biochar) can adsorb trace organic and metal contaminants. Some manganese oxide-coated sands oxidize electron-rich organic contaminants and adsorb metals during stormwater infiltration. Thus, reconfigured green infrastructure systems with engineered media could provide means of contaminant removal by sorption and redox processes. To enhance the treatment performance of conventional media, herein we propose sustainable, low-cost and low-energy reactive geomedia (biochar and synthesized manganese oxide-coated sand). We have conducted preliminary laboratory-scale batch experiments to investigate their removal capacities. Our results showed that biochar displayed faster sorption kinetics and capacity compared to the other studied materials (manganese oxide-coated sand or conventional sand). Regarding our suite of PMT organic contaminants, the studied biochar exhibited non-linear pseudo first-order adsorption behavior, with sorption rate values (i.e., k_1) ranging from 0.860 to 3.983 h⁻¹, and showed adsorbed amounts (i.e., q_e) ranging from 0.015 to 0.021 mg PMT/g adsorbent. Most of the contaminant removal occurred within the first 24 h and equilibrium was attained within 48 h. Bisphenol A, which is not considered persistent, was the only compound removed (via oxidation process) by manganese oxide-coated sand due to its electron-donating moieties. Sand, commonly used in infiltration schemes, showed no reactivity, highlighting the need to study alternative materials to separate persistent, mobile, and toxic organic contaminants from stormwater runoff.

3.12 Organic micropollutants in urban waters - occurrence, transformation, and treatment (Part II)

3.12.T-06 Mass Balance of Diethyltoluamide (DEET) in the Aquatic Environment

Michael Patrick¹, Ann-Kathrin Stalder², Nick Spitzhofer², Heinz Singer³ and Michael Burkhardt², (1)UMTEC, Eastern Switzerland University of Applied Sciences (OST), Rapperswil-Jona, Switzerland, (2)Eastern Switzerland University of Applied Sciences (OST), Switzerland, (3)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland

The biocide diethyltoluamide (DEET) is used worldwide as an insect repellent on human and animal skin. It is among the most frequently detected organic chemicals in wastewater, surface waters, and groundwater. The ubiquitous detection of DEET in Swiss waters, even during winter months, despite its apparent seasonal use as an insect repellent, has led to question the sources and fate of DEET in the environment and the validity of previous risk assessments for Switzerland. This study summarizes the occurrence, fate and emission dynamic of DEET in Swiss aquatic systems and attempts to clarify its sources to the Swiss aquatic environment. Environmental monitoring data are compared to newly obtained production and consumption data from the DEET Swiss supply chain, providing a first mass balance of DEET for Switzerland. The analysis of Swiss monitoring data suggests an annual Swiss consumption of 2 tons of DEET, which is consistent with the estimate of 2 to 12 tons derived from production data provided by manufacturers, distributors and formulators. These results indicate that, from a mass balance perspective, the widespread detection of DEET in Swiss waters can be corroborated by its consumption as an insect repellent alone. Based on these results, the established risk assessment methodology of the European Union and Switzerland under the Biocidal Products Regulation, the Emission Scenario Documents (ESD), were evaluated for DEET. It is shown that the ESD significantly overestimate the release and occurrence of DEET in Swiss surface waters and therefore provide a worst-case scenario that is consistent with the precautionary principle. In summary, this study provides a characterization of DEET occurrence in Swiss waters as well as its consumption to extrapolate a first indicative mass balance for Switzerland and compare this to established models for environmental risk assessment. This approach could be exemplary for other biocidal products whose emissions and occurrence are not well understood and which are characterized by higher ecotoxicity than DEET.

3.12.T-07 Wastewater of Formulating Pharmaceutical Industries As a Source for Peak Concentrations of Active Pharmaceutical Ingredients in Municipal Sewage Treatment PLANTS

Julian Bosshard¹, Anne Dax¹, Rebekka Gulde¹ and Heinz Singer¹, (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland

Pharmaceuticals in water bodies are of increasing concern due to their potential risk for aquatic organisms. A major source of emissions to surface waters are domestic wastewater treatment plants (WWTP) which also receive discharges from industries such as pharmaceutical production plants. Recent research indicates that these emissions significantly contribute to the load of active pharmaceutical ingredients in WWTP effluents and can cause short-term peak concentrations. However, knowledge on these emissions is scarce, especially for formulating pharmaceutical industries (FPIs). Therefore, this study aims to investigate a representative set of 8 WWTPs with inputs from FPIs throughout Switzerland. Since emissions from production sites are highly intermittent and enter the WWTPs as a pulse, sampling with high temporal resolution is crucial. To study the concentration dynamics, the MS2Field was deployed at the effluent of a WWTP. The MS2Field is a transportable trailer with a fully automated LC-HRMS platform, which can autonomously measure datasets with high temporal resolution. Every 20 minutes, a sample is taken from a bypass stream, filtered and measured with an RPLC-ESI-Q-Exactive HF setup. Influent and effluent of the other sites were investigated with daily composite samples and measured in the lab with an RPLC-ESI-Explorer240 setup. The high temporal resolution of the MS2Field gave unique insights into concentration dynamics of pharmaceuticals in a WWTP effluent, allowed to accurately capture maximum effluent concentrations and link concentration peaks to specific cleaning events at the production site. 11 out of 14 processed pharmaceuticals showed peak concentrations that were caused by industrial input with effluent concentrations up to 6'000 ng/L. For the other sites, industrial emissions were detected with maximum effluent concentrations up to 1'100, 460'000 and 79'000 ng/L. Although the amount of industrial wastewater is small compared to discharges from households and the loss rate from production low, emissions still make up a substantial fraction of the pharmaceutical load. Additionally, peak concentrations in the effluent can be relevant for risk assessment considerations in the receiving water. The generated knowledge aims to identify factors in the production and wastewater management that influence the amount of emissions from FPIs and hence help authorities and companies to take efficient and cost-effective measures.

3.12.T-08 Mixture Effects of Organic Contaminants in Stormwater Runoff and a Receiving Stream

Stephanie Spahr¹, Beate Escher², Michelle Engelhardt³, Andrea Gaertner⁴, Maria Koenig⁵, Martin Krauss⁶, Yuyuan Liu³, Yue Meng⁷, Rita Schlichting⁵, Christiane Zarfl⁸ and Clarissa Glaser⁹, (1)Ecohydrology and Biogeochemistry, Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin, Germany, (2)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (3)Eberhard Karls University of Tübingen, Germany, (4)Helmholtz Center for Environmental Research (UFZ) Leipzig, Leipzig, Germany, (5)Helmholtz Centre for Environmental Research - UFZ, Germany, (6)Helmholtz centre for environmental research - UFZ, Germany, (7)Helmholtz Center for Environmental Research - UFZ, Germany, (8)University of Tuebingen, Tuebingen, Germany, (9)Center for Applied Geosciences, Germany

Heavy rainfalls can lead to severe flood events and environmental degradation due to discharge of contaminated stormwater runoff into surface waters. Numerous organic chemicals are used in agriculture and urban areas including pesticides, biocides, flame retardants, and corrosion inhibitors. Many of these compounds have been detected in stormwater but the assessment of runoff quality remains challenging due to highly variable stormwater composition over time and space, the vast number of often unidentified chemicals, and unknown effects of chemical mixtures. In our study, we complemented chemical analyses with cell-based *in vitro* high-throughput bioassays to shed light on (i) sources of dissolved and particle-associated organic contaminants and

their mixture toxicity in stormwater runoff, and (ii) temporal dynamics of the chemical mixtures and toxicity in a receiving stream over the course of consecutive storm events. In June 2021, we captured three storm events in the Ammer catchment (close to Tübingen, Germany) during which we collected grab samples from potential pollution sources and time-proportional composite samples from the receiving stream (the Ammer River). We screened all samples for more than 600 organic contaminants using high resolution mass spectrometry, and performed *in vitro* bioassays to assess mixture effects (cytotoxicity; activation of the estrogen and aryl hydrocarbon receptors, oxidative stress response, and algal toxicity). While during dry weather the mixture toxicity in the Ammer River was dominated by wastewater treatment plant effluent, we identified additional rain-driven input pathways of bioactive organic contaminants into the river including runoff from industrial sites and residential areas, overflows of combined sewer basins, as well as agricultural tributaries. During consecutive storm events, the chemical mixture effects in the Ammer River followed the discharge peaks indicating that storms can repeatedly mobilize bioactive compounds from surfaces leading to a significant input of both particle-associated and dissolved organic contaminants into rivers. Iceberg modeling of stormwater mixture toxicity revealed that only a small fraction of the observed effects in bioassays can be explained by the quantified chemicals highlighting the need to improve stormwater monitoring and management strategies to reduce diffuse pollution of surface waters.

3.12.T-09 Identifying Bioactive Antimicrobials and Glucocorticoids in Effluent With Effect-Directed Analysis

Tim Jonkers¹, Corine Houtman², Timo Hamers³ and Marja Lamoree⁴, (1)VU University, Netherlands, (2)The Water Laboratory, Netherlands, (3)VU University Amsterdam, Institute for Environmental Studies (IVM), Netherlands, (4)VU University, Department Environment & Health, Netherlands

Antibiotics and synthetic glucocorticoids are both pharmaceuticals that are used to treat patients that suffer from inflammation. Antibiotics are prescribed to treat bacterial infections, whereas glucocorticoids are prescribed for their pain-relieving effects resulting from inflammatory disorders. The prescription rate of these drugs is high and leads to the detection of these compounds in the aquatic environment as they are not fully removed from wastewater. Once in the environment, these compounds may adversely affect environmental and human health. In this study, we aimed to identify bioactive antibiotics and glucocorticoids – including bioactive metabolites and transformation products – in wastewater effluent from a selected group of six Dutch wastewater treatment plants by applying Effect-Directed Analysis (EDA). An antibiotics bacterial cell-based assay and the GR-CALUX bioassay were used to identify biological activity in fractionated and unfractionated sample extracts. In this EDA approach, suspect and nontarget screening techniques were applied to features related to bioactive fractions. The unfractionated extracts that were tested in the antibiotics assay showed comparable IC50 values among samples: the highest and lowest IC50 value differed a factor of 2.4 (enrichment factors of approximately 9 - 22). The activity of unfractionated extracts in the GR-CALUX assay differed by a maximum factor of 2.9 (approximately 100 – 290 ng dexamethasone equivalents/L). The response in the fractionated extracts was also comparable among samples for both assays. The antibiotics bioassay chromatogram contained three regions with bioactive fractions for five out of six samples. On average, 4 out of 80 fractions were identified as bioactive. The GR-CALUX assay identified two bioactive regions in all extracts; on average 6 out of 80 fractions were bioactive. In the presentation, we will demonstrate the annotation of features related to bioactive fractions and the assignment of identification confidence levels.

3.12.T-10 Moderated Discussion-3.12

3.12 Organic micropollutants in urban waters - occurrence, transformation, and treatment (Virtual Only)

3.12.V-01 Adsorption of Selected Polycyclic Aromatic Hydrocarbons From Contaminated Water Using Regenerable Graphene Wool

Adedapo Adeola¹ and Patricia Forbes², (1)Department of Chemistry,, Unversity of Pretoria, Pretoria, South Africa, (2)University of Pretoria, South Africa

Polycyclic aromatic hydrocarbons are ubiquitous and carcinogenic micropollutants detected in water bodies and poses threat to human health and the environment. In this research, a novel graphene wool (GW) was used as an adsorbent material for the removal of phenanthrene (PHEN) and pyrene (PYR) in aqueous solution. Adsorption kinetics, adsorption isotherms, thermodynamics of adsorption and effect of pH, ionic strength, and temperature on the adsorption of PHEN and PYR onto GW from aqueous solution were investigated comprehensively. All isotherms and kinetic experimental data were fit to Langmuir, Freundlich, Temkin, Sips and Dubinin-Radushkevish (D-R) models, and pseudo-first-order and pseudo-second-order kinetic models. The adsorption kinetic data best fit the pseudo-second-order kinetic model for PHEN and PYR sorption with R^2 value >0.999 , and adsorption increased up to 24 h. The isotherm models which best represent the data obtained were the Sips model for PHEN and PYR. The Freundlich isotherm model was found to fit experimental data better than the Langmuir model, suggesting multilayer adsorption and pore-filling mechanism would best describe GW-PHEN and GW-PYR interactions. The maximum adsorption capacity of GW for PHEN and PYR was 5 and 20 mg g⁻¹ and removal efficiency was 99.9% and 99.1% respectively. The high adsorption capacity and regenerability/reusability of GW make it a very attractive material for the removal of hydrophobic organic micro-pollutants in water.

3.12.V-02 An Update on Estrogenic Compounds in the WATER of the Douro River Estuary (Portugal)

Maria Rocha, Frederico Silva and Prof. Eduardo Rocha, ICBAS and CIIMAR, University of Porto, Portugal, Portugal

The quantity and distribution of seventeen endocrine disruptor chemicals (EDCs), including oestrogens, phytoestrogens, sitosterol, and banned industrial pollutants, were examined in ten locations in the Douro River estuary. Surface water samples were obtained

in 2019. The waters were filtered and subjected to solid-phase extraction (SPE) to extract and pre-concentrate (4,000-fold) the EDCs after an examination of the physicochemical data (ammonia, nitrates, nitrites, and phosphates, for example). Before being analyzed using gas chromatography-mass spectrometry, the extracts were derivatized with BSTFA and 1% TMS (GC-MS). All of the EDCs studied have a high detection rate (on average 97%), indicating that they are common in this estuary. The presence of significant physiologic levels of oestrogens (up to 9 ng/L for estradiol, E2), phytoestrogens (up to 830 ng/L for biochanin A, BIO-A), and industrial pollutants (up to 3 g/L for nonylphenol di-ethoxylated, NP2EO) in nearby aquatic species implies an endocrine disruption risk. The global concentration of E2-equivalents (E2-EQs) at this site is 25 ng/L, with a hazard quotient (HQ) of 55, suggesting a high risk of local biota harm. Furthermore, the physicochemical data indicate that direct sewage flows, most likely from tourist boats, might cause injury. Finally, aside from their impacts on fauna, the presence of all studied components may have an impact on human health if they come into direct (fluvial beaches) or indirect (food) contact with the tested chemicals. Funding: Project ATLANTIDA (NORTE-01-0145-FEDER-000040), by NORTE 2020, under PORTUGAL 2020, through ERDF); FCT and ERDF UIDB/04423/2020 and UIDP/04423/2020; and ICBAS.

3.12.V-03 Carbon-Covered Alumina Supported ZnO Nanocatalysts With Enhanced Visible-Light Photocatalytic Performance for the Removal of Azo Dyes

Folawewo Abayomi¹ and Muhammad Bala², (1)UKZN, Westville, South Africa, (2)University of KwaZuluNatal Westville Durban South Africa, South Africa

In this study, economical and green catalysts were prepared as a positive step in the direct use of solar light for the degradation of wastewater polluted with industrial dyes. Hence, zinc oxide (ZnO) nanocatalysts were prepared by the sol-gel method using zinc acetate as the precursor and successfully embedded on carbon-covered alumina (CCA) supports. The catalysts were characterized by a variety of techniques that include XRD, HR-TEM, EIS and BET. All the new CCA-implanted catalysts were crystalline with high surface areas. The photocatalytic activities of all the catalysts were fully studied using tartrazine and sunset yellow azo dyes as model pollutants. In addition, full kinetics and mechanistic details are presented and analyzed.

3.12.V-04 Occurrences and Ecological Risks of Tamiflu Metabolites in Treated Wastewater in Taiwan

Wei-Yu Chen¹ and Bo-Yu Lin², (1)National University of Tainan, Tainan, Taiwan, (2)Kaohsiung Medical University, Taiwan
Humans highly use antiviral drugs Tamiflu during the flu season. The excreted active Tamiflu metabolites pass through wastewater treatment then discharge into rivers, which has sparked environmental concern potential ecological risks. This study aims to assess ecological risks posed by Tamiflu metabolites, oseltamivir ethylester (OE), and oseltamivir carboxylate (OC) of treated water in wastewater treatment plants (WWTPs) in Kaohsiung, Taiwan. We collected wastewater from primary and tertiary WWTPs during the flu season to detect the presence concentration of Tamiflu metabolites throughout the processing system of wastewater treatment and determine the removal efficiency. There is 100% OC detection in the tertiary WWTP, whereas only one-third of the influent and effluent samples can be detected OC in the primary WWTP. Major metabolite product OE was detected in all process systems in both WWTPs. Both WWTPs have low removal efficiency for Tamiflu metabolites, especially for OE. Surprisingly, the performance of tertiary WWTP is not significantly better than primary WWTP for removing Tamiflu metabolites. There are no ecological risk concerns to Tamiflu metabolites through treated water and rivers, even though highly frequency detection in OC and low removal efficiency.

3.12 Organic micropollutants in urban waters - occurrence, transformation, and treatment (Poster)

3.12.P-Th082 Stable Isotope Labelling With Heavy Ozone for Detection of Ozonation By-Products in Effluent Organic Matter

Elaine Jennings¹, Millary Sierra Oleda², Uwe Hübner³, Thorsten Reemtsma⁴ and Oliver Lechtenfeld⁵, (1)Analytical Chemistry, Helmholtz Center for Environmental Research (UFZ) Leipzig, Leipzig, Germany, (2)Technical University Munich, Germany, (3)Technical University of Munich, Germany, (4)Helmholtz Centre for Environmental Research, Germany, (5)Helmholtz Centre for Environmental Research – UFZ, Germany

Introduction Ozonation is a chemical oxidation method for the treatment of wastewater to enhance removal of contaminants. While lots of research has been conducted regarding the transformation of organic micropollutants with ozone, effluent organic matter (EfOM) is not well studied in terms of ozonation by-products (OBPs). Since EfOM is a major consumer of ozone, it is critical we understand the OBPs produced from EfOM. Ultra-high resolution mass spectrometry like FT-ICR-MS is the primary method for non-target analysis of complex mixtures like EfOM, but OBP detection is still limited due to complexity. With stable isotopically labeled heavy oxygen, labeled ozone can now be generated and reacted with EfOM to produce isotopically labeled OBPs. This mass label can be used to unambiguously identify OBPs formed from EfOM as well as contaminants of concern. By examining the ratio of produced OBPs with 18-O and 16-O formulas, we can better understand the reactions producing these OBPs. Since the ratio between labeled and non-labeled oxygen in our ozone generator can be controlled, we can monitor the production rate of the 18/16-O OBPs produced. By using model compounds, we can leverage this conserved ratio to better understand the OBPs found in EfOM. **Methods** Extracted EfOM was ozonated with 18-O mass labeled ozone. The custom ozone generator uses recirculation of 18-O heavy oxygen to produce mass labeled ozone. After ozonation, EfOM was measured using FT-ICR-MS to detect OBPs. **Results** The ozone generator successfully created 18-O labeled OBPs based on model compounds used with known ozone reaction mechanisms. OBPs from venlafaxine and sulfamethoxazole were produced with this heavy ozone and the mass labeled products detected. Over 2,000 OBPs with mass labeled oxygen can be detected in 18-O ozonated EfOM. All of these formulas are in a series with increasing numbers of 18-O (up to 5) found in the molecular formula. About 1,700 unique series are detected, confirming that these formulas are indeed generated through ozonation. Based on the purity of 18-O in the

system, a ratio between the isotopically labeled OBPs and the non-labeled OBPs is consistent for model compounds. In our experiment with 40% heavy oxygen in the system, venlafaxine produced an 18/16-O ratio of 0.78 for the primary ozonation product (venlafaxine-n-oxide). This ratio can be used to better validate 18-O labeled OBPs found in EfOM.

3.12.P-Th083 Physico-Chemical Properties and Environmental Fate Predictions of Dienogest and Its Transformation Products

Cassandra Johannessen¹, Melanie Le² and J. Mark Parnis², (1)Chemistry, Trent University, Peterborough, ON, Canada, (2)Trent University, Canada

Dienogest is synthetic steroid hormone widely used for human contraception. As of such, dienogest is commonly detected in surface waters near wastewater treatment plants (WWTPs), which is of concern due to dienogest's potential as an endocrine disrupting chemical. Due to the tendency of dienogest to transform in the environment, the environmental behaviour of 27 previously identified transformation products of dienogest were also investigated in this study. Primarily, two different transformation processes are examined in detail: metabolism and phototransformation. As many of the physico-chemical properties of dienogest and its metabolites have not yet been experimentally characterized, COSMO-RS solvation theory was used to estimate the key fate-determining properties of these compounds. Specifically, we report here estimates of vapour pressure, melting point, solubility in water, various environmental partitioning ratios, and atmospheric degradation rate constants for hydroxyl removal. The environmental fate and persistence of dienogest and its transformation products were then estimated using fugacity-based modelling. Using the fugacity-based Equilibrium Criterion (EQC) model, the chemicals are shown to remain in water with minimal partitioning into sediment, soil, and air, if released to water. The results of the fugacity-based modelling were examined in detail with respect to the structural modifications that occur during the transformation processes. This study provides a preliminary overview of the environmental fate and persistence of dienogest and its transformation products which can be used to inform future risk assessments.

3.12.P-Th084 Evaluation of Cytogenotoxic Potential and Embryotoxicity of KrishnaRaja Sagara (KRS) Cauvery River Water in Zebrafish (*Danio rerio*)

Abass Toba Anifowoshe¹, Debasish Roy², Somit Dutta² and Upendra Nongthomba², (1)Molecular Reproduction Development and Genetics, Indian Institute of Science, Bangalore, India, (2) Indian Institute of Science, India

*Polluted water is a major concern in our daily lives. Humans indiscriminately dumped thousands of chemicals and waste materials into the water, most of which are unknown and lack adequate toxicity data. The Cauvery River (CR), an interstate river in South India, show the presence of *Cyclops*, *Daphnia*, *Spirogyra*, and/or *Spirochaeta* which are bioindicators of water pollution at the three study stations (fast-flowing water [X], slow-flowing water [Y], and stagnant water [Z]). Total coliform and *E. coli* which are indicators of sewage contaminants by animals or humans were also detected. All physicochemical parameters tested, including heavy metals, were within the limit acceptable by standard organizations except for DO, BOD, and COD, which indicate hypoxic water conditions. As a result, both water samples and zebrafish larvae had significantly less oxygen when tested using SEM/EDS. Furthermore, for the first time in any water sample analysis globally, we discovered the presence of microplastics (polybutene, polyisobutene, and polymethylpentene) and cyclohexyl in CR water samples using Raman spectroscopy. Acute treatment of zebrafish (*Danio rerio*) embryos with the water samples generated reactive oxygen species (ROS), which triggered subcellular organelle dysfunctions, skeletal deformities, pericardial edema, and increased mortality. How pathogens/microplastics enter the aquatic environment and human food chain is critical for future prevention.*Anifowoshe AT, Roy D, Dutta S, Nongthomba U. Evaluation of Cytogenotoxic potential and Embryotoxicity of KRS- Cauvery River Water in Zebrafish (*Danio rerio*). **Currently Under review in Ecotoxicology and Environmental Safety.**

3.12.P-Th085 Facing Urban Contamination: Detection and Quantification of Organic Contaminants in Urban Water From Barcelona City (Spain) Using Lc-Hrms/Ms Orbitrap

Francesc Labad Roig¹, Nicola Montemurro², Marc Teixido³, Laura Scheiber⁴, Rotman Criollo⁵, Enric Vázquez⁶ and Sandra Pérez⁷, (1)CSIC - Spanish National Research Council, Spain, (2)Environmental Chemistry, Jordi Girona 18-26, null, Barcelona, Spain, (3)Spanish National Research Council (CSIC), Barcelona, Spain, (4)IDAEA-CISC, Spain, (5)IDAEA-CSIC, Spain, (6)Institute of Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain, (7)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain

Recently, municipalities have started developing and implementing stormwater and watershed management plans monitoring stormwater pollutants such as pathogens, nutrients, total suspended solids, toxic metals, and organic contaminants, e.g., polychlorinated biphenyls, polycyclic aromatic hydrocarbons, and certain pesticides and plasticizers. Most of these monitoring programs target priority regulated compounds, but the majority of compounds and their transformation products remain to be discovered and lack rigorous toxicity information. Although large efforts have been made in the last two decades to identify novel contaminants and their TPs, taking advantages of innovative analytical methodologies for specific compounds classes, an unbiased non-targeted approach is considered a viable tool for comprehensive characterization for stormwater contaminants. Nevertheless, last advances in Analytical instrumentation have enabled their rapid, accurate detection and quantification. Under this context, High-Resolution Mass Spectrometry is considered the most promising instrumentation, even if analytical standards are not available, to close the knowledge gap. Several studies have reported their occurrence in different environmental compartments (surface and groundwaters), and they have potential to cause adverse effects on human and environmental health. Here, the recollected urban water was first filtered under vacuum at 0,7 µm employing glass fiber filters and next, 500 mL of water was extracted by means of a Solid-phase extraction using a home-made cartridge containing four different sorbents: Hydrophilic-Lipophilic Balanced, weak anion exchange, weak cation exchange and priority pollutants. Then, cartridges were

eluted with a mixture of ethyl acetate and methanol using 5% ammonia and 2% formic acid in independent steps. Finally, the elution mixture was evaporated under gentle N₂ and reconstituted. Results prove the presence of organic contaminants in urban groundwater however, the majority of them reveals a low concentration in the aquifers. It is worth to mention that compounds with a low Log P showed more frequency of detection and concentration than the non-polar compounds studied. It has been demonstrated that organic pollutants are present in urban water from Barcelona. Persistent polar compounds were the main detected as they are unable to accumulate in soil, hence bypassing natural barriers ending in aquifers.

3.12.P-Th086 In-Stream Monitoring of Combined Sewer Overflow Impact Using a Combination of Continuous Probes and Passive Samplers

Tom Galle¹, Viola Huck², Denis Pittois² and Michael Bayerle², (1)ERIN, Luxembourg Institute of Science and Technology, Esch sur Alzette, Luxembourg, (2)Luxembourg Institute of Science and Technology LIST, Luxembourg

Combined sewer overflows can impact surface waters with classical organic pollution leading to oxygen deficits or ammonia exceedances but do also carry important loads of biocides and untreated micropollutants. These impacts are rarely monitored in urban settings with multiple potential outlets. Planning of retention structures in combined sewer systems are often based on theoretical hydraulic calculations/simulation without any pollutant load validation. Their true efficiency is therefore often largely unknown. This project gained quantitative information on combined sewer overflows via continuous in-stream measurement with probes in longitudinal profiles. The probes were mounted in an urban stream with respect to expected inputs by sewer systems. Two main parameters were used to detect discharged overflow loads: ammonium via an ion selective electrode and oxygen via membrane fluorescence detection. Ammonium proved to be reliable and easier to interpret because of its slower decay in surface waters. Within the 3 km observed it was relatively stable and hence fit for quantification of loads while oxygen often hit zero in-stream levels and was also strongly influenced by reaeration at high flow. Nevertheless, it was useful in making qualitative interpretations of overflow sources and corresponding locations. The project also introduced passive samplers as complementary method to detect overflow discharges on the basis of pharmaceutical and biocide emissions. Passive samplers are successful in a certain range where dilution by very large flood waves is not too important, but concentration shifts are yet distinguishable from baseflow (given the shorter exposure to flood waves). All in all, the techniques showed promise to assess the impact of overflows on surface waters and the pinpointing of areas of discharge, although overflow structures were too numerous and too close-range to be differentiated within one observed segment. Combined immission measurements and sewer modelling might be an interesting approach to improve the techniques.

3.12.P-Th087 The Pathway of Quaternary Ammonium Biocides to Surface Waters - an Environmental Forensics Approach

Andrea Mongelli¹, Pedro Carvalho² and Kai Bester³, (1)Aarhus Universitet, Denmark, (2)Aarhus University, Denmark, (3)Environmental Science, Aarhus University, Denmark

Quaternary ammonium compounds (QUATs) are surface-active, antimicrobial, high production volume chemicals with a broad range of application from agriculture or industrial processes to consumer products, like fabrics softeners, cleaning agent, disinfectant, preservatives and personal care products. QUATs are salts of positively charged polyatomic ions of the structure NR₄⁺, R being as alkyl group or an aryl group. Differences in the alkyl part lead to differences in classes of compounds such as: alkyldimethylbenzyl ammonium chlorides (BACs) with C8-18 alkyl groups; didecyldimethylammonium chlorides (DDACs) with C8-20 alkyl groups; tetradodecyl-ammonium chlorides (TDACs); alkyltrimethyl ammonium chlorides (ATMACs) with C10-C22 alkyl groups. This contribution aims to identify the different sources and inputs of QUATs for Danish surface waters. For this purpose, we linked the QUAT concentrations in surface waters to input from WWTPs, using the concentration of benzotriazole as a marker of the wastewater fraction in the respective water body. Both, Quaternary Ammonium Biocides and benzotriazoles were quantified by means of HPLC-MS/MS with direct injections after carefully removing all internal contamination of QUATs from the instrument. Each geographical data point is represented by duplicate samples to enable identifying contamination issues. Concentrations of QUATs were remarkable especially for BAC 12, 14 and 16, which ranged from 10 ng/L to 20.000 ng/L. While different WWTPs clearly contributed to the concentrations of BAC 12, 14 and 16 and were in selected parts of the rivers the only or dominant source, the highest concentrations (up to 10.000 ng/L) in surface waters originated from other sources. One other source was only active under rainy weather, corresponding to the suspected source: surface water runoff (e.g., roof runoff, as roofs are frequently treated with benzalkonium chlorides in Denmark). Another source, giving high inputs, was active under dry weather and could not yet be contextualized.

3.12.P-Th088 Difference in Reaction Pathways of Tramadol and Venlafaxine N-Oxide in Pure Water and Effluent Wastewater During Ozonation

Suman Kharel¹, Peter Tentscher² and Kai Bester³, (1)Aarhus Universitet, Denmark, (2)Aalborg University, Denmark, (3)Environmental Science, Aarhus University, Denmark

Advanced treatment technologies such as ozonation, activated carbon, membrane bioreactor, etc. have shown promising results in removing organic micropollutants like pharmaceuticals from wastewater. Ozonation can reduce the load by reacting pharmaceuticals with ozone and hydroxyl radicals that are formed during the technical ozonation process. While removing compounds they often get transformed to other products. Tramadol and Venlafaxine N-oxide are primary ozonation products of Tramadol and Venlafaxine. However, they react further in the presence of excess ozone. This study aims to explore the difference in yield of transformation products of Tramadol and Venlafaxine N-oxide due to different ozone dosing approach and the effect of water matrix. Most mechanistic studies are conducted in pure water. However, in this study we show that both removal and reaction pathways are significantly different in pure water compared to effluent wastewater. This is including the fact that the

yield of transformation products resulting from direct reaction with ozone is lower in effluent wastewater than pure water. Conversely, the yield of transformation products resulting from reaction with OH radical is higher in effluent wastewater.

3.12.P-Th089 Germany-Wide Biocides Monitoring in Sewage Treatment Plants

Christiane Meier¹, Korinna Ziegler², Maren Ahting³, Antje Ullrich³, Frank Sacher⁴ and Stephan Fuchs⁵, (1)Biocides, German Environment Agency (UBA), Dessau-Roßlau, Germany, (2)German Environment Agency (Umweltbundesamt), Germany, (3)German Environment Agency (UBA), Germany, (4)TZW DVGW-Technologiezentrum Wasser, Germany, (5)Karlsruhe Institute of Technology (KIT), Germany

The impact of biocides on the environment has increased in recent decades due to their increased use. In individual studies, biocidal active substances have been detected in many environmental compartments. However, as an evaluation of the German Environment Agency (UBA) shows, there is currently no representative picture of the actual environmental pollution beyond individual findings in Germany. One reason for this, is the fact that no systematic environmental monitoring has been carried out in Germany to date in relation to biocides. Therefore, this waste water project was initiated, which systematically investigated prioritised biocidal substances and transformation products in the influent and effluent of sewage treatment plants (STP), primary and excess sludge, as well as stormwater discharges and combined sewer overflows (CSO) over a period of one year. A total of 26 biocides (disinfectants, material preservatives and pest control products) were analysed in effluents of 29 STPs distributed over the entire federal territory (three of them purely served by a separate sewer system). Additionally, influent and sludge of five STPs, the discharge of two stormwater clarifiers and the discharge of six CSO tanks were investigated. Finally, more than 450 samples were analysed for biocides, but also typical sewage parameters for checking the operating condition of the STPs. Most biocides investigated were detected in a large number of samples above the analytical limit of detection. Some substances also exceeded the environmental quality standard (EQS) or the predicted no effect concentration (PNEC) for surface water. With the project results, for the first time a reliable nationwide statement is possible for a larger number of biocides regarding emissions from STPs into surface waters. A further ongoing project focusses on CSO discharges for receiving more insights on the importance of this little investigated entry path.

3.12.P-Th090 Nontarget Analysis of Polluted Surface Waters: A Case Study in Bangladesh

Bénilde Bonnefille¹, Oskar Karlsson², Rubhana Raqib³, M. Faruque Parvez⁴, M. Sirajul Islam³ and Jonathan Martin², (1)ACES, Stockholm University, Sweden, (2)Stockholm University, Sweden, (3) International Centre for Diarrhoeal Disease Research, Bangladesh, (4)Columbia University Mailman School of Public Health, United States

In Bangladesh, the high density of population and industry, as well as intensity of agriculture practices, leads to major surface water contamination, including by organic micropollutants. Given that Bangladesh's population also depends on local fish as a staple dietary component, this contamination poses unknown risk to both human and environmental health, thus here we undertook a surface water monitoring survey with comprehensive analysis by nontarget mass spectrometry. Surface waters were sampled from 12 sites located on 4 different rivers around the capital city, Dhaka. Samples were spiked with internal standards and filtered before analysis by liquid chromatography high-resolution mass spectrometry in 4 modes: positive and negative electrospray (\pm ESI), and atmospheric pressure chemical ionization (\pm APCI). Among 39,030 total detected molecular features, there was relatively little redundancy between modes, and over 26,000 unique features were detected. Given that 51.9-77.5% of the features in each mode were unique, the combination of these 4 ionization modes is necessary to cover the relevant chemical space in polluted surface waters. In a principal component analysis, components PC1 and PC2 explained 54.8% and 6.4% of the overall data variability, respectively, and the scores plot revealed two groups of samples separated by geographical location on PC1, and an upstream-downstream distribution on PC2. This suggested strong chemical profile differences between highly urbanized and more remote sampling sites, and a pollution gradient along the flowpath of rivers moving towards the Bay of Bengal. A nontarget workflow using open science tools allowed us to confirm or annotate many anthropogenic contaminants, including pharmaceuticals (e.g. diclofenac), pesticides (e.g. diuron), and industrial chemicals (e.g. anionic surfactants). An example annotation that may be related to local textile industry was indigo dye (level 2a, [4]), which had a high MS² similarity score (796/1000) compared to the public MS² database available on MS-DIAL website (v2021/04/13, <http://prime.psc.riken.jp/comprms/msdial/main.html>). Most compounds identified had a spatial distribution with higher response intensity closer to Dhaka. Work is ongoing to identify contaminants at higher confidence levels, their likely sources, and bioaccumulation in fish sold at local markets

3.12.P-Th091 Evaluation of the Efficiency of a New Secondary Biological Treatment Based on Ultrafiltration Membranes in Galindo Wastewater Treatment Plant

Narora Lopez, Iker Alvarez, Dennis Bilbao, Leire Mijangos, Mireia Irazola-Duñabeitia, Maitane Olivares, Nestor Etxebarria, Ailette Prieto and Olatz Zuloaga, University of the Basque Country, Spain

Wastewater treatment plants (WWTPs) are one of the major secondary sources of contaminants of emerging concern (CECs) to the environment, since conventional treatments implemented are not efficient enough for their complete removal. The objective of the present work was the analysis of the efficiency of a new wastewater secondary treatment based on membrane bioreactors. In this sense, the application of a multiresidue analysis of up to 337 emerging and priority contaminants ($\log K_{ow} = -4.2-6.8$) including 50 semi-volatile organic compounds (SVOCs), as well as a suspect screening for "unknown" compounds identification in different types of effluents, were the strategies implemented. Composite samples (24 h) of three WWTP effluents (one primary and two different secondary treatments, a conventional Biological Mix and another using ultrafiltration membranes) were taken during 9 weeks (February-May 2021) from Galindo WWTP located in Sestao, Biscay, Spain. Samples were preconcentrated by means of solid phase extraction (SPE) protocol using in-house prepared triphasic cartridges (Strata HR-X:ZT-WAX:ZT-WCX,

3:1:1). Cartridges elution was performed with two MeOH:EtOAc (1:1, v:v) solutions, the first containing 2% ammonia (v/v), and the other 1.7% (v/v) formic acid in the case of more polar compounds, whereas SVOCs were eluted with 12 mL of hexane:toluene (4:1, v:v). The detection of the contaminants was carried out by means of an ultrahigh performance liquid chromatograph coupled to a high resolution mass spectrometer q-Orbitrap (UHPLC-qOrbitrap) (Thermo Scientific Dionex UltiMate 3000 UHPLC coupled to a Thermo Scientific™ Q Exactive™ Focus quadrupole-Orbitrap mass spectrometer, Thermo, CA, USA) and gas chromatograph coupled to a quadrupole mass spectrometer (GC-MS) (Agilent 6890 gas chromatograph coupled to an Agilent 5975 mass spectrometer system, Agilent Technologies, Palo Alto, USA). For the suspect analysis the NORMAN database including more than 40000 compounds (www.norman-network.net) was used as suspect list as well as applying the constraint of being included in mzCloud database (www.mzcloud.org). It is necessary to emphasize that the application of a biological treatment with an ultrafiltration membrane seems do not improve the expectations of this type of WWTP treatments compared with the current conventional biological ones applied at the Galindo WWTP since several compounds used as efficiency indicators for new implemented treatments including carbamazepine, diclofenac or sulfamethoxazole were found at similar concentrations in both secondary treatments effluents.

3.12.P-Th092 Primary Degradation of Benzophenone-Type UV Filters in Lab Experiments and Their Structure-Related Endocrine Activity

Lale Carstensen¹, Sophie Banke², Sara Schubert², Dirk Jungmann³, Hilmar Börnick² and Stefan Stolte⁴, (1)Institute of Water Chemistry, TU Dresden, Dresden, Germany, (2)TU Dresden, Germany, (3)Dresden University of Technology, Germany, (4)Technical University of Dresden, Germany

Trace organic contaminants (TrOCs) are a diverse and expanding area of anthropogenic substances with possible dangerous effects on ecosystems and human health. One important group of TrOCs that have been getting more attention in research over the last years are benzophenone (BP)-type UV filters. As most UV filters are photostable and relatively hydrophobic, they tend to bioaccumulate in biota and soils or sediments with high organic content act as natural sinks. Residues have been detected in various aqueous matrices as well as in fish, possibly reaching humans due to bioaccumulation. Furthermore, BP-3 and its transformation product, BP-1, have been found in human urine after application of personal health care products to the skin. Some derivatives such as BP-1, BP-2, BP-3, and BP-8 have already been linked to coral bleaching and the structural similarity of BPs to estradiol links them to a potential endocrine activity which has been demonstrated in vivo and in vitro. Removal experiments have been conducted with a duration of two weeks with BP, BP-1, BP-2, BP-3, BP-4, BP-6, BP-7, BP-8, and BP-10 spiked into river water at mass concentration $C = 1 \mu\text{g/L}$. Trace analysis of BPs was carried out via UHPLC system (Nexera, Shimadzu) in combination with a tandem mass spectrometer (QTRAP 6500+, Sciex) according to a method developed at the institute. Removal of BPs under suboxic conditions (dissolved oxygen $< 1 \text{ mg/L}$) on pumice simulating soil passage during river bank filtration was investigated under different conditions. Primary decay of more than 50 % was observed for all BPs at pH 7 under biotic conditions. High and fast removal indicated by half-lives ($t_{1/2}$) of only 2 h was detected for BP-2, BP-1, as well as for BP-7, BP-10 and BP with $t_{1/2} < 12 \text{ h}$. Removal rates have been calculated by using the first order exponential decay fit. Hydrophobic BPs with estimated log KOC > 3.1 , namely, BP-10, BP-6, and BP-7, showed high removal (60-90 %) in abiotic experiments at pH 7, while BP-3 and BP-8 with lower estimated log KOC were removed less efficiently (50 %). However, BP-4 was removed very poorly due to its low sorption affinity. Structure-activity relationship rules regarding endocrine activity using yeast receptor gene assays could be confirmed for several BPs. High estrogenic activity was exhibited by BP-1 and BP-2 due to hydroxyl groups in para and ortho positions. Other substituents such as methoxy and chloride might have diminished the effect.

3.12.P-Th093 Organic Micropollutant Removal From Urban Waters by Nature-Based Solutions: Introduction to MULTISOURCE Project

Vaidotas Kisielius¹, Kai Bester², Carlos Arias³ and Pedro Carvalho⁴, (1)Environmental Science, Aarhus Universitet, Denmark, (2)Environmental Science, Aarhus University, Denmark, (3)Aarhus Universitet, Denmark, (4)Aarhus University, Denmark

MULTISOURCE is a starting up EU Horizon 2020 project “ModULar Tools for Integrating enhanced natural treatment SOLUTIONs in URban water CyclEs”. The project operates seven pilot plants of nature-based solutions treating wastewater, urban runoff and rainwater in France (INRAE), Belgium (Rietland), Italy (IRIDRA), Spain (ICRA), Norway (NIVA), Germany (UFZ) and USA (Montana State University). These nature-based solutions comprise green roofs, green walls, raingardens and constructed wetlands derived eco-technologies. These systems, besides water management, provide practical and aesthetic benefits and are currently under intense research. MULTISOURCE will demonstrate operation efficacy of the seven different pilot plants for seven different water types. Besides, it will develop innovative tools, methods and business models to support the technology upscale, assimilation and long-term maintenance. The pilot plants are integrated in urban infrastructure like building walls and parking lots and provide great potential for water reuse. In order to realize this potential, the installations must remove pathogens, nutrients, hazardous organic micropollutants and contaminants of emerging concern, including microplastics. MULTISOURCE will assess the occurrence and fate of the water contaminants within and beyond the current regulatory framework. We are particularly interested in the pilot efficiency for the micropollutant removal, which will be assessed in cooperation with the different project partners, including variations due to e.g. non-baseline operations and seasonality. For that, we are implementing several different analytical methods for suspect-screening and target analysis of over 300 relevant organic compounds. These include active pharmaceutical ingredients, pesticides, surfactants, drugs of abuse, petroleum constituents and combustion products and transformation products of some of these compound groups. Harmonised monitoring plan and tailored approach for each pilot ensuring comparability of the different infrastructures and water types has been developed. The first results of the micropollutant content and the pilot capacity for their treatment will be shown at the SETAC conference. The results will be further used for the planned environmental risk analyses and assessment of water reuse potential.

3.12.P-Th094 Occurrence and Mass Flows of Contaminants of Emerging Concern (CECs) in Sweden's Three Largest Lakes and Their Connected Rivers

Daniel Malnes¹, Lutz Ahrens², Stephan Köhler², Malin Forsberg² and Oksana Golovko³, (1)Swedish University of Agricultural Science, Sweden, (2)Swedish University of Agricultural Sciences, Sweden, (3)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences, Uppsala, Sweden

Contaminants of emerging concern (CECs) are of concern for the aquatic environment due to their possible adverse effects on the environment and humans. The overall aim of this study was to assess the occurrence and mass flows of CECs in Sweden's three largest lakes and their connected rivers. This study is the first of its kind in Sweden to systematically study CECs in the three largest lakes in Sweden. The occurrence and distribution of 112 CECs was investigated, including 73 pharmaceuticals, 13 perfluoroalkyl substances (PFASs), 8 industrial chemicals, 4 personal care products (PCPs), 3 parabens, 2 pesticides, and 4 other contaminants (mostly anthropogenic markers). This is one of the first studies reporting environmental concentrations of, for example, the industrial chemicals tributyl citrate acetate and 2,2'-dimorpholinyl-diethyl-ether. The CEC concentrations in river surface water were generally higher (31–5200 ng/L; median 440 ng/L) compared to lake locations (36–900 ng/L; median 190 ng/L). At urban lake sites, seasonal trends occurred for PCPs and parabens as well as for antihistamines, antidiabetics, antineoplastic agents, antibiotics, and fungicides. The median mass load of the rivers was 180 g/day (4.0–4300 g/day) with total mass loads of 5600 g/day to Lake Mälaren, 510 g/day to Lake Vättern and 5000 g/day to Lake Vänern. All three investigated lakes are used as drinking water reservoirs and further investigations of the impact of CECs on the ecosystem and human health are needed.

3.12.P-Th095 Investigation of a Multi-Stage Process for Wastewater Reclamation With Special FOCUS on Micropollutant Removal

Paul Genz¹, Victor Katayama² and Thorsten Reemtsma³, (1)Helmholtz Center for Environmental Research (UFZ) Leipzig, Germany, (2)Fraunhofer UMSICHT, Germany, (3)Helmholtz Centre for Environmental Research, Germany

New concepts for nutrient reclamation from wastewater through production of a liquid fertilizer can help to reduce agricultural irrigation water demand in water-scarce countries, as well as decrease micropollutant burden on treatment systems. However, it's most beneficial for reducing mineral fertilizer consumption. For reuse of nutrient-rich centrate water – side-product from sewage sludge treatment – a combined treatment process including a membrane-bio-reactor (MBR) and an electro dialysis (ED) membrane stack is envisioned as a multi-barrier concept for the abatement of plant-available micropollutants. Using a lab-scale setup, real wastewater was treated with this multi-stage process over the course of several months. Samples were analysed with LCMS targeting a set of 29 polar organic micropollutants across different molecular properties which potentially influence plant uptake such as molecular weight and pH-dependent polarity. Furthermore, ICP-MS/OES analysis were performed to monitor both nutrient dynamics as well as inorganic contaminant's removal. Results show that removal rates of the combined process for many investigated compounds such as diclofenac or gabapentin exceeded 90%. While the MBR is able to remove biodegradable compounds well, an increase in concentration of biological transformation products such as gabapentin-lactam was observed. Acting as a second treatment stage, the ED shows a median removal of >90% across all investigated compounds. Overall, experiments show that the investigated multi-stage process is able to produce a nutrient solution that meets legislative requirements of the EU for wastewater reuse. Additionally, by reducing the micropollutant burden in wastewater treatment plants, the investigated process can be integrated into a holistic future concept for wastewater treatment plants.

3.12.P-Th096 Cytotoxicity As a Proxy for Particle-Associated and Dissolved Organic Contaminant Loads in Rivers

Michelle Engelhardt¹, Stephanie Spahr², Beate Escher³, Andrea Gaertner⁴, Martin Krauss⁵, Maria Koenig⁴, Rita Schlichting⁴, Christiane Zarfl⁶ and Clarissa Glaser⁷, (1)Eberhard Karls University of Tübingen, Germany, (2)Ecology and Biogeochemistry, Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin, Germany, (3)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (4)Helmholtz Centre for Environmental Research – UFZ, Germany, (5)Helmholtz centre for environmental research - UFZ, Germany, (6)University of Tuebingen, Tuebingen, Germany, (7)Center for Applied Geosciences, Germany

Storm events lead to a mobilization of particulate matter, dissolved and particle-associated organic pollutants that pose a risk to river ecosystems. Target screening can hardly capture the broad range of compounds present in stormwater and receiving streams. Thus, an additional monitoring proxy that describes the overall chemical load in stormwater is needed. Each chemical in a mixture contributes, albeit with different potency, to cytotoxicity measured by reduction of cell viability after 24h in four human cell lines. Thus, the aim of this study was to investigate the applicability of cytotoxicity as a proxy for the organic contaminant load of rivers during storm events. Field investigations took place in the Ammer River (annual average discharge 0.87 m³ s⁻¹) close to Tübingen, Germany, during intense precipitation events in June 2021. The sampling site was located at the outlet of the gauged catchment (134 km²), thus, integrating inflowing water from all upstream tributaries and sewer overflows. During storm events, high-resolution temporal monitoring of discharge, suspended particles, particle characteristics, as well as of dissolved and particle-associated organic contaminants was conducted using both chemical analyses and cell-based *in vitro* bioassays. The cytotoxicity in the water phase (expressed as toxic units, TU), was similar among the cell lines. TU values followed the course of the hydrograph with highest TU values at the maximum or slightly after the discharge peak. This finding suggests that the chemical load is controlled by the transported volume of water despite the fact that different contaminant sources are likely to contribute to the water flux and pollutant load in the river at different time points of the hydrograph. For the particle-associated cytotoxicity, TU values are constant over the course of the events suggesting that the particle-associated cytotoxicity in the river is, similar to the water cytotoxicity, controlled by the particle load in the river. This highlights that the cytotoxicity is a suitable proxy to detect mixtures of organic compounds and, thus, assess the chemical load in rivers during storm events.

3.12.P-Th097 Organic Micropollutants: A CASE Study on Influent and Effluent Waters in Australia

Minna Saaristo¹, Simon Sharp¹, Gerardi Tarulli², Andrew Pask³ and Andrea Hindwood¹, (1)EPA Victoria, Australia, (2)University of Melbourne, Australia, (3)The University of Melbourne, Australia

Even though recycled water is becoming an increasingly valuable resource in a drying climate, there remains concerns about contamination with emerging contaminants. A current limitation of recycled waters is that wastewater treatment plants (WWTP) are not designed to treat organic micropollutants. As a result, the concentration, and risks of organic micropollutants is not well understood. This study evaluates pharmaceuticals and personal care products (PPCPs) and endocrine disrupting chemicals (EDCs) in influent and effluent water across 31 wastewater treatment plants (WWTP) in Victoria, Australia. This work had four specific aims: (1) quantify the type and concentration of PPCPs and EDCs in influent and effluents; (2) investigate removal efficiencies of treatment technologies; (3) examine toxicity using a receptor localisation assay; (4) conduct an extensive risk assessment. Influent and effluent water was sampled from 31 WWTPs in April–May 2021. Water samples were collected using passive samplers (polar organic chemical integrative sampler ‘POCIS’ 28 d deployment), and grab samples (24h composite). Samples were screened for 72 PPCPs and 21 EDCs. As a proxy for EDC-activity, we tested if effluent waters elicit changes in nuclear localisation of androgen or estrogen receptors, and expression of their respective target genes. We found that PPCPs concentrations in influent ranged from < 0.2–2,900 µg/L, and in effluent from < 0.02–8.1 µg/L. For EDCs, concentrations in influent waters ranged from < 0.02–12 µg/L and in effluent from < 0.001–0.54 µg/L. Of the 72 PPCPs, 48 were detected in grab samples and 70 in passive samplers. In influent, codeine was detected in 100% influent samples, while a further 16 PPCPs were detected in >90% of samples. In effluent, the most frequently detected PPCPs were lamotrigine, carbamazepine, amidotrizoate, oxazepam, and acesulfame K. We found that removal rates for PPCPs were compound specific. For example, paracetamol, caffeine and acesulfame K were all removed at a mean rate of >99, 99 and 97%, while carbamazepine and venlafaxine showed limited removal (mean rate 19–61%). Furthermore, for lamotrigine, there was no evidence of removal (-28%). In the receptor localisation assay, influent samples activated the estrogen receptor and induced expression of estrogen receptor target genes, demonstrating EDC-activity. Our study underlines the importance of multiple lines of evidence approach for risk assessment of organic micropollutants.

3.12.P-Th098 Urban or Agricultural Usage As Source of Widespread Groundwater Contamination With the Fungicidal Degradation Product Nn-Dimethylsulfamide

Christian Albers¹, Ulla Bollmann², Anders Johnsen³ and Liselotte Clausen⁴, (1)Geological Survey of Denmark and Greenland, Copenhagen, Denmark, (2)Geological Survey of Denmark and Greenland, Denmark, (3)Geochemistry, Geological Survey of Denmark and Greenland, Copenhagen K, Denmark, (4)HOFOR, Copenhagen, Denmark

Groundwater monitoring has revealed a widespread occurrence of *N,N*-dimethylsulfamide (DMS) in Danish groundwater. In 2020, DMS was detected in 33% of drinking water abstraction wells, exceeding 0.1 µg/L in 9% of the wells. DMS is a degradation product of the two fungicides tolylfluanid and dichlofluanid. In Denmark, these fungicides have been used in fruit orchards and strawberry fields from early 1970’s until 2007. In addition, they have been widely used in paint and wood preservatives until 2015. Urban use has not previously been expected to cause widespread pollution in aquifers, but the geographical distribution of contamination and the relative amounts of the fungicides used as biocide and pesticide suggest that the urban use could be of importance. We made a detailed investigation of DMS occurrence in soil, drainage systems and shallow groundwater in two model areas, where DMS exceeds the drinking water standard in nearby wells used for drinking water abstraction. One of the areas is dominated by wooden buildings (garden allotments) and one is dominated by agriculture, including historical strawberry fields. The analyses revealed the presence of the fungicides in soil at both areas, though highest in soil next to wooden buildings. DMS was found above the threshold limit for drinking water in both the drainage and shallow groundwater of both areas, confirming the presence of local sources. Hence urban environments seem to be equally important as a source for groundwater contamination with DMS as agricultural environments. Sorption and degradation data show that DMS hardly sorbs to soil and that it is recalcitrant in subsoil and at anoxic conditions. DMS is therefore likely to be widely present in Danish groundwater for several decades.

3.12.P-Th099 Assessing the Biodegradation of Water-Soluble Polymers in Wastewater Systems

Aaron Kintzi, Thilo Hofmann and Michael Zumstein, University of Vienna, Austria

While plastic materials have been one of the defining topics in environmental research in the last decade, very few studies focused on the environmental fate of water-soluble polymers. However, water-soluble polymers are used in large volumes across a wide range of applications, including home- and personal care products of which a large fraction enters the wastewater system and - depending on their persistence and removal - might end up in natural systems. In our work, we investigate the aerobic biodegradability and biotransformation of water-soluble polymers that are considered promising alternatives to conventionally used persistent water-soluble polymers. Thereby, we focus on polymer classes with structural similarities to naturally occurring macromolecules such as poly(amino acids) and modified polysaccharides, which we expect to be susceptible to breakdown by enzymes present in the wastewater. As the initial extracellular breakdown of polymers is considered the rate-limiting step in polymer biodegradation, we attempted to improve established respirometric polymer biodegradation testing schemes by focusing on the role of extracellular enzymes. For example, we assessed the effect of an incubation of the polymers with extracellular wastewater enzymes on the mineralization kinetics of polymers by wastewater microorganisms. Furthermore, we found that a prolonged pre-conditioning of the biological inoculum prior to polymer addition, which is often done in established testing schemes, might not be needed and can even be detrimental in the context of realistic experimental conditions. Given that polymer biodegradation rates can strongly depend on the presence of additional substrates, we additionally investigated the effects of co-substrates on the biodegradation kinetics of water-soluble polymers. Overall, this contribution presents ways towards more

realistic laboratory experiments for the assessment of water-soluble polymer biodegradation in wastewater and offers novel insights into the biodegradation process of water-soluble polymers in wastewater.

3.12.P-Th100 Occurrence and Distribution of Pharmaceuticals and Identification of Photo-Transformation Products in Intermittent Rivers

Olga Gómez Navarro¹, Nicola Montemurro², Lluís Bertrams Tubau³, Meritxell Abril³, Lorenzo Proia³ and Sandra Pérez⁴, (1)IDAEA- CSIC, Spain, (2)Environmental Chemistry, Jordi Girona 18-26, null, Barcelona, Spain, (3)BETA Technological Center - UVic, Spain, (4)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain

Due to climate change and population growth, treated wastewater has an increasing influence on intermittent streams and can even account as the main water input during most of the year. Besides, conventional wastewater treatment plants (WWTPs) barely remove organic contaminants such as pharmaceuticals, which consequently reach the aquatic system spreading their adverse effects on the aquatic environment and human health. Pharmaceutical residues have been frequently detected in river samples at concentrations of ng L⁻¹ or even higher. However, their concentration along the river may change due to natural attenuation processes. Once pharmaceuticals are in the environment, physico-chemical phenomena can occur such as hydrolysis or photolysis and consequently transformation products (TPs) are produced. TPs can sometimes result in greater toxicity than their precursors, thus, the study and identification of TPs is essential to assess the health of a watercourse. In this study, we aim to examine the presence of pharmaceuticals in different intermittent rivers, which are dominated by the wastewater effluent, and to study their fate and the possible natural attenuation. Surface water samples from the Osona region in Spain were sampled during the different seasons 2020-2021 and different sampling points were collected; upstream, the WWTP discharge point (DP), 20m after the WWTP DP and between 150m and 250m after the WWTP DP. All samples were extracted through a Solid Phase Extraction (SPE) using a homemade multilayer mix-bed SPE cartridge containing four different specific sorbents covering a wide range of polarities. Besides, lab-scale photolysis experiments were also performed in order to explore probable photo-TPs to be included in a suspect screening database to check their presence in the surface water samples studied. Target analysis for more than 100 pharmaceuticals was performed using liquid chromatography high-resolution mass spectrometry Q-Exactive Orbitrap. Over 50 pharmaceuticals were found and quantified in all six studied streams. Concerning lab-scale photolysis, around 10 photo-TPs were elucidated while only one photo-TP was found in the water samples. The detection of photo-TP provides evidence of photolysis and proves the importance of natural attenuation processes in rivers.

3.12.P-Th101 Mixture Effects of Organic Chemicals in a Highway Runoff Retention Pond

Nelly Wang¹, Beate Escher², Andrea Gaertner³, Clarissa Glaser⁴, Maria Koenig⁵, Martin Krauss⁶, Rita Schlichting⁵ and Stephanie Spahr⁷, (1)Eberhard Karls University of Tübingen, Germany, (2)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (3)Helmholtz Center for Environmental Research (UFZ) Leipzig, Leipzig, Germany, (4)Center for Applied Geosciences, Germany, (5)Helmholtz Centre for Environmental Research – UFZ, Germany, (6)Helmholtz centre for environmental research - UFZ, Germany, (7)Ecology and Biogeochemistry, Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin, Germany

Highway runoff contains complex contaminant mixtures that can pose risks to aquatic ecosystems and drinking water resources. Stormwater retention ponds are designed to store and treat runoff prior to discharge into surface waters with particular focus on particle removal. However, in addition to particle-associated pollution, highway runoff carries dissolved and mobile contaminants, which may not be removed well in conventional retention basins. Furthermore, numerous chemicals in highway runoff remain unknown but likely contribute to mixture toxicity. During an intense storm event in February 2021, we sampled highway runoff from a motorway in Germany (close to Tübingen, Germany) and tracked the dissolved and particle-associated chemical and toxicological profile of the runoff throughout a stormwater retention pond, which discharges into a stream. Sample treatment involved solid phase extraction to enrich dissolved contaminants as well as accelerated solvent extraction to extract contaminants from suspended particles and pond sediment. We screened all samples for more than 600 organic contaminants using high resolution mass spectrometry and performed several *in vitro* bioassays to assess mixture effects. While the highway runoff did not trigger any estrogenic activity nor neurotoxicity, we observed high cytotoxicity, activation of the aryl hydrocarbon receptor, and unexpectedly high binding to the peroxisome proliferator-activated receptor gamma. The observed effects in highway runoff were constant throughout the stormwater retention pond indicating low removal of both dissolved and particle-associated contaminants. In fact, numerous motor vehicle-related organic compounds such as benzothiazole and pyrene were detected in the influent and effluent of the stormwater retention pond with little or no decline in the concentration of the chemicals. The discharge of the stormwater retention pond contributed to the overall contaminant load in the receiving stream, which had a lower cytotoxicity than the pond outflow. Our results corroborate that street runoff carries significant toxic potential and needs improved treatment prior to release into the aquatic environment.

3.12.P-Th102 Evaluation of Contaminants Reduction by Advanced Waste Water Treatment Via Effect-Based Methods

Marcus Lukas¹, Martina Gutsche¹, Dagmar Winkelmann¹, Michael Stapf², Aleksandra Bogusz³ and Britta Lauritzen⁴, (1)German Environment Agency (UBA), Germany, (2)Kompetenzzentrum Wasser Berlin gGmbH, Germany, (3)Institute of Environmental Protection National Research Institute, Poland, (4)Hillerød Forsyning, Denmark

In the European Union's Water Framework Directive the contamination of water with active pharmaceutical ingredient (API) residues is considered as an emerging environmental concern. Municipal waste water treatment plants (WWTPs) are relevant point sources of APIs as they treat the wastewater from public households, hospitals, and industry of the connected catchment area. APIs have beneficial effects on human and animal health, but in the environment their effects are a global concern. The environmental fate of most pharmaceuticals and their effects on biota are poorly known. Conventional "state-of-the-art" WWTPs

can only remove APIs that are either easily biodegradable and/or absorbable to activated sludge, whereas others can pass the treatment process with no or only minor reductions. Therefore, reduction of a broad range of APIs can only be achieved by using targeted advanced waste water treatment techniques, such as ozonation. The EU interreg project 'Clear Waters from Pharmaceuticals' (CWPharma) focused on filling the gaps of knowledge, e.g., regarding environmental concentrations and ecotoxicological effects of APIs. The project studied the impact of ozonation and post-treatment on ecotoxicological endpoints and established a guideline for advanced API removal. During an implementation phase (CWPharma2) technical solutions such as ozonation and different post treatments have been further evaluated at five different WWTPs in Denmark, Sweden and Germany. The ecotoxicological tests identified in CWPharma regarding effects of estrogenicity (YES test), mutagenicity (Ames fluctuation test) and bioluminescence inhibition (Microtox test) have been performed with waste water samples of secondary effluent before and after ozonation and with additional filters or biofilm reactors as post-treatments. The present contribution will give insights in the ecotoxicological results of test with enriched samples (SPE enrichment). The findings demonstrate that effect-based methods are valuable tools to directly indicate a contaminant reduction via (advanced) waste water treatment, e.g. for estrogenic compounds, and therefore, allow conclusions on the effectiveness of different API emission reduction measures.

3.12.P-Th103 Fate of Benzotriazoles During Anaerobic Digestion of Sewage Sludge

Leonidas Koutsellis¹, Hans Peter Arp², Sarah Hale³, Georgia Gatidou¹, Stergios Vakalis¹, Olga-Ioanna Kalantzi⁴, Athanasios Stasinakis¹ and Michalis Fountoulakis¹, (1)University of the Aegean, Greece, (2)NGI, Norway, (3)Norwegian Geotechnical Institute (NGI), Norway, (4)Environment, University of the Aegean, Mytilene, Greece

In this study, lab-scale experiments were conducted to study the fate of benzotriazoles (BTRs) during anaerobic digestion of sewage sludge. These compounds are used in corrosion-inhibiting products, cooling fluids, de-icing fluids and dishwashing detergents and they are commonly found in Wastewater Treatment Plants treating domestic and industrial wastewater. A lab-scale CSTR anaerobic reactor was operated for a period of about six months at mesophilic conditions and at an HRT of 20 days using secondary sludge (from the Sewage Treatment Plant of Mytilene, Greece) as feed. The performance of the conventional anaerobic digestion was compared with that achieved in the presence of conductive material (magnetite) and when external low voltage (0.8V) was applied. In each experimental phase, the system was monitored for biogas/methane production and treatment efficiency (COD and VS removal as well as Volatile Fatty acids accumulation). When stable conditions were achieved in each experimental phase, a mixture of different BTRs was spiked in the reactor and samples were periodically taken to study the fate of target micropollutants during anaerobic digestion.

Acknowledgment: This project has received funding from the European Union's Horizon H2020 research and innovation program under grant agreement No 101036756.

3.12.P-Th104 Assessment of Watch List Chemical Occurrence in Surface WATER During a 4-Year Monitoring Programme

Fiona Regan¹, Imogen Rose Hands² and Blanaid White¹, (1)DCU Water Institute, Dublin City University, Ireland, (2)Dublin City University, Ireland

Water quality is impacted by chemical compounds from a range of anthropogenic sources. Some of these chemicals are monitored because of their risk is well known. However, emerging chemicals of concern which do not have adequate data on occurrence in the environment are being added to the Watch List. The first full WL was established in Decision 2015/495/EU (2015) [1]. The original WL contained 10 suspected micropollutants or groups of micropollutants (also known as Contaminants of Emerging Concern (CECs)), totalling 17 individual chemicals. The criteria used for inclusion into the WL can be summarised into two key elements. An analytical approach involving solid phase extraction and liquid chromatography tandem mass spectrometry was developed for monitoring Watch List substances under the Water Framework Directive in Irish surface waters. This is the first time data for the full expanse of the Watch List has been generated in Ireland. Conditions from SPE extraction to analysis were optimized for recovery of a broad range of compounds at the ng L⁻¹ concentration level. Two LC-MS methods were used, in which estrogens were determined separately to the other analytes. LC-MS/MS methods for the analysis of the full suite of WL chemicals were developed and applied to 21 field samples taken from around Ireland over a four-year period. An extraction and analysis method was developed for the majority of analytes in the WL which achieved targeted LODs set by European standards, however future work is required in order to achieve targeted LODs for the estrogen group. Significant effects from the sample matrix were observed, particularly in the 2020 set of samples in which very high sample turbidity was present, indicating these compounds are highly sensitive to matrix interferences.

3.12.P-Th105 Microwave Regeneration of Granular Activated Carbon Saturated With PFAS

Erica Gagliano¹, Pietro Falciglia¹, Yeakub Zaker², Tanju Karanfil² and Paolo Roccaro¹, (1)University of Catania, Italy, (2)Clemson University, United States

To date, adsorption through granular activated carbon (GAC) is considered a well-established treatment for PFAS removal from contaminated water. However, the regeneration of PFAS-exhausted GACs is currently an important challenge for both water utilities and activated carbon manufacturers. Indeed, regeneration techniques such as chemical, biological and thermal are energy-consuming and/or partial effective because of the unique properties of PFAS. Microwave (MW) irradiation is a promising alternative to conventional thermal heating that has been proposed as an innovative technique for regenerating GACs saturated with dyes and pharmaceutical compounds. This study investigates the application of an innovative regeneration technique based on MW irradiation for PFAS-saturated GACs. Specifically, the MW regeneration of a commercially available GAC saturated with perfluorooctanoic acid (PFOA) and perfluorooctane sulfonic acid (PFOS), selected as representative long-chain PFAS, was tested

through MW irradiation. The effectiveness of MW irradiation was assessed in terms of adsorption capacity recovery, while the effect of MW irradiation on GACs was examined by assessing the carbon weight loss percentages. The multiple-regeneration performance was also evaluated by conducting five successive adsorption/regeneration cycles. Moreover, the changes in BET surface area, pore volume, and pore size ascribed to several MW regeneration cycles were compared with virgin GAC properties. Textural properties of MW regenerated GAC did not noticeably differ from virgin ones. The obtained findings demonstrated that MW irradiation could effectively regenerate PFOS- and PFOA-saturated GACs. High temperatures eligible to desorb PFAS were reached in short irradiation times and the obtained values of adsorption capacity recovery jointly with a moderate weight loss encourage further investigations. Indeed, current investigations are focused on the regeneration of real field PFAS-saturated GACs in order to deeply explore the efficiency of MW regeneration in the co-presence of short-, long-chain PFAS and other water constituents.

3.12.P-Th106 Degradation and Ecotoxicity of Quaternary Ammonium Compounds (QACs) Subjected to Combined Vacuum UV and Uv-C Treatment

Lana Flanjak¹, Loukia Lipirou², Vasilios Sakkas² and Peter Roslev³, (1)Chemistry and Bioscience, Aalborg University, Denmark, (2)University of Ioannina, Greece, (3)Aalborg University, Denmark

Quaternary ammonium compounds (QACs) are active ingredients in a palette of commercially available disinfectants, sanitizers and biocides used across the globe because of their broad-spectrum antimicrobial properties. Application of QACs in Europe as pesticides, biocides and disinfectants is regulated by European Chemicals Agency (ECHA). Their widespread uses have resulted in frequent detection in many aquatic and terrestrial matrices including domestic wastewater, urban soils, surface waters and sediments. QACs have demonstrated efficacy in inactivation of more than 140 different pathogens, including SARS-CoV-2 virus and the use of these agents has increased concurrent with the emergence of the COVID-19 pandemic. However, increased QACs consumption is likely affecting the load of these compounds into the environment and investigation of environmental fate and effects on non-target organisms is in demand as well as technologies to mitigate environmental release. In this study, we examined the potential of combined Vacuum UV (185 nm) and UV-C (254 nm) irradiation (VUV/UVC) to degrade common QACs and decrease the ecotoxicity. Combined VUV/UVC irradiation has a potential to degrade QACs due to generation of reactive oxygen species (e.g., hydroxyl radicals) that interact with the target molecule. Our study showed that combined VUV/UVC irradiation facilitated rapid degradation of common QACs such as benzalkonium chloride, benzethonium chloride, didecyltrimethylammonium chloride, dodecyltrimethylammonium chloride, and hexadecyltrimethylammonium chloride. The efficiency of the degradation was affected by the initial QAC concentrations, the UV dose, and the water matrix. Toxicity of non-treated and UV-treated QACs was examined using a battery of test organisms from different trophic levels that included the luminescent bacterium *A. fischeri*, the gram-negative and gram-positive bacteria *E. coli* and *E. faecalis*, the freshwater microalga *R. subcapitata*, and the crustacean *D. magna*. The potential for trophic transfer of non-treated and UV-treated QACs in a simplified aquatic food web was also investigated. Test organisms from different trophic levels were included to better assess adverse effects of all bioactive compounds in UV treated samples including transformation products. The study suggests that combined VUV/UVC treatment of QACs resulted in significant photolysis coupled with noticeable decreases in toxicity to environmentally relevant organisms.

3.12.P-Th107 The Power of UV: Degradation and Toxicity Mitigation of Pesticides and Biocides by Combined Vacuum UV and Uv-C Treatment

Peter Roslev¹, Lana Flanjak², Oihane Del Puerto¹ and Nuno Gonçalves³, (1)Aalborg University, Denmark, (2)Chemistry and Bioscience, Aalborg University, Denmark, (3)Università di Torino, Italy

Pesticides and biocides are frequently detected as contaminants in groundwater and surface waters due to widespread societal use. Adverse effects have been reported for non-target organisms in a range of terrestrial and aquatic environments, and environmentally friendly methods for their mitigation are in demand. Advanced oxidation processes (AOPs) can potentially degrade organic contaminants in contaminated water and waste streams. UV based AOPs include Vacuum UV irradiation (VUV) that is considered a green technology that produces oxygen radicals including hydroxyl radical to degrade aquatic contaminants. However, the degradation efficiency and the toxicological profile of the process remain underinvestigated. This study investigated the potential of combined VUV (185 nm) and UVC (254 nm) irradiation (VUV/UVC) to degrade widely used herbicides, fungicides, and quaternary ammonium compounds (QACs) to decrease their toxicity. The study included the herbicide glyphosate and the transformation product AMPA, the triazole fungicide tebuconazole and the transformation product 1,2,4-triazole as well as common QACs. Glyphosate is the most widely used active ingredient in non-selective broad-spectrum herbicides, tebuconazole is an active ingredient in popular triazole fungicides used to control fungal diseases whereas QACs are used globally due to their broad-spectrum antimicrobial properties. Degradation kinetics, degradation mechanisms, and toxicity mitigation were investigated using different photoreactors. The results showed that combined VUV/UVC irradiation facilitated rapid degradation of common pesticides and biocides at the µg/L to mg/L level in different water matrices. The toxicity of non-treated and UV-treated pesticides and biocides was examined using a battery of test organisms with gram-negative and gram-positive bacteria (*A. fischeri*, *E. coli*, *E. faecalis* and *B. subtilis*), luminescent yeast (*S. cerevisiae* BLYR), filamentous fungi (*F. graminearum*), microalga (*R. subcapitata*), and crustaceans (*D. magna*). The test battery included organisms from different trophic levels to better assess adverse effects of all bioactive compounds in UV treated samples including transformation products. The study suggests that combined VUV/UVC treatment resulted in significant photolysis and noticeable decreases in aquatic toxicity of common pesticides and biocides due to mineralization of the parent compound or formation of less toxic transformation products.

3.12.P-Th108 Safeguarding Antibiotics Emission Into Aquatic Systems by Nature-Based Solutions

Pedro Carvalho¹, **Vaidotas Kisielius**², **René Kilian**³ and **Carlos Arias**⁴, (1)Aarhus University, Denmark, (2)Environmental Science, Aarhus Universitet, Denmark, (3)Kilian Water ApS, Denmark, (4)Aarhus Universitet, Denmark

Concerns on the occurrence of antibiotics, antimicrobial resistant microorganisms and microbial pathogens in aquatic ecosystems are increasing. So far, there is still little information and evidence about the capability of nature-based solutions (NBS) to reduce their impact on water quality. "Nature-based solutions to reduce antibiotics, pathogens and antimicrobial resistance in aquatic ecosystems" (NATURE) is a recently funded ERA-NET Cofund Aquatic Pollutants project with the aim of providing measures and technologies to reduce the impact of antibiotics on water quality. NBS are defined as "living solutions" inspired by nature to address various societal challenges in a resource-efficient and adaptable manner while delivering simultaneous economic, social, and environmental benefits. NATURE proposes to provide a holistic assessment of NBS as a management option of antibiotics from inland to coastal areas. Among the different specific objectives of the NATURE, we aim to evaluate and optimize the performance of secondary wastewater treatment by NBS. Aarhus University and Kilian Water ApS (Denmark) will work together to investigate the treatment of antibiotic residues by three different wetland designs: i) the most innovative hybrid bioelectrochemical wetland that will be benchmarked against ii) an aerated constructed wetland, and iii) a vertical flow constructed wetland. We will study similar size (approx. 125 PE sized beds) systems treating domestic wastewater implemented in Denmark. Systems will be monitored for 1 year by quantifying target model antibiotics and respective transformation products together with classical water quality parameters. In the second year of the project, operational conditions will be manipulated and the effects on treatment performance studied. Antibiotic resistance and pathogens will be further studied by other project partners. At SETAC Europe we will present the first monitoring results of antibiotic concentrations and treatment efficiency in the Danish pilot systems.

3.12.P-Th109 Ecotoxicological Characterization of Reverse Osmosis Concentrates and Antiscalants As Anti-Fouling Additives

Carolin Anna Cecile Bertold¹, **Sarah Johann**², **Florian Gigl**¹, **Anja Rohn**³, **Gerhard Schertzinger**⁴, **Beat Schmutz**⁵, **Sebastian Egner**⁵, **Dominik Armbruster**⁵, **Oliver Happel**⁵, **Henner Hollert**⁶ and **Sabrina Schiwy**⁷, (1)Goethe University Frankfurt am Main, Germany, (2)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Germany, (3)IWW Water Centre, Germany, (4)University of Duisburg-Essen, Germany, (5)ITZW: DVGW Water Technology Center, Germany, (6)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany, (7)Goethe University Frankfurt am Main, Germany

Modern techniques are steadily applied and optimized to ensure a high quality of drinking water. Therefore, purification processes, like membrane-filter technologies, including nanofiltration (NF) or reverse osmosis (RO), are used to meet these high-quality requirements. A concentrate is produced within the purification process, which is discharged directly or indirectly into surface waters. Additives, called antiscalants, that ensure a long membrane lifetime, and a mixture of anthropogenic trace substances are present in high concentrations in the concentrates. Antiscalants are mainly based on phosphonates- or polyacrylates that increase the solubility limit of free ions in the concentrate by complexation, reducing inorganic scaling on the membrane. However, they have a low biodegradability in the environment and can promote the migration of trace metals. Additionally, phosphate-based antiscalants contribute to the phosphorization of water and, thus to eutrophication. Therefore, in the *KonTriSol* project (funded by the Federal Ministry of Education and Research), different antiscalants (active ingredient and technical products) are ecotoxicologically evaluated. Additionally, selected concentrates from drinking water treatment plants are examined regarding their ecotoxicological potential. For this purpose, a bioassay battery is used to investigate acute (*Daphnia* immobilization test with *Daphnia magna*, algae growth inhibition test with *Raphidochelis subcapitata*, fish embryo acute toxicity test with *Danio rerio* and additional endpoints on mode of action, e.g. behavior alterations in light-dark transition test) and mechanism-specific toxicity (like PFAS-Calux on thyroid disruption). Subsequently, the investigated effects can be compared with those of the previously tested antiscalant and technical products. The first results obtained with an RO concentrate exhibited only toxicity to algae. However, the inhibitory effect of the RO concentrate on algae growth might be aside from possible inherent toxicity, caused by the nutrient complexing properties of Antiscalants, which will be addressed in more detail. The use of effect-based methods, consisting of mechanistic and whole organism-based tests, can provide a comprehensive overview of the ecotoxicological potential of the substances contained in the concentrates (including the respective antiscalant agents). The mechanism-specific tests can thereby contribute to identifying specific toxic substance groups.

3.13 Pelagic and Benthic Harmful algal blooms (HABs): The detection, fate, effects, monitoring, and management of blooms (Poster)

3.13.P-Mo193 Alterations on mRNA Expression of Interleukin Genes in Thymus and Spleen of Rats Orally Exposed to Cylindrospermopsin

Leticia Diez-Quijada, **Antonio Casas-Rodriguez**, **Remedios Guzman-Guillen**, **Ana Camean** and **Angeles Jos**, *Universidad de Sevilla, Spain*

Cylindrospermopsin (CYN) is an ubiquitous cyanotoxin with increasing incidence worldwide. Humans can be exposed to CYN mainly by oral route through the ingestion of water or food contaminated with the toxin. CYN has been classified as a cytotoxin but it targets mainly the liver but also other organs. Among its toxic effects its immunotoxicity is scarcely investigated. The aim of this work was to assess the influence of CYN (18.75; 37.5 and 75 µg/kg/day) on the mRNA expression of selected interleukin (IL) genes (*IL-1b*, *IL-2*, *IL-6*, *TNF*, *IFN-?*) in thymus and spleen of male and female rats orally exposed to the toxin for 28 days. The gene expression was evaluated by Quantitative Real-time Polymerase Chain Reaction (qPCR). Results obtained showed that CYN

produced immunomodulation mainly in thymus of rats exposed to the toxin. In the thymus, immunomodulatory effects were observed after exposure to 75 µg CYN/kg/day in most of the genes, regardless of the sex. Moreover, up-regulation of *IL-2*, *IL-6*, *TNF* and *IFN-γ* were shown in females at the lowest dose of 18.75 µg CYN/kg/day. However, in the spleen only *IL-1b* and *IL-2* (males), and *TNF* and *IFN-γ* (females) were modified after exposure to the toxin. These outcomes highlight that CYN induces changes in the mRNA expression of IL genes in rats orally exposed to the toxin. Further studies are needed to obtain a deepest view of the molecular mechanisms involved in CYN immunotoxicity. 3.13.P-Mo194 Toxic Effects of Crude Extracts of the Phytoplankton Biomass Collected in Valle DE Bravo, Mexico on Early Life Stages of Danio rerio

Maricruz Quintero-Serrano¹, **Miriam Hernández Zamora²** and **Fernando Martínez-Jeronimo³**, (1)Zoology, Instituto Politécnico Nacional-ENCB, Mexico City, DF, Mexico, (2)Instituto Politécnico Nacional-Escuela Nacional de Ciencias Biológicas, Mexico, (3)Mexico Regional Chapter, Mexico

The Valle de Bravo reservoir is one of the main contributors to the Cutzamala System, that supplies drinking water to the Metropolitan Zone of the Valley of Mexico. This reservoir has been impacted by domestic, agricultural and tourism activities, causing deterioration in water quality and promoting eutrophication and the development of Harmful Algal Blooms (HABs), which are noxious to aquatic biota and humans. In this study the effect of crude phytoplankton biomass extracts obtained from the reservoir was assessed on the early life stages of *Danio rerio*. Biomass samples were collected from six locations in Valle de Bravo reservoir during March to December 2019. Crude extracts were obtained by cell rupture and bioassays were performed on recently fertilized *D. rerio* eggs, testing concentrations of 0.01, 0.1, 1, 1, 10 and 100 mg/L (dry weight). Cyanotoxins and accessory pigments concentrations were quantified. The results indicate that the crude extracts produced lethal effects such as coagulation and embryo mortality, as well as sublethal effects, such as absence of pigmentation, yolk sac oedema, curved tail, and teratogenic effects. The highest concentration of cyanotoxins was 2.16 µg/L determined in June, while the concentration of pigments indicates the highest levels in the months of April, August and September. In conclusion, the presence and frequency of the observed effects were related to the concentration of microcystins and other potentially toxic secondary metabolites within the reservoir.

3.13.P-Mo195 Development of Reproducible Culture Methods to Produce Cyanotoxins to Be Used to Generate Acute and Chronic Endpoints for Freshwater Organisms

James M. Lazorchak¹, **Susanna DeCelles²**, **Alex Kascak²**, **William Thoeny²**, **Nicholas Dugan³**, **Toby Sanan⁴**, **Ian Struewing⁴**, **Joel Allen¹** and **Jingrang Lu⁵**, (1)U.S. Environmental Protection Agency, United States, (2)Pegasus co US EPA Cincinnati, United States, (3)U.S. EPA Cincinnati, United States, (4)U.S. EPA Office of Research and Development Cincinnati, United States, (5)U.S. EPA ORD Cincinnati, United States

There is a lack of information to estimate safe exposure levels for aquatic life to natural toxins produced by cyanobacteria. The uncertainty in concentrations and purity of standards for cyanotoxins, and their high cost, challenge their use for acute and chronic toxicity tests. An alternative approach was tested, using cultures of cyanobacteria and algae to generate toxins. In this study, we have established laboratory cultures of toxin producers *Microcystis aeruginosa* lab cultured environmental strain (microcystin), *Aphanizomenon flos-aquae* PCC7905 (cylindrospermopsin), and *Dolichospermum circinale* CS-337 (saxitoxin) as well as non-toxin strain of *A. flos-aquae*. Early tests were conducted with microcystins obtained by removing cells from culture media and lysing them. Microcystin concentrations varied if cell density and time since inoculation (~150 days) of culture were tracked, with 1.75×10^6 cells/mL resulting in a microcystin concentration of 885 µg/L, while 4.16×10^6 cells/mL yielded 37 µg/L. Acute tests conducted with *Ceriodaphnia dubia*, *Neocloeon triangulifer*, *Hyalella azteca*, and larval *Pimephales promelas* using microcystins, did not cause any lethality different from the control at concentrations as high as 74 µg/L. However, the non-toxin-producing strain of *A. flos-aquae* caused mortality greater than the controls to *N. triangulifer*. For chronic tests IC25 for total microcystins for *C. dubia*, *P. promelas*, *H. azteca*, *N. triangulifer* were 8.9, 74.0, 408.9, and 10.1 µg/L, respectively. Due to the variability in getting consistent intracellular toxin levels, an approach was taken to harvest *M. aeruginosa* cultures during stationary phase to quantify microcystin concentrations by ELISA. Reproducible toxin concentrations (varied < 20%) were attained in both 500-mL and 1000-mL cultures, however, lysed cell extracts were too low to use for testing. These cultures were maintained at 25 +/- 1°C under a 16:8 h light/dark cycle at $15 \pm 1 \mu\text{mol m}^{-2} \text{s}^{-1}$. A culture of this same species under lower temperature and illumination resulted in higher cell lysate concentrations after 6 to 12 months. These culture conditions were repeated, and the lysate concentrations were tested. Results of the new culture methods used for *M. aeruginosa* and acute and chronic toxicity results will be presented.

3.13.P-Mo196 Cylindrospermopsin, Anatoxin-a and Their Homologs in the Southern Czech Republic - Taxonomical, Analytical, and MOLECULAR Approaches

Ludek Blaha¹, **Lucie Blahova²**, **Ludek Sehnal³**, **Olga Lepsova-Skacelova⁴**, **Vendula Szmucova³**, **Pavel Babica⁵**, **Klara Hilscherova⁶**, **Jonna Teikari⁷** and **Kaarina Sivonen³**, (1)RECETOX, Masaryk University, Faculty of Science, Brno, Czech Republic, (2)RECETOX, Masaryk University, RECETOX, Brno, Czech Republic, (3)Masaryk University, RECETOX, Czech Republic, (4)University of South Bohemia, Czech Republic, (5)Institute of Botany, ASCR, Czech Republic, (6)Masaryk University, Faculty of Science, RECETOX, Czech Republic, (7)University of Helsinki, Finland

Water bloom-forming cyanobacteria have severe impacts on freshwater quality including production of cyanobacterial toxins.

Despite of extensive research There is lack of information on the occurrence of neuro- and cyto-toxic toxins and their structural analogs as well as cyanobacterial taxa producing these toxins¹. The present study aimed to map levels of anatoxin-a (ATX), cylindrospermopsin (CYN) and their homologs along with the occurrence of *anaC* and *cyrJ* genes in laboratory strains and in water blooms from the Czech Republic providing thus the first integrative study combining analytical and molecular-biology approaches. Phytoplankton samples for taxonomical, toxin and molecular biology analyses were collected from the surface water in 16 localities in the southern regions of the Czech Republic. Freeze-dried biomass samples were extracted by acidified 75% v/v methanol and analysed by LC-MS for the content of microcystins, ATX and its homologs (HATX, DATX, DHATX), and CYN and its homolog 7-deoxyCYN. Qualitative PCR analysis of *cyrJ* and *anaC* genes was performed using DNA extracted from cyanobacterial biomass samples. **1. 2. 3.** The presence of CYN, ATX and their homologs HATX and 7-deoxyCYN was confirmed in phytoplankton biomass from 6 out of 16 pre-selected reservoirs. The presence of CYN and 7-deoxyCYN (up to 4.3 mg/g biomass d.w.; Píseňský pond) correlated with the presence of *cyrJ* gene. The corresponding calculated dissolved concentrations were 1.8 and 1.2 mg/L for CYN and 7-deoxyCYN, respectively. Interestingly, the biomass that contained both CYN and *cyrJ* gene was dominated by invasive cyanobacteria *Raphidiopsis raciborskii* (*Cylindrospermopsis raciborskii*) and *Cuspidothrix issatschenkoi*, and these cyanobacterial species might be newly described CYN producers in Europe. We further provided some of the first data on the occurrence of ATX and its congeners in the Czech Republic. ATX and HATX were detected in 4 natural biomass samples. The max concentration was 2.8 mg/g biomass d.w. for ATX and HATX. The calculated max dissolved concentrations were 365 ng/L for ATX (Site 13) and 12 ng/L for HATX (Site 8). Co-occurrence of *anaC* genes and neurotoxins (ATX, HATX) was not found in any sample. Interestingly, traces of ATX without confirmation of the *anaC* gene were observed in 2015, while contrary results (*anaC* gene but no ATX) were previously observed in 2013 in one reservoir (Stankov). The relevance of ATX congeners was further supported by analyses of laboratory strains, where levels of ATX congeners were about 10-times higher than those of the ATX itself.

3.13.P-Mo197 Trace Level Analysis of Odorants in Drinking Water Using High-Capacity-Sorptive Extraction

Jan Peter Mayer¹, Caroline Widdowson² and Rachael Szafnauer², (1)Markes International Ltd, Germany, (2)Markes International, United Kingdom

The presence of volatile organic compounds (VOCs) in drinking water even at trace-level can have a significant effect on consumer experience. The naturally occurring compounds (*e.g.*, geosmin) have particularly strong odours and are often the source of complaints to water companies, while other emerging odorants (*e.g.* isopropyl methoxy-pyrazine) are also of concern. International methods (*e.g.* ISO 17943 and the Chinese regulation GB 57493) define low detection limits (*e.g.* 1 ppt for TCA) for these compounds. This study focuses on five malodorous compounds that are regulated across international regulations, which have been regularly associated with pelagic and benthic harmful algal blooms (HABs). Reliable detection of these compounds is therefore important, but is challenged by their low odour thresholds, which are typically at the low ng/L level. By using multi-phase (DVB/CWR/PDMS) high-capacity sorptive extraction (HiSorb) combined with further analyte preconcentration using sub-ambient trapping, low levels of odorants can be analysed while maintaining peak shape, for increased signal-to-noise response, excellent linearity, low MDLs and highly reproducible results. The low detection limits enable water distribution facilities to detect malodorous compounds before consumers can. With the more robust, inert stainless-steel high capacity sorptive extraction probes similar results are achieved. The addition of multiple phases (DVB and CWR) to the HiSorb probes enables extraction of more polar compounds, that may also indicate the presence of HABs. In this study, we demonstrate the fully automated sampling and detection of odorants at ng/L levels in water using headspace HiSorb technique based on the principle of sorptive extraction and how trap-based preconcentration benefits the sensitivity, robustness and increases sample throughput, all of which is compliant with GB 57493 and ISO 17943.

3.14 Persistent, Mobile and Toxic (PMT/vPvM) substances: New Perspectives and Developments in their Assessment, Management and Regulation

3.14.T-01 Sfc-Ms Based Smart Screening of Groundwater for PMT/VPvM Compounds

Till Meier¹, Philipp Deist², Claire Wulf², Maolida Nihemaiti², Urs Berger³ and Thorsten Reemtsma⁴, (1)Analytical Chemistry, Helmholtz Centre for Environmental Research GmbH - UFZ, Leipzig, Germany, (2)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (3)Helmholtz centre for environmental research - UFZ, Germany, (4)Helmholtz Centre for Environmental Research, Germany

Persistent and mobile (PM) chemicals (also called PMOCs or in terms of regulations PMT/vPvM) infiltrate aquifers much faster than common compounds. Neither PMT/vPvM substances nor the compartment groundwater is considered by the regulation of REACH chemicals explicitly. This regulative gap originates from a knowledge gap: Especially the very mobile substances cannot be detected by common analytical methods like reversed phase chromatography coupled the mass spectrometry (RP-MS). Hence, the occurrence of PMT/vPvM compounds in groundwater is widely unknown. However, more than 55 % of EU drinking water is gained from groundwater. To protect the pollution of groundwater, the mobility and persistency of PMT/vPvM chemicals need to be accessed. The occurrence of PMT/vPvM chemicals in groundwater helps to estimate the PM characteristics necessary, to infiltrate this compartment. Hence, findings in the field help, how to narrow down the characteristics of PMT/vPvM substances, to put groundwater into risk. A screen smart study was conducted, which is crucial and urgently needed to reduce the analytical and knowledge gap by identifying hitherto unknown PMT/vPvM contaminants in groundwater. A new large volume generic enrichment method based on freeze-drying was developed to overcome the low injection volumes, coherently linked with the analysis of the extremely polar ones in the group of PMT/vPvM substances. In combination with supercritical fluid chromatography mass spectrometry (SFC-HR-MS) unknown PMT/vPvM chemicals were identified in groundwater. Total 15

compounds were identified, most of which are predicted to be negatively charged and with a negative logD in the relevant environment. Some of the identified compounds are toxic to reproduction, endocrine disruptors, or potentially carcinogenic. This study represents one important first step to identify the occurrence of PM compounds and thereby underlining the necessity of further extensive monitoring of these substances in groundwater, to access the mobility and persistence characteristics in field.

3.14.T-02 Persistence Assessment in Water-Sediment Systems

Carolin Seller¹, Birge Oezel Duygan¹ and Kathrin Fenner², (1)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Environmental Chemistry, Eawag & University of Zurich, Switzerland

In surface waters, aerobic biotransformation is considered the most dominant removal pathway for many contaminants. Therefore, international regulatory frameworks require the assessment of a substance's potential for biotransformation in laboratory studies following OECD 308/ 309 guidelines prior to its marketing authorization. To date, several shortcomings of OECD 308/ 309 studies have been elucidated; generally, study outcomes are often highly variable and not reproducible. A thorough understanding of relevant transformation processes and system-specific differences is still missing. Here, we performed laboratory studies with >40 compounds (i) as suspension tests containing sediment concentrations within and beyond standards defined in the OECD 309 guideline, and (ii) in a stagnant system in which a sediment layer is covered by a water column, i.e., OECD 308-type experiments. Outcomes of suspensions tests were highly variable and displayed striking inter-replicate and inter-study variabilities resulting in lag phases and chemical half-lives that differed by up to two order of magnitude for the same compound. When analyzing data of standard and modified OECD 308-type experiments, which employed sediment-water ratios of 1:3 and 1:10 (v/v), respectively, inter-replicate variabilities were strongly reduced. However, during standard OECD 308 studies, large fractions of compound mass tended to accumulate in the sediment layer and were not available for biotransformation, resulting in half-lives exceeding the typical duration of standard OECD 308 studies. Furthermore, with phase transfer processes dominating compound removal from the water column, outcomes of standard OECD 308 studies were found to be strongly dependent on properties of the employed sediment. Reduced sediment content in modified OECD 308-type studies compared to the standard OECD 308 setup allowed to shift observed processes from sorption to (bio)transformation. Compared to standard OECD 308/ 309 studies, the modified OECD 308-type system showed little inter-replicate and inter-study variability and improved observability of biotransformation for the majority of the investigated compounds. Overall, modified OECD 308-type studies thus allow for a better interpretability of a compound's potential for aerobic biotransformation.

3.14.T-03 Leachability As a Process-Based Method to Determine the Mobility of Chemicals in a PMT / vPvM Framework

Bernhard Jene¹ and Michael Klein², (1)BASF SE, Germany, (2)Fraunhofer IME, Germany

PMT and vPvM are envisaged as new hazard classifications for CLP to indicate chemicals with potential to reach drinking water sources by passing natural barriers like soil or riverbank sediments. As new criterion for mobility the Koc-value is proposed to be used to decide on mobile (M) or very mobile (vM) classification. However, in the ECETOC technical report No 139, evidence is provided that the Koc alone is a poor metric for the potential of chemicals to reach drinking water sources since this is mainly the result of the combination of both, sorption and degradation. The FOCUS framework for leaching of PPP through soil to groundwater which is a regularly updated approach that has been used for many years in a regulatory context is proposed as alternative. Most relevant processes such as degradation and sorption in soil as well as influences of climate, soil types and plants under representative European conditions are considered. Since PMT hazard classification for CLP must be based on substance inherent properties and should be independent of exposure leachability is defined as percentage leached mass related to the mass at the soil surface. Simulations were carried out with FOCUS-PELMO for all groundwater scenarios. The reference temperature for DT50 was set to 12 °C (ECHA guidance). Winter cereals was used and substance application was simulated at each month to consider the variation of the weather. The 80th percentile annual mass flux was related to the annual applied mass yielding the leachability in percentage. The average leachability of all scenarios was finally used as metric. Results of a sensitivity analysis show that leachability decreases rapidly with increasing Koc values and decreasing DT50 value. Substances that rapidly degrade in soil and sediment do not have the potential to reach drinking water sources despite low sorption although they might be classified as P or vP due to their persistency in other media like natural surface water (e.g. OECD 309). The use of the leachability approach for the M and vM assessment within PMT represents a much higher degree of realism than using a simple Koc-value. Due to the conservative assumption of only one meter transport distance and since transport times in the scenario for leachability are in the same order of magnitude as in typical bank filtration situations the results are in principle also transferable to such a drinking water protection scenario.

3.14.T-04 A Framework to Address Challenging Substance Properties and Improve the Use of Weight-Of-Evidence in Persistence Assessments - Outcome of the CEFIC-LRI ECO52 Project

Christopher Hughes¹, Megan Griffiths, MSc², Emma Pemberton², David M Brown³, Eleonore Delouvrier⁴, Stefan Hahn⁵, Dieter Hennecke⁶, Michael Klein⁷, Judith Klein⁸ and Graham Whale⁹, (1)Ricardo Energy & Environment, Chester, United Kingdom, (2)Ricardo Energy & Environment, United Kingdom, (3)Ricardo, United Kingdom, (4)Ricardo Energy and Environment, United Kingdom, (5)Fraunhofer ITEM, Hannover, Germany, (6)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (7)Fraunhofer IME, Germany, (8)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (9)SHELL, United Kingdom

Chemical persistence plays a key role in the determination of environmental exposure, making it an important component in risk assessment and regulation. However, existing frameworks under which persistence is assessed have shown some challenges. Chemical degradation rates are variable and dependent upon a number of factors including environmental conditions, which is difficult to address in a weight of evidence approach. In addition, many substances are problematic, or fall outside the

applicability domain of existing frameworks due to their specific characteristics. These include substances with certain phys-chem properties that render them difficult to test, substances of unknown composition, complex reaction products or biological materials (UVCBs), and polymeric substances. Finally, evaluating degradation half-lives using a compartment-by-compartment approach is overly simplistic, and neglects dynamic multimedia exchanges and degradation processes that may have an important bearing on the overall persistence of a substance in the environment. The CEFIC-LRI ECO52 project aims to address these issues by improving available guidance for persistence assessment of substances, including those considered problematic to evaluate under the current frameworks. This presentation will discuss the overall outcome of this CEFIC-LRI project, and the assessment framework for persistence that has been developed to deliver three important elements: 1) Improved guidance on weight of evidence determination, incorporating bioavailability as well as critical processes and compartments of concern, leading to more robust and consistent decision-making in line with persistence protection goals. 2) Provisions for the assessment of substances currently problematic or outside the applicability domain of persistence frameworks, namely difficult test substances, UVCBs and polymers (including microplastics). 3) A workable methodology for incorporation of multimedia fate modelling and 'overall persistence' consideration into the persistence assessment framework. It is anticipated that these developments will lead to improvements to the transparency, consistency and robustness of persistence assessments and their applicability to a range of substance types in the future.

3.14.T-05 Trifluoroacetate Leaching Potential From Fluorinated Herbicides - a Balancing and FOCUS Modelling

Approach

Franziska Jentzsch¹, Miriam Diehle², Helena Banning³ and Christina Pickl⁴, (1)German Environment Agency (Umweltbundesamt), Germany, (2)Umweltbundesamt, Germany, (3)Federal Environment Agency (Umweltbundesamt), Germany, (4)German Environment Agency, Germany

Trifluoroacetate (TFA) is a very mobile, highly soluble and very persistent substance which originates from various chemicals containing a C-CF₃-group. One major source are plant protection products (PPP), which underlie aerobic degradation in soil and form TFA that enters groundwater via direct leaching. Accordingly, TFA was detected in many water bodies in elevated concentrations and is present in drinking water as well. During the approval process of active substances in PPP on EU level, the formation of TFA is not systematically investigated. Moreover, the potential of a precursor to form TFA during aerobic degradation studies may remain unrevealed as a specific analytical method is required. If TFA formation is then overlooked during the approval process, TFA is not included into groundwater risk assessment. The present work aims at estimating TFA entries into groundwater despite the lack of experimental data. We investigate whether TFA formation is an issue when using PPP and whether it may need more attention during the EU approval process of active substances. Here, we present the results for eleven herbicidal substances. Firstly, the TFA formation potential of the precursors was balanced and refined by an inclusion of mean production areas of the respective crops in the EU. Secondly, groundwater concentrations were modelled with FOCUS PEARL based on the peer reviewed endpoints published by the European Food Safety Authority (EFSA). Metabolism schemes were used as specified for groundwater modelling in the EFSA conclusions/renewal assessment reports modified for TFA formation and excluding those metabolites that do not contain a C-CF₃-group. Balancing of TFA emission potential shows that TFA might be emitted in high amounts and on a large area within the EU. The results of groundwater modelling indicate a medium to high leaching potential for TFA from all herbicides and crops considered. Hence, TFA formation and leaching to groundwater requires more attention in the approval of active substances used in PPP. TFA formation should be investigated in aerobic degradation studies for all substances containing a C-CF₃-group as standard data requirement and included into groundwater risk assessment to obtain a more realistic insight into TFA entries. Furthermore, these results may be used for groundwater monitoring concepts and in support of local minimization strategies in vulnerable areas.

3.14 Persistent, Mobile and Toxic (PMT/vPvM) substances: New Perspectives and Developments in their Assessment, Management and Regulation (Virtual Only)

3.14.V-01 Are the Persistence and Mobility of Chemicals Linked to Their Potential to Contaminate Drinking WATER?

Li Li¹, Zhizhen Zhang¹, Alessandro Sangion², Shenghong Wang³, Trevor Brown⁴ and Jon Arnot⁵, (1)University of Nevada, Reno, United States, (2)ARC Arnot Research and Consulting Inc. and University of Toronto Scarborough, Canada, (3)University of Nevada Reno, United States, (4)TNB Research, Canada, (5)ARC Arnot Research & Consulting Inc., Canada

Persistent (P) and Mobile (M) organic chemicals are considered emerging threats to the environment and drinking water because they can be transported long distances, penetrate natural and artificial barriers, and resist removal by traditional water treatment procedures. Bright-line P and M hazard criteria have been proposed as proxies for evaluating the potential for chemicals to reach and contaminate drinking water. While these screening criteria are simple and straightforward, it remains unclear whether, and to what extent, they capture the complex reality of chemical transport in the environment and hence adequately represent a chemical's potential for contaminating drinking water. In this work, we compare and contrast proposed P and M hazard criteria with concentrations in drinking water predicted by a fate and transport model, based on the data of 112,000+ discrete organic chemicals registered in chemical inventories. We evaluate whether chemicals with the greatest potential to contaminate drinking water are those scored high in both the P and M assessments. We find that while chemicals scored high in P and M indicators tend to possess a higher potential to contaminate drinking water, the difference in the potential between high and low P- and M-level chemicals is not statistically significant. Screening chemicals based on P and M indicators alone may overestimate the occurrence of certain chemicals in drinking water and hence causes "false positive" cases. While there is some value in identifying these types of chemicals, we also demonstrate it is also possible and prudent to characterize these chemicals in terms of exposure and potential risk. This work addresses the academic and regulatory need for better understanding the processes and properties relating

to drinking water contamination and for developing and evaluating scientifically defensible methods and criteria to identify and potentially regulate chemicals of concern for the safe and sustainable use of chemicals in commerce.

3.14.V-02 Interpolation and Extrapolation of Polyparameter Linear Free Energy Relationships (PP-LFERs) to Predict Partition Coefficients

Satoshi Endo, National Institute for Environmental Studies (NIES), Japan

Polyparameter linear free energy relationships (PP-LFERs) predict equilibrium partition coefficients (K) of diverse neutral organic compounds and thus are useful to evaluate the mobility of chemicals. PP-LFERs describe the free-energy contributions of all intermolecular interactions relevant to solute solvation using five compound descriptors, undergo training with experimental data through the least-square multiple linear regression method, and generally have a broad range of applicability. Like any other empirical model, the prediction accuracy of a PP-LFER depends on the quality of calibration, and extrapolations outside the model calibration domain are expected to be less accurate than interpolations. Moreover, a long-range extrapolation should more likely generate a large error than a short-range extrapolation. However, quantitative evaluation of interpolation and extrapolation of PP-LFERs has seldom been performed. In this study, the applicability domain (AD) of PP-LFERs is evaluated by calculation of the leverage (h_j), a measure of distance from the calibration domain as defined by the five compound descriptors. Simulations with experimental data illustrate that the root mean squared error of predictions indeed increases with h_j . Moreover, extreme prediction outliers occur more frequently when h_j exceeds the common threshold of $3h_{\text{mean}}$, where h_{mean} is the mean of leverages of all training compounds. Nevertheless, well-calibrated PP-LFERs with many (e.g., 100) and diverse training data are surprisingly robust against extrapolation. Per and polyfluorinated alkyl substances (PFASs) with large F/C ratios and organosilicon compounds (OSCs) have characteristic interaction properties and thus are always outside the domain of calibration if none of them are included in the training set. Thus, these compounds must be extrapolated by typical PP-LFERs and be prone to elevated prediction errors. Published PP-LFERs are evaluated with 25 AD probe chemicals in terms of the domain of calibration, which shows that existing PP-LFERs are differently biased; highly polar chemicals and/or highly hydrophobic chemicals are often out of the calibration domain in addition to PFASs and OSCs.

3.14.V-03 Online Analysis of Gas and Particle Phase Trifluoroacetic Acid

Jessica Clouthier, Shira Joudan, Trevor VandenBoer and Cora Young, York University, Canada

Trifluoroacetic acid (TFA) is an ultrashort chain perfluoroalkyl carboxylic acid (PFCA) containing two carbons that is expected to increase in the environment following the Montreal Protocol-mandated chlorofluorocarbon (CFC) replacements. TFA is highly polar, stable in the environment, and highly soluble in water making them very persistent and very mobile (vPvM). Current atmospheric sampling methods for short-chain PFCA mainly use offline sampling techniques, such as measuring gaseous TFA with annular denuders and particulate TFA with quartz filters on collection timescales of several hours to days. The atmospheric processes (e.g. gas-particle partitioning) that drive production and fate of ultrashort-chain PFCA occur on faster timescales. As a result, these slow measurements offer limited insight into these processes. Faster analyses can give extremely valuable information on the temporal trends and concentrations of analytes. There is currently a gap in research of simultaneous semi-continuous analysis of gaseous and particulate TFA. This study collected gas and particle phases hourly in Toronto, ON Canada using an ambient ion chromatograph mass spectrometer (AIM-IC-MS). The benefit of this is it can simultaneously analyze major inorganic and organic charged ions that assist in understanding the behavior of gas-particle partitioning. By coupling the AIM-IC to a mass spectrometer (AIM-IC-MS), we will demonstrate: i) the extended capability of the technique to ultra-trace chemical species, including TFA; and ii) the first in situ measurements of gas and particle TFA in the ambient atmosphere. TFA was present in almost all samples with higher amounts of gas phase TFA compared to the particle phase. Variation of TFA concentrations throughout a day can be seen with an average of total TFA at $2.4 \pm 0.9 \text{ ng m}^{-3}$ in November. This represents an increase in atmospheric TFA previously reported in the early 2000s.

3.14.V-04 PMT and vPvM Substances in Republic of Korea

Yoonah Jeong, KICT, Korea, South

Persistent, mobile and toxic (PMT) substances and very persistent and very mobile (vPvM) substances have been received the deserved attention. The intrinsic properties of PMT and vPvM substances hamper consistent and reliable monitoring, control, and regulation of those chemicals. In this study, PMT and vPvM substances are categorized and prioritized to construct a new database of the Republic of Korea. The construction of PMT and vPvM substances database would be the first step of discussion on how to deal with PMT and vPvM substances. Herein, several indicators were considered including the consumption and use of substances, detection frequency in environment, detected concentration, and toxicity. Over 100 compounds were selected, many of which were overlapped with the existing list in EU commission. With the produced database, the analysis methods of PMT and vPvM substances in environment were proposed by using passive sampling approach.

3.14 Persistent, Mobile and Toxic (PMT/vPvM) substances: New Perspectives and Developments in their Assessment, Management and Regulation (Poster)

3.14.P-We110 Environmental Behaviour and Mobility of Heterocyclic PAHs - Hazard Classification Towards PMT and PBT Concepts at Screening Level

Goksu Celik¹, Stefan Stolte² and Marta Markiewicz³, (1)Institute of Water Chemistry, Technische Universität Dresden, Dresden, Germany, (2)Technical University of Dresden, Germany, (3)Institute of Water Chemistry, Technical University of Dresden, Dresden, Germany

Heterocyclic polyaromatic hydrocarbons (heterocyclic PAHs) are of particular interest for environmental and human impact assessment due to their environmental abundance, indication of persistence, environmental mobility and poor data availability in many aspects. Heterocyclic PAHs have frequently been detected in the environment along with homocyclic PAHs, often near petroleum-contaminated sites. More importantly, the detection of heterocyclic PAHs in areas not specifically impacted by coal or oil mining, or processing activities, suggests high atmospheric or geohydrological mobility of heterocyclic PAHs accompanied by lack of degradation or their formation from other primary contaminants. Nevertheless, little attention has been paid to heterocyclic PAHs so far in terms of environmental behavior or hazard assessment. To address this, we first experimentally determined the physicochemical properties of 18 two- to five-ring heterocyclic PAHs, namely octanol-water partition coefficient, water solubility, and organic carbon-water partition coefficient (K_{oc}). In view of the increasing pressure on (drinking) water resources caused by persistent and mobile organics, the heterocyclic PAHs under study were classified into mobility classes based on $\log K_{oc}$ values, which were obtained from simulation tests using HPLC. Out of 18 compounds 11 were identified as potentially persistent, seven as mobile or very mobile and 11 as bioaccumulative or very bioaccumulative based on screening-level QSAR models using newly obtained experimental physicochemical data.

3.14.P-We111 Using the Concept of Essential Use to Manage PMT/VPvM Substances in Consumer Products: A Case-Study for Cosmetics

Joanke van Dijk¹, Romain Figuière², Stefan Dekker³, Annemarie van Wezel⁴ and Ian Cousins⁵, (1)Environmental Sciences, Copernicus Institute of Sustainable Development - Utrecht University, Utrecht, Netherlands, (2)Department of Environmental science, Stockholm University, Stockholm, Sweden, (3)Copernicus Institute of Sustainable Development - Utrecht University, Netherlands, (4)University of Amsterdam/IBED Institute, Amsterdam, Netherlands, (5)Stockholm University, Sweden

Due to their specific properties, substances that are mobile, persistent and toxic or very persistent and very mobile (PMT/vPvMs) can pose risks to water bodies. These substances are mainly unregulated, however, this is likely going to change in light of the publication of the Chemical Strategy for Sustainability in October 2020. Here, the European Commission expressed the aim to classify PMT/vPvMs as “substances of concern”. Furthermore, they announced their intention to extend the “essential-use concept” to risk management to ensure that consumer products do not contain harmful chemicals. The essential-use concept has previously been shown to be a useful tool to guide the phase-out of ozone-depleting substances under the Montreal Protocol, and has recently been suggested as a tool to guide the phase-out of other problematic groups of substances such as per- and polyfluoroalkyl substances. Extending the implementation of the essential-use concept to PMT/vPvMs requires a sufficient understanding of the current uses of substances and of the availability, suitability, and hazardous properties of alternatives. Currently, PMT/vPvMs are used in a diverse range of applications, including in cosmetic products. Studies indicated that cosmetic products contain a large number of chemicals with potential hazardous properties and that their use contributes to the occurrence of these chemicals in the environment. This emphasises the importance to manage hazardous substances, including PMT/vPvMs, in cosmetic products to both protect human and environmental health. Here, we aim to identify PMT/vPvMs in cosmetics products based on database searches. An initial screening of products based on a list of 20 PMT/vPvM showed that circa 6.4% of cosmetic products contain these substances. Haircare products (13.0%) and make-up (6.7%) are the two product groups with the highest share of PMT/vPvMs. Three of the most occurring substances -CI 16035 (colourant and hair dyeing agent), Benzophenone-4 (light stabilizer, UV absorber and UV filter) and Climbazole (anti-seborrheic and preservative)- were selected as case-study chemicals to explore the suitability of the concepts of essential-use and alternative assessment to manage and replace PMT/vPvMs in consumer products.

3.14.P-We112 Current Status of the Implementation of the PMT/VPvM Criteria Into CLP and REACH Regulation

Michael Neumann, IV 2.3 Chemicals, German Environment Agency (UBA), Desau-Rosslau, Germany

The European Green Deal (EGD) sets an ambitious zero pollution vision for 2030. The overall objective is to reduce the pollution of air, water and soil to levels that are not harmful to human health and the environment. In this context the European Commission published on October 14th 2020 its Chemicals Strategy for Sustainability Towards a Toxic-Free Environment (CSS). The CSS is one important pillar of the Zero-Pollution Ambition for a Toxic Free Environment. The European Union has one of the most comprehensive and ambitious legislations on chemicals globally. The Regulation on the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) (COM, 2006) and the Regulation on the Classification, Labelling and Packaging of hazardous substances (CLP) are the two horizontal legislations on chemicals in the European Union. The European Commission aims to finalise the legislative proposal for the revision of the REACH Regulation by the end of 2022. The European Commission also aims to strengthen the CLP regulation as cornerstones of EU chemicals legislation. The “One substance, one assessment” process will ensure simplification and greater transparency of chemical hazard assessment. In 2021 the process started to amend the CLP Regulation to introduce new hazard classes on endocrine disruptors, PBTs/vPvBs and PMTs/vPvMs and apply them across all legislation. On September 24th 2021 the Commission proposed new hazard classes and criteria in the CLP Regulation to fully address environmental toxicity, persistency, mobility and bioaccumulation. Initial discussion took place at ECHA’s PBT expert group. In an ad hoc meeting of CARACAL on September 30th 2021 the criteria for PBT/vPvB and PMT/vPvM have been discussed and subsequently commented in writing by the MS Cas, industry, NGOs and stakeholders. The underlying goal of adding new hazard classes related to PMT and vPvM is to protect natural resources that could be used for drinking purposes from chemical pollution. Here we will present the current status of the implementation of the PMT/vPvM criteria into CLP and REACH regulation since November 2021. We will present a summary and overview of the written comments and analyse the differences in the different sets of PMT/vPvM criteria. The new hazard classes PMT and vPvM will be applied to substances detected in raw water and drinking water.

3.14.P-We113 ZeroPM - Zero Pollution of Persistent, Mobile Substances

Hans Peter Arp¹, Ian John Allan², Athanasios Stasinakis³, Ian Cousins⁴, Sylvia Escher⁵, Greta Goldenman⁶, Todd Gouin⁷, Stefan Hahn⁸, Annette Bitsch⁵, Timo Hamers⁹, Olga-Ioanna Kalantzi¹⁰, Anna Lennquist¹¹, Melanie Muro⁶, Sabine Pahl¹², Gregory Peters¹³, Marcel Riegel¹⁴, Marco Scheurer¹⁵, Ivo Schliebner¹⁶, Emma Schymanski¹⁷, Bert Van Bavel¹⁸, Marjorie van Duursen¹⁹, Zhanyun Wang²⁰ and Sarah Hale²¹, (1)NGI, Norway, (2)Norwegian Institute for Water Research, Norway, (3)University of the Aegean, Greece, (4)Stockholm University, Sweden, (5)Fraunhofer ITEM, Germany, (6)Milieu Consulting, Belgium, (7)TG Environmental Research, Sharnbrook, United Kingdom, (8)Fraunhofer ITEM, Hannover, Germany, (9)VU University Amsterdam, Institute for Environmental Studies (IVM), Netherlands, (10)Environment, University of the Aegean, Mytilene, Greece, (11)ChemSec, Göteborg, Sweden, (12)University of Vienna, Austria, (13)Chalmers University of Technology, Sweden, (14)DVGW-Technologiezentrum Wasser (TZW), Germany, (15)Water Technology Center TZW Karlsruhe, Germany, (16)UBA, Germany, (17)University of Luxembourg, Luxembourg, (18)NIVA, Norway, (19)Vrije Universiteit Amsterdam, Netherlands, (20)ETH Zurich, Switzerland, (21)Norwegian Geotechnical Institute (NGI), Norway

Announcing the recently funded H2020 Project ZeroPM – Zero Pollution of Persistent, Mobile substances. ZeroPM will interlink and synergize three strategies to protect the environment and human health from persistent, mobile substances: Prevent, Prioritize and Remove. The project is rooted on EU's Chemicals Strategy for Sustainability towards a toxic free environment. To choose the PM substances for which this is most urgent, ZeroPM will Prioritize PM substances and substance groups through the development and application of robust screening and prioritization tools. These tools will identify all PM substances on the global chemical market, taking into consideration their production, use, presence in the circular economy, exposure, hazards and risks. To Remove, ZeroPM will focus on geographically impacted areas and prioritized groups of PM substances, and develop next generation remediation methods to remove PM substances from water resources, drinking water and sludge-derived products. *Acknowledgment: This project has received funding from the European Union's Horizon H2020 research and innovation program under grant agreement No 101036756*

3.14.P-We114 ZeroPM - Catalyzing the Market Transition Away From Persistent and Mobile Chemicals

Anna Lennquist¹, Jonatan Kleimark², Sarah Hale³ and Hans Peter Arp⁴, (1)ChemSec, Göteborg, Sweden, (2)Chemsec, Sweden, (3)Norwegian Geotechnical Institute (NGI), Norway, (4)NGI, Norway

The ZeroPM workpackage “Market Transition” will work in close collaboration with industry (manufacturers and downstream users) to provide fit for purpose web-based tools to support companies at different stages of the market transition. Mainly three different tools to support this transition will be developed or updated: The SIN (Substitute it Now) List, the ChemSec Marketplace and a brand new “PFAS guide”. The SIN List is itself an “early warning” of chemicals that will be regulated and is often ahead of the much slower official regulatory process. As such it drives innovation in the chemical industry, having about 50 000 users per years from all over the globe. By using the results from the other work packages, an update of the SIN List with additional PM chemicals is planned for 2025. The ChemSec Marketplace gathers green chemical innovations in one place and allows chemical producers to advertise their products free of charge. This is a unique and much appreciated resource for different types of companies, as well as for regulators. Information on safer alternatives to PM substances, derived within the ZeroPM program will be published also as adds on the Marketplace website throughout the project. Finally, a brand new “PFAS guide” for companies supporting them in the identification of PFAS in their products or manufacturing processes will be established. Using the different available inventories on PFAS uses, many of which have been produced by project partners, an easily accessible interactive tool will be built in close collaboration with companies representing the target group. This project has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement No 101036756

3.14.P-We115 Comparison of NER Formation in Soil (OECD 307) and Water-Sediment (OECD 308) Degradation Study Using ¹⁴C Labelled Phenanthrene

Boris Meisterjahn¹, Prasit Shrestha², Dieter Hennecke¹, Neil Wang³, Christopher Hughes⁴, Louise Camenzuli⁵, Delina Lyon⁶ and Alberto Martin-Aparicio⁶, (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Fraunhofer-IME, Germany, (3)TOTALENERGIES, France, (4)Ricardo Energy & Environment, Chester, United Kingdom, (5)ExxonMobil, Belgium, (6)CONCAWE, Belgium

Biodegradation data of chemicals are necessary for regulatory use and often generated using standard tests (e.g. soil degradation according to OECD 307 and water-sediment degradation according to OECD 308). In these tests many chemicals may form non-extractable residues (NER) which can be quantified only if the test is conducted with isotopic labelled chemicals. NER include by definition physically entrapped parent compound and/or transformation products (type I NER), which is potentially remobilizable and hazardous, non-remobilizable covalently bound (type II NER) and biogenic (type III NER) fractions. For characterization of these fractions, procedures such as silylation for release of type I or acidic hydrolysis for determination of type III NER have been proposed and tested in soil degradation studies. These procedures are also gradually being applied to sediment degradation studies, but so far experimental data are very rare. The aim of this work was to apply 1) the proposed procedure of type I NER determination to samples from a water/sediment study and 2) to compare the total NER and type I NER formation in soil and water-sediment degradation studies using the same test substance. The degradation of ¹⁴C-labelled Phenanthrene was tested in (i) two different soils according to OECD 307 and (ii) two different water/sediments systems according to OECD 308. The studies were run for a duration of 120d and 103d for soil and sediment, respectively. Soil samples were exhaustively extracted by solvent extraction followed by harsh extraction using accelerated solvent extraction (ASE). The sediment samples were extracted analogously, but ASE was only performed on a subset of samples, and deemed unnecessary due to low additional recoveries (< 5% of applied radioactivity (AR)). The remaining total NERs were quantified by combustion analysis and the extracted soil residues subjected to the silylation procedure. For the soil and sediment degradation studies, the total NER fraction after 28d

ranged from 35.5-39.3% AR and 35.3-41.5% AR respectively. Towards end of incubation, total NER decreased in both studies to 25.5-26.3 %AR for soil and 29.7-40.3%AR for sediments. Higher amount of parent could be identified in the silylation extracts of sediments (9.6 %AR parent in 16.9%AR released (28d)) compared to soil (~2.1 %AR in 14.7%AR released (14d)). The release of relevant amounts of parent from NER and the impact on persistency assessment will be discussed.

3.14.P-We116 Risk Indicators for PMT/vPvM Substances

Hans Peter Arp¹, Ulrich Borchers², Michael Neumann³, Isabelle Neuwald⁴, Karsten Nödler⁵, Marco Scheurer⁶, Ivo Schliebner⁷, Jona Schulze⁸, Laura Wiegand², Vassil Valkov², Daniel Zahn⁴ and Sarah Hale⁹, (1)NGI, Norway, (2)IWW Water Centre, Germany, (3)IV 2.3 Chemicals, German Environment Agency (UBA), Desau-Rosslau, Germany, (4)Hochschule Fresenius, Germany, (5)ITZW: DVGW-Technologiezentrum Wasser (German Water Centre), Germany, (6)Water Technology Center TZW Karlsruhe, Germany, (7)UBA, Germany, (8)German Federal Environment Agency (UBA), Germany, (9)Norwegian Geotechnical Institute (NGI), Norway

Substances that are very persistent in the environment and very mobile in the aquatic environment (vPvM); or, substances that are persistent in the environment, mobile in the aquatic environment and toxic (PMT) are of concern to the sources of our drinking water. A review of substances detected in drinking water and groundwater found that 43% of them are REACH registered (referring to the EU REACH Regulation (EC) No 1907/2006). Further, REACH registered substances were the most likely to be found at higher concentrations (above 0.1 µg/L). We developed guidelines to prospectively or retrospectively use the REACH registration process to identify PMT/vPvM substances. Special considerations for data uncertainty are presented via the implementation of a “traffic light” system. The guidance was applied to all 22400 REACH registered substances as of September 2019, and in addition 1308 substances that were reported as detected in various fresh water monitoring studies. The results of a PMT/vPvM hazard assessment for these substances will be presented. For a subset of these substances, a risk indicator assessment was developed that in addition of looking at the hazard of PMT/vPvM substances, also considers other factors associated with exposure and risk.

3.14.P-We117 ZeroPM - Policy Analysis, Development and Assessment

Gretta Goldenman¹, Michael Neumann², Melanie Muro¹, Tugce Tugran¹, Julia Lietzmann¹, Florent Pelsy¹, Lise Oulès¹, Mariya Gancheva¹, Alicia McNeill¹, Ivo Schliebner³, Jona Schulze⁴, Alexander Badry⁵, Hans Peter Arp⁶ and Sarah Hale⁷, (1)Milieu Consulting, Belgium, (2)IV 2.3 Chemicals, German Environment Agency (UBA), Desau-Rosslau, Germany, (3)UBA, Germany, (4)German Federal Environment Agency (UBA), Germany, (5)German Environment Agency (Umweltbundesamt), Germany, (6)NGI, Norway, (7)Norwegian Geotechnical Institute (NGI), Norway

The H2020 Project ZeroPM – Zero Pollution of Persistent, Mobile substances will include a work package focused on identifying policy changes to more effectively prevent PM substances from entering the environment. It will analyse policy objectives and targets formulated at European and international levels, including the EU Chemicals Strategy and the upcoming Zero Pollution Action Plan for Water, Soil and Air. Sources will include relevant environmental, sector, product and substance legislation, as well as stakeholder interviews and workshops. This evidence base will be used to spot opportunities and gaps in the existing policy/legal framework and to develop and assess policy options for minimizing emissions of PM substances. Work products will include policy briefs presenting key findings and recommendations for actions, along with roadmaps for meeting zero-pollution ambitions. *Acknowledgment: This project has received funding from the European Union's Horizon H2020 research and innovation program under grant agreement No 101036756.*

3.14.P-We118 ZeroPM - Removal of PM Substances

Olga-Ioanna Kalantzi¹, Marcel Riegel², Hans Peter Arp³, Sarah Hale⁴, Michalis Fountoulakis⁵, Stergios Vakalis⁵ and Athanasios Stasinakis⁵, (1)Environment, University of the Aegean, Mytilene, Greece, (2)DVGW-Technologiezentrum Wasser (TZW), Germany, (3)NGI, Norway, (4)Norwegian Geotechnical Institute (NGI), Norway, (5)University of the Aegean, Greece

In the H2020 Project ZeroPM – Zero Pollution of Persistent, Mobile substances, there will be a Work Package dealing with the removal of persistent and mobile (PM) substances.

Within this Work Package, geographically impacted areas and prioritized groups of PM substances like PFAS will be focused and developed next generation remediation methods to remove PM substances from water resources, drinking water and sludge-derived products will be investigated. Various aspects of PM substance exposure in drinking water, water resources and sludge will be investigated through three test sites in Germany and Greece. It will be demonstrated how and if legacy PM substance pollution can be remediated.

Specifically, monitoring methods and strategies will be initially developed and applied to facilitate the evaluation of the different water treatment methods. This will include both the adaption of existing technologies for on-site real time monitoring and innovative methods including passive sampling (PS), high-resolution analysis of PM substances and sum or group parameters to overcome shortcomings of existing analytical methods. For the treatment of contaminated groundwater, two advanced and innovative technical solutions for the PM substances will be tested. Concerning wastewater and sludge management, lab and pilot scale experiments will be conducted for PM substance contaminated sludge and wastewater in order to evaluate removal efficiency and to gain insight into degradation pathways, using a combination of new and improved biological and thermal treatment processes.

Acknowledgment: This project has received funding from the European Union's Horizon H2020 research and innovation program under grant agreement No 101036756.

3.14.P-We119 ZeroPM - Risk Assessment

Todd Gouin¹, Annette Bitsch², Sylvia Escher², Stefan Hahn³, Timo Hamers⁴, Marjorie van Duursen⁵, Hans Peter Arp⁶ and Sarah Hale⁷, (1)TG Environmental Research, Sharnbrook, United Kingdom, (2)Fraunhofer ITEM, Germany, (3)Fraunhofer ITEM, Hannover, Germany, (4)VU University Amsterdam, Institute for Environmental Studies (IVM), Netherlands, (5)Vrije Universiteit Amsterdam, Netherlands, (6)NGI, Norway, (7)Norwegian Geotechnical Institute (NGI), Norway

In the H2020 Project ZeroPM – Zero Pollution of Persistent, Mobile substances, there will be a Work Package dealing with the development and application of risk assessment methods targeted for chemicals identified as persistent and mobile (PM). Within the Risk Assessment Work Package there will be an emphasis towards the development of a multimedia fate model aimed at estimating environmental concentrations based on an evaluation of multi-pathway exposures of chemicals into the environment. The predicted environmental concentration will then be used to derive an external human exposure concentration to PM substances in drinking water. The estimated drinking water concentration will be used in combination with the development of a physiologically based pharmacokinetic (PBPK) model, which will translate in vitro effect concentrations to human relevant internal doses of PM substances and external exposure scenarios, and vice versa. To support the ability to relate exposure to an adverse effect concentration, a toolbox for PM hazard assessment will be developed using a suite of in vitro and in silico methods targeting the main toxicological endpoints of concern. Ultimately, risk will be derived with results communicated using a risk matrix approach that can be used for screening and prioritization of PM substances based on integration of exposure and hazard data (contributing to WP3 and single substance regulation). The risk matrix approach will thus be used both retrospectively, whereby the approach can be evaluated against known PM substances, but is anticipated to provide valuable prospective insight by enabling the screening and identification of bioactive contaminants of emerging concern with substance properties consistent with potential PM substances.

3.14.P-We120 Expanding the Biodegradation Database in enviPath to Predict Transformation Products and Half-Lives and in Soil and Sediment

Jasmin Hafner¹, Moritz Salz², Emanuel Schmid³, Kunyang Zhang¹ and Kathrin Fenner⁴, (1)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)University of Zurich, Switzerland, (3)ETH Zurich, Switzerland, (4)Environmental Chemistry, Eawag & University of Zurich, Switzerland

Computational models of microbial biodegradation processes are designed to predict biotransformation pathways and half-lives of organic pollutants, but they require big amounts of accessible, standardized biodegradation data, which are difficult to obtain. To this end, the online platform enviPath has been established in the past [1]. It contains biodegradation pathways and half-lives for chemicals in the environment, complemented by metadata on study conditions. An integrated pathway prediction engine proposes potential biotransformation products and pathways. These predictions are performed by biotransformation rules and guided by a machine learning algorithm trained on the experimental data in enviPath. In this work, we build upon existing resources in enviPath to accommodate data from additional environmental compartments. The first environment-specific dataset has been published for pesticide degradation in soil (OECD 307) [2]. Here, we expanded the enviPath framework to accommodate experimental data from water-sediment systems (OECD 308), and we imported study data for pesticides from public regulatory dossiers. In addition, we added biodegradation data for activated sludge (OECD 314b) to lay the foundation for read-across approaches from sludge to soil and sediment studies. Adding new data types for more chemicals creates new opportunities for half-life modeling, prediction of transformation products, and reading across different environments. The enviPath web server is publicly available, and accessible via an Application Programming Interface (API) to facilitate integration into custom modeling workflows. Hopefully, the expansion of enviPath will open new avenues for modeling persistence of organic pollutants in different environments by providing standardized, easily accessible biodegradation data obtained from regulatory-type standard simulation studies. 3.14.P-We121 Modelling Biodegradation of Organic Chemicals - Is Initial Degradation Concentration an Insensitive Parameter?

Andreas Libonati Brock¹, Stefan Trapp² and Matthias Kästner³, (1)DTU Environment, DTU Sustain, Kgs. Lyngby, Denmark, (2)DTU Environment, Denmark, (3)Helmholtz Centre for Environmental Research GmbH – UFZ, Germany

Persistence is a key criterion in chemical risk assessment, and high persistence of any substance is of major concern. In chemical regulation, persistence is assessed in environmental simulation tests according to OECD technical guidelines and often with ¹⁴C-radioactive-labeled compounds. Typically, significant amounts of non-extractable residues (NER) of the label remain in the matrix. Part of this NER, named biogenic NER or bioNER, is formed by microbial biomass and microbial residues, which is of no concern in the persistence assessment. The degradation kinetics as well as the formation of bioNER can be simulated using Michaelis-Menten kinetics (v_{max} and K_s) combined with calculated biomass growth derived from theoretical growth yields [1, 2, 3]. This approach allows to extract, by inverse modelling and model calibration, kinetic parameters for microbial growth and metabolism and also enables the prediction of the bioNER formation. Different descriptors have been used to describe the total biomass and the degrader biomass. However, in the present study we can show that the initial amount of degraders may be an insensitive parameter for the model simulations: initial degrader biomass does affect the time passing until the exponential growth phase of the microbial population sets in (i.e. the lag phase) but has little effect on the final distribution of the applied label.

Therefore, initial values can be selected which are typical for the type of experiment (e.g. soil, water, water and sediment) and the inoculum. Once the growth and metabolism parameters have been determined by inverse calibration, the outcome is transferable to other compartments, with other initial conditions and concentrations, as well as to real environments. Inverse model simulations will allow to re-evaluate existing or future OECD test results without the necessity to measure bioNER or microbial population densities, to derive realistic, scientifically sound and transferable descriptions of degradation kinetics, and thus supports rational persistence assessment under consideration of NER formation without additional experimental effort. 3.14.P-We122 Biodegradation of Heterocyclic Polyaromatic Hydrocarbons - Ready Biodegradability, Microbial Adaptation, Primary Biodegradation

Goksu Celik¹, Stefan Stolte² and Marta Markiewicz³, (1)Institute of Water Chemistry, Technische Universität Dresden, Dresden, Germany, (2)Technical University of Dresden, Germany, (3)Institute of Water Chemistry, Technical University of Dresden, Dresden, Germany

The past decades have witnessed ongoing progress in understanding the hazard potential of heterocyclic polyaromatic hydrocarbons (heterocyclic PAHs). Heterocyclic PAHs are often less hydrophobic and more water-soluble than their homocyclic equivalents, and are therefore more mobile and bioavailable in aqueous compartments. Large heterocyclic PAHs, although more polar than homocyclic equivalents, also have high affinity to soil organic matter and might be bioaccumulative. Smaller heterocyclic PAHs on the other hand are potentially mobile in soils and are not expected to bioaccumulate in biota. Due to their potentially hazardous properties, the elimination of heterocyclic PAHs from the environment is of paramount importance that mandates investigation. In this work, we tested the ready biodegradability of nine heterocyclic PAHs using the manometric respirometry method under aerobic conditions. None of the tested compounds proved to be readily biodegradable. The microbial community was then adapted to the test substances, but no improvement in mineralization was observed after a 60-day of adaptation period. Several compounds were found to be “inhibitory” to the microbiota adapted to test substances for 250 days, even when loaded at the lowest concentration (3 mg/L) viable for the manometric system. With the aim of seeking more feasible conditions for testing biodegradability of heterocyclic PAHs, a primary biodegradation test was designed following the course of biodegradation via GC/MS. After two successful primary biodegradation tests supplemented with abiotic controls, carbazole, dibenzofuran, benzo[a]acridine, and benzo[c]carbazole underwent primary biodegradation, with only carbazole (100%) and benzo[a]acridine (70%) showing high levels of biodegradation, which improved slightly in the second primary biodegradation test with longer adaptation period (120 days) compared to first run (75-day adaptation). Although compound removals were observed in primary biodegradation tests ($C_{\text{start}}=0.16$ mg/L), any oxygen consumption was not detected in the manometric system ($C_{\text{start}}=15$ mg/L), which could be due to the toxic effects of the compounds on microorganisms at high test concentrations. Yet, no evidence of biodegradation was detected for the rest of heterocyclic PAHs. These results suggest that the persistence potential of heterocyclic PAHs should not be underestimated, and urgent steps should be taken to closely monitor these compounds in the environment.

3.14.P-We123 Identification of Degradation Products - an ECHA Decision CASE Study for a Non-Readily but Inherently Biodegradable Substance

Georg Kreutzer¹, Karen Jenner², Diane Petermann³ and Thomas Dutriez³, (1)RAPS, Givaudan SA, Vernier, Switzerland, (2)Givaudan, United Kingdom, (3)Givaudan Suisse SA, Switzerland

The identification of degradation products is a standard information requirement of REACH Annex IX (?100tpa substances). We received an ECHA decision requesting this information for a substance that was not readily biodegradable but inherently biodegradable and not persistent based on positive results in enhanced biodegradation screening tests. ECHA considered that this information was needed in relation to the PBT/vPvB assessment. Two extended 301F ready biodegradability studies were included in the original dossier in which the pass level of 60% was achieved by day 42. Both studies met the conditions outlined in ECHA guidance (Chapter R.11) for when positive results from an enhanced screening may be used to conclude that a substance is not P/vP. However, it is noted that the ECHA guidance includes the proviso “together with other supporting information”. ECHA requested the identification of the degradation products by using an appropriate and suitable test method. The method had to be substance specific and, if analytically possible, the identification, stability, behaviour and molar quantity of the metabolites relative to the parent were to be evaluated. In this poster, we present how we successfully addressed this information requirement by conducting a new extended 301F test with the inclusion of substance specific analysis. The registered substance is an organic nitrile. It was hypothesised that the most probable primary metabolites are the corresponding amide and acid. Reference samples were synthesised from the parent substance. The concentrations of parent and target metabolites were quantitatively monitored by LC-MS throughout the test (e.g. day 0,1,4,7,14,21,28 and 60). At the end of the test, the parent substance was below the limit of detection, indicating complete primary biodegradation. Very low levels of the two metabolites were detected during the test. The target metabolite analysis coupled with the high BOD at the end of the test (73% day 60) indicates that any metabolites formed following primary degradation are transient and not persistent. This was supported by CATALOGIC predictions. With the submission of this new data, ECHA considered the request in the decision as met, and the information requirement fulfilled. Therefore, this case study demonstrates how OECD 301 studies can be used to garner additional information on the biodegradability of chemicals to assess persistence and avoid the need for higher tier simulation testing.

3.14.P-We124 Modifications of Simulation Study Test Design to Improve Testing of Chemicals and Biocides

Silke Fiebig, Natalie Horn, Gregor Panek, Marc Flügel and Stephan Goller, Noack Laboratorien GmbH, Germany

The calculation reliable degradation half-lives is of utmost importance for the persistency assessment of a chemical. To determine the transformation and corresponding degradation half-lives of chemicals in environmental compartments like soil, sediment and water, simulation studies acc. to OECD test guidelines 307, 308 and 309 are requested by the authorities. These guidelines were developed about 20 years ago, with the focus on pesticide regulation. Hence the general procedures of these studies mainly consider the properties of pesticides. To derive reliable degradation half-lives, the experimental approach of a simulation study must consider the physico-chemical properties and degradation behaviour of the substance to be tested. As the physico-chemical properties and degradation behaviour of chemicals and biocides often differ significantly from pesticides, the “standard” test design, used longtime for pesticides, is often not suitable for these substances. Especially for volatile substances and substances with fast mineralization, adaptations and improvements of the test design are necessary. Modifications of the test design to increase the reliability of degradation half-lives will be presented.

3.14.P-We125 Data Criteria Used for PBT/VPvB Assessment in the Community Rolling Action Plan (CoRAP) Substance Evaluations Under REACH

Christopher Hughes¹, Megan Griffiths, MSc², Eleonore Delouvrier³, Delina Lyon⁴, Louise Camenzuli⁵, Alberto Martin-Aparicio⁴, Neil Wang⁶, David Saunders⁷, Sergio Villalobos⁸ and Emma Pemberton⁹, (1)Ricardo Energy & Environment, Chester, United Kingdom, (2)Ricardo Energy & Environment, United Kingdom, (3)Ricardo Energy and Environment, United Kingdom, (4)CONCAWE, Belgium, (5)ExxonMobil, Belgium, (6)TOTALENERGIES, France, (7)Shell International, Netherlands, (8)BP, Naperville, Illinois, United States, (9)Ricardo Energy & Environment, UK

Substances that do not readily breakdown in the environment and have the potential to bioaccumulate in organisms and biomagnify through food webs may pose a potential risk to human health and the environment. Managing risks from such substances to ensure safe, sustainable use is challenging. Under the REACH regulation, substances that are persistent, bioaccumulative and toxic (PBT), and very persistent, very bioaccumulative (vPvB) substances are identified as Substances of Very High Concern (SVHC) and are prioritised for risk management. Specific screening and assessment criteria for persistence, bioaccumulation, and toxicity are detailed in REACH Annex XIII, including the need for a weight-of-evidence determination. This requires all available relevant information to be considered in a single determination for the identification of a PBT or a vPvB substance. The variety and complexity of data which may be available for a substance and considered within a weight-of-evidence determination can inevitably pose a challenge for data evaluation and PBT identification. Extensive guidance is available under REACH to support assessment of substances. This is updated periodically as regulatory and scientific developments occur. In addition, there have been efforts made recently to improve the guidance available for weight-of-evidence determinations, to facilitate consistency, transparency, and predictability in decisions (OECD, 2019; ECHA, 2020; Suter et al., 2020). We describe here a retrospective, systematic appraisal of data used for PBT identification under REACH, to provide further insight on the types of data used in the decision-making process, how a weight-of-evidence was applied and to inform development of further guidance. Publicly available data for previous substance evaluations have been examined against the detailed guidance set out by ECHA and the wider scientific literature, to identify critical data quality criteria with regards to adequacy, reliability and relevance used in decision making. The approach to weight of evidence determination for each substance has been captured. We describe an overview of our analysis, and where relevant, opportunities for improving PBT/vPvB assessments. Such information can also be used by scientists generating test data to improve the likelihood that their information can be used in a regulatory context.

3.14.P-We126 Transformation Products of Pharmaceuticals - Comparison of Predictions With Observations in Environmental Simulation Studies

Leo Trostel¹, Claudia Coll², Jasmin Hafner² and Kathrin Fenner³, (1)Uchem, Eawag & University of Zurich, Switzerland, (2)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (3)Environmental Chemistry, Eawag & University of Zurich, Switzerland

Active pharmaceutical ingredients (APIs) and their transformation products (TPs) are commonly found in the environment. However, the environmental fate and risks are known for a relatively small portion of these. The use of prediction software, such as enviPath [1], could facilitate the identification and risk assessment of TPs. These tools are able to recognize functional groups and predict reactions based on existing biotransformation rules. However, sensitivity and selectivity of predictions are expected to be low because of missing rules and prediction of irrelevant TPs due to combinatorial explosion, particularly when applied to chemical moieties not previously contained in the underlying databases. In this work, we aimed to compare predicted TPs from different pathway prediction algorithms to experimentally observed TPs in biotransformation tests run with activated sludge from a municipal wastewater treatment plant. For this purpose, we selected 46 APIs that were structurally diverse, and for which data from standard soil and water-sediment studies (OECD 307/308) were available. By analyzing samples from batch experiments with LC-HRMS/MS, we will identify TPs using suspect and non-target screening. Experimentally obtained degradation pathways will be compared to predicted ones to identify missing transformation rules, indicated by non-predicted TPs, and discrepancies in probabilities for existing transformation rules. Further, the comparison of TPs between sludge experiments and standard OECD 307/308 will allow us to assess if biotransformation pathways observed in sludge biotransformation experiments reflect those observed in soil and water-sediment simulation tests. We expect to observe several unreported TPs, which were readily predicted by *in silico* methods, and anticipate to improve current prediction methods. Since the tools are freely accessible, they will support scientists, regulators and manufacturers to estimate environmental fate with little effort. [1] Wicker et al. 3.14.P-We127 Improving Available Guidance for Persistence Assessment of Substances (CEFIC-LRI ECO52) - Using Overall Persistency in a Weight-Of Evidence for Persistence Assessment

Judith Klein¹, Michael Klein², Christopher Hughes³ and Stefan Hahn⁴, (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (2)Fraunhofer IME, Germany, (3)Ricardo Energy & Environment, Chester, United Kingdom, (4)Fraunhofer ITEM, Hannover, Germany

Chemical persistence plays a key role in the determination of environmental exposure making it an important component in risk assessment and regulation. However, existing frameworks under which persistence is assessed have shown some limitations. Chemical degradation rates are prone to wide variability depending on environmental conditions, which is difficult to address in a weight of evidence approach. In addition, many substances are problematic, or fall outside the applicability domain of existing frameworks due to their specific characteristics. Finally, evaluating degradation half-lives using a compartment-by-compartment approach is overly simplistic, and neglects dynamic multimedia exchanges and degradation processes that may have an important bearing on the overall persistence of a substance in the environment. This CEFIC-LRI project aims to address these issues by improving available guidance for persistence assessment of substances, including those considered problematic to evaluate under the current frameworks. Multi-media fate modelling (e.g. Mackay Level III) can in principle support weight-of-evidence (WoE) for persistence assessment especially with focus on justification for compartment of specific concern as well as on identification of remaining concern in untested compartments. However, according to the current guidance R.11 the distribution modelling results should only be regarded as qualitative or semi-quantitative and a case-by-case evaluation is needed. In this project, the overall persistency approach as well as dynamic multimedia fugacity box models (Level IV) has been evaluated to get a better understanding on persistence. The aim is to evaluate how multimedia modelling and overall fate can be incorporated to improve the robustness of current persistence assessment methodologies. Sensitivity analysis as well as case studies will be presented which illustrate the options how to use multimedia modelling in a weight-of-evidence approach.

3.14.P-We128 Regulatory and Technical Challenges of the Interpretation of Non-Extractable Residues in Persistence Assessment

Hans Allmendinger¹, Marie Collard², Bjoern Hidding³, Neil Wang⁴, Nathalie Vallotton⁵, Amaya János⁶ and Philipp Dalkmann⁷, (1)Currenta GmbH, Germany, (2)Solvay SA, Belgium, (3)BASF SE, Germany, (4)ARKEMA France, France, (5)Dow Europe GmbH, Switzerland, (6)CEFIC - European Chemical Industry Council, Belgium, (7)Environmental Safety, Bayer Crop Science, Germany

Biodegradation simulation tests provide key information in the assessment of the Persistence of a substance. Information is generated on the degradation of the parent substance and formation of metabolites and non-extractable residues (NER). Based on the non-ability to extract a fraction of residues with use of aggressive extraction procedures, NER have been regarded as a non-bioavailable sink in the environmental matrix. This interpretation prevailed when Persistence criteria were developed for regulatory purposes. The ECHA guidance on PBT assessment reflects a concern for NER to remobilize. The inclusion of NER in kinetics modeling has implication on the derivation of DT50 via introduction of a discrepancy between the current assessment approach and that used when the criteria were originally established. Consideration of NER-Type 1 as parent substance in kinetics modelling artificially increases the DT50 when compared to the P/vP cut-off criteria set in 2006. In addition, many technical challenges still remain to be addressed before any final decision can be made on the best way forward. While some extraction methods such as pressurized liquid extraction (PLE), Silylation and/or EDTA extraction can be suitable, none of them have been validated in this context. From experience, it is impractical to rely only on a non-standardized guidance document. There is a need for method standardization and inter-laboratory validation to increase method reliability (including among laboratories) prior to inclusion of agreed approach(es) in regulatory guidelines. Finally, the method to be applied will be very dependent on the substance and/or the chosen test method. Eventually, a non-mandatory, stepwise approach could be reasonable if it allows for flexibility (e.g. choices according to the needs and evidence already available). Conclusively, round-robin tests would be helpful to gather more insight into whether the various proposed extractions are suitable and feasible in the context of NER investigation and evaluation. Once the details are resolved and specific investigations are performed on a broader basis at the technical level, the results can be placed into a context potentially suitable for the assessment of persistence. Inclusion of historical substances used in the derivation of the P screening criteria in the validation of the testing approach would provide insights into the implications for assessing persistence.

3.14.P-We129 Integrating Bioavailability Measurements in Persistence Assessments of Partially-Biodegradable Organic Chemicals in Soil

Rosa Posada¹, Carmen Fernández-López², Dieter Hennecke³ and José Julio Ortega Calvo¹, (1)IRNAS CSIC, Spain, (2)UCAM, Spain, (3)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany

The integration of bioavailability assessments in standardized procedures for monitoring the biological transformation of organic chemicals in soil would help to explain biodegradation rates, leading to more realistic assessments of persistence and risk, especially with partial transformation reactions. We prospect this integration through a two-steps procedure: the first one was to follow the biodegradation (by the OECD 307 guideline) of ¹⁴C-labelled chemicals (pyrene –a PAH- and carbamazepine-a pharmaceutical compound) under solid-phase conditions leading to partial transformation products. The second step was to assess bioavailability of the parent chemicals and the metabolites at different stages of this incubation, using a standardized method (ISO 16751:2020) with soils samples at the start and the end of the incubation. This ISO method relies on the amount of contaminant

present in the matrix that can be released to the aqueous phase after 20 h in a well-mixed water soil mixture and in the presence of a receiving hydrophobic phase (Tenax). Because the ISO method was originally designed for non-polar compounds with $K_{ow} > 3$, the method was slightly adapted to carbamazepine ($K_{ow} = 2.7$), by changing the soil/water/Tenax ratio and the extraction period. The combined use of liquid scintillation and HPLC fractionation allowed the determination of the phase distribution in our system of the ^{14}C -labelled parent compound and metabolites among soil, water and Tenax. In the case of pyrene, the cometabolic transformation carried out by the microbial inoculum (*Pseudomonas putida* G7 cells, Fernández-López, et al., 2021) in the soil accounted for 40 % of the initial concentration (4 mg/kg), from which only 3 % were present as hydrophilic transformation products that were not trapped by Tenax but partitioned into the water. The rest remained as non-bioavailable residues. However, the bioavailable pyrene fraction in soil passed well to the Tenax and decreased as long as cometabolism proceeded, closing well the mass balances (>90 %). These results indicate that cometabolism decreased efficiently the risks from pyrene in the soil. The same approach was employed with carbamazepine, obtaining very interesting preliminary results on the phase distribution of this pharmaceutical compound and its metabolites in soil.

3.14.P-We130 Harmonization of EU Chemicals Hazard Assessment Via the Envisaged CLP Revision - What Is the Impact on Plant Protection Products (PPPs)?

Philipp Dalkmann¹, Thorsten Junge², Dragan Jevtic² and Dieter Schaefer², (1)Environmental Safety, Bayer Crop Science, Germany, (2)Bayer Crop Science, Germany

As part of the EU Commission “Chemical Strategy for Sustainability Towards a Toxic-Free Environment” a revision of the Classification, Packaging and Labelling (CLP) regulation is planned, including the introduction of new hazard classes on Persistent, Bioaccumulative, Toxic (PBT) and very Persistent, very Bioaccumulative (vPvB) substances, as well as Persistent, Mobile, Toxic (PMT) and very Persistent, very Mobile (vPvM) substances. This results in the implementation of an overarching hazard assessment tool, applicable across all chemical legislations, e.g. for industrial chemicals, biocidal products and plant protection products (PPPs), but ignores legislation-specific differences for derivation of trigger endpoints and consequences of a potential hazard classification. For PPPs, assessment criteria according to DG SANCO PBT/vPvB guidance (SANCO, 2012) are currently applicable, which, however, would be displaced by REACH Annex XIII PBT/vPvB guidance criteria with the planned CLP revision. On the one hand, this would lead to the applicability of REACH P/vP criteria (e.g., half-life (DT_{50}) values normalized to 12°C, consideration of metabolites and non-extractable residues (NER)), deviating from SANCO P/vP criteria (e.g., reference temperature for DT_{50} derivation of 20°C, no consideration of metabolites and NER). On the other hand, an additional hazard class for mobility will be applicable for PPPs in the frame of a PMT/vPvM assessment, ignoring the fact that a thorough groundwater risk assessment for PPPs is already in place. With mobility criteria currently under discussion, solely relying on adsorption properties ($\log K_{oc}$), this would lead to a high proportion of PPPs classified as “M” or “vM”. Consequently, the application of REACH Annex XIII criteria would lead to a high proportion of non-approved PPPs classifying as “PMT” or “vPvM” and to a significant number of PPPs classifying as “Candidates for Substitution” (CfS). We will provide data to highlight the impact of the planned regulatory changes on the authorization of PPPs. Overall, these developments result in a high degree of uncertainty, especially for the applicants of PPPs (but also for European and Member State authorities, farmers and citizens). There is no clarity for the applicant on how a P and M assessment for PPPs should be performed in the future with hazard classes and criteria implemented according to the current proposal.

3.14.P-We131 Harmonization of EU Chemicals Hazard Assessment Via the Envisaged CLP Revision - What Is the Impact on Plant Protection Products (PPPs)? 2

Philipp Dalkmann¹, Thorsten Junge², Dragan Jevtic² and Dieter Schaefer², (1)Environmental Safety, Bayer Crop Science, Germany, (2)Bayer Crop Science, Germany

3.14.P-We132 Assessment of the Persistence of Ionic and Ionisable Organic Chemicals Under REACH

Daniela Classen¹, Juliane Ackermann² and Andreas Schaeffer³, (1)German Environment Agency, Germany, (2)German Environment Agency (Umweltbundesamt), Germany, (3)Institute Environmental Research, RWTH Aachen University, Aachen, Germany

For the protection of humans and the environment, the identification and regulation of chemicals with persistent (P), bioaccumulative (B) and toxic (T) properties are a central element within the environmental assessment. The criteria for the identification of PBT substances under REACH (Registration, Evaluation and Authorization of Chemicals) and the guidance for the PBT-assessment have been developed for neutral organic molecules. Thus, it is unknown, if the current assessment strategy for PBT substances is applicable on ionic and ionisable compounds. Due to their charge, ionic and ionisable substances behave differently in the environment compared to neutral substances. Cationic, anionic and amphoteric chemicals change their characteristics (e.g. water solubility, log K_{ow}) as a function of the environmental pH and their acid and base dissociation constants. Consequently, the distribution of these substances within the environmental compartments, e.g. portions of the chemicals being dissolved in the water phase and adsorbed to solid phases, are affected. This, at the same time, will influence the bioavailability of ionic substances for potentially decomposing microorganisms, governing their biotic degradation and persistence. In order to improve the evaluation of the persistence of ionic and ionisable substances, we compared the fate and the distribution of an anionic and cationic substance compared to a chemical without any charge with identical molecular core structures. The distribution of three different ¹⁴C-labelled chemicals within a soil test system according to their mineralized, extractable and non-extractable portion were determined. The influence of positive and negative charges on the biodegradability will be elucidated.

3.14.P-We133 New Approach for Consideration of Non-Extractable Residues (NER) in Persistence Assessment Suitable in Regulatory Practice

Astrid Wiemann¹, Ulrich Jöhncke², Jana Schmidt², Daniela Claßen³, Gunther Speichert², Anna Pissarello² and Dieter Hennecke⁴, (1)IV 2.2, UBA Umweltbundesamt, Dessau-Roßlau, Germany, (2)German Environment Agency (UBA), Germany, (3)German Environment Agency (Umweltbundesamt), Germany, (4)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany

Non-extractable residues (NER) are formed in transformation simulation tests in soil and sediment according to OECD 307, 308 and 309. Besides substance properties and soil/sediment type, the amount of NER strongly depends on the extraction methods. However, a standardised extraction procedure for determination of total NER is lacking. Thus, the boundary between extractable fraction and NER is currently not precisely specified. From a regulatory view, NER are of significance for persistence assessment to identify PBT, vPvB, or POP substances. NER are formed by various processes. They can be reversibly bound by adsorption or physical entrapment (**type I**) and pose a potential risk to the environment (hidden hazards). But they can also be covalently bound to organic matter (**type II**) or transformed into biomass (biogenic NER, **type III**) without risk to be remobilised again (safe sink). Up to now, a standardised or commonly accepted method to distinguish between the different NER types does not exist, but has been in the focus of ECHA (NER discussion paper 2018) and the German UBA (BfG project). These approaches differ to a certain extent. BfG proposes a pragmatic, standardisable procedure without further chemical analysis of the different extracts. The ECHA approach focuses on NER specification and analytical determination of bio-NER, sequestered, and covalently bound NER. In 2018, UBA funded an additional project to compare the existing approaches and testing strategies and to check for practicability. The aim was to develop a refined approach to assess their hazard potential with respect to the general applicability for an adequate persistence assessment including NER. For this purpose, simulation tests in soil (OECD 307) with the ¹⁴C- and ¹³C-labelled substances Bromoxynil, Isoproturon und Sulfadiazine were carried out. Different extraction methods were applied aiming to develop a standard procedure for total NER determination. Subsequently, EDTA extraction, silylation and acidic hydrolysis had been performed and compared in order to characterise the different NER types formed. In February 2021, UBA and its research partners organised an EU-wide workshop to present the results of the project and two proposals for the consideration of NER for discussion with scientists, stakeholders and regulators. Taking into account the comments from the workshop and a subsequent public consultation, one harmonised approach suitable for regulatory practice has now been developed.

3.14.P-We134 Insights Into Biodegradation of Functional Polymers Using Omics

Soumya Daturpalli, Sabrina Gruener and Catherine Gigandet, BASF SE, Germany

Functional polymers are used in many applications in our daily life as for example in detergents and cosmetic products. These materials are normally discarded down the drain and are treated in waste-water treatment plants. Therefore, a fundamental understanding of their biodegradability is of great importance. OECD testing guidelines are normally used to investigate the persistency of substances. However, these guidelines have been historically developed for small molecules and adaptation might be required for polymeric materials. In this work we investigate the biodegradation of a model class of functional polymers with OECD 301 F test and adaptations thereof. In addition enrichment experiments combined with metagenomics and metatranscriptomics are utilized to elucidate the biodegradation process of selected readily biodegradable functional polymers. Through this method we can identify which microbes are responsible for the biodegradation of the polymer, what oligomeric/monomeric units are taken up by the microbes and which biochemical pathway is responsible in the microorganisms to digest the polymer. Using the metagenomic results we further investigate the mechanism of degradation of the polymers with the help of metaproteomics and other analytical techniques. Using this approach, we can demonstrate that synthetic polymers such as the ones presented in this study are truly biodegradable. Furthermore, our results prove the potential to use omics to investigate

biodegradability of polymeric materials, to understand which microbes are involved in their biodegradation and what is the regulatory pathway through which the polymers are processed.

3.14.P-We135 ZeroPM - Substance Grouping

Hans Peter Arp¹, Emma Schymanski², Zhanyun Wang³, Raoul Wolf⁴ and Sarah Hale⁵, (1)NGI, Norway, (2)University of Luxembourg, Luxembourg, (3)ETH Zurich, Switzerland, (4)Norwegian Geotechnical Institute (NGI), Oslo, Norway, (5)Norwegian Geotechnical Institute (NGI), Norway

In the H2020 Project ZeroPM – Zero Pollution of Persistent, Mobile substances, there will be work package devoted to Substance Grouping. Substance Grouping is seen as a key strategy to avoid “regrettable substitution” in which one hazardous substance in the market is substituted with another hazardous substitute. This is particularly the case where the new hazardous substance was structurally similar to the one that replaced it. There are several examples of this with decabromodiphenylether being replaced by decabromodiphenylethane, bisphenol a being replaced with bisphenol s, perfluorooctylsulfonate being replaced by perfluorobutylsulfonate, etc. This work package will identify all persistent, mobile and toxic/very persistent very mobile (PMT/vPvM) substances on the global market and develop a novel PMT/vPvM substance grouping approach to inform assessment, prioritization, substitution, regulation and removal. This substance grouping can take three forms, such as grouping based on common transformation products, grouping based on read-across of moieties that are causing the hazard and grouping based on extreme persistency leading. This work will start using case studies of suspected PMT/vPvM substance groups: small PFAS, triazines and triazoles, and later work towards expanding this work for other groups within the global chemical inventory. Examples include grouping all short-chain PFAS as a similar hazardous class, grouping precursors of melamine like cyromelamine with melamin, and non-persistent triazole containing compounds with persistent triazole transformation products. Acknowledgment: This project has received funding from the European Union's Horizon H2020 research and innovation program under grant agreement No 101036756.

3.14 Persistent, Mobile and Toxic (PMT/vPvM) substances: New Perspectives and Developments in their Assessment, Management and Regulation (Poster Corner)

3.14.PC-We19 Biotransformation of Chemicals in Water-Sediment Systems: Comparison of Low-Level Spiking and No Spiking in a Modified OECD 309 Test

Run Tian¹, Malte Posselt², Kathrin Fenner³ and Michael McLachlan⁴, (1)Stockholm University ACES, Stockholm, Sweden, (2)Stockholm University, Rosersberg, Sweden, (3)Environmental Chemistry, Eawag & University of Zurich, Switzerland, (4)Department of Environmental Science, Stockholm University, Stockholm, Sweden

The OECD 309 test for studying aquatic biotransformation of chemicals in laboratory experiments has several shortcomings including poor reproducibility and questionable environmental relevance. To ameliorate these weaknesses, a modified biotransformation test system was evaluated using river water and sediment from 3 different rivers, Fyrisån (FYR), Enköpingsån (ENK), and Hågaån (HÅG), in Sweden. We modified 5 aspects of the test: 1. The experiments were started within 5 hours of sampling to minimize disturbance of the microbial communities; 2. The sediment concentration was increased to 50 g wet solids L⁻¹ to achieve more stable microbial communities in the reactor; 3. The incubation bottle was sealed to prevent changes in the ionization state of chemicals due to pH changes induced by outgassing of CO₂ from the oversaturated river water; 4. The amount of chemical spiked was reduced or the chemicals were not spiked at all to minimize the effect of spiking on the microbial community and biotransformation rate; 5. The length of the test was reduced to 14 days to minimize microbial community changes associated with long incubation periods. Three incubation groups with no spiking, 0.5 µg/L spiking, and 5 µg/L spiking were set up with five replicates in each group. We measured the dissipation of 56 substances in the FYR and ENK suspensions and of 80 substances in the HÅG suspensions. The dissipation kinetics of these substances are compared between the different incubation groups to see whether low-level spiking provides comparable results to no spiking as well as good reproducibility.

3.14.PC-We20 Effectiveness of Ready Biodegradability Tests As a Stringent Screening for Persistence in All Environmental Compartments

Alberto Martin-Aparicio¹, Delina Lyon², Louise Camenzuli³, Neil Wang⁴, David Saunders⁵, Christopher Hughes⁶ and Yves Verhaegen², (1)European Petroleum Refiners Association, Belgium, (2)CONCAWE, Belgium, (3)ExxonMobil, Belgium, (4)ARKEMA France, France, (5)Shell International, Netherlands, (6)Ricardo Energy & Environment, Chester, United Kingdom

The assessment of persistence under REACH is based on a tiered testing strategy (described in the PBT ECHA guidance R.11) which logically starts with cheap, fast and stringent methods, and gradually progresses to recommend more complex and time-consuming methodologies, if needed. The traditional starting point for testing biodegradability is the ready biodegradability test (RBT), like the OECD 301 series, which are considered so stringent that a “pass” level in a reliable RBT test is normally considered as sufficient information to conclude a substance as “not persistent” in any environmental compartment. Higher tier information on biodegradability would be generated by performing simulation tests (OECD 307, 308 and 309), which are compartment specific for soil, sediment and freshwater. This implies that a half-life leading to a conclusion of “not persistent” in a simulation test for a given compartment does not clear the suspicion of persistence in the other compartments, while a conclusion of “not persistent” in a RBT should be applicable to all environmental compartments. Here we determine the likelihood of a readily biodegradable substance being persistent in any environmental compartment by analysing a dataset of substances for which both RBT data and simulation test data exist, generated with the help of the OECD QSAR Toolbox and manual analysis of the data in ECHA’s database. The data collected underwent a quality check to flag tests which report half-lives but have issues casting doubts on their validity. Amongst 320 data points for simulation tests on substances with ready biodegradability

information reported, there were no substances that passed a ready biodegradability test for which reliable simulation data information would indicate persistence in any compartment. From those substances identified as “not readily biodegradable”, the vast majority were not persistent according to the half-lives reported, supporting the idea that the screening test is stringent enough to cover persistence in all environmental compartments.

3.14.PC-We21 Potential of Read-Across Approaches for the Biotransformation of Organic Contaminants Between Activated Sludge and Standard OECD 307 - 308 Tests

Claudia Coll¹ and Kathrin Fenner², (1)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Environmental Chemistry, Eawag & University of Zurich, Switzerland

The degradation half-lives (DT50) derived from the standard tests OECD 307 and 308 are commonly used to assess persistence of a chemical in soil and water-sediments systems. However, these tests are time- and resource-consuming compared to the experiments in activated sludge proposed in [1], which showed that DT50s of agrochemicals in soil could be estimated from 48h-tests in activated sludge. Our goal is to assess further the opportunities to read-across biotransformation kinetics observed in activated sludge to the soil and sediment-water compartments for a set of structurally diverse organic contaminants. We performed experiments using activated sludge from a local WWTP to study the biotransformation of 20 previously investigated agrochemicals and 48 newly added pharmaceuticals with available DT50s from OECD 307 and/or 308. Concentrations of the chemicals were measured using LC-HRMS to determine DT50s and screen for transformation products (TPs). Our outcomes with the 20 agrochemicals showed reproducibility of previous results[1] and consistency in sludge DT50 outcomes. We obtained the best predictions of the respective OECD 307-DT50s with models using the sludge DT50 and the experimentally determined Koc to correct for differences in bioavailability of the chemicals in soil vs sludge. Additionally, suspect screening of TPs suggests that the biotransformation pathways of the agrochemicals in activated sludge largely overlap with the observed biotransformation pathways in soil. Based on preliminary results showing some qualitative agreement between pharmaceuticals persistent in activated sludge and in OECD 308, we will investigate to what extent the read-across approaches trained for the agrochemicals are also applicable to estimate half-lives of pharmaceuticals in standard OECD 307/308 systems. We hope to demonstrate that under certain constraints, activated sludge biotransformation tests provide an opportunity for easier assessment of persistence of organic contaminants. [1] K. 3.15 Plastics in the terrestrial environment: improving understanding of occurrence and impacts as analytics improve

3.15.T-01 Vertical Microplastic Distribution in Agricultural Soils After Long-Term Treatment With Sewage Sludge

Wiebke Mareile Heinze¹, Zacharias Steinmetz² and Geert Cornelis³, (1)Swedish University of Agricultural Science, Sweden, (2)University of Koblenz-Landau, Germany, (3)SLU Fakturamottagning, Sweden

Microplastic pollution of terrestrial ecosystems and its potential impact on ecosystem services is increasingly perceived as a threat. While the number of studies demonstrating microplastic presence in agricultural soil under different management systems is increasing, there is still a considerable knowledge gap on the potential mobility of microplastics. Laboratory-based process studies indicate transport of microplastics. However, field investigations of microplastic distribution in the soil profile are still lacking which makes it challenging to understand their long-term fate and local impact. The objective of this study was thus to investigate the abundance and spatial distribution of microplastics in soil profiles from a long-term field experiment, including field plots exposed to 25 years of bi-annual sewage sludge application in contrast to field plots without fertilization. To this end, soil cores of 90 cm depth were taken and segmented into 10 cm thick layers, except the plough layer (0-20 cm). Polyethylene (PE), polystyrene (PS) and polypropylene (PP) microplastics below 2 mm size were then analysed using pyrolysis gas chromatography mass spectrometry after density separation and subsequent organic solvent extraction with 1,2,4-TCB and *p*-xylene. Microplastic abundance and differences between treatments were polymer-specific with PE being more abundant when sewage sludge was applied to the soil. In contrast, PS and PP were less strongly related to sewage sludge applications and detected in occasional single instances in both treatments. The detection of PE, PS and PP in control plots indicates that the area may be exposed to other more diffuse input sources, albeit at low levels. Notably, all microplastics were at least partly detected below the plough layer (0-20 cm). PE was detected in significant levels down to approximately 40-50 cm in the soil profile, which is likely attributed to transport processes within the soil profile. On the one hand, this emphasizes the need to consider deeper soil layers for accurate mass estimates and monitoring purposes; on the other hand, our results indicate that depending on the soil properties, soils may act as a temporary sink for microplastics. Further investigations on soil physical and biological properties are needed to understand the observed transport depth of microplastics and make reliable estimates on the temporal dimension of microplastic migration in the soil profile.

3.15.T-02 Plastic Aging in Soil

Alexandra Foetisch¹, Montserrat Filella², Benjamin Watts³, Maeva Bragoni⁴ and Moritz Bigalke⁵, (1)Geography, University of Bern, Bern, Switzerland, (2)Institute F.-A. Forel, University of Geneva, Switzerland, (3)Paul Scherer Institute, Switzerland, (4)University of Bern, Switzerland, (5)University of Bern, Switzerland

The micro- (MP) and nanoplastic (NP) contamination of soil is of great importance as huge amounts of plastic are emitted in the environment and the yearly amount of MP added to agricultural soil alone exceed the amount emitted to the world ocean. Over

time, MP/NP in soils can be affected by physical, chemical and biological factors, which change their chemical structure, size, shape and surface properties. Most of the current methods of MP/NP identification rely on specific optical properties and chemical spectra. When the properties of plastic are altered by the aging of the material, these methods can fail to identify them properly, leading to an underestimation of the potential environmental issue of MP/NP. In order to understand how plastic age in soil, MP were collected from agricultural soils in Switzerland and homemade MP/NP particles of PE, PET, PA, PU and PC were incubated in two different soils for 3 months or 1 year. MP were microtomed into thin sections and the change of chemical composition from the surface towards the bulk material of the particle was analysed by STXM-NEXAFS. Additionally, their surface was investigated by acquiring SEM picture in order to characterize possible physical changes. **1. 2.** Several of the MP particles found in the agricultural fields showed a chemical variation along the gradient from the surface of the particles towards the bulk material. The transition between the surface structure to the bulk material occurs to some hundred nm. From the incubation experiment only the particles incubated for 3 months could be analyzed so far. For these particles no significant effect of the incubation could be observed, indicating that 3 month is too short to cause significant aging of MP surfaces. However, we expect changes of the surface of the particles to be visible after 1 year incubation and to change according to the soil used and the polymer incubated. The preliminary results show that the surface of MP changes its chemical structure while being buried in the soil. However, this process takes time and no changes of the surface could be observed after three month of incubation in two different soils.

3.15.T-03 When Do Micro-Or Nanoplastics Play a Role in the Relocation of Contaminants in Agricultural Soil?

Stephanie Castan¹, Charlotte Henkel², Thorsten Huffer² and Thilo Hofmann³, (1)EDGE-Environmental Geoscience, University of Vienna, Vienna, Austria, (2)University of Vienna, Vienna, Austria, (3)University of Vienna, Austria

Insufficient waste management in combination with slow degradation rates contribute to the ubiquitous accumulation of micro- and nanoplastics (MNP) in environmental systems and particularly agricultural soils. Atmospheric transport and wind drift carry airborne MNP into soils but especially fertilization with compost or sewage sludge, containing high amounts of MNP, as well as degrading mulch films contribute to the plastic load in agricultural soils. MNP carry pollutants that have either been added as functional additives during the production, or have been passively sorbed during their life cycle. Therefore, concerns are frequently voiced that MNP transport the associated contaminants into deeper soil layers or even into groundwater. In this study we aim to elucidate whether and to what extent MNP facilitate the vertical transport of organic contaminants in agricultural soil. For this, we calculated the ratio between transport time of the MNP in soil and the desorption time of the sorbed contaminants by means of two diffusion models for MNP between 0.1-1000 μm . By reviewing diffusion coefficients and distribution coefficients for the most prevalent polymers and contaminants as reported in the literature, this study could show that at a flow velocity of 1 m/a in the soil the contaminants establish equilibrium with the surrounding soil phases too fast to be transported by MNP, regardless of the governing diffusion mechanism. Only under preferential flow conditions with a flow velocity of 1 m/h, MNP >100 μm may transport hydrophobic contaminants with $\log K_{ow} > 5$ beyond one meter soil depth. However, this requires that continuous preferential flow conditions prevail and that the particles are fully mobile therein. Although MNP constitute a pathway of organic contaminants to agricultural soils, this study suggests that particularly compared to the multitude of natural mobile colloids in soil, the role of MNP as contaminant vector is rather overestimated. Nonetheless, the introduction of MNP into agricultural fields requires stricter regulation as MNP that carry contaminants release these in the upper soil layers, inducing detrimental effects on soil organisms, crops and ultimately the consumer.

3.15.T-04 Long Term Contamination of Plastic Mulch and Pesticides Residues Effects on the Lettuce Growth

Nicolas Beriot¹, Raul Zornoza², Esperanza Huerta Lwanga³ and Violette Geissen⁴, (1)WUR, Netherlands, (2)UPCT, Spain, (3)Wageningen University & Research, Netherlands, (4)Alterra Wageningen University and Research Centre, Netherlands

In arid and semi-arid regions, the use of plastic mulch and pesticides in conventional agriculture is nearly ubiquitous. The most common plastic used for mulching is Low Density Polyethylene (LDPE). LDPE mulch needs to be removed after harvest and LDPE debris accumulates in the environment. Some plastic producers have tried to improve the degradation processes of plastic to avoid plastic mulch removal and plastic debris accumulation by adding pro-oxidant additives to LDPE, so called Pro-oxidant Additive Containing (PAC) plastics or by using biodegradable plastic polymers. However PAC plastics leave residues when ploughed into the soil and some biodegradable plastic don't degrade as fast as expected in the field conditions. Similarly pesticides are known also to accumulate in the soil. Studies investigating the effect of these contaminants on the soil fertility most often consider pristine plastic or single pesticides. We investigated the effect of one year incubation of plastic debris and pesticides in soil on the growth of lettuces in south east Spain. More precisely, we tested three plastic mulch residues and 3 commercial pesticides, including a treatment with the cocktail of the 3 pesticides compared to controls for a total of 20 treatments. The plastic mulches were first exposed 3 months to the summer weather in the field, cleaned, cut, grounded into macro- and micro-plastics debris and added in 1kg soil mesocosm at a 0.2% content w/w. Pesticides were applied 3 times, every 6 months, following the prescribed application doses. The 1kg soil mesocosms were left 1 year, protected from the wind and were irrigated to recreate farming conditions. After one year lettuces seedlings, *Lactuca sativa*, were planted in the incubated soil. The plant growth was assessed during the growing period (number of leaves, chlorophyll content, stomatal conduction) and at the harvest (fresh and dry biomass, leaf area, stem diameter). Preliminary results indicate that lettuces growing in soil incubated with the tested biodegradable plastic produced a significantly lower biomass compared to the control or the soil incubated with LDPE plastic.

3.15.T-05 Earthworms Ingest Microplastic Fibres and NanoPlastics With Effects on Egestion Rate and Long-Term Retention

Elma Lahive¹, Richard Cross², Aafke Saarloos³, Alice A. Horton⁴, Claus Svendsen⁵, Rudolf Hufenus⁶ and Denise M Mitrano⁷,

(1)UK Centre for Ecology and Hydrology, United Kingdom, (2)UK Centre for Ecology & Hydrology, United Kingdom, (3)Wageningen University, Nederland, (4)National Oceanography Centre, United Kingdom, (5)CEH, Wallingford, United Kingdom, (6)Empa Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (7)Environmental Systems Science, ETH Zurich, Zurich, Switzerland

Microplastic fibres (MPFs) and nanoplastics (NPs) have the potential to be hazardous to soil organisms. Understanding uptake into organisms is key in assessing these effects, but this is often limited by the analytical challenges to quantify smaller-sized plastics in complex matrices. This study used MPFs and NPs containing inorganic tracers (In, Pd) to quantify uptake in the earthworm *Lumbricus terrestris*. Following seven days exposure, tracer concentrations were measured in earthworms and faeces. Earthworms exposed to 500 µg MPFs/g soil retained an estimated 32 MPFs in their tissues, while at 5000 µg MPFs/g earthworms retained between 2 and 593 MPFs. High variation in body burdens of MPFs was linked to soil retention in earthworms and reduced faeces production, suggesting egestion was being affected by MPFs. NPs uptake and elimination was also assessed over a more extended time-period of 42 days. After 1 day, NPs were no longer detectable in faeces during the elimination phase. However, some retention of NPs in the earthworm was estimated, not linked to retained soil, indicating not all NPs were eliminated. MPFs and NPs uptake can be quantified in earthworms and both particle types can be retained beyond the depuration period, suggesting the potential for longer-term accumulation

3.15.V-01 Expression of Immune-Related Genes in Haemocytes of *Porcellio scaber* After Exposure to Microplastics in Soil: A CASE of Tyre Particles

Andraž Dolar¹, **Damjana Drobne²**, **Mojca Narat³** and **Anita Jemec⁴**, (1)Biology, Biotechnical faculty, Ljubljana, Slovenia, (2)University of Ljubljana, Slovenia, (3)University of Ljubljana, Biotechnical Faculty, Slovenia, (4)University of Ljubljana, Biotechnical Fac., Slovenia

Expression of immune-related genes in haemocytes of *Porcellio scaber* after exposure to microplastics in soil: a case of tyre particles **Andraž Dolar^{1*}**, **Damjana Drobne¹**, **Mojca Narat²**, **Anita Jemec Kokalj¹** ¹University of Ljubljana, Biotechnical Faculty, Department of Biology, Jamnikarjeva 101, SI-1000 Ljubljana, Slovenia ²University of Ljubljana, Biotechnical Faculty, Department of Animal Science, Jamnikarjeva 101, SI-1000 Ljubljana, Slovenia * presenting author Tyre particles, are produced by tyre wear and are one of the largest sources of microplastics to the environment, accounting for nearly 6 million tonnes of particles per year worldwide. Because these particles also contain a variety of potentially harmful chemicals (e.g., metals and organic compounds), this property could increase the risk of adverse effects of these particles on soil invertebrates. The aim of this study was to evaluate the expression of immune-related genes in the haemolymph cells (haemocytes) of woodlice *Porcellio scaber* after two different exposure durations (4-days and 14-days) to tyre particles of 1.5% w/w in standard natural soil Lufa 2.2. Tyre particles were produced from mixed end-of-life passenger car tires by cryo-milling and sieving to the size below 180 µm (mean size of 102.9 µm). Nine immune-related genes, namely catalase (*Cat*), manganese superoxide dismutase (*MnSod*), nitric oxide synthase (*Nos*), cyclophilin G (*CypG*), prophenoloxidase activating factor 2a (*Ppae2a*), Down syndrome cell adhesion molecule (*Dscam*), toll-like receptor 4 (*Toll4*), myeloid differentiation factor 88 (*MyD88*), and masquerade (*Mas*)-like protein, were selected to evaluate innate immune response of woodlice after exposure to microplastics. Relative gene expression of selected genes was calculated by the 2^{-ΔΔCt} method using β-actin and elongation factor 2 as reference genes. We observed changes in the expression levels of *Cat*, *MnSod*, *Nos*, *Toll4*, and *MyD88* genes in haemocytes of woodlice exposed to tyre particles in soil compared to the control group. After a 4-day exposure to 1.5% tyre particles in soil, the expression levels of the *Cat* and *Toll4* genes was increased, while after a 14-day exposure, we found increased expression levels of the *Nos*, *Toll4*, and *MyD88* genes and decreased expression of the *MnSod* gene compared with the control. These results showed that exposure to microplastics induce innate immune response of woodlice. Moreover, we found that a 4-day exposure to tyre particles significantly affected the number of haemocytes in the haemolymph of woodlice, especially granulocytes, while no change in haemocyte number was observed after a 14-day exposure. This indicates that organisms responded to exposure to tyre particles in soil, but did not cause adverse effects. This study has demonstrated the usefulness of gene expression analysis as a screening tool for assessing the response of *P. scaber* to various environmental stressors.

3.15.V-02 No Adverse Effects of Irregular Shaped Biodegradable Microplastics on the Reproduction of the Springtail *Folsomia candida* (Willem 1902) at Nowadays Environmentally Realistic Concentrations

Uwe Schnepf¹, **Maria von Moers-Meißner²** and **Franz Brümmer³**, (1)IBBS, University of Stuttgart, Stuttgart, Germany, (2)Universität Stuttgart, Germany, (3)University of Stuttgart, Germany

Microplastics (MP) are a novel set of entities with potentially harmful impact on wildlife worldwide. Effects are, for example, modulated by particle size, shape and polymer type. Especially for edaphic organisms the ecotoxicity of plastics is still poorly understood. Soil could be contaminated with plastics and also biodegradable plastics from various sources. For instance, fertilizers produced in bio-waste treatment plants often contain impurities like garbage bags made of a blend of polybutylene adipate terephthalate and polylactid acid (PBAT/PLA), resulting in the release of MP to soil. To investigate their influence on the standard soil arthropod *Folsomia candida*, we here conducted an OECD No. 232 reproduction test. For this, LUFA 2.2 standard soil was spiked with irregular shaped PBAT/PLA particles (D₅₀ = 73 µm with an IQR of 52 µm) using eight different MP concentrations ranging from 0.0043 to 1.5000 % [w/w]. It was hypothesized that the higher the dose, the greater the reduction in the number of offspring. Compared to the control, only the highest dose showed a biologically meaningful percentage change of reproduction of -34 % (95 % CI [-51 %, -18 %], Tamhane-Dunnett test: (t(10) = -3.15, p = .069). Note that the experiment was not valid as the

coefficient of variance of the number of juveniles in the control was 40 %. Overall, our results suggest that there is no dose-response pattern but only a relevant effect for very high MP concentrations that are much higher than nowadays common global concentrations of < 0.00045 %. Consequently, at recent exposure, short-term adverse effects of biodegradable MP on the reproduction of *F. candida* are very unlikely. To avoid ecological surprise in the soil ecosystem, future effect studies should also take into account the variety of MP, their manifold interactions with both biotic and abiotic factors as well as other endpoints like avoidance or stress markers and perform experiments with multiple species over many generations.

3.15 Plastics in the terrestrial environment: improving understanding of occurrence and impacts as analytics improve (Poster)

3.15.P-Tu167 An Alternative Method for Identification of Microplastics

Urška Šunta, Franja Prosenč, Mrs. Pia Leban, Polonca Trebše, Tjaša Griessler Bulc and Mojca Bavcon Kralj, University of Ljubljana, Faculty of Health Sciences, Slovenia

Microplastics (MPs) can be introduced in the terrestrial environment through atmospheric deposition, irrigation with wastewater, illegal waste dumpings, and the use of plastic in agriculture, such as mulching. For identification and quantification of MPs in soils, the soil samples should be pretreated using chemical and physical methods, such as drying, sieving, flotation, filtration, extraction, digestion, etc. After that MPs can be identified using destructive methods (pyrolysis gas chromatography-mass spectrometry (GC-MS), thermal desorption GC-MS) or non-destructive methods (ATR-FTIR and Raman spectroscopy, SEM). So far, none of the methods is standardised for the identification of MPs in soil samples, however, pyrolysis GC-MS, FTIR, and Raman spectroscopy are in the process of standardisation to use in the case of water and wastewater samples [3]. Not all laboratories have the necessary instruments to carry out qualitative analyses for MPs determination in environmental samples, therefore with this research, an alternative method is proposed for the determination of MPs in the sample that is based on headspace solid-phase microextraction and GC-MS analysis (HS-SPME-GC-MS). MPs of five polymer types (polyethylene terephthalate (PET), polystyrene (PS), polyvinyl chloride (PVC), polypropylene (PP), polyethylene (PE)) and in two size ranges (1-5 mm and 100 µm-1 mm) were used to develop the method. Based on the production of polymer characteristic compounds at the thermal degradation of MPs, and extraction of polymer specific fragment ions, it was possible to identify PET, PS, PVC, PP, and PE on their own, in polymer blend, in with MPs and microalgae spiked alluvial soil, and in a compost sample. The developed HS-SPME-GC-MS method shows the potential to become an acceptable alternative method for the determination of MPs in environmental samples.

3.15.P-Tu168 Green Surfactant-Free Synthesis and Characterisation of Palladium-Doped Polystyrene Particles for Environmental Fate Studies

Jan Koeser and Martin Hoppe, German Federal Institute for Geosciences and Natural Resources, Germany

Recently, research efforts have increased to understand the fate and impact of plastics in the soil environment. Due to the background of natural organic matter in the environment, the quantification of polymers in environmental matrices is challenging. Therefore, the use of well-characterised model particles is mandatory to assess the fate of nanoplastics in soil. The quantification and localisation of these particles is alleviated by doping with metals with no natural background in the environment, e.g. palladium (Pd). In this work, we follow Mitrano et al.¹ and synthesise polystyrene particles in the range of up to 500 nm doped with Pd as tracer material. This synthesis has three stages: (I) synthesis of monodisperse spherical polystyrene particles according to Nichols,² (II) formation of Pd nanoparticles on the particle surface following Xu et al.³, and (III) coating of the doped particles with polystyrene to prevent Pd release and the change of the particle surface properties, which are key for the interaction in environmental matrices. We use only the essential educts styrene, divinylbenzene, K₂S₂O₈, Pd(NO₃)₂ and glucose to exclude effects from comonomers, contamination from reducing agents or detergents in environmental fate studies. The synthesised particles were characterised by light scattering methods and electron microscopy. The particles' Pd content and the potential Pd release were analysed by inductively coupled plasma mass spectrometry after digestion. The particles were successfully doped with 0.36% Pd nanoparticles and coated with polystyrene. Stability experiments show excellent colloidal stability with a zeta potential of approx. -70 mV and a stable hydrodynamic diameter of approx. 450 nm. Under light acidic conditions, the chemical stability of the particles was satisfactory with a Pd release 70.4%. This implied the good applicability of the synthesised particles for environmental fate studies. (1) Mitrano DM, Beltzung A, Frehland S, Schmiedgruber M, Cingolani A, Schmidt F. 2019. 3.15.P-Tu169 Microplastics in Composts - Identification and Quantification of Microplastic Contents Using a Thermal Decomposition Method

Yosri Wiesner¹, Axel Mueller², Claus-Gerhard Bannick³, Marius Bednarz³, Ulrike Braun⁴ and Korinna Altmann⁵, (1)6.6, Bundesanstalt für Materialforschung und -prüfung (BAM), Germany, (2)Bundesanstalt für Materialforschung und -prüfung (BAM), Germany, (3)German Environment Agency (Umweltbundesamt) / III 2.6, Germany, (4)German Federal Environment Agency (UBA), Germany, (5)Federal Institute for Materials Research and Testing (BAM), Germany

The ubiquitous presence of unintended plastics in the environment has been an issue in scientific studies and public debate. Recent studies on MP findings are focused mainly on aquatic systems, while little is known about MP in terrestrial ecosystems. Fermentation residues, sewage sludge and compost are secondary raw material fertilizers and represent a possible input path of

plastics in soils. Soils are final sinks for micro plastics. In this context, samples were taken in a combined fermentation and composting plant in Germany to get real compost samples which were investigated. Existing regulations include requirements for total contents of plastics in combination with visual determination methods. In order to avoid possible underdeterminations, precise detection methods should be used in the future from a scientific point of view. For this reason, the use of thermoanalytical detection is an appropriate way. Spectroscopic methods such as Raman or FTIR are not suitable for determining the mass content of microplastic, as these output a particle number. In Germany, compost is a potential vector for MP in soil due to its use as fertilizer. Therefore, we show the application of ThermoExtractionDesorption-GasChromatography-MassSpectrometry (TED-GC-MS) as a fast, integral analytical technique, which in contrast to the spectroscopic methods does not measure the number of particles but a mass content. In a nitrogen atmosphere the sample is pyrolyzed to 600 °C and an excerpt of the pyrolysis gases is collected on a solid phase adsorber. Afterwards, the decomposition gases are desorbed and measured in a GC-MS system. Characteristic pyrolysis products of each polymer can be used to identify the polymer type and determine the mass contents in the present sample. For the first time the work represents a routine procedure for the determination of plastics in composts and fermentation residues. This current study will also give inside in various important aspects of sample preparation, which include a meaningful size fractionation, a necessary density separation regarding the removal of inorganic contents and at finally a homogenization.

3.15.P-Tu170 Towards Improving the Analytical Methods to Assess the Biodegradation of Microplastics in Soil Environments

Grace Davies¹, Iseult Lynch², Stefan Krause³, Samantha Marshall⁴ and Massimiliano Mascelloni⁴, (1)University of Birmingham, Birmingham, United Kingdom, (2)School of Geography, Earth and Environmental Sciences, University of Birmingham, Birmingham, United Kingdom, (3)University of Birmingham, United Kingdom, (4)Syngenta Ltd, United Kingdom

Microplastics are an emerging contaminant of concern to soil due to their small size and resistance to biodegradation. It is estimated that 36,000 tonnes of microplastics are intentionally released to the environment each year, which is equivalent to ~10 billion plastic bottles (ECHA, 2019). Many of these end up in agricultural soil which is a major sink for microplastic pollution; around 23,500 tonnes of microplastics are directly attributable to the agriculture and horticulture industries due to the application of controlled release fertilisers, fertiliser additives, treated seeds, and capsule suspension plant protection products (ECHA, 2019). This direct application of intentionally produced microplastics is preventable, thereby leading to restrictions on their use by the European Chemicals Agency, via the phased replacement and restriction of single-use plastics. Within the new restrictions, it is specified that biodegradable polymers can be used as alternatives to traditional plastics where appropriate. This has led to the development of biodegradable alternatives for use in pesticide applications. Biodegradable plastics are degradable by microorganisms and undergo significant changes in chemical structure under specific environmental conditions (aerobic conditions in the dark at 20 °C with degradation within 120 days). This gives the expectation that biodegradable polymers should be completely biodegraded by microorganisms into carbon dioxide, water, and organic material, with no fragmentation into smaller microplastics or nano-plastic particles under standardised test conditions, although methods to confirm this are not yet available. To ensure that newly developed polymers are fully biodegrading in the environment, standardised analytical methods are required that can accurately identify and quantify microplastics/polymer fragments in the soil environment to assess the level of biodegradation in conjunction with standard tests for biodegradation. This poster outlines how the adaptation of current soil analytical methods for use with biodegradable microplastics, and how these could be used in conjunction with standard biodegradation tests (ISO 17556 and OECD 307) to ascertain if newly developed polymers for use with crop protection products are completely biodegrading in the soil environment.

3.15.P-Tu171 What Is the Impact of Agricultural Mulch Films on Terrestrial Ecosystems?

Carmen Wolf¹, Mike Wenzel², Matin Funck², Björn Fischer³, Kristin Nehren³, Ralf Bertling⁴, Mona Duhme⁴, Dieter Hennecke⁵, Karlheinz Weinfurter⁶, Antonia Weltmeyer⁷, Kristina Bitter⁸, Martina Roß-Nickoll⁸, Lars Blank⁸, Henner Hollert⁹, Pauline Ruiz¹⁰, Svenja Dahl¹⁰, Christof Asbach¹¹ and Jochen Tuerk², (1)Institute of Energy and Environmental Technology e.V. - IUTA, Germany, (2)Institute of Energy and Environmental Technology e.V. (IUTA), Germany, (3)Fischer GmbH, Germany, (4)Fraunhofer UMSICHT, Germany, (5)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (6)Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Germany, (7)Institute for Environmental Research, RWTH Aachen, Aachen, Germany, (8)RWTH Aachen University, Germany, (9)Goethe University Frankfurt am Main, Germany, (10)nova Institut GmbH, Germany, (11)Institute of Energy and Environmental Technology e.V. (IUTA), Germany

As plastics production continues to grow worldwide, plastics in the environment are becoming increasingly relevant. In the “iMulch” project, the effect of agricultural mulch film on soil ecosystems and organisms using different perspectives were analysed. A Method for the analysis of microplastics in soil samples was developed for Raman spectroscopy and Thermo extraction desorption Gas chromatography mass spectrometry (TED-GCMS). The aging of the mulch film was analysed in laboratory and mesocosm soil test and additionally in a laboratory sewage treatment plant. The transport and fate of the mulch polymers in soils using ¹⁴C marked polymers in outdoor lysimeter experiments was investigated- Experiments examining effects of the mulch fragments on organism were conducted. The “upcycling” of mulch films by bacteria was investigated. A life cycle assessment of conventional and biodegradable agricultural mulch films was conducted. An avoidance and substitution strategy was derived from the results with the aim of reducing plastic film fragments in the environment. This presentation will give you an overview of the results of this project.

3.15.P-Tu172 Fate and Effect of Doped and Non-Doped Microplastic Particles Under Environmental Relevant Conditions in an Outdoor Lysimeter Study

Karsten Schlich¹, Marie Winter², Ruben Schlinkert², Jan Koester³ and Martin Hoppe³, (1)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Fraunhofer IME, Germany, (3)German Federal Institute for Geosciences and Natural Resources, Germany

Plastics in the environment are considered one of the key challenges of the 21st century. The application of sludge to agricultural soils as fertilizer will lead to microplastic (MP) contamination of soils. For a comprehensive risk assessment information on the fate and effect of MPs in soil is needed. There is a lack of information for the terrestrial environment, because detection and speciation of MP in soil is extremely challenging. Thus, the use of model particles is inevitable. Our aim was to investigate the fate and effect of polystyrene particles (PS-P) and polystyrene particles with a core of silver nanoparticles (Ag-PS-P) in a sewage treatment plant (STP) and a subsequent outdoor lysimeter study. Both particles were synthesised by emulsion polymerization and characterized by scanning electron microscopy (SEM) and dynamic light scattering (DLS). The particles were added into single STPs for 12 days following the OECD 303A. Samples were taken from sludge and effluent to determine the fate of the MPs. In addition, the effect on the microorganisms was investigated by measurements of the DOC elimination. After 12 days, the sludge was dewatered. To achieve three consecutive test concentrations, the sludge of the two treatments (PS-P, Ag-PS-P) was mixed with control sludge. Afterwards, 1.67 g dry matter sludge of each treatment were added per kg dry soil. Three replicates of 5 kg dry matter soil were prepared for each treatment. The replicates were incubated outdoor and wheat was sowed on each lysimeter. Over 4 month leachate samples were taken at regular intervals and the effect on soil microorganisms (substrate induced respiration (SIR), potential ammonium oxidation (PAO)) was examined. After dialysis and dilution, all particles were present as single particles, which was confirmed by DLS. The SEM pictures showed that one silver core particles was centrally located in most of the PS-P. No impact on the DOC elimination of the STP due to the MPs was observed. There were no PS-P detected in the effluent samples by SEM, indicating that most of the particles were retained by the sewage sludge. This could be verified by analysis of the pure sewage sludge and soil samples. Single particles were detected non-aggregated in the sewage sludge and soil. There was no effect due to the PS-P on SIR and PAO throughout the 3-month exposure period. The Ag-PS-P affected the PAO (inhibition < 20%) after long-term incubation indicating a toxic effect due to released Ag ions.

3.15.P-Tu173 Validation of Microplastic Accumulation in Agricultural Fields Receiving Wastewater Sludge

Nanna Klemmensen¹, Jes Vollertsen² and Rupa Chand², (1)Thomas manns vej 23, Aalborg University, Denmark, (2)Aalborg University, Denmark

Microplastic (MP) are formed when plastic items are exposed to wind, weather, and wear. Some accumulate on urban surfaces and are washed off during rain and conveyed to wastewater treatment plants (WWTP). MP are also generated in households and industries and conveyed to the WWTP. This leads to high levels in the WWTP sludge. When agricultural fields are treated with such sludge, a possible pathway for MP accumulation in soil is created – the extent of accumulation is however still largely unknown. This study investigates the occurrence of MP in the size range of 5000 to 10 µm in agricultural fields that have received WWTP sludge, with the objective to increase the knowledge on, and determine the accumulation of, MP in such fields. Samples were collected from Copenhagen University's CRUCIAL test fields in Taastrup and two other Danish fields. Two CRUCIAL fields that had received WWTP sludge were sampled intensively by taking 12 samples in total. Here the spatial variation of MP over short and longer range is accounted for. To serve as a baseline for background MP concentration in soils, samples were collected from two CRUCIAL fields which had not received sludge and the two other agricultural fields. Approximately 280 g of soil was treated for each sample location to extract MP. Five basic steps were applied: Oxidation, flotation, enzymatic treatment, second oxidation, and second flotation. The extracts were analysed using FTIR imaging for particles < 500 µm, where after the software siMPle was used to identify and quantify MP. Particles > 500 µm were analysed by ATR-FTIR. Of the detected MPs more than 95% were of acrylic, acrylic paint, polyamide (PA), polyethylene (PE), polyester, polypropylene (PP), polystyrene (PS), polyurethane (PU), polyvinylchloride (PVC). The most abundant polymer type was PP. As an example of results, the MP concentration in one field that had received sludge varied by roughly one order of magnitude, from 7586 MP to 47689 MP pr. kg, at sampling points just 13 meters apart.

3.15.P-Tu174 Impact of Doped and Undoped Polystyrene Particles on Soil and PLANTS

Martin Hoppe¹, Jan Koester², Axel Lamparter² and Karsten Schlich³, (1)Groundwater and soil, BGR, Hannover, Germany, (2)German Federal Institute for Geosciences and Natural Resources, Germany, (3)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany

Impacts of microplastic (MP) on the terrestrial environment have been largely overlooked. This might be explained by the general lack of adequate analytical methods for extracting and detecting MP and nanoplastic (NP) in complex organic soil matrices. This methodical gap illustrates the urgent need of well-characterized model particles that can help to develop methods to investigate the fate and bioavailability of MP and NP in soil. According to Mitrano et al. (2019), quantifying and localising these particles in soil and plants will be improved by doping the particles with metals that have no natural background in soil, e.g. palladium (Pd). Here, we applied Pd-doped polystyrene particles (PS-Pd-PS-P) and pure polystyrene particles (PS-P) to soil to test their fate and impact in a long-term toxicity test for plants. The particles were synthesized in our lab by emulsion polymerization. Three different concentrations of the PS-P and the PS-Pd-PS-P were characterized. Subsequently, the particle dispersions were applied to a Cambisol and a Podzol. According to ISO 22030, the spiked soil samples were used in a chronic plant growth inhibition test with *Avena sativa* L. Moreover, the response of ammonium oxidizing bacteria (AOB) to the spiked soil samples was investigated (ISO 15685). The PS-P and the PS-Pd-PS-P were in the expected sub-µ size range and showed a high colloidal stability. This can be explained by their negative zeta potential. The particles occurred as non-homoaggregated particles in the soil matrix. The Pd-doping was detectable in the soil and in or at the plant roots which is why the particles are suitable to test their fate in soil and plants. The test on chronic toxicity in higher plants fulfilled all validity criteria. In each of the three test concentrations of the

Cambisol, no statistically significant effects were found on shoot length, shoot fresh and dry weight, shoot water content and fresh and dry weight of the flowers. No concentration dependent inhibition could be observed. The water content of the flowers in all approaches differed significantly from the control. For the Cambisol, the inhibition was between 19 and 49% for PS-Pd-PS-P while inhibition for PS-P ranged from 2 to 25%. For the Podzol, the inhibition was lower compared to Cambisol and ranged from 8 to 35% for PS-Pd-PS-P and from 2 to 21% for PS-P. The obtained inhibitions indicated a concentration dependent effect due to the particles. No effects on the AOB were observed.

3.15.P-Tu175 Identifying Factors Controlling Nano and Microplastic Uptake and Impacts on a Crop Plant: *Cucumis sativus*

Diana Alejandra Moreno¹, Héloïse Chouteau², Denise M Mitrano³, Mohammad Wazne⁴, Magali Albignac⁵, Alexandra Ter Halle⁵ and Camille Larue², (1)Laboratoire EcoLab, Ecologie Fonctionnelle et Environnement (UMR5245 CNRS-Université de Toulouse), Castanet-tolosan, France, (2)Laboratoire EcoLab, Ecologie Fonctionnelle et Environnement (UMR5245 CNRS-Université de Toulouse), France, (3)Environmental Systems Science, ETH Zurich, Zurich, Switzerland, (4)LEHNA, CNRS UMR 5023, Université Lyon 1, France, (5)University of Toulouse, CNRS / IMRCP laboratory, France

Terrestrial ecosystems might be the greatest recipient of plastic waste. It is estimated that the concentration of plastic fragments could be up to 6.7 % of the soil weight in highly polluted environments. Agrosystems are likely to be the most contaminated terrestrial system besides landfills, with multiple pathways for plastics to enter soils such as sewage sludge, wastewater and mulching and subsequently crop plants may be impacted. Currently, little is known about the fate and hazards of microplastics (MPs) and nanoplastics (NPs) in plants due to technical difficulties to analyze particles in complex matrices. In addition, more information is needed to determine how physicochemical properties and environmental factors affect the hazards of plastics. Consequently, this work aimed at determining the effect of different types of plastics varying in polymer (PS, PA, PE), particle size (nano vs. micro), shape (spheres, fragments, fibers) and weathering state (pristine vs. environmentally aged). The effects of varying exposure concentrations of MPs and NPs (0, 10, and 100 mg/kg) were assessed after 28 days in different plant growth scenarios (soil, sand, and hydroponics) on the development and metabolism of cucumber (*Cucumis sativus*). As anticipated, results showed that exposure scenario was critical to plastic toxicity. In particular, phytotoxicity was higher in hydroponic exposures (e.g., decreased foliar biomass and area up to 50 % and 80%, respectively) while effects were less prevalent when MPs and NPs were in both sand and soil. The influence of physico-chemical parameters of the particles after plant exposure in sand suggested that particle size was the main controlling factor, with MPs having no significant effects while NP exposure led to phytotoxicity symptoms. In particular, a 50% decrease in fresh root biomass was shown, suggesting that NPs could impact root growth. In ongoing work, nutrient and plastic concentrations in leaves will be assessed by ICP-MS and py-GC-MS respectively.

3.15.P-Tu176 Investigating the Link Between Above- and Below-Ground Plastic Pollution and Plasticiser Occurrence

Alex Billings¹, Kevin Jones², M. Gloria Pereira³ and David Spurgeon³, (1)UK Centre for Ecology & Hydrology (UKCEH), Lancaster, United Kingdom, (2)Lancaster University, United Kingdom, (3)Centre for Ecology & Hydrology, United Kingdom

In addition to the physical impacts of plastic particles on terrestrial organisms, toxicity will likely arise from additives associated with the polymer matrix, such as plasticisers. Historically, phthalates have been the most widely used class of plasticiser. However, concerns and restrictions surrounding the use of certain phthalates in Europe have coincided with an increase in the use of emerging non-phthalate plasticisers over the past 15 years. Despite this, the occurrence and levels of these emerging plasticisers in the terrestrial environment remains unknown. Could it be that the successors to phthalates are accumulating in soils? The occurrence of plasticisers in soils has been linked with point sources (e.g. sites of intensive agriculture), but the impact of diffuse plastic litter associated with e.g. urban areas or mismanagement of plastic waste is less well-studied. Constraining the links between the profiles of plastic and plasticiser contamination in soils will grant insights into the sources of plasticisers in the terrestrial environment. However, to date there has been no published work regarding the co-occurrence of above- and below-ground polymer and soil plasticiser contamination. Our study utilises recent developments in the field of microplastics research (e.g. semi-automated analytical pipelines capable of characterisation and semi-quantification of microplastics), alongside established analytical techniques such as GC-MS, to investigate the nature of these links in field samples collected from a range of land uses. We have developed a method to simultaneously extract and quantify a suite of legacy (i.e. phthalate) and emerging plasticisers from soil samples. There is a lack of data regarding the terrestrial occurrence of plastics in the UK. There is no data on emerging plasticisers in UK soils, whilst surveys of phthalates across various land uses have been primarily limited to the phthalate DEHP. Thus, the samples collected during this study also provide a unique insight into the status of plastics, phthalates, and emerging plasticisers in the UK terrestrial environment.

3.15.P-Tu177 Plant Response to Microplastics From Conventional and Biodegradable Mulching Films

Liisa Maunuksela¹, Essi Roininen², Ansa Palojärvi³ and Salla Kristiina Selonen⁴, (1)Finnish Food Authority, Helsinki, Finland, (2)Finnish Food Authority, Finland, (3)Natural Resources Institute Finland (Luke), Finland, (4)Suomen ympäristökeskus, Finland

Mulching film products have been developed for agriculture and horticulture to facilitate cultivation, reduce the need for plant protection products and improve agriculture profitability. Biodegradable films replacing conventional plastic cover films are typically not collected from the application site, but instead left to degrade in the soil. However, degradation rate in northern conditions is assumed to be slower than under ideal laboratory conditions, and consequently plastic particles may accumulate and act as sources of microplastics in the soil. Therefore, it is essential to assess the potential risks for the safe use of these materials and prevent degradation of soil quality and fertility in the long run. In this study, we examined the effects of mulching film particles (< 1 mm) on Chinese cabbage (*Brassica pekinensis*) seed germination and plant growth rate in controlled conditions. Assessment of plant response to three different microplastic types was performed using one conventional and two biodegradable

plastics both in concentrations of 0.1% and 1% with three replicate plants for each concentration. Plant biotests were performed on two separate occasions: immediately after microplastic addition in control soil and after two months of mixture incubation. Results from these experiments will be presented. This study is part of the project “Microplastics in agricultural soil – Sources, effects and reduction (MicrAgri)” funded by the Ministry of Agriculture and Forestry of Finland, from the Makera Fund.

3.15.P-Tu178 Circular Economy in Agriculture - the Case of Microplastics

Franja Prosenč¹, Mrs. Pia Leban¹, Urška Šunta², Tjaša Griessler Bulc¹ and Darja Isteni², (1)University of Ljubljana, Faculty of Health Sciences, Slovenia, (2)University of Ljubljana, Slovenia

Continuing population growth is driving global food demand, with agricultural activity expanding to keep pace. The linear functionality (take-use-dispose) in agriculture is causing irreversible environmental problems, therefore, a transition to a circular economy is encouraged. E.g., treated municipal wastewater can be used for irrigation and by-products of wastewater treatment and bio-waste processing can be used as fertilisers and soil amendments. Microplastics have been found to affect soil microorganisms, nutrient cycling, and plant growth; however, the effects are varying depending on their size, concentration, shape, and composition. To evaluate the realistic effects, quantification and classification of plastic contaminants in these resources and the receiving agricultural soil are needed. In this study, small plastic particles (< 2 mm and >2 mm) in (1) organic fertilisers – biowaste compost and sludge; and (2) soil – irrigated with wastewater and soil fertilised with compost were quantified and classified. Organic fertilisers, such as sludge from the wastewater treatment plant and biowaste compost are highly contaminated with plastic particles, both larger (>2 mm) as well as microplastics (< 2 mm). Interestingly, compost samples contained more plastic contaminants as compared to sludge, namely between 607 and 1186 of plastic particles (>2 mm) per kg of dry weight (dw) compost vs. 235 per kg of dw sludge. Soil fertilised with compost exhibited elevated plastic contamination as compared to the control soil fertilised with mineral fertilisers. In tilled soil, the abundance was more than four times the number in the control soil (38 vs. 9 particles/kg dw soil), whereas, in soil that was not tilled, the difference was more than twofold (16 vs. 6 particles/kg dw soil). Interestingly, tilled soil, fertilised with compost contained more than twice as many plastic particles as compared to soil fertilised with compost that did not undergo tillage. Soil irrigated with wastewater, on the other hand, exhibited only slightly elevated concentrations of plastic contaminants as compared to the control soil (5.8 vs. 3.4 of >2 mm particles/kg dw soil, and 28.3 vs. 25.8 of < 2 mm particles/kg dw soil). The results of this study will contribute towards a better understanding of the plastic contamination in agricultural soil originating from resource reuse. Additionally, they will facilitate a better experimental design of plastic effect studies.

3.15.P-Tu179 Citizen Science to Investigate Plastic Degradation in the Soil Environment

Arthur Compin¹, Meïssa Jellibi¹, Régis Céreghino¹ and Camille Larue², (1)CNRS, France, (2)CNRS, Castanet Tolosan, France

One of the 10 major environmental challenges facing our society is that of plastic waste with an annual production of around 360 million tons of which only 8% are recycled. Among the alternatives developed to face this issue is the synthesis of so-called biodegradable plastics. However, to date their biodegradation status is based on their complete degradation within three months in controlled conditions. In the wild, where they mostly end-up, many biotic and abiotic factors can influence the plastic degradation rate such as humidity, temperature or soil biogeochemistry. The issue of plastic pollution affects everyone as a citizen and consumer and therefore is an ideal subject to develop a citizen science approach. Furthermore, this approach is particularly effective in answering ecological questions at scales of time and space that cannot be covered by a research team under lab conditions making it possible to study the effect of geographic gradients over long periods of time. The PlastiZen project aim at involving participants in a scientific experimental design over a 3-month period. The objectives of the project are (i) to verify the biodegradability of this type of plastics (kinetics measurements) along a wide gradient of locations in France, (ii) to identify the controlling factors (soil texture, pH, organic matter, C/N, pluviometry, temperature, microbial activity) and (iii) to raise public awareness of the issues surrounding the consumption of single-use plastic and their end-of-life. With more than 100 participants to date, we have been able to highlight a wide diversity in the degradation rate of the “biodegradable” plastics ranging from a complete degradation (down to microplastic particles) in some locations to no visible degradation in some other places. After 3 months, the majority of the plastics buried by the participants were damaged but did not completely disappear. The main controlling factor identified in this study was the amount of cumulative rain over the considered period followed by microbial activity, temperature and to a lesser extent soil pH. Finally, another interesting aspect of such citizen science project is to be able to compile social science data about public perception and behavior related with plastic consumption and in particular highlight the evolution of participant habits after their participation to the program.

3.15.P-Tu180 Are Biodegradables Increasing or Solving the Microplastic Pollution? Correlating Particle Size, Copolymer Degradation, and CO₂ Generation During Biodegradation in Compost and Soil

Wendel Wohleben, Dr.¹, Markus Rückel², Lars Meyer², Patrizia Pfohl², Glauco Battagliarin², Patrick Bolduan², Thorsten Huffer³, Michael Zumstein³ and Thilo Hofmann³, (1)Material Physics & Analytics AND Experimental Toxicology & Ecology, BASF SE, Germany, (2)BASF SE, Germany, (3)University of Vienna, Austria

Bans, reporting and labelling requirements for intentionally added primary microplastics shall avoid their release into the environment during or after use. Biodegradable polymers are derogated from the restriction proposed by the European Chemicals Agency. Biodegradation is based on microbial oxidation and hydrolysis processes that result in the complete transformation of polymer carbon into biomass and CO₂. And yet, the ability to biodegrade in specific compartments is no excuse for littering. For intentional application in the environment, e.g. mulch films in agriculture, biodegradable polymers could contribute to the solution to the plastic pollution crisis – if they do not contribute to the issue: One may hypothesize that fragments of the original polymer part could form during the degradation processes, and/or that only certain components degrade. Part of the answer is provided by

isotope labeling of monomers, tracking their integration into biomass. Here we develop another sensitive tool by extracting and counting polymer particles during their biodegradation in compost and soil. Specifically, we studied biodegradation of PBAT-PLA copolymer blend and of PBSeT copolymer, and benchmarked them against LDPE as conventional non-degradable alternative. The materials were either dosed as 250 μm particles (considered as worst-case), or as 15 μm film (representing mulch film applications). Both industrial composting, relevant for packaging goods, and soil conditions, relevant for agricultural applications, were tested. During biodegradation (ISO 14855, ISO 17556), CO_2 evolution was monitored. Using a non-destructive and efficient extraction protocol, the particle number and size distribution, and the state of copolymer degradation were assessed via fluorescence microscopy and chemically selective Raman microscopy. Staining selectivity was additionally cross-checked by an independent incubation of a bespoke dye-labeled PBAT-PLA copolymer. Our results revealed that particle numbers dropped from the ISO-compliant initial dosing of about 80,000 particles per gram of compost to the limit of detection (LOD). At 90% CO_2 , more than 99.93% of particles have been removed. The time-resolved kinetics demonstrated that the degradation of first large, then small particles preceded the metabolism to CO_2 . Based on measured CO_2 release, and measured particle size fractions, we also inferred the kinetics of dissolved polymer as it is being metabolized.

3.16 Poly- and perfluoroalkyl substances (PFASs): Addressing Urgent Questions in the 21st Century (Part I)

3.16.T-01 Which of the (Mixed) Fluorinated, Chlorinated and Brominated N-Alkanes Are Persistent Organic Pollutants?

Xiaolei Li¹, Tannia Chevez¹, Amila De Silva², Derek C.G. Muir², Sonya Kleywegt³, Andre Simpson⁴, Myrna Simpson⁵ and Karl Jobst¹, (1)Memorial University of Newfoundland, Canada, (2)Environment and Climate Change Canada, Canada, (3)Ontario Ministry of Environment, Conservation and Parks, Canada, (4)University of Toronto Scarborough, Canada, (5)University of Toronto, Canada

Short-chain polychlorinated n-alkanes are ubiquitous industrial chemicals widely recognized as persistent organic pollutants. They represent only a small fraction of the 184,600 elemental compositions (C_{10-25}) and the myriad isomers of all possible (mixed) halogenated n-alkanes (PXAs). This study prioritizes the PXAs on the basis of their potential to persist, bioaccumulate and undergo long-range transport guided by quantitative structure-property relationships (QSPR), density functional theory (DFT), chemical fate models and partitioning space. The QSPR results narrow the list to 966 elemental compositions, of which 352 (23 Br, 83 Cl/F, 119 Br/Cl and 127 Br/F) are likely constituents of substances used as lubricants, plasticizers, and flame retardants. Complementary DFT calculations suggest that an additional 1367 elemental compositions characterized by a greater number of carbon and fluorine atoms, but fewer chlorine and bromine atoms, may also pose a risk. The results of this study underline the urgent need to identify and monitor these suspected pollutants.

3.16.T-02 Volatile PFAS in Air: Developing Methods for Targeted Analysis and Discovery of Non-Target Volatile PFAS

Carlos Gil¹, Jan Peter Mayser², Stefan Koschinski¹, Laura Miles³ and Maria Jaimés¹, (1)Markes International GmbH, Germany, (2)Markes International Ltd, Germany, (3)Markes International, UK

Per- and polyfluorinated alkyl substances (PFAS) are analysed mainly by liquid chromatography, as traditionally the focus has been on monitoring PFAS in soil and water, targeting mainly the ionic PFAS species. Nevertheless, trace PFAS quantities in air is today also of concern from human health and environmental perspectives, and the analytical technology required by air monitoring scientists to address this area is already available and tested. Modern analytical TD-GC-MS systems were designed specifically for monitoring trace-level organic vapours and recent developments in automated TD technology have meant these methods can be applied to more and more challenging compounds. With the wide range of different chemistries as displayed within the wide-range of PFAS compounds, this TD technology can be implemented to monitor PFAS in air. The aim of this study was to evaluate the performance of the latest off-the-shelf sorbent tube sampling and automated TD-GC-MS analytical technology for analysing volatile and semi-volatile PFAS. This study focused on perfluoroalkyl carboxylic acids (C4 to C14), fluorotelomer alcohols (FTOHs), fluorotelomer acrylates (FTAcres) and fluorotelomer sulfonamides (FOSAs). These compounds have been shown to be widely distributed within indoor air, because of their high volatility and the wide use of PFAS compounds within everyday objects in our household. Additionally, in air the ionic species are less relevant. Often overlooked is the fact that also very volatile perfluorinated hydrocarbons (C1 to C3), also known as potent greenhouse gases and ozone depleting substances, are part of PFAS family. However, these require whole-air sampling using canisters, online monitoring or offline sampling bags and were not included in this study but have the potential to be included within the analytical system. Method development was carried out in the same manner as for all VOCs analysis. Guidelines from established methods, like the US EPA TO-17 can directly be transferred into this type of analysis. As single quadrupole MS with EI are often used for standard air monitoring methodology, this detector was chosen for the project, however it should be noted that other detectors may improve the sensitivity. Excellent method performance (linearity, repeatability in the order of 5% or less, storage stability tested up to 15 days, etc.) was demonstrated across the range of compounds tested, including low or sub-ppt detection limits for all compounds.

3.16.T-03 Total Oxidizable Precursors Assay for Human Serum: A Tool for Holistic Per- and Polyfluoroalkyl Substances (PFAS) Exposure Assessment

Lara Cioni¹, Vladimir Nikiforov² and Dorte Herzke³, (1)NILU- Norwegian Institute for Air Research, Norway, (2)NILU - Norwegian Institute for Air Research, Norway, (3)Environmental Chemistry, NILU - Norwegian Institute for Air Research, Tromsø, Norway

Per- and polyfluoroalkyl substances (PFAS) are a class of industrial chemicals that have been detected worldwide in the environment, in wildlife and in humans. Even if over 4700 PFAS are registered in the market, only few of them are commonly analyzed in human samples and some fluorine mass-balance studies are showing that currently measured PFAS might not be

enough to describe the full extent of PFAS human exposure. Among the underlooked PFAS in human samples, precursors are of concern for human health because these compounds can be metabolized to perfluoroalkyl acids (PFAA) that are already known to be toxic. To look for both known and unknown precursors in human serum an adaptation of the total oxidizable precursors assay (TOPA) was developed. In the TOP assay precursors are converted to easy to measure PFAA by oxidation with heat-activated persulfate under alkaline conditions. The total oxidizable precursors are then quantified by measuring the PFAA produced by oxidation. The TOPA was introduced as a complementary tool for water analysis and had to be modified to be applied to small volumes of human serum samples. Modifications to the method were tested on reference serum samples spiked with model precursors. To fully convert the model substances the heating at 85°C had to be extended and a large excess of oxidant was needed. However, even when precursors were fully converted, the yield of identified oxidation products was not always 100%, ranging from 33 to 100%. As there can be precursors that are not at all or not fully converted to PFAA, care must be taken in quantifying the total amount of precursors present using the sum of PFAA produced by oxidation. Unequivocal information on the structure of the oxidizable part vanishes, but the distribution of products is a good indication of that, as well as of the structure of the original perfluorinated part. In general, the products are perfluorocarboxylic acids with the same or shorter perfluorinated chain, but for some precursors PFOS and perfluoroethercarboxylic acids can also be observed as oxidation products. The final method can be used to determine well known PFAS and oxidizable precursors using only one small serum aliquot. The TOP assay is a valuable tool to estimate the contribution of precursors present in human serum directly linked to human exposure, indicating their structure and type without requiring additional sample amounts, instrumentations or standards.

3.16.T-04 How Open and FAIR Cheminformatics Can Support the Discovery, Analysis and Assessment of PFAS

Emma Schymanski¹, Parviel Chirsir¹, Jian Zhang², Paul Thiessen², Rick Helmus³, Mohammad Sadia⁴, Annemarie van Wezel⁵ and Evan Bolton², (1)University of Luxembourg, Luxembourg, (2)National Institutes of Health, United States, (3)University of Amsterdam/Institute for Biodiversity and Ecosystem Dynamics (IBED), Netherlands, (4)University of Amsterdam, Amsterdam, Netherlands, (5)University of Amsterdam/IBED Institute, Amsterdam, Netherlands

The ever-increasing concerns about poly and perfluoroalkyl substances (PFAS) and calls for action upon them as a class has spurred intense debates on how to define and enumerate the “PFAS Chemical Space”. There are now a number of PFAS lists openly available to the community. These include the OECD PFAS list of ~4700 PFAS (ENV/JM/MONO(2018)7) and the US EPA PFASMASTER list of ~9000 PFAS. Over 30 more are available on resources such as the CompTox Chemicals Dashboard (https://comptox.epa.gov/dashboard/chemical_lists/?search=PFAS) and the NORMAN Suspect List Exchange (<https://zenodo.org/communities/norman-sle/search?page=1&size=20&q=PFAS>). However, searching the large open chemical collection PubChem (<https://pubchem.ncbi.nlm.nih.gov/>; 111 million chemicals) reveals that ~6 million entries match the latest OECD PFAS definition where PFAS “contains at least one alkyl CF₂ group”. Navigating this space is challenging, between the tens of PFAS routinely monitored, thousands on existing lists, and the millions existing in databases. This work demonstrates how the cross-resource integration of information between the NORMAN Suspect List Exchange and PubChem can facilitate closing the gaps in major open databases and fast-track publication of new structures identified in research (*e.g.*, PFAS transformation products; previously undocumented PFAS) including detailed annotations such as reactions, spectral fragmentation patterns, collision cross section values and even NMR spectra. By highlighting and building on existing PubChem functionality, this in turn offers extensive bulk property calculations, patent information, available annotation (such as: uses, toxicity, and biomedical literature), download files, and advanced programmatic access. Since discovery of PFAS in the environment is critical, a relevant subset of PFAS in PubChem (~255K chemicals with –CF₂CF₂–) is made available as a PFAS database for non-target or suspect screening mass spectrometry efforts for incorporation into open software such as patRoan (<https://rickhismus.github.io/patRoan/>), MetFrag (<https://msbi.ipb-halle.de/MetFrag/>) and more. A set of findable, accessible, interoperable, reusable (FAIR) templates are provided to enhance data sharing between resources and increase the availability of FAIR datasets for future data-hungry computational developments such as literature/patent mining, transformation product prediction (*e.g.* BioTransformer) and/or automated PFAS classification efforts.

3.16.T-05 Horizontal and Vertical Distribution of Perfluoroalkyl Acids (PFAAs) in the WATER Column of the Atlantic Ocean

Eleni Savvidou¹, Bo Sha², Matthew Salter², Ian Cousins² and Jana Johansson², (1)Stockholm University ACES, Sweden, (2)Stockholm University, Sweden

Perfluoroalkyl acids (PFAAs) are widely used synthetic chemicals and can be the degradation products of so-called precursors. They are characterized by unique physicochemical properties such as strong surface activity and stability. Another feature of PFAAs is that they are all mobile and highly persistent, which makes their occurrence in the environment problematic. Additionally, long-chain PFAAs are bioaccumulative and have been linked to adverse health effects in humans and wildlife. The oceans are thought to be the terminal sinks for these persistent substances but little is known about their fate in the water column. This study aimed to map the concentrations of PFAAs (with 6-12 carbon atoms (C₆-C₁₂)) in the surface and deep ocean, thus adding high quality analytical data to the currently limited database. Seawater depth profiles at 29 sampling stations were collected during the 29th Atlantic Meridional Transect (AMT29) cruise from the UK to southern Chile, and analyzed using high-performance liquid chromatography coupled with high resolution mass spectrometry. The generated data revealed a major PFAA input from the Mediterranean Sea through the Mediterranean Outflow Water that flows into the Atlantic Ocean. Elevated concentrations were observed in the English Channel as well. Another outstanding feature were accumulated concentrations of PFAAs at the eastern edge of the Northern Atlantic Subtropical Gyre. The highest PFAA median concentrations were measured in the Northern Hemisphere (n=119) with 61 pg L⁻¹, whereas for the Southern Hemisphere (n=77) a median concentration of 22 pg L⁻¹ was estimated. The composition at the surface was dominated by PFHxA, PFHpA, PFOA and PFNA. Trends with depth

within the water column were observable, showing that PFAA homologues with 6-9 carbons (C6-C9) dominated in surface waters, while longer-chain PFAAs (C10-C11) reached intermediate depths (500-1500 m). This is due to the increasing sorption affinity with increasing chain-length, so it is suspected that long-chain PFAAs sorb relatively strongly to organic matter and get transported downwards the water column.

3.16 Poly- and perfluoroalkyl substances (PFASs): Addressing Urgent Questions in the 21st Century (Part II)

3.16.T-06 The TOP Assay Uncovers Unknown PFAS in German Soils With Background Concentrations

Nicole Bandow¹, Jan Koschorreck², Mareike Mersmann³, Joerg Wellnitz¹ and Frank Sacher⁴, (1)German Environment Agency, Germany, (2)Umweltbundesamt, Umweltbundesamt, Berlin, Germany, (3)North Rhine-Westphalia Office of Nature, Germany, (4)ITZW DVGW-Technologiezentrum Wasser, Germany

Per- and polyfluoroalkyl substances (PFAS) are highly persistent and have been found worldwide in many compartments. Their persistence in combination with toxic effects on environmental and human health have resulted in a ban of individual compounds and in an ongoing substitution by other PFAS. Today, PFAS are estimated to consist of more than 10,000 compounds including precursors and polymers making analysis of all single compounds impossible. To overcome this analytical gap, sum parameters, e.g. the total oxidizable precursor assay (TOP assay), have been developed and results indicate that the amount of unknown PFAS in the environment is in general higher than what is revealed by the analysis of individual well-known PFAS. Two studies were performed in Germany aiming to provide more information on the importance of precursors for PFAS background levels in soils as well as their spatial and temporal trends: Samples from the German environment species bank (time period 2002-2018) represent different ecosystem types of German soils. 20 top soil samples collected in North Rhine-Westphalia represent different land uses (agricultural land, grassland and forest). PFAS were detected in all soils and forestry samples showed highest concentrations before TOP assay. The soils from the specimen bank are often dominated by PFOS and PFOA. Sum concentrations of PFAS (C4-C13) range from 0.1 µg/kg for a agricultural used soil to 25 µg/kg in the organic layer of a forestry type location. The samples from the second study were also analyzed for ultrashort-chain PFAS such as TFA and PFPrA. The main components in these samples were TFA, PFBA, PFOA and PFOS. The PFAS concentrations (C2-C13) ranged from 0.8 -12.5 µg/kg and without TFA and PFPrA from 0.5 to 4.5 µg/kg. In the first study the increase after TOP assay varies strongly with sampling locations and years and ranges from no increase to an increase of 160 % for a low contaminated sample from an urban conurbation. In the second study most samples show much higher PFAS sum concentrations in soil after using TOP Assay. In some soils, also high increases of TFA concentrations were observed which may have another source than PFAS precursors, e.g. pesticides. The presence of unknown PFAS underlines the need for a more comprehensive strategy in PFAS regulation including precursors and substitutes and the prevention of further PFAS release to soils.

3.16.T-07 Perfluorinated Alkyl Substances Around Industrial Sites - Elevated Levels Can Cause Health Problems

Jacob de Boer, VU University, Netherlands

1. Introduction At several places in the world the production of per- and polyfluorinated alkyl substances (PFAS) has led to high levels of these compounds in the neighbourhoods of PFAS producing plants. In 2021, high levels of perfluorooctane sulphonic acid (PFOS) were found near a plant of 3M in Zwijndrecht, very close to Antwerp, Belgium. We analysed blood samples of inhabitants of Zwijndrecht, as well as local fish, sediment, surface water and drinking water. 2. Materials and methods Blood samples were taken from 16 persons that lived and/or worked within a few kilometers from the 3M site in Zwijndrecht. All persons completed a questionnaire in which they answered a series of questions about their background, age, gender, die, etc. Flounder, marine vegetables, and surface water were sampled from the Western Scheldt at the Dutch/Belgian border and Antwerp harbour. Drinking (tap) water was sampled in Antwerp. A set of 17 PFAS was determined in all samples by LC-MS/MS analysis on an LC-Sciex Exion LC AD coupled to a Sciex 6500+ triple-quad MS, using an Xbridge BEH C18 XP 150 x 2.1 mm, 2.5 µm column and electrospray ionisation. 3. Results and discussion PFOS was dominant in all samples (2.1 – 1100 mg/L). The recent opinion on PFAS of the European Food Safety Agency (EFSA) gives a safe level of PFAS in human blood that is based on the sum of four PFAS congeners: PFOA, PFOS, PFHxS and PFNA. This sum should not be higher than 6.9 mg/L. The maximum value found was 1154 mg/L, which is 167-fold the norm. Most of the persons studied consumed vegetables or fruit from their own gardens and/or ate eggs from their own chickens. Based on these results (Table 1) a larger study on PFAS in human blood was initiated by the Flemish authorities in 800 persons living within a circle of 3 km around the 3M site. That study confirmed the here presented results. 90% of the PFAS concentrations found in the larger study exceeded the EFSA guidelines of 6.9 mg/L. Western Scheldt fish, sediment and water samples confirmed the PFOS pollution from Antwerp. The PFOS concentration in flounder was 24 mg/kg, lower than determined by Chu et al. [4] who found 322 mg/kg in 2006. The perfluoro-1-butane-sulfonamide (FBSA) detected by Chu et al. was also found by in our study. The results of this study urge much better inventories of current PFAS production plants.

3.16.T-08 An Outdoor Aging Study to Investigate the Release of Per- and Polyfluoroalkyl Substances (PFAS) From Functional Textiles

Steffen Schellenberger¹, Ioannis Liagkouridis², Raed Awad³, Stuart Khan⁴, Merle Plassmann⁵, Gregory Peters⁶, Jonathan Benskin⁵ and Ian Cousins⁵, (1)RISE Research Institutes of Sweden, Sweden, (2)ITM - Stockholm University, Sweden, (3)IVL Swedish Environmental Institute, Sweden, (4)University of New South Wales, Afghanistan, (5)Stockholm University, Sweden, (6)Chalmers University of Technology, Sweden

Functional textiles were investigated for the emission of per- and polyfluoroalkyl substances (PFAS) via a real time outdoor weathering experiment in Sydney, Australia. Different side-chain fluorinated polymers (SFPs) (with C₄F₉SO₂-R, C₆F₁₃-C₂H₄-R

and C₈F₁₇-C₂H₄-R side-chains) were applied to polyamide (PA)-based textile fabrics and exposed on a rooftop to multiple natural stressors, including direct sunlight, precipitation, wind, and heat for up to 6 months. Thereafter, additional stress was applied to the fabrics via washing and abrasion. A multi-platform analytical approach was used for textile characterization which revealed losses of both low molecular weight PFAS and PFAS-containing textile fragments (e.g. microfibrils) throughout weathering. The loss of color and water repellency of the textiles accompanied these changes. Targeted analysis showed that weathering led to formation of a distinct PFAA pattern for each SFP-based textile finish. Overall, this work provides evidence for two distinct emission pathways from SFP-coated textiles during weathering: a) loss and subsequent transformation of low molecular weight PFAA-precursors residuals, and b) loss of textile fibers/particles containing polymeric PFAS which could eventually lead to formation of persistent PFAAs in the environment.

3.16.T-09 PFAS in Drinking Water in Norway; Generally, Very Low Levels but Elevated Concentrations Were Detected Near Known PFAS Sources

Merete Grung¹, Kine Bæk², Thomas Rundberget², Dag Hjermandt² and Hans Jørgen Halvorsen³, (1)NIVA, Oslo, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)MOVAR, Norway

PFAS are contaminants that can be found in most ecosystems. Norway has had no production of PFAS, but PFOS have been used in fire-fighting foams and have been employed at a few industrial sites. In Norway, drinking water originates mostly from surface water. Norway has reported very few analytical measurements of PFAS in drinking water, and data was therefore warranted. Drinking water from 20 different drinking sources and 11 different waterworks were sampled and sent to NIVA for analyses of 31 PFAS, including the PFAS in EU's drinking water directive and a few other PFAS groups expected to be found in water (FTS; fluorotelomer sulfonic acids and PFASA; perfluoroalkane sulfonamides). Both source water (n=94) and finished drinking water (n=70) were analysed. The surface waters had a wide geographical spread east-west-south, but not northern part. Information about the technology used for treating the water was categorised (3 categories) to calculate removal efficiency (based on PFAS detected above 2×LOQ in source water). PFOS and brPFOS had the highest detection frequencies (95% in surface water and 89% and 94% in drinking water). Other PFAS that were frequently detected included PFBS and short PFCA (perfluorinated carboxylic acids, PFBA to PFNA) and PFHxS. Five PFAS were only detected in one drinking water source (PFBA, PFPS, PFHpS, N-EtFOSAA and PFHxSA). 15 of the measured PFAS were not detected above the LOQ in any samples representing mainly long PFCA and PFSA (perfluorosulfonic acids). The median number of PFAS in drinking water was 3, but up to 14 PFAS were detected in one sample. The lower bound sum of 20 PFAS included in EU's drinking water directive, was 0.28 ng/L (source water), while the maximum was 23 ng/L. For drinking water, the median was 0.26 ng/L and the maximum 12 ng/L. Denmark has regulated drinking water with a limit for the sum of 4 PFAS, risk assessed by EFSA, to 2 ng/L. Only one waterworks in Norway had levels above this limit in drinking water. The treatment efficiency at the waterworks were calculated based on PFAS concentrations in source water and drinking water taken the same day. The removal efficiency of PFAS for treatments with a combination of coagulation, dissolved air flotation, filtration and granulated activated carbon performed better for removing PFAS (ca. 60% removal of PFOS and brPFOS) than other categories. Details of the removal efficiency for different treatment stages at one treatment facility will be presented.

3.16 Poly- and perfluoroalkyl substances (PFASs): Addressing Urgent Questions in the 21st Century (Virtual Only)

3.16.V-01 Application of Standard Fate and Transport Modeling Approaches for Evaluating PFAS Compounds in Groundwater

Gerco Hoogeweg, Brenna Kent, Raghu Vamshi and Amy Ritter, Waterborne Environmental, Inc., United States

Per- and polyfluoroalkyl substances (PFAS) used in numerous consumer products and industrial applications make their way into the environment through multiple pathways. Vastness of the chemical group, with thousands of distinct PFAS and their widespread uses have led to their ubiquitous occurrence in the environment. These contaminants are receiving increased attention due to their persistence and toxicity to environmental and human health. Several small and large-scale monitoring programs have shown widespread presence of these compounds in air, surface and ground water, and soil media. USEPA has been prioritizing ongoing work to better understand and eventually reduce the potential exposure and risks caused by these chemicals. Reliable modeling tools to evaluate the fate and transport of these chemicals are critical to the development of risk assessment and remediation strategies. To date, limited work has been done to better understand the fate and transport of these complex chemicals in the environment using existing modeling approaches. Rising public interest and increasing regulatory action has made the need for modeling an important next step in advancing the understanding of these persistent chemicals. This work will focus on applying standard modeling approaches to understand the fate and transport of PFAS. Two models, HYDRUS and PEARL, were used to simulate PFAS measured under standardized conditions. As a case study, these models were then applied to simulate a PFAS chemical to two study areas in the United States. Results from modeling were compared with available groundwater monitoring data for the study areas. The practical utility of the standard modeling approaches for application to address the PFAS challenges over small and large geographies are discussed.

3.16.V-02 Multimedia Fate and Intake Fractions of PFAS Precursors and Terminal Degradation Products

Natalie A Kerr¹, Olivier Jolliet² and Peter Fantke³, (1)University of Michigan, Ann Arbor, United States, (2)University of Michigan, United States, (3)Technical University of Denmark, Denmark

Here we present a database of physicochemical properties for over 70 PFAS, yield data for seven precursors in air, soil, freshwater, and freshwater sediment, and present an easily adaptable method to derive intake fractions of both precursors and terminal degradation products from multimedia transport throughout the environment. The database contains prioritized

experimental and estimated data, and supplies the critical input parameters needed to run a USEtox®-based model, which allows for the comparison of fate factors and intake fractions among different families of PFAS, and by chain length. This also provides a path for identifying the driving parameters of fate and transport for different PFAS. We use this data to calculate the total intake fractions by inhalation and ingestion associated with seven precursors (fluorotelomer alcohols and sulfonates) emitted to different compartments; each precursor's emission resulted in different intake profiles of terminal degradation products up to 0.01 kg.product.intake/kg.precursor.emitted. The total intake of terminal degradation products is more than intake of the initial parent compound in all cases. These results demonstrate the importance of considering multimedia transport of precursors, as they contribute significantly to direct exposure to PFAS. Future research should prioritize intermedia studies of fluorotelomer alcohols and sulfonates, and other precursors. Future risk assessments should consider multimedia transport and terminal degradation product exposure. Further toxicological studies on mixtures are needed as this work shows that individual precursor emission will result in the intake of multiple terminal degradation products.

3.16 Poly- and perfluoroalkyl substances (PFASs): Addressing Urgent Questions in the 21st Century (Poster)

3.16.P-Th110 What Happened to the Molecules? - Results and Molar Balances of 6: 2 and 8: 2 Polyfluoroalkyl Phosphate Diesters (diPAPs) After a Two-Year Soil Column Study Raise Questions

Eva Weidemann¹, René Lämmer², Thorsten Stahl³, Bernd Göckener², Mark Buecking⁴, Jörn Breuer⁵, Janine Kowalczyk⁶, Hildegard Just⁶, Runa Boeddinghaus⁵ and Matthias Gaßmann⁷, (1)Hydrology and Substance Balance, University of Kassel, Kassel, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallingenberg, Germany, (3)Chemisches und Veterinäruntersuchungsamt Münsterland-Emscher-Lippe (CVUA-MEL), Germany, (4)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (5)Agricultural Technology Centre Augustenberg, Germany, (6)German Federal Institute for Risk Assessment BfR, Germany, (7)University of Kassel, Germany

PFAS (per- and polyfluorinated alkyl substances) have been the subject of continued environmental concerns for decades. Due to the ubiquitous occurrence of these anthropogenic “forever chemicals,” they represent a problem that must be dealt with on a global level. PFAAs (perfluoroalkyl acids), a group of PFAS, of which some compounds are already declared as PBT (persistent, bioaccumulative, toxic), are the final transformation products of transformable PFAS, called precursors. Polyfluoroalkyl phosphate esters (PAP), a group of precursors with different variations (e.g., diPAP), are found in paper industry products and thus also in agricultural lands after application of contaminated paper sludge polluted composts. Here, the first study on the simultaneous leaching and transformation behavior of diPAPs in soils is described, which may provide insights into possible cases of real-world contamination. Therefore, two representatives of diPAPs, 6:2 and 8:2 diPAP, were studied in 2-year soil column experiments, with a weekly water input of 35 ml, a biweekly analysis of eluate and a soil analysis at the end of study. 1.47 μmol and 1.17 μmol for 6:2 diPAP and 8:2 diPAP, respectively, were mixed into the topsoils. Due to the properties of diPAPs, a maximum conversion of 1 mol diPAPs equals 2 mol of PFAAs was taken as the base of molar balance calculations. After two years, the following molar amounts of PFAAs related to the initial molar amount of 6:2 diPAP were found in the leaching water: PFPeA (26.0 mol-%) > PFHxA (11.8 mol-%) > PFBA (4.0 mol-%) > PFHpA (0.1 mol-%). In the 8:2 diPAP study the major transformation product in leaching water was PFOA (16.5 mol-%) followed by PFHpA (3.2 mol-%), PFHxA (1.1 mol-%), PFPeA (0.9 mol-%) and PFBA (0.6 mol-%). 6.1 mol-% of 6:2 diPAP and 44.7 mol-% of 8:2 diPAP were still found in the topsoil layers at the end of the experiment, which shows a solely leaching potential of transformation products and a high sorption behaviour of both diPAPs. Small quantities of PFAAs in soil (6:2 diPAP: 0.9 mol %, 8:2 diPAP: 1.4 mol-%) cannot account for missing quantities in molar balances (6:2 diPAP: 51.0 mol-%, 8:2 diPAP: 31.6 mol-%). This loss may be related to the emergence of NERs (non-extractable residues), volatilisation of intermediates, not-quantified intermediates and/or loss through sorption on vessels. In other studies, missing/declining amounts were also explained by NERs, but the process by which this occurs remains unknown.

3.16.P-Th111 Analysing the Alternatives to Poly- and Perfluoroalkyl Substances Using Multicriteria Decision Analysis and Applying the Essential-Use Concept: A Fluorosurfactant Case Study

Rachel Lucy London¹, Juliane Glüge² and Martin Scheringer², (1)Institute for Biogeochemistry and Pollutant Dynamics, ETH Zürich, Zürich, Switzerland, (2)ETH Zurich, Switzerland

Poly- and perfluoroalkyl substances (PFASs) are persistent, problematic, but often useful. European regulators plan to restrict PFASs and phase out uses not deemed essential for society. However, there are few case studies of the application of essential use concept in the literature. Analyses of the available alternatives must be carried out to identify uses that could be considered “substitutable” and to avoid regrettable substitution. In this case study alternatives to PFAS in coatings, paints and varnishes were investigated using multicriteria decision analysis (MCDA). The outcome of this was then applied to determine the essentiality of PFAS for this use. An established fluorosurfactant, 2 novel shorter-chain PFASs, and 2 nonfluorinated alternatives were identified. Data were gathered from the literature and in-silico tools for the substances and their anticipated environmental degradation products. These data were used to evaluate the performance of each alternative for each attribute contributing to objectives of low environmental hazard, low human health hazard, high functionality, and low cost. Weights for these attributes were derived to reflect the priorities of different stakeholders and the scores aggregated. Once the alternatives had been analysed the essentiality of PFAS for this use was determined. This case study demonstrates one possible application of the essential-use concept and contributes to the ongoing discussion surrounding this concept.

3.16.P-Th112 Implications of Results From a Multi-Generational Zebrafish PFOS Exposure-Response Study on Regulatory Thresholds for Protection of Aquatic Life

David W. Moore¹, Kurt A. Gust², Natalia Reyero³, Mitchell Wilbanks⁴, Erik Mylroie⁵, Catherine Cox⁶, Ashley Kimble⁷, Jason Conder⁸ and Jennifer Arblaster⁸, (1)U.S. Army Corps of Engineers, United States, (2)U.S. Army Engineer Research and Development Center, United States, (3)USACE Engineer Research and Development Center, United States, (4)US Army Engineer Research and Development Center, United States, (5)USACE-ERDC-EL, United States, (6)ORISE Fellow at USACE ERDC, Wallis and Futuna Islands, (7)US Army Engineer Research & Development Center, United States, (8)Geosyntec Consultants, Inc., United States

The Environmental Protection Authority (EPA) of Victoria, Australia released water quality guidelines in 2016 for PFOS that included a freshwater 99% species protection level of 0.00023 µg/L, a values more than 100X to 1000X lower than screening values put forth by other regulatory agencies. Derivation of this exceedingly low threshold was driven largely, if not almost entirely, by results from a single study (Keiter et al. 2012), a multi-generational exposure of the zebrafish (*Danio rerio*) to PFOS, which reported reduced growth at 0.6 µg/L. Arblaster et al. (2017) previously described the limitations of the Keiter et al. (2012) study and how the 0.6 µg/L threshold, a value more than 10-fold lower than the next lowest toxicity value, affected the species sensitivity distribution used to derive the Australian WQ guideline. Despite the limitations of the Keiter et al. (2012) study design (e.g., low replication, small and unevenly spaced exposure range, and limited exposure verification), the reported result obviously had a significant influence on the Australian guidance and has the potential to influence future regulatory threshold values. Consequently, the USACE ERDC in collaboration with the USEPA and with support from SERDP, a coalition of businesses, conducted a multi-generational study of the effects of PFOS exposure on zebrafish using a more robust experimental design (e.g., 6 exposure concentrations [0.1, 0.6, 3.2, 20 & 100 ppb], 5 replicates, exposure concentration verification/validation) and an expanded suite of test endpoints (vitellogenin, RNA seq, histopathology). Based on results from this study involving 180-day exposures of both the parental (P1) and first familial (F1) generations, the strongest evidence of potential ecologically significant effects on zebrafish occurred at the 100 µg/L exposure concentration (i.e., the highest level evaluated) which showed potential effects on survival and growth, but no effects on reproduction. Results from this study provide strong evidence supporting an adverse effect threshold of 100 µg/L rather than the 0.6 µg/L (as reported by Keiter et al. 2012). The implications of these results are very significant, because the 100 µg/L threshold concentration translates to a 99% protection value of 1.3 µg/L rather than 0.00023 µg/L (as put forward by the EPA of Victoria, Australia). This presentation will describe and report the results from the USACE ERDC study and emphasize the importance of the technical basis for development of credible threshold concentrations.

3.16.P-Th113 Development and Demonstration of Volatile and Semi-Volatile Per- and Polyfluoroalkyl Substances (PFAS) GC-MS Methods on Select NIST Reference Materials

Alix E. Rodowa¹, Ryan Falkenstein-Smith², Bruce Benner² and Jessica Reiner³, (1)National Institute of Standards and Technology, Gaithersburg, MD, (2)The National Institute of Standards and Technology, United States, (3)National Institute of Standards and Technology, United States

Per- and polyfluoroalkyl substances (PFAS) are emerging contaminants of concern, and have been observed in consumer products, consumer byproducts (e.g., dust, wastewater, and landfill leachate), and environmental compartments including humans and biota. As a result, routine monitoring methods, method development, and commercial analysis of these compounds have become more widely available. Current commercial methods typically target ionic, less volatile PFAS by liquid chromatography tandem mass spectrometry (LC-MS/MS). However, volatile and semi-volatile analytes are not commonly included despite the fact that volatile and ionic PFAS are known to co-occur as a result of manufacturing processes. Further, volatile PFAS are commonly excluded due to their poor sensitivity by LC-MS/MS and a lack of materials available to validate analytical methods (e.g., Standard Reference Materials (SRMs) and analytical standards). To fill this data gap, multiple instrumental methods for twelve volatile and semi-volatile PFAS including 4:2, 5:2s, 6:2, 7:2s, 8:2, and 10:2 fluorotelomer alcohols, 8:2 and 10:2 perfluoroalkyl acrylates and perfluoroalkyl acetates, and methyl- and ethylperfluorooctanesulfonamide, have been developed for electrospray ionization gas-chromatography mass spectrometry (EI GC-MS). To demonstrate the efficacy of the methodology two Standard Reference Materials (SRMs) from NIST, SRM 2585 Organic Contaminants in House Dust and SRM 2781 Domestic Sludge were selected for quantitative evaluation of GC amenable PFAS. Each of these materials represents a different analytical compartment, and both materials have reported concentrations of ionic PFAS by LC-MS/MS on their Certificates of Analysis. The observed volatile PFAS concentrations in the selected SRMs are subsequently evaluated across instrumentation (two separate GC platforms) and across acquisition modes to evaluate accuracy and precision. These volatile PFAS measurements add value to the volatile PFAS knowledge-base and provide needed methodological, analytical validation materials.

3.16.P-Th114 Modelling the Environmental Distribution of GenX: From Point Source to Remote Areas

Wouter Gebbink¹, Michael Crookes², Oliver Warwick³ and Claire Massey⁴, (1)PFA Brussels, Belgium, (2)Peter Fisk Associates Ltd., United Kingdom, (3)Peter Fisk Associates Limited, United Kingdom, (4)Environment Agency, England, United Kingdom

Per- and poly fluoroalkyl substances (PFAS) are a group of chemicals that includes several thousand fluorinated substances. PFAS are known for their persistent nature once released into the environment and several PFAS possess chemical properties which makes them mobile in the aquatic environment. A particular concern for these types of substances is that they may have the potential to travel to areas far from the point of release and eventually reach concentrations that could result in adverse environmental effects. To investigate the travel potential of mobile PFAS, GenX [hexafluoropropylene oxide dimer acid (HFPO-DA)] was selected as an example PFAS. Data on chemical properties used for the modelling were obtained from open access sources. There is one known fluorochemical production plant in Europe (in the Netherlands) which uses GenX in the production of fluoropolymers and data on tonnages and/or releases to water and/or air between 2012 and 2019 were reviewed. Predicted environmental concentrations (PECs) were estimated at local, regional and continental scales using the EUSES model as well as the Multimedia Stock Pollution Tool (MUST) which allows for time-dependent emission scenarios. Based on emission data, PECs

for surface water at the local scale ranged from 3 µg/L in 2012 up to around 8 µg/L in 2017. For 2019, when emissions to water were reduced, the local PEC was estimated at about 0.007 µg/L. Existing monitoring data measured downstream of the GenX processing site were generally a factor of around 10 lower than the local PECs. Freshwater PECs followed the emission pattern with the highest regional and continental concentrations estimated in 2017 at 0.026 µg/L and 0.0025 µg/L respectively. These PECs are generally higher than monitoring data from surface water samples collected in the Netherlands and elsewhere in Europe. Further modelling showed that when emissions are ceased, water PECs at the regional scale decrease rapidly within 1 year. However, they will take up to 2 years to decrease to near zero at the continental scale. The modelling suggests that local and regional concentrations of GenX are expected to respond quickly to changes in emission. Furthermore, in order to reach surface water concentrations that would surpass the water quality limit set by national authorities, the annual amount released into the regional scale would have to be >4 times higher than the highest reported emissions to water.

3.16.P-Th115 Assessing Human Health Risks From Per- and Polyfluoroalkyl Substances (PFAS) Via Drinking Water

Mohammad Sadia¹, Ingeborg Nollen², Thomas L ter Laak³, Antonia Praetorius⁴ and Annemarie van Wezel⁵, (1)University of Amsterdam IBED Institute, Netherlands, (2)University of Amsterdam/IBED Institute, Nederland, (3)KWR, Netherlands, (4)University of Amsterdam/IBED Institute, Netherlands, (5)University of Amsterdam/IBED Institute, Amsterdam, Netherlands

Per- and polyfluoroalkyl substances (PFAS) are a group of water-soluble chemical compounds that have a wide range of applications but are also very persistent and show hazardous properties. The European Food Safety Authority (EFSA) has concluded that drinking water and food are the main PFAS exposure routes for humans and recommends a safe level for the total weekly intake (TWI) of 4.4 ng/kg b.w. for the sum of four PFAS. This study investigates the human exposure levels to PFAS, including very polar ultrashort-chain (C1-C3) and branched isomers of PFAS, in drinking water and evaluates the human risk based on the EFSA TWI. An analytical method for determining trace levels of 56 targeted PFAS in drinking water (including the ultrashort-chain PFAS and branched isomers) was developed by using solid-phase extraction, chromatographic separation (UPLC CSH C18 column), and heated electrospray ionization (ESI). The method showed effective elimination of matrix effects produced by using heated ESI as an ion source in HRMS. The method was successfully applied to 18 drinking water samples in the Netherlands from different water sources (groundwater and surface water) and their corresponding raw water. The limit of detection (LOD) for targeted analytes was in the range of 9 pg/L-100 pg/L, except for TFA and PFPrA with a higher LOD of 35440 pg/L and 240 pg/L, respectively. The ultrashort-chain PFAS (0.09 µg/L - 1.1 µg/L) followed by the perfluoroalkyl carboxylic acids (PFCA) (5.2 ng/L - 79.5 ng/L) were the dominant classes. The analysis of variance for PFCA, perfluoroalkyl sulfonic acid (PFSA), and precursors showed statistically significant differences between drinking water originating from different sources. No statistically significant difference was found for the ultrashort-chain PFAS. The branched isomer contribution to the sum of linear and branched for PFOS (29% to 64%), and PFHxS (17% to 24%) were different from the original production ratio (20-30% branched for PFOS, and ~ 5% branched for PFHxS). Drinking water produced from surface water, except for two samples using a GAC filtration step in their treatment processes, exceeded the safe value derived from the EFSA-TWI. Further research is required to better assess the exposure to higher levels of ultrashort-chain PFAS and branched isomers present in drinking water. Extra efforts should be directed for protecting the groundwater reservoir from the very polar compounds like ultrashort-chain PFAS.

3.16.P-Th116 Suspect and Non-Target Screening Method Development for PFAS Using Lc-Hrms

Svante Bertil Rehnstam¹, Mai-Britt Czeschka² and Lutz Ahrens³, (1)Lennart Hjelms vag 9, Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden, (2)Technische Universität Braunschweig, Germany, (3)Swedish University of Agricultural Sciences, Sweden

Per- and polyfluorinated substances (PFAS) are man-made chemicals which have unique lipophobic and hydrophobic properties, and thus has found much use in various products around the world for its non-stick properties. However, PFAS can pose a health risk and is bioaccumulative, which in turn makes it a persistent organic pollutant and with its unique chemical properties highly mobile. Currently there are over 4000 registered PFAS in multiple publicly available databases such as the US EPA, Norman Network, and the Swedish Chemical Agency, but still only a very small fraction of those are monitored in routine analyses. Furthermore, new destructive treatment techniques are being developed to break down PFASs. Little is known about the production of PFAS transformation products that may occur from these treatments. The research aims to develop a method that can perform both suspect screening and non-target screening of PFAS to elucidate the contaminants that are missed in common routine analyses. Liquid chromatography-high-resolution mass spectrometry will be utilized for the development of these screening methods. With the high-resolution mass spectrometry the accurate masses obtained can be compared to online databases for identifying suspects. The suspects can then be further identified with MS² experiments and with authentic standards. For the non-target screening, novel software approaches will be utilized to identify new PFASs. Appropriate mass spectrometry methods such as Data-Dependent Analysis (DDA), and Data-Independent Analysis (DIA) will be utilized to obtain as much information as possible of the samples. The final results will elucidate the presence of previously known PFASs and newly created PFAS transformation products that may occur from destructive treatments.

3.16.P-Th117 PFAS in Recycled Fertilisers: Potential Issues, Identified Uncertainties, and Need for Monitoring

Nele Deleebeeck and Laura Lefevre, Arcadis Belgium, Belgium

The findings presented in this publication resulted from an assessment which was performed in view of a project for the European Commission, Directorate General Environment. In this project, the exposure and risk of contaminants/impurities of potential concern in fertilisers needed to be assessed, to identify contaminants/impurities or fertilisers for which additional regulatory measures may be required. PFAS were identified as one of the (groups of) contaminants for which an assessment was required.

The focus was on the assessment of fertilisers based on or containing recycled materials derived from sewage sludge. PFOA and PFHxA were assessed as representative for the long-chain and short-chain PFAS, respectively. As one of the major data gaps identified was evidence on the removal efficiency of recycling processes, an indicative ‘screening’ assessment was performed assuming a concentration of PFOA and PFHxA equal to an existing national concentration limit for fertilisers. It should be noted that the outcome of the assessment, in which predicted exposure is compared to Environmental Quality Standards and Tolerable Daily/Weekly Intakes, is to be considered as ‘indicative’, as the obtained ratios are not to be interpreted as true risk quotients for substances following a ‘non-threshold’ approach. As exceedances of established standards have been calculated for PFOA as representative of long-chain PFAS, mainly for secondary poisoning and humans exposed via the environment, it became clear that it is of utmost importance to verify that recycling processes of which the output materials are used in/as fertilisers can guarantee a very high removal efficiency. If this cannot be guaranteed, further build-up of PFAS in the environment due to increasing use of recycled fertilisers could not be avoided. It should be noted that the views expressed in the poster are those of the contractor with the context of the service contract 070201/2019/817112/SER/ENV.B2 and according to the terms of reference associated with that contract.

3.16.P-Th118 Current Gaps and Research Needs of Adsorption Process As the BEST Available Treatment Technology for PFAS Removal From WATER

Erica Gagliano, Pietro Falciglia, Federico Vagliasindi and Paolo Roccaro, University of Catania, Italy

Per- and polyfluoroalkyl substances (PFAS) are a large group of anthropogenic compounds that received particular attention due to their persistence and toxicity. The recalcitrant behaviour of PFAS along with their chemical properties nicknames them as “forever chemicals” and poses challenges to conventional water and wastewater treatment processes. Adsorption process is the most extensively implemented technology for PFAS removal. PFAS adsorption onto granular activated carbon (GAC) or anion exchange resin (AER) is a field-proven technology. However, several limitations of prior researches dealing with adsorption processes can be highlighted. Available literature reveals that the adsorption efficiency depends on PFAS chain length and functional group. The adsorption mechanisms of short- and long-chain PFAS are different due to their different structure and hydrophobicity. Short-chain PFAS are more hydrophilic and tend to be less adsorbed than long-chain ones. While, at the same chain length, perfluoroalkyl sulfonic acids (PFSAs) are removed better than perfluoroalkyl carboxylic acids (PFCAs). Adsorption capacity also depends on adsorbents properties. The acrylic resins are more effective for PFAS removal than styrenic resins, while macroporous resins exhibit better uptake than gel resins. Similarly, macro- and meso-porous GAC exhibited better long-chain PFAS removal. Despite its properties are similar to AC, biochar exhibits lower adsorption capacity than AC. During adsorption processes, organic matter, specifically natural organic matter (NOM), could interact with PFAS through electrostatic and/or hydrophobic interactions, affecting the adsorption efficiency of adsorbent materials. Despite the widespread application, the main drawback and limitation is currently the regeneration of PFAS-saturated adsorbents which is essential to renew the adsorption capacity and to recover adsorbate PFAS. Conversely, a relevant knowledge gap regarding thermal regeneration techniques for PFAS-saturated GAC should be highlighted. To sum up, AERs are more effective than AC for both long- and short-chain PFAS removal, while the adsorption capacity of short-chain PFAS is lower than that observed for long-chain ones. Extensive research efforts should be routed to the investigation of effective regeneration techniques. Consequently, economic assessments should also address adsorbents disposal and/or regeneration.

3.16.P-Th119 Sorption of PFAS to Activated and Non-Activated Waste Biochars for In Situ Remediation of Pfas-Contaminated Soil and WATER

Katinka Muri Krahn¹, Erlend Sørmo², Gabriela Castro Valera³, Hans Peter Arp⁴ and Gerard Cornelissen², (1)Norwegian Geotechnical Institute, Oslo, Norway, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)Norwegian University of Science and Technology (NTNU), Norway, (4)NGI, Norway

Due to considerable persistence, bioaccumulation, and toxicity of per- and polyfluoroalkyl substances (PFASs), remediation of soil and water contaminated with PFAS is urgently needed. The potential for using various organic waste materials in the production of biochar sorbents for PFAS has sparked great interest among researchers. In a recent study by Sørmo et al. (2021), eight activated waste timber biochars applied with a 5% amendment dose to heavily PFAS-contaminated, low-TOC (1.6%) soil, reduced leachate concentration with 98-100%. Since strong sorption was seen for these waste timber biochars, the present work tested the sorption behavior of two biochars from sewage sludge pyrolyzed at 700 °C to C4-9 perfluorinated carboxylic acids (PFCAs). The sludge feedstocks were 1) Ullensaker sludge (ULS) containing PFAS-enriched wastewater from Oslo Airport, and 2) Biorest Lindum (BRL), a sludge digestate. In laboratory batch experiments, we prepared ten-point biochar-water sorption isotherms with ULS and BRL and six-point soil-biochar-water isotherms using a clean, sandy soil (1.3% TOC) and biochar at 2% w/w spiked with both a PFCA cocktail and C4-9 individually. Previous studies of pyrolyzed sewage sludge conclude with poor sorption to PFAS. However, a preliminary analysis of a selection of ULS batch samples (n=22/178) indicate sorption almost as strong to ULS as clean wood chips, the experimental control. The initial spike concentrations were reduced with >98% for all PFCAs tested, where K_d ranged from 4.29-5.85 by increasing chain length in accordance with the literature. Even though elemental composition analysis of ULS is yet to be conducted, sludge char is expected to have low carbon content, porosity, and internal surface area—properties associated with poor sorption—and instead be enriched with minerals, especially iron oxides. Since ULS sorbs stronger than expected, we speculate that the sorption mechanisms between this biochar and PFAS is not dominated by hydrophobic interactions that were observed for waste timber in Sørmo et al., but by electrostatic forces between mineral phases in the sludge matrix and the carboxylate groups of PFCAs. The high sorption capacity of ULS is promising for the implementation of a sustainable and cost-effective waste management method of problematic wastes such as contaminated sewage sludge, and will be an important contributor to a circular economy. Note: Complete results will be presented in May 2022.

3.16.P-Th120 Short-Chain Per- and Polyfluoroalkyl Substances (PFAS) Effects on Human Phase I Biotransformation Enzymes

Megan Solan¹ and Ramon Lavado², (1)Baylor University, (2)Baylor University, United States

Per- and polyfluoroalkyl substances (PFAS) are a class of compounds that have been of interest to human and ecological risk assessors in recent years because they are found ubiquitously and there is evidence for adverse health effects in humans. Newer, short-chain alternatives have been developed to mitigate some of the toxic effects observed with the long-chain variants. However, there is a significant lack of toxicity data pertaining to these compounds, and even less is known about their effects in the context of exposures with other xenobiotics. A previous study has suggested that two of the legacy PFAS, perfluorooctanoate (PFOA) and perfluorooctane sulfonate (PFOS), are able to reduce the expression of important CYP-enzymes in human liver cells following exposure. We evaluated the activity of two phase I biotransformation pathways (CYP1A1 and CYP3A4) following exposure to short-chain PFAS, including perfluorobutane sulfonic acid (PFBS), 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)-propanoate (GenX), perfluorohexane sulfonate (PFHxS), perfluorohexanoic acid (PFHxA), 6:2 fluorotelomer alcohol (6:2 FTOH), using a differentiated human liver cell line (HepaRG). In addition to the cell lines, the inhibitory potential of the long-chain and short-chain PFAS was also evaluated in human CYP1A1, -1A2, -2C19, -2D6, -2E1, and 2B6 supersomes. Following single exposures, each of the compounds was co-exposed to known CYP enzyme inducers, Rifampicin and Benzo(a)pyrene, to evaluate the inhibition potential of the short-chain PFAS. Our results indicate that the interference of short-chain PFAS with CYP1A1 and CYP3A4 enzymes could potentially lead to adverse outcomes resulting from the inability of biotransformation pathways to function as needed.

3.16.P-Th121 An Analysis of How the Current REACH Processes May Serve As a Basis for Implementing the "Essential-Use" Concept for PFASs

Zhanyun Wang¹, Romain Figuière² and Ian Cousins³, (1)ETH Zurich, Switzerland, (2)Department of Environmental science, Stockholm University, Stockholm, Sweden, (3)Stockholm University, Sweden

Per- and polyfluoroalkyl substances (PFASs) are a class of synthetic organic substances with diverse structures, properties, uses, bioaccumulation potentials, environmental mobilities and toxicities. Despite this high diversity, all PFASs are alike in that they contain perfluoroalkyl moieties that are extremely resistant to environmental and metabolic degradation. The vast majority of PFASs are therefore either non-degradable or transform ultimately into stable terminal transformation products (which are still PFASs). Many have argued that this high persistence is sufficient concern for their management as a chemical class, for all "non-essential" uses of PFASs to be phased out, and for fostering research, innovation and transition to safer alternatives in the case of uses that currently are essential. Currently, five European Union (EU) Member States have announced that they are preparing a wide restriction proposal for the entire class of PFASs under the EU Chemicals Regulation--REACH. This study aims to shed light on what has generally been established under REACH with relevance to the "essential-use" concept. In particular, it analyzes which argumentations have been used to conclude on individual exemptions in the current REACH restriction process. This analysis is then used to evaluate whether and how future application of the "essential-use" concept under REACH could be possible, also for improving the legislation.

3.16.P-Th122 The New Definition of PFAS - Too Long to Be True?

Vladimir Nikiforov, NILU - Norwegian Institute for Air Research, Norway

The recently proposed definition of PFAS - Per- and Polyfluoroalkyl Substances - reads: "PFASs are defined as fluorinated substances that contain at least one fully fluorinated methyl or methylene carbon atom (without any H/Cl/Br/I atom attached to it), i.e., with a few noted exceptions, any chemical with at least a perfluorinated methyl group (?CF₃) or a perfluorinated methylene group (?CF₂?) is a PFAS". With this broad definition the PFAS universe includes too many substances that are too far from the original meaning of the term PFAS; at the same time it inexcusably excludes a number of really dangerous fluorinated chemicals. First, the definition can be shortened to: PFASs are chemicals with a non-terminal CF₂ group, not connected to H, Cl, Br or I. Indeed, each CF₃-group is nothing, but a CF₂-group connected to F, and, therefore, there is no need to mention both. There is no justification for exclusion of CF₂-groups connected to H, Cl, Br or I and terminal ones. Indeed, CFC-113 and CFC-113a, HFC-134 and HFC-134a must fall into the same group. Removal of "noted exceptions" will shorten the definition to: PFAS are chemicals with CF₂ group. The laconic four-words definition - chemicals with CF₂ group - will be easy to use by non-experts. The romantic title, "forever chemicals", reflects the spirit of PFAS - extreme persistence due to effect of polyfluorination. This must be reflected in the definition of PFAS. Then PFAS - the term already in our hearts - can be redefined as Persistent FluoroAliphatic Substances. All non-aromatic substances are aliphatic and include alkyl, cycloalkyl, bicycloalkyl and alkylene derivatives. All persistent substances of OECD definition will be included, and a few other important ones. Non-persistent substances of OECD definition could be classified as Precursors of PFAS (PPFASs) or Potential Precursors of PFAS (PPPFASs). Yes, it will probably take a scientist and not a software to relate a formula to PFAS or not.

3.17 Qualitative and quantitative methodologies for the biomonitoring of environmental organic pollutants and their metabolites

3.17.T-01 Development and Optimization of an Extraction Method Based on Use/D-Spe for the Analysis of Pollutants of Emerging Concern in Invasive and Native Aquatic Biota From l'Albufera Natural Park (Spain)

Diana Manjarrés¹, Nicola Montemurro², Dyana Vitale³, Yolanda Pico³ and Sandra Perez⁴, (1)Ins of Environ Assessment & Water Resch (IDAEA-CSIC), Spain, (2)Environmental Chemistry, Jordi Girona 18-26, null, Barcelona, Spain, (3)University of Valencia, Spain, (4)IDAEA-CSIC, Spain

Exotic species such as *Procambarus clarkii*, *Corbicula fluminea*, and *Leopomis gibbosus* have become invasive species in Spain for some decades because they have managed to adapt in Mediterranean wetlands, including the Natural Park of L'Albufera (Valencia). This kind of species, as well as native fauna such as *Anodonta sp.*, may be exposed to a wide range of emerging contaminants and they could be used as bioindicators to assess chemical exposure and pressure on freshwater ecosystem species. In this study, we developed and optimized an extraction method assisted by ultrasound and d-SPE for the simultaneous determination and quantification of different pollutants of emerging concern including 91 pharmaceuticals (PhACs), 11 flame retardants, 21 PFAs, and 55 pesticides. For this purpose, four extraction solvents (1) ACN:iPrOH (3:1) + 0.1%, (2) ACN + 0.1% F.A, (3) MeOH/H₂O (7:3) + 1% F.A (4) MeOH and three cleaning sorbents (1) Z-sep, (2) Z-sep+ (3) Z-sep/C18 were tested. Recovery efficiency tests were performed for each of them and the solvent and sorbent with which the best results were obtained were validated in two of the matrices (*Procambarus clarkii* and *Anodonta sp.*). To demonstrate the effectiveness of the method, wild samples of the invasive species were collected from L'Albufera Natural Park. Preliminary results indicate the presence of some PhACs such as sulfamethoxazole, citalopram, cotinine, tramadol, and methadone.

3.17.T-02 Chemometers: An Integrative Tool for Studying Chemicals in Biota and Surrounding Abiotic Media

*Elisa Rojo-Nieto*¹, *Eva Barbara Reiter*², *Theo Wernicke*³ and *Annika Jahnke*⁴, (1)Department of Ecological Chemistry, Helmholtz Centre for Environmental Research GmbH - UFZ, Leipzig, Germany, (2)Helmholtz-Zentrum für Umweltforschung GmbH - UFZ, Leipzig, Germany, (3)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (4)Helmholtz Centre for Environmental Research - UFZ GmbH, Germany

Chemometers are a common and well-defined polymer reference phase for passive equilibrium sampling of a large range of organic pollutants in different matrices like biota, sediment and water. By bringing the *chemometer* into direct contact with the sample, the chemicals partition between the sample and the polymer until a thermodynamic equilibrium is established. As the *chemometers* are defined as a common reference phase, the chemical concentrations in the *chemometers* at equilibrium can be directly compared between different biotic and abiotic compartments and organisms of different trophic levels. This approach has opened a new analytical window for determining the chemical activity of pollutants, which is one of the main drivers for partitioning, biouptake and toxicity. It allows to express the data on a common basis, as the equilibrium partitioning concentrations in the silicone, circumventing normalization, and the extracts of the *chemometers* can both be submitted to chemical analysis and/or to bioanalytical profiling. The *chemometers* have proven to be a relevant tool to evaluate chemical pollutants in biota, and we are currently applying them in diverse applications, amongst others to study (I) the thermodynamics of bioaccumulation in aquatic environments using multimedia sampling in a remote Swedish lake, (II) the internal exposure in marine mammal tissues from the German North and Baltic Sea coasts, and (III) passive sampling in the abiotic compartments sediment and water from German rivers with different patterns and levels of pollution as a proxy for chemical concentrations in biota. This presentation will give an overview of our related activities and applications of *chemometers* aimed at characterizing the complex environmental exposure by mixtures of pollutants at high trophic levels using a common reference phase. An outlook will cover future plans for applications to describe the lifelong exposure to mixtures of pollutants, the so-called exposome, of top predators.

3.17.T-03 FR Exposure Assessment of E-Waste Dismantlers Using Different Sampling Strategies

*Alex Balasch Garcia*¹, *María López*², *Cristina Reche*³, *Mar Viana*², *Teresa Moreno*⁴ and *Ethel Eljarrat*⁵, (1)IDAEA- CSIC, Spain, (2)IDAEA CSIC, Spain, (3)IDAEA CSIC Barcelona, Spain, (4)Institute of Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain, (5)IDAEA-CSIC, Spain

Nowadays electronic waste (e-waste) is the fastest growing waste on the planet. In 2019, 54 million tonnes were generated in the world, while only a 17% of them were recycled. A growth to 75 million tonnes is expected for 2030. E-waste is usually made of plastic, ceramics, glass or metal, that are valuable and reusable materials when they are properly recycled, which results into an increase of the e-waste recycling industry. Potentially toxic substances as flame retardants (FRs) can be released to the air during recycling process, which can suppose a risk for the employees. Sampling was conducted in an e-waste dismantling facility from Catalonia (Spain), where a wide range of products were recycled. Facility was divided in two floors that were sampled separately, grinding floor and cathode-ray tube (CRT) dismantling floor. Employees wore cotton t-shirts and polydimethylsiloxane wristbands during workday and they returned it once finished. Airborne fine particulate matter (PM_{2.5}) was also collected. Organophosphate esters (OPEs) and halogenated flame retardants (HFRs), specifically polybrominated diphenyl ethers (PBDEs), novel brominated FRs (NBFRs) and dechloranes, were analysed in all samples. OPEs by TFC-LC-MS-MS and HFRs by GC-MS-MS. OPEs, PBDEs and NBFRs were detected in all samples, but dechloranes were not detected in PM_{2.5} samples from grinding area neither in one from CRT area. PM_{2.5} samples presented higher concentrations of FRs in CRT area compared with grinding area. Concentration levels detected in PM_{2.5} were higher than those reported from other studies in Australian population, but similar to the ones reported from an e-waste dismantling facility from Canada. Results from wristbands show also the exposure difference between areas, as in PM_{2.5}. Comparing profiles of both sampling methods there were found some differences. Percentage contribution to the OPEs was 3% for DCP in PM_{2.5}, while it increased to 36% in wristbands, being the most contributing OPE in this matrix. For PBDEs, the second compound with highest contribution was different in each sampling method, being BDE-183 in PM_{2.5} and BDE-99 in wristbands. Dechloranes were detected in all wristband samples, but only in two samples of PM_{2.5}. NBFRs presented similar profiles in both sampling methods.

3.17.T-04 Comparison of Sample Treatment Procedures for Human Exposome Evaluation in Urine Through Suspect Screening

*Mikel Musatadi*¹, *Francesca De Angelis*², *Leire Mijangos*¹, *Ailette Prieto*¹, *Maitane Olivares*¹, *Olatz Zuloaga*¹ and *Asier Andrés-*

Maguregi³, (1)University of the Basque Country, Spain, (2)University of Pisa, Italy, (3)Department of Analytical Chemistry, University of the Basque Country, Spain

The concept of exposome has gained popularity in recent years due to the constant exposure to chemical compounds that humans face. Those compounds can be found everywhere, from personal care products (PCPs) to plastic materials or biocides, and can easily be introduced to our organisms. Within our bodies, xenobiotics are usually metabolized (mostly as glucuronides) with the aim of increasing their polarity in order to be excreted through urine. This is why urine has become the most relevant biofluid for exposome monitorization in humans. Most works in the literature are limited to selected analytes, instead of analyzing as many compounds as possible. Therefore, in this work, several procedures (solid phase extraction, liquid-liquid extraction and “dilute and shoot” (SPE, LLE and DS)) have been tested not only for target analysis of a wide variety of analytes (230 targets), but also for identifying other suspects (more than 4000) and glucuronides by means of LC-HRMS. Synthetic urine samples were spiked at 5, 15 and 30 ng g⁻¹ with the target analytes and absolute recoveries were calculated at each spiking-level. Although best recoveries were obtained with LLE overall, most phthalate metabolites were not recovered with that technique, which is a relevant exposome biomarker family. With SPE instead, all families were detected even though lower recoveries were achieved. However, with surrogate correction, apparent recoveries were statistically comparable. Lastly, DS showed the worst results at low spiking level due to the lack of preconcentration and high matrix effect at the detection. Regarding the real urine samples, they were treated with and without enzymatic hydrolysis for glucuronide deconjugation and several xenobiotics were quantified in the 3 volunteers at ng g⁻¹ level. Moreover, suspect screening was performed for detecting other exposome related compounds besides the ones included in the target analysis method. In this case, samples treated with SPE differed from LLE and DS independently of the volunteer, due to the considerably higher number of xenobiotics identified with SPE. A similar tendency was observed for the non-target analysis of glucuronides, where many more glucuronides were detected with SPE.

3.17.T-05 New Methods for Confirmation of Pesticide Metabolites in Human Biomonitoring

Carolin Huber¹, Rosalie Nijssen², Arjen Lommen³, Herbert Oberacher⁴, Werner Brack⁵, Tobias Schulze⁶, Marco Blokland³, Frederike van Tricht², Hans Mol², Chiara Maria Vitale⁷, Elliott James Price⁷, Jana Klanova⁷, Kevin Wagner⁸, Laurent DEBRAUWER⁹, Borja Garlito Molina¹⁰, Olga Pardo Marin¹¹, Nuria Leon¹¹, Jean-Philippe Antignac¹² and Martin Krauss⁶, (1)Helmholtz Center for Environmental Research - UFZ, Germany, (2)Wageningen Food Safety Research, Wageningen University & Research, Nederland, (3)Wageningen Food Safety Research, Wageningen University & Research, Netherlands, (4)Medical University of Innsbruck, Austria, (5)Helmholtz Centre for Environmental Research – UFZ, Germany, (6)Helmholtz centre for environmental research - UFZ, Germany, (7)Masaryk University, Czech Republic, (8)INRAE, Toxalim, France, (9)INRA UMR 1331 TOXALIM, research centre in food toxicology, France, (10)Foundation for the Promotion of Health and Biomedical Research of the Valencia Region, Spain, (11)FISABIO, Spain, (12)LABERCA UMR 1329 INRA, France

Chemicals of emerging concern include a wide range of different chemical groups, among them pesticides, which are widely used in modern agriculture or as ingredients of biocidal products. Human biomonitoring (HBM) assesses the internal exposure to pesticides, with urine being the most common matrix analyzed. HBM of pesticides is challenging because of the high number of pesticides, the fact that in most cases they are not excreted as such, but as many possible or even unknown metabolites, and the unavailability of analytical reference standards of the metabolites. This calls for qualitative HRMS-based screening methods to assess overall exposure. The result of such screening methods are mostly tentative detects which require a follow-up confirmatory analysis. We present new methods for confirmation of pesticide metabolites in human urine by applying liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS) and computational data analysis tools. As proof of the concept for our methods, we exemplify the application on the urine samples of the large-scale SPECIMEn (Survey on Pesticide Mixtures in Europe) study within the HBM4EU project (www.hbm4eu.eu). For the confirmation of *phase I metabolites* (mainly formed by CYP-450 mediated oxidative reactions), we present a high-throughput strategy by generating phase I metabolites *in-vitro* by incubation of the pesticides with highly pooled human liver S9 extract. The extracted retention time and the reference tandem mass spectra are matched with spectra received from representative urine samples. For the confirmation of *phase II metabolites* (formed by conjugation reactions), we studied the comparability of the tandem mass spectra of the conjugated metabolite with the unconjugated species. Based on our observations on glucuronidated drugs in a clinical dataset, we developed a strategy to modify the tandem mass spectra of conjugates to compare them with reference spectra of the deconjugated species. In total, we confirmed eight parent pesticides and more than 30 pesticides metabolites (confidence level 1, 2a/b according to Schymanski et al.) in the dataset of the SPECIMEn study. This demonstrates the applicability of the described method for the confirmation of pesticide metabolites, increasing the confidence of tentative annotations. The obtained list of pesticide metabolites will help in further quantitative studies to select possible biomarkers of exposure. As expected, we detected more metabolites than parent pesticides, which highlights the need for novel approaches to overcome limited standard availability and also include more pesticide metabolites in HBM studies.

3.17 Qualitative and quantitative methodologies for the biomonitoring of environmental organic pollutants and their metabolites (Poster)

3.17.P-Tu181 Constructed Wetlands As an Efficient Technology to Remove Organic Contaminants From Municipal Treated Wastewater

Nuria López Vincent¹, Nicola Montemurro², Alberto Cruz-Alcalde³, Jordi Llado⁴, Xavier Borrell-Diaz⁵, Olga Onuki³, Ana Piera Santacruz³, Laura Poch⁵ and Sandra Perez⁵, (1)Department of Environmental Chemistry, IDAEA-CSIC, Barcelona, Spain, (2)Environmental Chemistry, Jordi Girona 18-26, null, Barcelona, Spain, (3)Universitat de Barcelona, Spain, (4)Universitat Politècnica de Catalunya (UPC), Spain, (5)IDAEA-CSIC, Spain

Ensuring water quality and safety is one of the most important environmental challenges of this century. To improve and reuse water, wastewater treatment plants (WWTPs) have been implemented to reduce the pollution of industrial and urban wastewater through different treatments and processes. However, WWTPs are identified as a major source of organic contaminants (OCs) in aquatic environments because they cannot remove them. The occurrence of OCs in aquatic environments could pose a risk to human health and environment. Thus, specific treatments are needed to remove these OCs and preserve the environment. Although some processes have been tested, research on nature-based treatments to that proposed are limited. In this study, four constructed wetlands (CW) were assembled at semi-pilot scale in vertical CW with recirculation. Each one was filled with 30 L of spiked secondary wastewater from the WWTP located in Barcelona (Spain). Each microcosm was made using methacrylate box (L: 100 cm, W: 30 cm, H: 30 cm) filled with first layer of cobbles, a second layer of volcanic rocks, a third layer of fine gravel and, finally, a layer of sand. In three of them, an additional layer of burnt cork, almond shell or chestnut shell was added. These wastes present high adsorption properties, which could help improve the efficiency of CW promoting the circular economy. The last one, without any adsorbent, was used as control. The concentration of the target MPs was analysed using high-resolution mass spectrometry Q-Exactive Orbitrap. Suspended solids and dissolved organic carbon were also determined in each experiment. Finally, to determine the suitability of this technique for reuse in agriculture, the treated effluents will be tested to irrigate lettuce samples that will be subjected to analysis of residues. The preliminary results in the “control wetland” revealed that more than 80% of some OCs were removed at 4 days of retention time. However, the OCs with high log_{Kow} were eliminated less than 40% in the same system. For its part, the suspended solids were removed about 80%. **Acknowledgements:** This work was financially supported by Spanish national project TRAPPER (CICLIC, RTI2018-097158-B-C33) and “Agencia Estatal de Investigación” from the Spanish Ministry of Science and Innovation and the IDAEA-CSIC, a Centre of Excellence Severo Ochoa (CEX2018-000794-S). 3.17.P-Tu182 Evaluation of Aromatic Amines Levels in Textile Products From Spain and Brazil

Marilia Souza¹, Nieves González², Marta Herrero Casado², Montse Marques², Marti Nadal³, Fernando Barbosa Junior⁴ and Jose Domingo², (1)TecnATox | Universitat Rovira i Virgili, Spain, (2)Universitat Rovira i Virgili, Spain, (3)University Rovira i Virgili, Spain, (4)University of São Paulo, Brazil

Azo dyes are commonly used in the textile industry. These colorful compounds are insoluble in water and are synthesized into the fiber during the dyeing process. The fundamental composition of azo precursors contains one or more aromatic amine molecules (AAs), currently considered as emerging pollutants by regulatory agencies. It has been demonstrated that after exposure to textile products containing azo dyes, skin bacteria reduce azo dyes and then release AAs, eventually absorbed through skin. These compounds are polar organic chemicals that derive from aromatic hydrocarbons and show a widespread distribution. The International Agency for Research on Cancer (IARC) classified the AAs into three categories: known, probable, and possible human carcinogens. This study is aimed at determining the content of AAs in organic and non-organic clothes from Spain and Brazil. Fifty-eight aromatic amines, regulated and non-regulated, were included. Of them, twenty-two amines are known carcinogens and regulated under the European Union (REACH regulation; No. 1907/2006), such as 2-naphthylamine and 4-chloroaniline. Commercial samples bought in both Spain and Brazil were made of different fabric materials, including cotton, wool, silk, polyamide, acrylic, viscose, and polyester. The selected items were from pregnant women, newborns, and children, vulnerable groups of the populations to develop adverse effects after chemicals exposure. The sample preparation method was based on ISO DIN EN 14362-1 (Spanish Standard UNE-EN, September 2017), with adaptations. The instrumental analysis was performed employing high-performance liquid chromatography (HPLC) with an interface of Orbitrap Exploris™ 120 mass spectrometer (Thermo Scientific™), while the chromatographic separation was carried out using an Acquity UPLC BEH C18 (1.7 μm, 2.1 x 150 mm). The data of this project will be relevant to support public health federal/national agencies to establish the baseline values for aromatic amines in textile products.

3.17.P-Tu183 Advanced Throughput Analytical Strategies for the Comprehensive HRMS Screening of Organic Micropollutants in Marine Mammals From the Baltic Sea

Georgios Gkotsis¹, Maria-Christina Nika², Nikiforos Alygizakis², Konstantinos Vasilatos², Anita Kunitzer³, Linnea Cervin⁴, Sara Persson⁴, Anna Roos⁴, Anders Galatius⁵, Peter Oswald⁶, Farina Reij⁷, Michael Dähne⁷, Linda Westphal⁷, Simon Rohner⁸, Ursula Siebert⁸, Iwona Pawliczka vel Pawlik⁹, Jaroslav Slobodnik⁶ and Nikolaos Thomaidis², (1)Chemistry, National and Kapodistrian University of Athens, Athens, Greece, (2)National and Kapodistrian University of Athens, Greece, (3)German Environment Agency (UBA), Germany, (4)Swedish Museum of Natural History, Sweden, (5)Aarhus Universitet, Denmark, (6)Environmental Institute, Slovak Republic, (7)German Oceanographic Museum, Germany, (8)University of Veterinary Medicine Hannover, Germany, (9)University of Gdansk, Poland

The systematic monitoring of organic micropollutants in the aquatic ecosystem has revealed the ubiquitous presence of numerous anthropogenic chemicals in different environmental compartments, such as water, sediments, and biota. Although there is established knowledge on the presence of regulated priority pollutants and their adverse effects on the aquatic organisms, monitoring data for emerging contaminants are still scarce. High Resolution Mass Spectrometry (HRMS) - based workflows appear to be a powerful tool for the simultaneous determination of organic micropollutants, having a wide range of uses, applications and physicochemical properties, as well as their (bio)transformation products. Consequently, there is an urgent need for sufficient occurrence data to be able to evaluate the emergence of these compounds and initiate risk mitigation measures. Biomonitoring studies using wildlife can be a valuable source of data for the assessment of the territorial and the temporal distribution of organic micropollutants. Furthermore, chemicals detected in organisms are possibly highly bio-accumulative (B) and persistent (P), thus fulfilling two out of three PBT criteria considered under REACH legislation. Therefore, the systematic biomonitoring of organic micropollutants will contribute to the assessment of the EU risk mitigation measures, but will also

provide insights into the emergence of these chemicals, the ecosystem condition, and the potential adverse effects on the human health. In the current biomonitoring survey, a holistic analytical approach was applied for the determination of organic micropollutants in marine mammal specimens, combining complementary chromatographic techniques and ionization modes coupled to HRMS (LC-ESI-QToF MS and GC-APCI-QToF MS). In this context, 11 liver samples from 4 different marine mammal species (common dolphin, harbour porpoise, harbour seal and grey seal), collected from the Baltic Sea, were analyzed following state-of-the-art analytical methodologies. Generic and validated analytical protocols were employed and the acquired HRMS chromatograms were screened for the presence of more than 2,400 known and 65,000 environmentally relevant suspect organic micropollutants following wide-scope target and suspect screening methodologies, respectively. Moreover, all HRMS data were digitally archived in the NORMAN Digital Sample Freezing Platform for further retrospective suspect screening.

3.17.P-Tu184 From Target to Suspect and Non-Target Screening of Endocrine Disrupting Compounds in Human Urine

Mikel Musatadi, Claudia Caballero, Leire Mijangos, Ailette Prieto, Maitane Olivares and Olatz Zuloaga, University of the Basque Country, Spain

Synthetic organic compounds are useful for a wide variety of applications, since they are key components of personal care products, plastics or several biocides, among others. However, they get leached from those materials, becoming ubiquitous and posing a serious threat to humans' welfare. In this scenario, endocrine disrupting compounds (EDCs) have been in the spotlight in recent years, since they interfere with the endocrine system, leading to adverse health issues. Within our bodies, EDCs are metabolized in order to be excreted through urine. Therefore, urine has become the most important biofluid for exposome monitorization in humans. Regarding the quantification of EDCs in urine, liquid chromatography coupled to low resolution tandem mass spectrometry (LC-MS/MS) is mostly used through target analysis approaches. However, with the emerge of high resolution mass spectrometry (HRMS), new analysis possibilities are possible, such as, suspect and non-target screening (SNTS). Consequently, the identification of other compounds that are usually overlooked in most routine analysis is possible. At the present work, an analytical method based on the use of both LC-MS/MS and LC-HRMS/MS techniques for target and SNTS in human urine has been developed. Firstly, the target analysis method for 24 EDCs (including bisphenols, parabens, benzophenones, phthalates, triclosan and triclocarban) was optimized deeply, studying the enzymatic hydrolysis, clean-up by solid-phase extraction and analysis by LC-MS/MS. Then, the method was fully validated, obtaining satisfactory figures of merit and applied to volunteers' samples, in which several EDCs were quantified. For instance, benzophenone-3 ($0.2 - 13 \text{ ng g}^{-1}$), bisphenol A ($7.7 - 13.7 \text{ ng g}^{-1}$), methyl 3,5-dihydroxybenzoate ($8 - 254 \text{ ng g}^{-1}$), mono butyl phthalate ($2 - 17 \text{ ng g}^{-1}$) and triclosan ($0.3 - 9 \text{ ng g}^{-1}$) were found at higher concentrations than the rest of the analytes. Nevertheless, the presence of other analogues was detected as well. In addition, the target analysis method was extended to suspect analysis (almost 4000 suspects) and non-target analysis (molecules containing S, Cl or Br atoms) with the data obtained from LC-HRMS/MS. That strategy allowed detecting other 74 compounds (personal care products, plasticizers and exposome biomarkers) that would not be noticed in typical routine target analysis approaches due to the reduced number of target analytes.

3.17.P-Tu185 Active Bumblebees As Passive Samplers

Lena Benner¹, Luisa Coder², Martina Roß-Nickoll³ and Andreas Schäffer³, (1)RWTH Aachen University, Aachen, Germany, (2)RWTH Aachen University/ Institute for Environmental Research, Germany, (3)RWTH Aachen University, Germany

The decline of insect populations is gaining increased public attention, as the lack of key pollinators becomes a pressing issue for agriculture. Natural habitats for pollinators such as honey bees and bumblebees are being lost due to fragmentation, land-use changes, the use of fertilizers and the application of pesticides. This forces pollinators into urban surroundings, where they find small scale habitats in parks and green infrastructure. In urban, as well as agrarian landscapes, various anthropogenic activities lead to diverse pollutant emissions. In both habitats, pollinators are expected to be exposed to these pollutant profiles during their lifetime, e.g. during foraging flights. Until now, most research has focussed on honey bees, while data on pollutant loads of non-Apis pollinators is rare. *Bombus terrestris* is a common pollinator in cities and agrarian landscapes and has a more spatially restricted foraging behaviour. This makes *B. terrestris* well suited as a bioindicator representing the exposure of pollinators to various chemical profiles in anthropogenically influenced landscapes at high spatial resolution. In this study, commercial *B. terrestris* hives were placed at six locations in and around the city of Aachen, Germany, three in urban and three in agrarian surroundings. Foragers were caught when returning to the hive one and two month after placement of the hives. Individual bumblebees were extracted using a modified QuEChERS method and analysed for 26 target pesticides using HPLC-MS/MS. At every sampling location, at least one of the target pesticides was found. The results show that the individual pesticide load of bumblebees is variable between individuals from the same site (containing no pesticides up to five pesticides). This could be caused by individual foraging decisions and indicate complex pollution patterns in small scale habitat structure. No location or land-use specific pollution patterns were found over time. Rather, pesticide residues changed with the sampling time. Urban bumblebees had a significantly higher weight, possibly an indicator for a higher foraging success in the city compared to the agricultural fields. The ubiquitous presence of pesticides shown in this study should be taken into account when evaluating the risks to pollinators not only in Germany, but in all of Europe.

3.17.P-Tu186 Concentrations of Two Bisphenols, Three Parabens and Eight Perfluoroalkyl Compounds in Hair From 114 Volunteers From Liege, Wallonia

Julien Claessens, Corinne Charlier and Catherine Pirard, University of Liege, Belgium

Today, biomonitoring is principally performed using blood or urine. Blood is generally considered to reflect cumulative exposure especially for persistent organic pollutants. On the other hand, urine is commonly used for biomonitoring of rapidly eliminated substances. Beside these two main matrices, hair has gained attention as an alternative matrix for biomonitoring of environmental

pollutants because of the easiness of sample collection and storage, the extended detection window, and the possibility to reflect cumulative exposure. Even though this last decade the number of studies focused on hair biomonitoring of organic pollutants has increased, for certain chemicals hair concentration values remain scarce and many geographical regions haven't been covered yet. Therefore there is a need to provide data of hair biomonitoring from different regions and by different laboratories. This work presents the results of the first monitoring study of 2 bisphenols, 3 parabens and 8 perfluoroalkyl compounds in the hair from 114 volunteers (living in the city of Liege Belgium) using UPLC-MS/MS method. Each volunteer provided one hair sample and information related to age, gender, smoking status, hair treatments (none, dyeing, discoloration) and hair length (short, medium, long). Results showed high detection frequencies for six chemicals. The most frequently quantified compounds in the population were: bisphenol S (97.4%, median= 31.9pg.mg⁻¹), methylparaben (94.7%, median=28.9pg.mg⁻¹), bisphenol A (93.9%, median=46.6pg.mg⁻¹), ethylparaben (66.7%, median=5.2pg.mg⁻¹), propylparaben (54.8%, median=16.4pg.mg⁻¹) and PFOA (46.4%, median < 0.2pg.mg⁻¹). Other perfluoroalkyl compounds were rarely detected. Few statistical analyses were performed and only age was positively correlated with propylparaben concentration in the whole population and this correlation was strengthened in women group. Although blood seems to remain the most suitable matrix for exposure assessment to perfluoroalkyl compounds, our results demonstrate that hair analysis would be a promising approach for future biomonitoring studies of bisphenols and parabens.

3.17.P-Tu187 Is There Any Potential Role of Endocrine Disruptors on the Development of Gestational Diabetes Mellitus? A Pilot Study of INSULIN Cohort (Catalonia, Spain)

Montse Marques¹, Pablo Gago Ferrero², Elena Sanchez-Resino¹, Rubén Gil-Solsona³, Daniel Gutierrez-Martin³, Nuria Taltavull¹, Montserrat Ingles⁴, Miriam Romeu⁴, Ana Megia⁴, Adrian Covaci⁵ and Jose Domingo¹, (1)Universitat Rovira i Virgili, Spain, (2)IDAEA-CSIC, Spain, (3)Institute of Environmental Assessment and Water Research ? Severo Ochoa Excellence Center (IDAEA), Spanish Council of Scientific Research (CSIC), Spain, (4)Hospital Universitari de Tarragona Joan XXIII, Institut d'Investigació Sanitària Pere Virgili, Universitat Rovira i Virgili, Spain, (5)University of Antwerp, Belgium

The incidence of Gestational Diabetes Mellitus (GDM) has increased in the past 20 years, and it is now diagnosed in up to 7-10% of all pregnancies. This is a significant current public health concern, as GDM is associated with adverse consequences, including preeclampsia, birth complications, and cesarean delivery, as well as with long-term risk of type 2 diabetes mellitus, obesity, and cardiovascular disease for both the mother and child. A number of environmental factors can cause beta cell stress, including the developmental exposure to Endocrine-Disrupting Chemicals (EDCs). The role of EDCs on the development of GDM is a topic of recent concern, but with inconclusive results yet. The present pilot study was aimed at assessing the exposure to EDCs of pregnant women invited to join INSULIN, a cohort of gestational diabetes built at Hospital Joan XXIII (Tarragona, Catalonia, Spain). Sociodemographic, dietary and life-style determinants were linked to the occurrence of the EDCs and clinical data, including the development of GD during pregnancy. The occurrence of BPA and 10 BPA analogues (BPF, BPS, BPAF, BPAP, BPB, BPE, BPG, BPM, BPP, BPZ), phthalates metabolites (mono-ethyl, mono-butyl and mono-methyl); and parabens and their metabolites (methyl-, ethyl-, propyl- and butyl-) were assessed in urine (from the 12-week of pregnancy and delivery), mother blood (delivery), cord blood and/or placenta of 40 pregnant women. High detection rates of BPs, phthalate and parabens were found in urine and mother blood, but also their detection in placenta and cord blood, might be slightly related to the use of plastic and personal care products, along with the consumption of canned foodstuffs according to the results of the individual questionnaire filled on the 30-week of pregnancy. Albeit the premature state of the results do not allow identifying a potential role of a target EDC (or a mixture of EDCs) on the development of GDM, we can confirm the widespread presence of these EDCs in our daily life, which might become a hazard for the health of vulnerable population groups, such as pregnant women and their newborns.

3.17.P-Tu188 Breastfeeding Infants' Exposure to Endocrine Disruptors and Neurotoxic Substances: Earlyfood Study

Joaquim Rovira¹, María Ángeles Martínez², Nora Exposito Lorenzo¹, Montse Mari³, Sara Cunha⁴, Jose Fernandes⁵, Antonio Marques⁶, Isa Marmelo⁶, Marti Nadal¹, Jose Domingo² and Marta Schuhmacher⁷, (1)University Rovira i Virgili, Spain, (2)Universitat Rovira i Virgili, Spain, (3)Rovira i Virgili University, Spain, (4)University of Porto, Portugal, (5)REQUIMTELAQV, Portugal, (6)IPMA, I.P., Portugal, (7)Rovira i Virgili University, Spain

It is well known that breastfeeding is a gold standard for new-born nutrition with several benefits for both infants and women. However, some pollutants, including endocrine disruptors and neuro-toxics, were detected in breast milk. Biomonitoring breast milk can give information on current chemical exposition of infants and, in addition, on current and historical exposure of breastfeeding mothers. In present study, the levels of several pollutants, including persistent organic pollutants (DDT, DDE, HCB, PCBs and PBDEs), an organophosphate pesticide (chlorpyrifos), bisphenol A, tetrabromobisphenol A, per and polyfluoroalkyl substances (including PFOA, PFNA and PFOS), toxic elements (such as As, Cr, Hg, Pb, and methylmercury-MeHg) and essential elements (such as Na, K, Ca) were analysed. Results showed that maternal characteristic such as age and BMI were able to influence the levels of POPs (DDT, DDE and PCBs). Smoking, including passive smoking, mothers presented higher levels of As, Cr and Mn in breast milk. Higher levels of PCBs were detected in Spain born and primiparous mothers compared to non- and multiparous women. Breast milk from low-income mothers presented higher DDT and DDE levels than high-income mothers. Intake of PFOS and PFOA through breastmilk are higher than tolerable daily intakes (TDI) established by EFSA. For chlorpyrifos, despite no safe exposure levels have been established, this compound was detected in several samples. Although the clear health benefits of breastfeeding, exposure to the cocktail of hazardous substances and their interaction and mixing effects must be considered. This cocktail of toxic substances is not exclusive of breast milk, but also infant formula. The adverse effects of these chemical mixtures (that include endocrine disruptors and neurotoxic substances) on babies' health are unknown. Thus, increase the necessity of future research in the field.

3.17.P-Tu189 Temporal Trends in Occurrence and Risk of Pesticides in European Streams

Andreas Scharmüller¹, Gerhard Schäfer² and Ralf Bernhard Schaefer³, (1)University Koblenz-Landau, Germany, (2)University of Strasbourg CNRS, France, (3)University of Koblenz-Landau, Germany

Besides climate change and habitat deterioration, pollution with chemicals is an important agent of global change. In this regard, freshwater ecosystems are of particular concern, because of the importance of water security and freshwater biodiversity for human prosperity. Agrochemicals, such as pesticides are increasingly sold and applied all over the world and their usage is expected to increase with climate change. Pesticides enter the aquatic ecosystems through diffuse runoff from adjacent agricultural fields. This may lead to a constant occurrence of pesticides in freshwater systems and associated risks to organisms. However, the seasonal trends of pesticide exposure has not been studied over a larger spatial scaling, including a wide range of pesticides and countries. In the present study, we investigated the seasonal occurrence and risk of pesticides in streams across Europe. We therefore analyzed data from governmental monitoring programs in European streams. Upstream from the sampling sites we delineated stream catchments to calculate land use parameters therein. As a risk measure we calculated Toxic Units (TU) for different organism groups (i.e. algae, invertebrates, fish) as the decadic logarithm of the measured in stream concentrations divided by the median effective concentrations (EC50). We identified spring as the period with the most significant increases, exhibiting country-specific trends though. Additionally, increased occurrence was detected during end of summer and autumn months. Individual pesticides of the same class showed mostly similar trends in occurrence, though this did not hold true for all pesticides. Seasonal risk trends also showed significant increases during spring months. Lastly, we found that agriculture in the catchment strongly influences the occurrence and risk of pesticides in streams. Current monitoring data allows to delineate the seasonal presence of well tested pesticides as well as their associated risk trends. Though the latter might underestimate the actual risk. Modelling seasonal trends largely depends on the availability and quality of pesticide monitoring data, which currently differs a lot between European countries.

3.17.P-Tu190 Assessing the Presence of Pesticides in UK Bird Species

Priyasha Vijendra¹, Cannelle Tassin de Montaigu² and Dave Goulson², (1)School of Life Sciences, University of Sussex, UK, (2)School of Life Sciences, University of Sussex, United Kingdom

The introduction of pesticides has dramatically altered the farming landscape, but they also contaminate and exert different effects on the surrounding environment. Few studies investigate the occurrence of pesticides in terrestrial birds. This study aims to identify and quantify the levels of pesticides from feathers obtained from birds from across the UK. Samples were collected by trained volunteers from 15 common bird species found in the UK. This study aims to contribute to previous studies that revealed the presence of neonicotinoids in house sparrow feathers. We aim to assess feather samples for the presence of 18 pesticides which include imidacloprid, prothioconazole and pendimethalin. Pesticide presence will be quantified using UHPLC/MS-MS. This study will highlight the levels of pesticide exposure in the selected bird species and the levels of contamination within the agricultural habitat.

3.18 Taking up the Nanoplastics Challenge: Materials, Methods and Impacts

3.18.T-01 Is Mechanical Degradation of Macroplastics a Suitable Approach for Obtaining Environmentally Relevant Nanoplastics?

Milica Velimirovic¹, Jef De Wit², Eduardo Bolea-Fernandez³, Kristof Tirez⁴ and Frank Vanhaecke³, (1)Department of chemistry, Ghent University (UGent), Ghent, Belgium, (2)Flemish Institute for Technological Research (VITO), Belgium, (3)Ghent University, Belgium, (4)Flemish Institute for Technological Research VITO, Belgium

The occurrence of nanoplastics (NPs) in the environment is a matter of increasing concern and deserves proper attention. However, there is still a lack of analytical tools for straightforward monitoring of NPs at environmentally relevant levels in different matrices. In addition, environmentally relevant NPs are needed for further *in vitro* and toxicological studies, in which critical properties of the NPs present in the environment are very important. Consequently, the main aim of this study was to investigate whether high-energy ball milling of commercially available polyethylene perler beads containing Ti (6.1 g/kg) as a white pigment can be a potential route to produce environmentally relevant NPs. STEM images, DLS size measurements of mechanically produced polyethylene nanoparticle samples dispersed in 0.1% Novachem and transient signals and integrated intensity distributions obtained for the same particles measured using ICP-MS operated in single-event mode via the monitoring of ⁴⁷Ti⁺ suggested that mechanical degradation of macroplastics is indeed a possible route for the production of environmentally relevant NPs. However, our research also shows that during high-energy ball milling of macroplastics into environmentally relevant NPs, significant zirconium contamination occurs. As such, the NPs produced by using high-energy ball milling could not be used for *in vitro* and toxicological studies. Therefore, additional production routes are needed for providing NPs relevant for *in vitro* and toxicological studies.

3.18.T-02 Development of Test Methods and Standards for Separating and Characterizing Environmental NanoPlastics in Aqueous Media

John Pettibone, Justin Gorham and Joseph Conny, National Institute of Standards and Technology, United States

The impact of marine debris and plastic waste, including the formation of microplastics and nanoplastics (MNP), on environmental and human health are areas of growing concern. The exposure risk of these materials resulting from accumulation, degradation, and other changes to interfacial properties after release cannot be evaluated with current separation and quantification methods, especially in the sub-micrometer regimes. To begin addressing the measurement requirements necessary for more accurate risk assessment, parallel development of control test materials and the analytical tools, methods and guides, are necessary

to more accurately identify, characterize, and quantify MNP in complex matrices. Importantly, the control materials need to behave similarly to field collected samples (e.g., composition, colloidal properties, and size) to ensure method efficiency for targeted applications. This presentation will focus on the development of sample handling methods for cryomilled samples, produced from both controls and environmentally sourced plastics, generated through collaborative efforts to produce size-binned MNP samples in concentrations that are suitable for investigation with current spectroscopic and spectrometric methods. We will present the relative separation efficiencies obtained from fractionation and filtration methods for select, pure polymer controls, which will be used to compare the size distributions determined using light scattering and particle population analysis. Using isolated MNP fractions with characterized size distributions, we will present the size dependent properties and relative performance metrics for commonly implemented spectroscopy and spectrometric methods to improve reproducibility and examine heterogeneity for different preparation procedures.

3.18.T-03 Characterization of Nanoplastics, Fibrils, and Microplastics Released During Washing, Abrasion and Weathering of Polyester Textiles

Tong Yang¹ and Bernd Nowack², (1)EMPA Technology & Society Lab, St.Gallen, Switzerland, (2)Empa – Swiss Federal Laboratories for Material Science and Technology, Technology and Society Laboratory, Lerchenfeldstrasse 5, 9014 St. Gallen, Switzerland

Nanoplastics (defined here as plastic particles smaller than 1000 nm) released during the daily use of plastic products are gaining increasing attention due to their potential effects on human and environmental health. Formation of nanoplastics has been reported so far for diverse plastic products under varying conditions of use. The washing of synthetic textiles has been identified as an important source of microplastic fibers (MPF) released to the environment. In addition, abrasion of textiles was shown to induce further fragmentation of fibers and subsequent formation of much smaller and shorter fibrils. The formation of micro- and nanoplastics during weathering was rarely investigated. The aim of this work was to identify whether washing and wearing of textiles also results in the formation of nanoplastics. We designed washing, abrasion and weathering experiments to investigate the morphology, number, and size of micro- and nanoplastics released from polyester textiles. Using a combination of techniques including scanning transmission X-ray microspectroscopy (STXM), scanning electron microscopy (SEM), transmission electron microscopy (TEM), and nanoparticle tracking analysis (NTA), we were able to quantify nanoplastics (average hydrodynamic diameter 173–188 nm), microplastic fibrils (diameter $3 \pm 1 \mu\text{m}$, length 20–160 μm), and MPFs (diameter $16 \pm 7 \mu\text{m}$, length up to 5 mm). The presence of polyester nanoplastics was confirmed by the near edge X-ray absorption fine spectra (NEXAFS) of the nanoparticles in the abrasion and washing samples for particles larger than 100 nm. We estimated that in the abraded samples, 1 g of fleece textile released an average of 2.1×10^{11} nanoplastic particles (1.4 mg), 1.4×10^4 MPFs (1.0 mg), and 5.3×10^5 fibrils (0.5 mg) based on SEM images and NTA. In the nonabraded samples, 1 g of textile released an average of 3.3×10^{11} nanoplastic particles (2.1 mg), 2.8×10^3 MPFs (0.2 mg), and no fibrils. The present study is the first to show a significant release of polyester nanoplastics during the washing and abrasion of synthetic textiles.

3.18.T-04 Quantification of Nanoplastic Uptake Into the Across the Fish Intestine Using Palladium-Doped Nanopolystyrene Particles

Nathaniel Clark¹, Farhan R. Khan², Denise M Mitrano³, David Boyle⁴, Charlotte Crowther⁵ and Richard Thompson⁶, (1)University of Plymouth, Plymouth, United Kingdom, (2)NORCE (Norwegian Research Center), Norway, (3)Environmental Systems Science, ETH Zurich, Zurich, Switzerland, (4)Cobalt Institute, Afghanistan, (5)Plymouth University, United Kingdom, (6)University of Plymouth, United Kingdom

Fish are widely reported to ingest microplastics with low levels accumulating in the tissues, but due to analytical constraints, much less is known about the accumulation of nanoplastics via the gut. Recently, the labeling of plastics with inorganic metals (e.g., palladium) has allowed measurements of nanoplastic uptake. The aim of the current study was to quantitatively assess the uptake of palladium-doped nano-polystyrene particles (PS-Pd NPs) by the fish gut. The first experiment used an *ex vivo* gut sac system, whereby the entire gastrointestinal tract of fish was removed, and the anterior, mid and hind intestine regions were separated into each compartment. Each compartment was filled with either an unexposed control (gut physiological saline) or saline containing PS-Pd NPs ($1 \mu\text{g Pd mL}^{-1}$). The gut sacs were exposed for 4 hours and then dissected into the mucosa, muscularis and serosal saline for Pd measurements via inductively coupled plasma mass spectrometry (ICP-MS). The second experiment was an *in vivo* feeding study, whereby fish were fed either an unexposed control (no added Pd), or 10 mg Pd kg^{-1} as PS-Pd NPs for 7 days and then sampled for internal tissues. Using single particle ICP-MS, the particle number concentration for a given Pd mass concentration was calculated and used to determine the number of PS-Pd NPs in both experiments. The gut sac showed that in 4 hours between 200-700 million nanoplastics (2.5-9.4% of the administered nanoplastics) can enter the mucosa and muscularis layers of the intestine. Of the particles taken up, up to 700,000 of the nanoplastics (0.6%) cross the gut epithelium of the anterior intestine and exit into the serosal saline. These data provide a proof-of-concept study, suggesting the potential for nanoplastics to distribute throughout the body. The uptake of the PS-Pd NPs was confirmed in the *in vivo* experiment. After 7 days, there was detectable Pd in the PS-Pd NP treatment. For instance, the kidney and carcass had total Pd concentrations of 65.6 ± 25.4 and $2.2 \pm 0.4 \text{ ng Pd g}^{-1} \text{ dw}$. When the Pd mass concentrations were converted to number of particles, the total number of particles accumulated after 7 days into the fish was $34.2 \pm 6.6 \times 10^6$ particles. In summary, our studies are the first quantitative assessments of the uptake of nanoplastics by the fish gut, and the presence of nanoplastics in the carcass raises concerns around the potential trophic transfer of nanoplastics to humans.

3.18.T-05 Assessment of Drinking Water Treatment Processes in Nanoplastics Removal: Laboratory-scale, Pilot- Scale and Modelling Studies

Gerardo Pulido-Reyes¹, Leonardo Magherini², Carlo Bianco², Rajandrea Sethi², Urs von Gunten¹, Ralf Kaegi¹ and Denise M Mitrano³, (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Politecnico di Torino, Italy, (3)Environmental Systems Science, ETH Zurich, Zurich, Switzerland

Microplastics have been detected in both potable water sources and tap water, leading to questions about the efficacy of current water treatment practices to remove these particles. Due to analytical difficulties, the detection of nanoplastics (NPs) both in the environment and in potable water is still challenging, however, it is hypothesized that water resources already contain NPs. The aim of this study was to investigate the NPs removal efficiency through several stages of the drinking water treatment plant (DWTP). Using metal doped NPs allowed us to quantify these particles in the treated water and in the filter media, where they were possibly retained. We measured breakthrough curves of NPs through sand and activated carbon filled columns in the laboratory and pilot-scale equivalents under different conditions to understand the processes which impact NPs retention. The MNMs software (Micro- and Nano-particles transport, filtration and clogging Model Suite) was used to model the breakthrough curves obtained from the pilot-scale DWTP to derive the hydrodynamic parameters of the filtration systems and used to simulate the behaviour of NPs in full-scale DWTP. In laboratory-scale column experiments, the filter length and flow rate impacted NPs retention in the filter media (sand and activated carbon). We assessed both pristine and aged sand and activated carbon, where the presence of a biofilm, which naturally occurs on the filter media, further reduced the concentration of NPs in treated water. In agreement with laboratory studies, results from the pilot-scale DWTP showed higher retention of NPs in the sand filtration opposed to activated carbon, in part due to the increased biofilm layer (Schmutzdecke). Both experimental and modeling results indicate a high capability of the filtration units in DWTPs to remove NPs from the source water across the entire treatment chain (>99%), and the slow sand filtration dominated NPs removal (3.6 log removal). As slow sand filtration systems are slowly decreasing in popularity due to space and economic requirements for upkeep, this highlights the importance of testing other drinking water treatment configurations for their efficacy of removing NPs throughout the water treatment chain. The results of this study can serve as a baseline for assessing the performance of DWTPs to remove NPs from polluted water sources and the capability of current water treatment infrastructure to provide plastic-free, potable water.

3.18 Taking up the Nanoplastics Challenge: Materials, Methods and Impacts (Virtual Only)

3.18.V-01 Three Stage Size-Selective Nano- and Micro-Plastic Particle Porous Membrane Filter System for Analytical Workflows

Paul-Tiberiu Miclea¹, Susanne Richter² and Christian Hagendorf², (1)Fraunhofer CSP, Germany, (2)Fraunhofer Center for Silicon Photovoltaics, Germany

A quantitative metrology and testing of nano and micro-plastic (NMP) particles in liquids and air requires suitable representative methods for sampling, preparation and detection for all NMP size ranges from 50 nm to larger than 150 μm . For this purpose, filter materials have to be configured to allow a size selective analysis of NMP particles and polymer types and implemented in the analytical workflows. Analytical routes for particle sizes in the range of several 10 μm are nowadays well established, such that current scientific efforts are focused on entering nano particle dimensions with diameters down to 10 nm. A major challenge lies in the availability of cascade filter setups spanning several orders of magnitude in a single filtration workflow with appropriate NMP analytic routines. In this work, we are presenting a three-stage cascade filtration system, that should be used for water as well as for air filtration. The corresponding analytical workflow will be implemented and tested on well-defined NMP test material. The NMP test material is composed of a mixture of PET micro plastic reference material, monodisperse PMMA particles and monodisperse PS particles. The novel cascade filter system contains three filters made of microporous and nanoporous Si as well as nanoporous aluminum oxide (AlOx) membranes, thus realizing the required NMP size selectivity. In our experiments we demonstrate the successful NMP size separation on Si and AlOx filter substrates. Using the filters subsequently as analytical substrates, leads to an enhanced flexibility in the application of μRaman , SEM, and AFM instrumentation. We are able to analyze NMP properties, e.g. particle shape, size, spectroscopic fingerprints - optical and chemical, both qualitatively and quantitatively. Finally, requirements and limitations for a standardized NMP filtration and analytic workflow will be discussed.

3.18.V-02 Understanding NanoPlastics Interaction With Minerals of Freshwater Weathering Sequence in Riverine Environment

Aniket Choudhary¹ and Gopala Krishna Darbha², (1)Earth Sciences, Indian Institute of Science Education and Research Kolkata India, Kolkata, India, (2)Indian Institute of science education and research Kolkata India, India

Recent scientific evidence predicts the massive accumulation of nanoplastics (NPs) in freshwater, especially in a riverine environment. The majority of NPs research has highly focused on the marine environment, knowing the fact that rivers are major carrier of NPs to the oceans, very handful of work has been done in understanding NPs behavior in a riverine system. River water continuously erodes the rock's surface and releases suspended minerals fraction in water, which can interact with NPs and further impact their bioavailability and transport to the oceans. Keeping this natural scenario in mind, for the first time, we sought to investigate NPs interaction with a typical weathered sequence of minerals in the river water (fig. 1a) under varying environmental conditions. Most abundant, primary mineral feldspar and its weathering originated secondary minerals, i.e., kaolinite and gibbsite, were investigated for interaction with NPs using aggregation and batch sorption experiments. The impact of environmental parameters like varying major ions, pH, humic acid, and natural aqueous matrix, i.e., river water, on the mineral-NPs interaction was studied in detail. Experimental data modeling using non-linear kinetic and isotherm models and theoretical calculation using DLVO theory were further performed to enhance understanding of minerals-NPs interaction. Adsorption isotherm results (fig. 1b) revealed that, gibbsite exhibits maximum sorption of NPs due to its amorphous nature, large size, and positive surface charge. Whereas, continuous adsorption-desorption and limited sorption capacity of feldspar and kaolinite can be attributed to their

negative surface charge, larger size, crystalline nature, and physical sorption. Also, microscopic analysis studies suggested strong gibbsite-NPs interaction. This work also revealed that apart from surface charge of minerals, their size, crystalline and amorphous nature also play a vital role in adsorption of NPs. Overall, this study provides a clear insights of NPs interaction with abundantly occurring minerals (feldspar, kaolinite, and gibbsite) in riverine environments, which can ultimately govern the fate and transport of NPs.

3.18 Taking up the Nanoplastics Challenge: Materials, Methods and Impacts (Poster)

3.18.P-Tu191 Interaction of Marine Algae and Nanoplastics, and the Possible Impact on the Bioavailability of Nanoplastics to Primary Consumers Through the Food-Pathway

Marie Sioen¹, Maaike Vercauteren², Ronny Blust³, Colin Janssen⁴, Raewyn Town⁵ and Prof. Jana Asselman⁶, (1)Laboratory of Environmental Toxicology and Aquatic Ecology - GhEnToxLab, University of Ghent, Ghent, Belgium, (2)Ghent University, Ghent, Belgium, (3)University of Antwerp, Belgium, (4)University of Ghent, Belgium, (5)Systemic Physiological and Ecotoxicological Research (SPHERE), University of Antwerp, Belgium, (6)Ghent University, Belgium

Plastic pollution is a global problem. While macro- and microplastics are largely studied in terms of environmental concentrations and toxicity, a knowledge gap exists regarding nanoplastics (1-1000 nm diameter). These enter our environment both as primary products, engineered for cosmetic and pharmaceutical purposes, and as secondary degradation products. However, due to deficient sampling methods and analytical identification methods, information on environmental concentrations is lacking. Nevertheless, it is assumed that the exposure route, extent and rate of bio-uptake, and the nature of adverse effects will differ from those of microplastics, due to the reactivity features of nanoscale entities and the fact that they are small enough to cross biological barriers. The aim of the study is to investigate the interaction between marine phytoplankton species and nanoplastics. We want to analyze whether there is an interaction, and what sort of interaction (aggregate formation, adsorption of the particles on the algal cell surface or absorption of the particles into the algae cell). Subsequently, we will analyze EPS production to investigate whether algae-aggregate formation is affected by the nanoplastics' presence. Analysis of the quantity of particles that interact with algae is done using flow cytometry and visual inspection of interactions was performed using fluorescence microscopy. The algae species used for the experiment were *Rhodomonas salina* and *Isychrysis galbana*, which are relevant algal species for the North Sea food web. Both species are exposed to concentrations of nanoplastics, that were assumed to be environmentally realistic, using data on micro-plastic concentrations in the North-Sea and the conversion factor of 10^{14} as proposed by Besseling et al., 2019. This factor is based on mass conservation principles, for the fragmentation of spherical particles with a size of > 0.1 mm – 5 mm into 100 nm particles. The nanoplastics used are fragmented hydrophilic PET and polystyrene with a broad unimodal size distribution: diameter in the range from 40 nm to 5 μ m. As a control, non-plastic nanoparticles will be used to differentiate between plastic-specific and particle-specific effects. This research will be valuable for studying the effect of algae-NP interaction and provides relevant information on algae as a potential exposure pathway for marine copepod species such as *Nitocra spinipes* and *Acartia tonsa*.

3.18.P-Tu192 Generation of Test Nanoplastics From Consumer Products Through Cryomilling

Bryan J. Harper and Stacey L Harper, Oregon State University, United States

Concerns over increasing levels of environmental plastic pollution have led to advances in the production and use of biologically-based plastics, with the biodegradable fraction of these materials showing promise in alleviating environmental risk. The evaluation of risk requires toxicity evaluation; however, at the nano-scale, very few test materials are available and most commercially available nanoplastics are spherical polystyrene. We investigated methods for generating nano-scale test materials through cryomilling and fractionation of consumer products including traditional petroleum-based polypropylene (PP) drinking straws and bio-based polylactic acid (PLA) drinking straws. Test materials were first generated as dry cryomilled materials, then suspended in various waters and fractionated using 1 μ m filters to generate nano-scale test materials (< 1000 nm), and then quantified using nanoparticle tracking analysis (NTA). In addition, materials were generated in both ceramic and stainless-steel milling chambers to test for potential metal contamination by the stainless chambers. Lastly, we investigated methods for concentrating the nano-scale particles using dialysis in a polyethylene glycol (PEG) solution. The results showed the both PP and PLA straws did generate nano-scale particles following cryomilling with the PLA making significantly more nanoparticles per unit initial mass than PP (2.9×10^9 and 4.7×10^8 particles/mL, respectively). Particle sizes as measured by NTA were not significantly different with diameters of 201 and 180 nm for PP and PLA, respectively. Extraction of the materials with concentrated nitric acid and subsequent ICP-MS determinations showed no significant metal contamination was found from the use of the stainless-steel chamber relative to ceramic. The estimated mass-based concentration of nanoparticles generated is 0.2 μ g/ml for PP and 1.1 μ g/ml for PLA from 1 g cryomilled material per 45ml suspension solution. Although these concentrations are low, the nano-scale particles can be further concentrated using dialysis with PEG to remove the water and concentrate the particles. Thus, the generation of nano-scale plastic test materials can be accomplished; however, techniques need be further optimized to generate higher concentrations of nano-scale test particles to facilitate concentration-response testing.

3.18.P-Tu193 Advancing Our Understanding of Plastic Fragmentation in the Environment Through a Mechanistic Model of Micro- and Nanoplastic Fragmentation

Sam Harrison¹, Patrizia Pfohl², Wendel Wohlleben, Dr.³, Richard Cross⁴, Joana Sipe⁵, Mark Wiesner⁵, Antonia Praetorius⁶, Katherine Santizo², Gbotemi Adediran⁷ and Claus Svendsen⁸, (1)UK Centre for Ecology & Hydrology, Lancaster, United Kingdom, (2)BASF SE, Germany, (3)Material Physics & Analytics AND Experimental Toxicology & Ecology, BASF SE, Germany, (4)UK Centre for Ecology & Hydrology, United Kingdom, (5)Duke University, United States, (6)University of

Amsterdam/IBED Institute, Netherlands, (7)The University of Edinburgh, United Kingdom, (8)CEH, Wallingford, United Kingdom

The potential for plastics to degrade and fragment towards nano-sized particles in the environment is raising concerns about the divergent fate, hazard and ultimately risk of different sized plastic particles. For example, nanoplastics may be more readily able to permeate biological membranes, and they may follow different fate pathways enabled by their potential to aggregate to natural environmental particles. However, there is currently limited understanding of the fragmentation process, including the influence of different environmental stresses in altering the susceptibility of plastics to fragment. We are addressing this by developing an open-source mechanistic model of Micro and NanoPlastic degradation and FRAGMENTation in the ENvironment (FRAGMENT-MNP). Our model is underpinned by an experimental database of how different environmental factors - such as UV light, hydrolysis, temperature and biodegradation - alter the susceptibility of a broad range of polymers to fragmentation by mechanical shear, and is validated by assessing the long-term fate of polymers exposed to combinations of these stresses in realistic environmental media. FRAGMENT-MNP aims to be pragmatic in terms of the information users must provide, thus making it a useful tool for stakeholders, such as industry and regulators. To further enable this, guidance on protocols to obtain the required input information and using the model is being developed. This pragmatism and a focus on technical interoperability will enable its integration into other models, such as those for fate and exposure. Herein, we will present the first version of FRAGMENT-MNP and its interface, including indicative results demonstrating the use of the model and highlighting the importance of certain parameters in determining plastic fragmentation. Ultimately, this work will help us gain mechanistic insights into fragmentation rates and resulting size distributions of various polymers under realistic environmental conditions, providing a significant step forward in our understanding of plastic fragmentation and nanoplastic pollution in the environment.

3.18.P-Tu194 NanoRelease: Microplastic Fragmentation Rates, Degradation and Dissociation for Modeling Purposes

Patrizia Pfohl¹, Maria del Prado Domercq², Antonia Praetorius³, Thorsten Huffer⁴, Thilo Hofmann⁵ and Wendel Wohlleben, Dr.⁶, (1)BASF SE, Germany, (2)Environmental Science, Stockholm University, ACES, Stockholm, Sweden, (3)University of Amsterdam/IBED Institute, Netherlands, (4)University of Vienna, Vienna, Austria, (5)University of Vienna, Austria, (6)Material Physics & Analytics AND Experimental Toxicology & Ecology, BASF SE, Germany

Nanoplastics are suspected to behave differently from microplastics, leading to increasing concerns due to their potentially higher bioavailability. Insights into fragmentation and degradation mechanisms of microplastics into micro- and nanoplastic fragments and other degradation products are still limited and literature barely provides data on fragmentation and degradation rates. For this reason we adapted the NanoRelease protocol (originally developed to quantify released fragments from macroplastics under weathering) to simulate UV aging of microplastics at the beach and mechanical abrasion in the surf zone for a UV-dose-dependent assessment and size-selective quantification of micro- and nanoplastic fragments released after environmental degradation. We determine the amount, shape and sizes of released polyamide-6 (PA-6) and thermoplastic polyurethane (TPU) fragments and dissolved organics with increasing duration of UV irradiation, as well as the chemical properties of the polymers themselves. Our test materials are relevant for primary microplastic powders commercialized for additive manufacturing. But since microplastic fragmentation and degradation strongly depends on the chemical composition, the established protocol can be applied for all types of polymers. The used methods include analytical ultracentrifugation, UV-Vis spectroscopy, scanning electron microscopy, Fourier-transformed infrared spectroscopy, total organic carbon and gel permeation chromatography. The measured rates can serve to validate mechanistic microplastic fragmentation models (FRAGMENT-MNP, Cefic LRI) and can be used to parameterize microplastic fate models that include degradation terms (The Full Multi). Pragmatic approaches (e.g. assuming a shrinking sphere by layered degradation of a specific thickness in a specified time) combined with the generated data can serve for micro- and nanoplastic half-time predictions. This can be relevant when selecting longer lasting materials for certain applications to evaluate and to improve their sustainability.

3.18.P-Tu195 Detection and Formation Mechanisms of Secondary Nanoplastic Released From Drinking Water Bottles

Francesco Fumagalli¹, Anna Winkler², Claudia Cella³, Paolo Tremolada² and Douglas Gilliland⁴, (1)European Commission JRC, Ispra, Italy, (2)State University of Milan, Italy, (3)European Commission-Joint Research Centre, Italy, (4)European Commission, Joint Research Centre / Directorate F Health, Consumers and Reference Materials, Italy

Since nanoplastics are currently considered potentially hazardous to the environment and human health, reliability of studies on nanoplastic exposure becomes crucial. However, analytical challenges limit our understanding of their formation and detection, thus hampering their biological interactions assessment. Here we provide a combined approach to quantitatively and qualitatively detect the release of nanoplastics in water matrix and, in particular, to measure direct exposure of consumers by simulated use of drinking water plastic bottles. We measured that the polyethylene sealing of the bottles released particles with a size distribution ranging from few hundreds nanometers up to about one micron and estimated a mass release in the order of few tenths of nanograms per opening/closing cycle. We observe that mechanical stress alters the physical-chemical characteristics of the generated secondary nanoplastics and degrades the material properties compared to the original bulk source, thus complicating their spectroscopic chemical identification. Our findings demonstrate that understanding material degradation processes is therefore crucial for identifying and quantifying nanoplastics in real samples. Moreover, methods allowing quantitative studies on the release of nanoplastic as a source of exposure are considered essential for proper assessment of their potential health hazards and to promote improvements in consumer products plastic packaging design.

3.18.P-Tu196 Methodological Development for the Characterization of Small Microplastics and NanoPlastics in Seawater

The release of plastics into the environment is universally recognised as a major threat not only to terrestrial and marine ecosystems, but potentially also to human health. Their increasing presence in the environment is causing global concern about potential risks to human health through contamination of food, water, soil and air [1]. This concern is mainly related to the degradation of plastic materials into micrometer and nanometer sized particles that can more easily accumulate in the body. Plastic particles are present in all environmental compartments, particularly in soils, sediments and waters, deep and superficial, marine and continental. Quantitative data on these particles are still scarce and not very conclusive because the studies are recent and the measurement protocols are not harmonised. Despite the large number of papers in the field, the research topic is very young with little stabilised methodologies and standardised analytical approaches. The use of different analytical methods and units of measurement in scientific reports and studies for understanding the impact of pollution on ecosystems and human health makes it difficult to compare results and exploit existing data. The MICROPLAST project, financed by the ACTIA 2020 programme, in connection with RMT ProPack Food, a French network for food technology institutes, was focuses on the evaluation of sampling and characterisation methods for micro-nano-plastics disseminated in the marine environment, supporting the sampling campaigns in the Mediterranean Sea carried out by SEA Plastics. SEA Plastics is an organization led by engineering students, to contribute to research on microplastics and to raise awareness about plastic pollution. The aim of the work was to define an analytical strategy to extract/purify/concentrate MP from seawater samples, separate them according to their size using Asymmetrical Flow-Field Flow Fractionation multidetector system (AF4-MD) and characterise the size, shape, chemical identity and concentration by Raman microscopy and pyrolysis coupled to gas chromatography mass spectrometry (pyr-GC-MS).

3.18.P-Tu197 Towards the Analysis of Real Samples Using Online-Coupled Field-Flow Fractionation-Raman Microspectroscopy: Importance of Suitable Reference Materials

Maximilian Huber¹, Irina Beer¹, Fanny Caputo², Jérémie Parot³, Vanessa Sogne⁴, Florian Meier⁴, Martin Elsner¹ and Natalia Ivleva¹, (1)Technical University of Munich, Germany, (2)LNE, France, (3)SINTEF Industry, Norway, (4)Postnova Analytics GmbH, Germany

While several techniques have been developed in the past years to face the challenge of nanoplastics analysis, proper development, optimization and validation require suitable reference materials. Commercially available materials are often limited to monodisperse, spherical particles and a small material range. These reference particles are not expected to resemble particles found in real samples. Shape, particle size distribution, material properties, ageing state and surface chemistry is presumed to vary a lot in environmental samples. These differences between real samples and references can affect sample preparation and detection methods alike. To emphasize this issue, reference materials which can better emulate environmentally relevant nanoplastics than the previously used monodisperse, spherical (plastic) particles were tested in a recently developed online-coupling of field-flow fractionation (FFF) and Raman microspectroscopy (RM). Online FFF-RM system allows for the analysis of (plastic) particles in a size range from 100 nm to 5 μ m, which is not fully accessible to common optical microscopy methods. Specifically, the FFF system is used to separate particles (where multi-angle light scattering (MALS) detector can provide the corresponding size information) while chemical identification is performed by RM. A flow cell enables the chemical characterization via RM in an online-coupled mode to the FFF systems. This online detection is enabled by the optical forces of the Raman laser (Raman tweezers) where particles are trapped in the focus of the laser beam and held long enough for acquisition of spectra. In this work online-coupling of centrifugal FFF (CF3, which allows for the separation of particles according to their size and density) and RM is successfully applied for the size-resolved chemical identification of reference particles (including mono- and polydisperse nanoplastics made of PE, PS and PMMA as well as various inorganic nanoparticles) in different mixtures. RM-based identification of rod-shaped particles using this technique remains challenging, however. This might be explained by the requirement of stronger optical trapping for these shapes. It underlines (i) the need for further setup development (ii) involving suitable reference materials. The information gained here can support this development: to detect, and choose more realistic reference materials to foster the proper development and optimization of (novel) analytical techniques.

3.18.P-Tu198 Analysis of Small Microplastics and NanoPlastics in Complex Matrices: Towards a Strategic Toolbox

Mathilde Falcou-Prefol¹, Maaike Vercauteren², Colin Janssen³, Ronny Blust⁴, Prof. Jana Asselman⁵ and Raewyn Town⁶, (1)University of Antwerpen, Antwerp, Belgium, (2)Ghent University, Ghent, Belgium, (3)University of Ghent, Belgium, (4)University of Antwerp, Belgium, (5)Ghent University, Belgium, (6)Systemic Physiological and Ecotoxicological Research (SPHERE), University of Antwerp, Belgium

Plastic pollution is ubiquitous and persistent in the aquatic environment where a mixture of plastic particles is found. Environmental plastic particles are heterogeneous in terms of both physical (e.g. size, shape, density, porosity, colour) and chemical properties (e.g. polymer type, surface charge, polarity, presence of additives or persistent organic pollutants). A strong international research effort has been made over the past decade, notably on methods development, to analyse plastic items with dimensions between 1 μ m and 5 mm known as microplastics (MPs). However, MPs will eventually degrade in the environment - with a concomitant modification of their initial characteristics - to successively smaller entities, eventually reaching the nano-size range: they are then denoted as nanoplastics (dimensions < 1 μ m; NPs). Nanoplastics are expected to be widely present in the environment, but there is a paucity of reliable data on the concentration and distribution of small MPs (dimensions < 10 μ m) and NPs in environmental matrices. These small particles are less investigated notably because of sampling and analytical challenges. Concomitantly, there are knowledge gaps in understanding their effects and interactions with biota. Indeed, based on their size, NPs are able to cross biological barriers and thus have the potential to bioaccumulate and induce long-term effects on biota. Bioaccumulation of NPs also poses a potential risk for human health if accumulation occurs in tissues that are consumed by

humans. In such case there may also be economic consequences when economically important marine and estuarine species are involved. The current lack of relevant and standardized method(s) for quantification of MPs and NPs precludes the development of robust environmental risk assessment strategies. The objective of the present work is to first identify a suite of reliable and efficient methods for determination of the concentration and distribution of small MPs and NPs in complex environmental matrices including information on their physical and chemical characteristics. The developed analytical toolbox will provide the means to establish realistic input values for further ecotoxicological studies and risk assessment regarding plastic particles with size smaller than 10 μm .

3.18.P-Tu199 Disentangling Fate and Uptake of Plastic Nanoparticles in Semi-Natural Wetland Ecosystems

Franca Ståbile¹, **Mikael T. Ekvall**², **W. G. Chalani U. Soorasena**², **Pierina I. Rivas-Comerlati**³, **Temitope Nwachukwu**⁴, **Julian Gallego-Urrea**⁴ and **Lars-Anders Hansson**², (1)Department of Biology, Lund University, Lund, Sweden, (2)Lund University, Sweden, (3)Aquatic Ecology, Lund University, Lund, Sweden, (4)University of Gothenburg, Sweden

Given the tremendous amount of plastic waste, there is a need to assess the fate and environmental effects of nano-plastic particles (NPPs) in natural ecosystems. We have used metal cored NPPs to track and quantify them using standard methods for trace metal analytics (e.g., inductively coupled plasma mass spectrometry (ICP-MS)). In this study, we aimed to evaluate the transport, fate and uptake of NPPs using constructed freshwater wetlands and polystyrene nanoparticles labelled with a gold core (size: 88 ± 11 nm). Twelve constructed wetlands were set up in glass aquaria in a greenhouse. The wetlands were divided in two areas: a small lake where *Asellus aquaticus* and *Daphnia magna* were introduced, and a sediment area with macrophytes originating from natural wetlands. Each wetland was fed with tap water (3 ml/min) using a peristaltic pump, that flowed through the wetland towards an outlet in the opposite side. The NPPs used had an Au core (size: 13 ± 1 nm) surrounded by SiO_2 and a polystyrene shell with a negatively charged surface. NPPs were added weekly for 10 weeks to the lake area of the treatment wetlands ($n = 6$, randomly assigned; NPPs concentrations: approx. 0.2 mg/l of polystyrene). Water samples from each wetland's lake were collected weekly, and from the outlet were taken three times per week throughout the experiment. Furthermore, at the end of the experiment (week 10), animals, sediment and macrophytes were sampled. All samples were analysed using ICP-MS to quantify NPPs distribution within the system. We show that although some NPPs moved through the wetland following the NPPs pulses, a considerable part of the NPPs were retained in sediment and in macrophytes roots, and interestingly, significantly more than in macrophytes leaves. In addition, NPPs were taken up by both *D. magna* and *A. aquaticus*, but *D. magna* showed a significantly higher uptake. Overall, the present study can contribute to determine which environmental process might guide the fate of NPPs in natural freshwater ecosystems.

3.18.P-Tu200 Micro- and Nanoplastic Transfer in Freezing Saltwater: Implications for Their Fate in Polar Waters

Alice Pradel¹, **Maud Gautier**², **Dominique Bavay**² and **Julien Gigault**³, (1)Université de Rennes 1, France, (2)Univ Rennes, CNRS, France, (3)TAKUVIK CNRS, Université Laval, France

Plastic debris accumulates in the Arctic Ocean by way of oceanic and atmospheric circulation. High concentrations of microplastics (1 μm to 5 mm) have been measured, and nanoplastics ($< 1 \mu\text{m}$) are expected to be abundant as well. Microplastics accumulate in sea ice compared to the underlying seawater. However, due to the technical difficulty of quantifying nanoplastics in environmental matrices, the fate of nanoplastics at this seawater/ice interface is unknown. Therefore, experimental approaches that model this environmental interface and use models of nanoplastic particles are essential to fill this knowledge gap. This study investigates the fate of micro- and nanoplastics during sea-ice formation. A novel experimental setup simulates the growth of sea ice by progressively freezing a saline solution. After different durations of freezing, the concentrations of NaCl, natural organic matter, microplastics, and nanoplastics were measured in the ice and liquid. Micro- and nanoplastic distribution coefficients between saltwater and ice were determined, reflecting their behavior during congelation sea-ice growth. The results show that microplastics are retained in ice while nanoplastics are expelled from it. This is due to the colloidal properties of nanoplastics, which confer them a high diffusion coefficient. Furthermore, natural organic matter plays a crucial role in stabilizing nanoplastics at this interface. This highlights the fact that due to their different properties, the environmental fate of submicrometric plastic debris must be studied separately from that of microplastics. These results raise new questions concerning the impact of micro- and nanoplastics in fragile polar environments and the analytical strategy to detect them. This study has been published in Environmental Sciences Processes and Impacts <https://doi.org/10.1039/D1EM00280E>

3.18.P-Tu201 Ecotoxicity Assessment of NanoPlastics on Environmentally Relevant Planktonic Species: Does the Biological Filter Mesh-Size Influence Bioconcentration of Nanometric Plastic Particles?

Marisa Passos¹, **Miren Cajaraville**², **Nicoletta Riccardi**³, **Gabriella Schirizzi**⁴, **Jessica Ponti**⁵, **Rita La Spina**⁶, **Andrea Valsesia**⁷ and **Douglas Gilliland**⁸, (1)EU Commission JRC, Ispra (VA), Italy, (2)University of the Basque Country, Spain, (3)National Research Council of Italy, Italy, (4)European Commission, Ispra, Italy, (5)European Commission, Joint Research Centre, Italy, (6)JRC, European Commission, Joint Research Centre, Italy, (7)European Commission DG Joint Research Centre, Italy, (8)European Commission, Joint Research Centre / Directorate F Health, Consumers and Reference Materials, Italy

Size-assorted plastic debris incidence is an environmental threat currently acknowledged worldwide, even in the most remote biomes [1]. Together to their persistency [2], their high specific surface area makes nanometric plastic particles (nanoplastics) more likely to pose an ecotoxicity risk owing to the impact of their greater reactivity (given their inferior size) [3] on their environmental fate [4] [5]. Taking into account that any particulates below 100 nanometers are more prone to cross relevant biological barriers, “nano” ought to be the size range to target when undertaking an ecotoxicity assessment. However, unequivocal cellular and systemic (eco)toxicity evidence associated to nanoplastics exposure have yet to be demonstrated. Most studies reporting ecotoxic data do not test environmentally relevant nanoplastics nor do use environmentally relevant (nominal)

concentrations. In this work, environmentally (aquatic) relevant planktonic species were exposed to different (standard, synthesized and cryomilled) nanoplastics (size range < 1 µm) for 24 h, considering nonstandard experimental designs (Figure 1). Dynamic light scattering and zeta potential measurements had been previously performed to study aggregation/agglomeration of nanoplastics on ultra-pure water and on microorganisms' specific culture media. Data on microorganisms/nanoplastics interactions were gathered by dark field microscopy, SEM and TEM analysis. Taken together, these results pinpoint the need to refine and reorient the perspective on where and what to look at when assessing nanoplastics aquatic toxicity.

3.19 Trace element biogeochemistry, exposure and impacts in ecosystems (Part I)

3.19.T-01 Copper Sources to Water: An Apportionment Exercise for the EU27

Sean Comber¹, Stijn Baken², Genevieve Deviller³, Graham Merrington⁴, Adam Peters⁵, Iain A Wilson⁴ and Pasquale Borrelli⁶, (1)Plymouth University, Plymouth, United Kingdom, (2)European Copper Institute, Brussels, Belgium, (3)DERAC, France, (4)WCA Environment Limited, United Kingdom, (5)wca, United Kingdom, (6)Università degli Studi di Pavia, Italy

Although large emitters report for priority chemicals through the European Pollution Release and Transfer Register (E-PRTR) little is known on a Member State scale regarding total emissions to water including diffuse as well as point sources. This project focussed on estimating loads to water for copper for all significant sources including industry, sewage treatment plants, surface runoff (from traffic, architecture and atmospheric deposition), septic tanks, agriculture (from plant protection products, biosolids, fertilisers, manures and atmospheric deposition), aquaculture, boat transport (from antifoulant leaching), natural processes (atmospheric deposition, groundwater sources and soil loss). To achieve this, a combination of European datasets (Eurostat databases), literature and industry data were utilised to generate export coefficients which could be multiplied by activity rates to generate loads. A total of around 8,000 tons of copper per annum was estimated to enter freshwaters of the EU27, with around half of that (3,849 tons per year) entering transitional and coastal waters. The main inputs to freshwater were natural processes, predominantly copper associated with soil loss (2,900 tons per year) followed by agricultural and urban runoff at 1,848 and 1,839 tons per year, respectively. Agricultural emissions were dominated by the use of copper in biocides used in vineyards, particularly high for Italy and Spain, and farmyard manure. Urban runoff was dominated by copper use in brake linings followed by architecture, which is prevalent in Germany, Italy and Austria. Antifoulants from boats (3,561 tons per year) dominated saline water loads of copper. Calculated as a per capita basis, loadings to water ranged from 10 (Belgium) to 68 (Latvia) grams Cu per capita per year, the latter's high value reflected high rates of shipping associated with its Baltic ports. Where possible estimates of uncertainty were performed, highlighting a lack of confidence in data from abandoned mines and many variables and assumptions relating to urban runoff load estimates. For the first time, this study has quantified sources across an exhaustive list of point and diffuse inputs of copper to the aquatic environment, which have been combined to generate loads on a per country basis, summed to provide continental scale estimates.

3.19.T-02 Dynamic and Equilibrium Speciation Information Can Be Integrated to Predict Availability

Josep Galceran¹, Kevin Rosales-Segovia², Jordi Sans-Duñó³, Encarna Companys³, Jaume Puy³, Berta Alcalde⁴, Enriqueta Antico⁵ and Claudia Fontas⁵, (1)Chemistry, Universitat de Lleida, Lleida, Spain, (2)Univ. de Lleida, (3)Universitat de Lleida and AGROTECNIO, Spain, (4)Universitat de Girona, Spain, (5)University of Girona, Spain

Chemical speciation has been, since long ago, recognized as a key predictor of biouptake and toxicity of many elements. The Free Ion Activity Model (FIAM) and the Biotic Ligand Model (BLM) highlight the relevance of the free form of the metal ion (i.e. just the hexa-aquo complex) and correspond to the equilibrium speciation approach. Several analytical techniques to provide free metal ion concentrations have been developed, such as Ion Selective Electrodes (ISE), Ion Exchange Technique (IET), Donnan Membrane Technique (DMT), etc. Alternatively, dynamic speciation, focussing on the flux of toxicant/nutrient reaching the biota/sensor, has been suggested to be more relevant in some systems. Among the analytical techniques for dynamic speciation, we find Scanned Stripping Chronopotentiometry (SSCP), Dynamic Ion Exchange Technique (DIET), Permeation Liquid Membrane (PLM), etc. For each dynamic technique, its diffusion length plays a crucial role in determining its resulting flux and the ensuing lability degree. Comparison of results from different techniques has been hindered by the fact that equilibrium techniques provide a concentration, while –in general- dynamic techniques provide a flux. In this contribution, we are going to define a labile concentration for each dynamic technique and integrate equilibrium and dynamic concentrations in a single plot, called “effective concentration signature”. This plot, combined with the characteristic lengths of the techniques, will provide estimates for the maximum available supply of the element that a medium can provide to an organism from a known (or estimated) characteristic diffusion length for the considered uptake. These new concepts will be illustrated for the particular case of Zn in a Mediterranean stream (Osor), using 5 analytical techniques: AGNES (Absence of Gradients and Nernstian Equilibrium Stripping), PIM (Polymer Inclusion Membrane), LASV (Linear Anodic Stripping Voltammetry), DGT (Diffusion Gradients in Thin-films) and inductively coupled plasma mass spectrometry (ICP-MS). *Acknowledgement* - Support from the Spanish Ministry of Science and Innovation (Project PID2019-107033GB funded by MCIN/AEI/10.13039/501100011033), from UdL (JSD) and from FISDUR-Generalitat de Catalunya (KRS).

3.19.T-03 Prediction of Metal Ecotoxicity in Soils Based on Interpretation of a Standardized Batch Test With siMPle BLM Models

Charlotta Tiberg¹, Erik Smolders², Mats Fröberg³, Jon Petter Gustafsson⁴ and Dan Kleja³, (1)management of contaminated sites, Swedish Geotechnical Institute, Stockholm, Sweden, (2)Katholieke Universiteit Leuven, Belgium, (3)Swedish Geotechnical Institute, Sweden, (4)Swedish University of Agricultural Sciences, Sweden

There is a need for easy-to-perform methods for site-specific assessment of ecotoxicological risks at metal contaminated sites.

Soil extracts from standardized batch tests with dilute CaCl₂ performed to assess mobility of contaminants at contaminated sites has a potential to be used also to assess ecotoxicological risks. Such soil extracts could potentially give a measure of the concentration of metals in the soil solution that is available to soil organisms and plants, thereby including effects of soil properties and contaminant 'ageing'. We have investigated the possibility to use a 0.001 M CaCl₂ batch test (ISO 21268-2) combined with biotic ligand models (BLMs) for assessment of ecotoxicity in soils. Concentrations of free metal ions (Cu²⁺, Zn²⁺) in soil extracts obtained with the batch test were linked to responses in ecotoxicity tests (microbial processes, plants and invertebrates) previously performed on metal spiked soils. Batch tests were performed with archived soil materials that were spiked using the same protocol as in the original studies. Then, the EC_x values based on free metal concentrations in soil extracts were related to pH by linear regressions. The model performance was compared to effects in field-contaminated soils. Our results indicate a pH dependence of EC₅₀ values based on free metal ions in the soil extracts, especially for Cu²⁺ where R² ranged from 0.83 to 0.93. Correlations for Zn²⁺ had R² 0.39 to 0.92. Comparing effect concentrations based on pH adjusted Cu²⁺ and Zn²⁺ in soil extracts from spiked and field contaminated soil samples, the toxic responses were similar. This indicates a potential of the calibrated models to assess toxic effects in field-contaminated soils, taking differences in soil properties and effects of contaminant 'ageing' into account. Consequently, evaluation of standardized 0.001 M CaCl₂ batch tests with a simplified BLM can provide the basis for an easy-to-use tool for site specific risk assessment of metal ecotoxicity in soil. Such a tool would also be applicable to soils containing sorbents with properties that differ from natural soil components e.g ash, soot or amendment with biochars.

3.19.T-04 Assessing the Sensitivity of Benthic Macroinvertebrate Communities to Zinc in the Field

Adam Peters¹, Iain A Wilson², Dean Leverett³, Christopher Cooper⁴, Howard Winbow⁴ and Frank Van Assche⁵, (1)wca, United Kingdom, (2)WCA Environment Limited, United Kingdom, (3)WCA-Environment Ltd, Faringdon, United Kingdom, (4)International Zinc Association, Belgium, (5)IZA, Belgium

Zinc is ubiquitous in the natural environment. The natural background level of zinc can be frequently enriched in downstream surface waters by anthropogenic activities that result in emissions from both controlled point and diffuse sources. Environmental Quality Standards (EQS) are typically derived from the results of laboratory studies on single species, and although there may be a significant number of individual species that are tested for zinc toxicity this will always be much more limited than the diversity of species that are found in real ecosystems. Furthermore, in these single species tests, usually only one stressor is being studied. Consequently, there is always some uncertainty surrounding the protectiveness of an EQS when it is applied to real ecosystems containing a multitude of chemical and physical stressors. A threshold derived based on the total abundance of eight sensitive taxa could potentially be used as an indicator of the overall ecosystem sensitivity. However, the inclusion of some responsive, but relatively insensitive taxa in this ecological response metric could bias the results from it towards a higher threshold. To assess this possibility, the least sensitive species were progressively removed from the collective ecological metric, basing the analysis on a progressively smaller number of the more sensitive species. There is a compromise between the robustness of the analysis and the sensitivity of the sub-community that the analysis is based on. Analyses that are based on fewer species or taxa may provide a more sensitive result, but are subject to greater levels of uncertainty because of the proportion of low exposure sites at which that none of the taxa that are included in the analysis are present due to the habitat being unsuitable. This approach was able to assess this real ecosystem data and evaluate the uncertainty associated with the protection provided by the EQS for zinc.

3.19.T-05 Deriving Nickel (Ni(II)) and Chromium (Cr(III)) Based Environmentally Safe Olivine Guidelines for Coastal Enhanced Silicate Weathering

Gunter Flipkens¹, Ronny Blust¹ and Raewyn Town², (1)University of Antwerp, Belgium, (2)Systemic Physiological and Ecotoxicological Research (SPHERE), University of Antwerp, Belgium

Active removal of 150 – 1180 gigatons of carbon dioxide (CO₂) from the atmosphere is needed to keep global warming below 1.5 °C. Negative emission technologies (NETs) such as coastal enhanced olivine weathering could help achieve this goal. Coastal enhanced olivine weathering aims to speed up the natural CO₂-consuming chemical weathering of the silicate mineral olivine (Mg₂xFe₂(1-x)SiO₄) by dispersing finely ground source rock in dynamic coastal waters. However, olivine contains nickel (Ni) and chromium (Cr), which may pose a risk to marine biota during a gigaton-scale coastal application. Currently, olivine toxicity data is lacking, but marine environmental quality standards (EQS) for Ni and Cr considered individually are available. Therefore, this study aimed to derive a maximum amount of olivine that could be dispersed in the coastal seas without exceedance of the Ni or Cr EQS. Calculations were made for the two limiting application scenarios in which all Ni and Cr released during olivine weathering end up in either the water column or the sediment. Results showed that metal concentrations in the water column are unlikely to exceed existing EQS due to the large seawater dilution effect. However, sedimentary metal concentrations could exceed EQS, and pose a potential risk to benthic marine biota, once application exceeds 1.4 kg of olivine m⁻² of seabed. Accordingly, on a global scale a maximum of 39 Gt of olivine could be dispersed, and the equivalent amount of CO₂ could be sequestered during the 21st century. On the basis of current EQS, we conclude that adverse environmental impacts from Ni and Cr release could reduce the applicability of olivine in coastal enhanced silicate weathering. Our findings call for more in-depth studies on the potential toxicity of olivine toward benthic marine biota, especially in regard to bioavailability and metal mixture toxicity.

3.19 Trace element biogeochemistry, exposure and impacts in ecosystems (Part II)

3.19.T-06 Mercury in Terrestrial Vertebrates and Possible Biomagnification in Foodchains in Switzerland

Sabnam Mahat¹, Marie Ryser², Bettina Almasi³ and Adrien Mestrot¹, (1)University of Bern, Switzerland, (2)Vetsuisse,

Switzerland, (3)Swiss Ornithological Institute, Switzerland

The majority of atmospheric mercury is estimated to be deposited in terrestrial environments, which becomes an important place of transfer and bioaccumulation in local food chains. The assessment values for mercury in Switzerland are available only for fish for human consumption and the international assessment values for mercury is available to protect top predators only in aquatic food chains. Mercury is toxic to organisms even in sublethal doses: it is persistent, bioaccumulates and biomagnifies. Hence, there is a need to define the environmental quality standard for meat from game for human consumption and to protect apex predators in terrestrial food chains. This study focuses on mercury concentrations measured in terrestrial vertebrates in Switzerland providing an evidence of bioaccumulation of mercury in terrestrial vertebrates, and aims to assess the possible biomagnification up the trophic level. Mercury was measured in the tissues samples (muscle, liver, kidney) of roe deer and eurasian lynx, and feathers of barn owls. Total mercury (T-Hg) was measured using Direct Mercury Analyser. Methylmercury (MeHg) was measured using HPLC-ICP-MS using a single step extraction in L-cysteine. Fresh weight T-Hg in roe deer muscle (n=81), liver (n=66) and kidney (n=68) ranged between 0.28-31.73 µg/kg, 0.73-78.39 µg/kg and 2.96-975.94 µg/kg respectively. Fresh weight T-Hg in lynx muscle (n=27), liver (n=29) and kidney (n=38) ranged between 2.74-194.39 µg/kg, 3.29-201.44 µg/kg and 3.43-423.01 µg/kg respectively. Dry weight T-Hg in down feathers of 12 barn owls ranged between 54.12-185.16 µg/kg. Levels measured above the limit of quantification of 0.03ng implies bioaccumulation in the terrestrial vertebrates in Switzerland. Significant difference ($p < 0.05$) was found in mean T-Hg concentration in muscle of roe deer (prey) and lynx (predator), with a biomagnification factor of 10. Hence, mercury could biomagnify up the trophic level also in the terrestrial food chain.

3.19.T-07 Titanium Dioxide Nanoparticles Modulate the Accumulation of Inorganic and Methyl Mercury by Crustacean *Daphnia magna*

Vera Slaveykova¹ and Mengting Li², (1)University of Geneva, Geneva, Switzerland, (2)University of Geneva, Switzerland

The overarching goal of the present study was to explore the role of nTiO₂ on the uptake and depuration of two major aquatic mercury species (inorganic, IHg and monomethyl mercury, MeHg) by *D. magna* through waterborne exposure and algal diets. To obtain an insight into the role of nTiO₂ on the accumulation of IHg/MeHg through water-, particle- and alga-borne exposures, *D. magna* was: (i) treated with mixtures of 2x10⁻⁸M IHg/MeHg and 20 or 200 mgL⁻¹nTiO₂; (ii) exposed to nTiO₂ pre-treated with IHg/MeHg; (iii) feed on alga *Chlamydomonas reinhardtii* pre-treated with IHg/MeHg; (in the absence and presence of nTiO₂). The results were compared with exposure of *D. magna* to dissolved IHg/MeHg alone. Experiments were performed in synthetic freshwater and in three independent replicates. nTiO₂ particles used in this study have a primary particle size of 5 nm, 100% anatase, purity 99.8%. *D. magna* was exposed for 2h to measure the intake of Hg, than transferred to clean standard freshwater without any food for depuration for 22h. Total accumulated Hg (THg=IHg+MeHg) in *D. magna* by atomic absorption spectrometry using the Advanced Hg Analyzer AMA 254 (Altec s.r.l., Czech Republic) and expressed in mg kg⁻¹ dry weight of biomass. The stability of nTiO₂ suspensions was also characterized. The results of the present study demonstrated the complex role of nTiO₂ played in the accumulation by zooplankton of two major Hg species present in the aquatic environment – IHg and MeHg. IHg has higher reactivity to nTiO₂, than MeHg, while MeHg has higher reactivity with living organisms, such as alga and daphnids. nTiO₂ played an important role, but dual role in the accumulation of both Hg species through the waterborne and foodborne exposure by reducing the assimilation efficiency for both IHg and MeHg through waterborne exposure, but increasing assimilation efficiency for MeHg when *D. magna* was fed on alga pre-treated with MeHg. nTiO₂ led to greater trophic transfer efficiency for both IHg and MeHg through feeding on TiO₂ pre-treated with IHg/MeHg, but lessened trophic transfer efficiency for both IHg and MeHg through feeding on alga pre-treated with Hg. The present results will help to better understand the role of nTiO₂ on bioavailability and trophic transfer of global contaminants, such as mercury, known to bioaccumulate and biomagnify in the aquatic environment.

3.19.T-08 Methylmercury Trophic Transfer: How Exposure Methods Affect Aquatic Invertebrate Biomagnification

Cailin Mackenzie¹, Tiffany Garcia² and Collin Eagles-Smith³, (1)Oregon State University, United States, (2)Fisheries, Wildlife, and Conservation Sciences, Oregon State University, Corvallis, OR, (3)U.S. Geological Survey, United States

Representative laboratory studies of contaminant cycling depend on mimicking naturally relevant conditions in an unnatural setting. Some toxicants, like methylmercury (MeHg), are highly complex in their freshwater trophic transfer, with field studies documenting wide variability in biomagnification rates. Experimental work is essential to understand this variability, yet the efficacy of laboratory methods to characterize MeHg transfer in aquatic food webs remains questionable. Our work unpacks how different methodologies affect trophic transfer of MeHg from oligochaete prey (*Lumbriculus variegatus*) to larval dragonfly predators (Anisoptera sp) using three different methodologies. We quantified dragonfly dietary bioaccumulation from prey dosed aqueously with MeHg-chloride vs MeHg-cysteine, and with prey dosed dietarily with MeHg-contaminated algae. All experiments used 4 MeHg concentrations and ran for 5-8 weeks. We also evaluated impacts of exposure on dragonfly growth, body condition, feeding rate, predator avoidance behavior, and immune response. Preliminary data suggest that dragonflies bioaccumulate MeHg in a dose dependent manner but there is no difference between MeHg-chloride and MeHg-cysteine trophic transfer ($p > 0.5$, Welch's t-test). All dosed treatments showed biomagnification factors less than 3, decreasing with increasing mercury dose. Prey dosed dietarily with MeHg contaminated algae further refined our study by exploring how increasing exposure realism impacts biomagnification. Whether these data indicate constraints in laboratory methods testing or a realistic view of biomagnification patterns occurring in nature will be explored. We will also present results of a meta-analysis quantifying effect size and variability drivers in predatory invertebrate MeHg biomagnification reported in the literature. Environmentally representative laboratory methods are critical to accurately quantify contaminant risk and characterize toxicity, and successful future monitoring and modeling efforts depend on deeper examination of dietary accumulation by predatory invertebrates.

3.19.T-09 Improving Toxicokinetic-Toxicodynamic Models for Metals: Interspecific Variability of Mechanisms Within the Genus *Daphnia*

*Simon Ewald Hansul*¹, *Andreas Fettweis*², *Erik Smolders*³ and *Karel De Schamphelaere*⁴, (1)Ghent University (UGent), Ghent, Belgium, (2)KULeuven, Belgium, (3)KULeuven -BE0419.052.173, Belgium, (4)Ghent University (UGent), Belgium

To advance the ecological relevance of Environmental Risk Assessment (ERA) of metals, effects of metals and metal mixtures on the level of communities and ecosystems need to be understood, and should be predictable based on information from lower levels of organization. To this end, toxicokinetic-toxicodynamic (TKTD) models need to be developed for multiple species and metals to provide the link between individual-level single-metal and community-level combined effects. Dynamic Energy Budget (DEB) theory provides a framework that makes such models applicable in a range of ecological scenarios. A set of four DEB-based toxicodynamic mechanisms (costs for structure, maintenance costs, assimilation efficiency, reproduction efficiency), typically applied one-at-a-time, has been used to model toxicity of a variety of substances, including metals, to a variety of organisms. For metals, there is reason to expect that the necessity to deviate from this standard approach is the rule rather than the exception, due to their potentially wide range of effects on lower levels of organization. We conducted life-table experiments with three species of *Daphnia*, exposed singly to Cu, Ni and Zn and inferred TKTD mechanisms within an Individual-Based Modelling (IBM) approach, providing insight into interspecific variability in TKTD mechanisms of metals, and the potential need to widen the range of DEB-based mechanisms that need to be considered. We found considerable interspecific variability not only in terms of sensitivity, but also in terms of the quality of effects on reproduction, carapace length and survival. The standard approach (four basic mechanisms applied one-at-a-time) was sufficient to explain observed effects in some cases (e.g., effects of Ni and Zn to *D. magna*), but not in others (e.g., effects of Ni to *D. pulex*). In those cases, multiple mechanisms acting simultaneously, including stimulating effects, need to be assumed in order to explain observed effects. Our findings indicate limited generalizability of mechanistic insight gained from standard test species, even among closely related species, and highlights the relevance of natural diversity for ERA.

3.19.T-10 Importance of Including All Life Cycle Effects When Modelling Copper Effects on Brook Trout (*Salvelinus fontinalis*) Populations

*Sharon Desire Janssen*¹, *Karel Viaene*², *Patrick Van Sprang*² and *Karel De Schamphelaere*¹, (1)Ghent University (UGent), Belgium, (2)ARCHE Consulting, Belgium

Population models can be helpful to predict population-level effects based on already available toxicity data on individual-level endpoints. For copper (Cu) effects on trout, most studies have been performed with early life stages. However, true population-level effects may be missed if the risk analysis is based solely on early-life stage effects. Therefore, the aim of this study was to predict population-level effects of Cu on a brook trout (*Salvelinus fontinalis*) population using a population model based on observed individual-level effects of a full life cycle study and an early-life stage study. We hypothesized that the population-level to individual-level effect concentration ratio would be smaller for predictions based on the life-cycle study than for predictions based on the early-life study. Population-level effects of Cu on a brook trout population were predicted with an Individual Based Model (i.e. inSTREAM-Gen) based on observed individual-level effects from either a full life cycle study or an early life stage study. Effects of Cu on individual-level endpoints were implemented based on relative effects compared to the control. For the life cycle study, we combined endpoints on survival, growth, reproduction, and development and for the early-life stage study, we implemented effects of hatching success, survival, and growth of yolk-sac larvae. Population-level NOEC (NOEC_{pop}) values were determined as the highest concentration for which no effect larger than 10% on trout density compared to the control was predicted. Furthermore, predictions based solely on the early-life stage effects of the full life-cycle study (hatching success, hatching time and survival and growth of yolk-sac larvae) were made. In addition, we assessed the effect of the implementation method of survival on the predicted NOEC_{pop}: Individual Tolerance (IT) vs Stochastic Death (SD). Overall, our results showed higher ratios of NOEC_{pop} to individual-level NOEC based on the early-life stage study (> 2.6 to 4.2) than for the life-cycle study (0.4 – 1.0). This was supported by simulations based solely on the early-life stage effects of the life-cycle study (ratios ? 3.4). This confirms our hypothesis that predictions of population-level effects could underestimate true population effects if solely based on early-life stage effects. Furthermore, we found that the implementation method of survival effects (IT or SD) is important for the predicted NOEC_{pop}.

3.19 Trace element biogeochemistry, exposure and impacts in ecosystems (Part III)

3.19.T-11 The Exposure and Fate of Platinum in the Freshwater Environment: An EcoToxicological Approach

*Johannes Hendrik Erasmus*¹, *Nicholas J Smit*², *Sonja Zimmermann*³, *Wynand Malherbe*⁴, *Armin Lorenz*⁵, *Milen Nachev*³, *Bernd Sures*³ and *Victor Wepener*⁶, (1)North-West University, South Africa, (2)NorthWest University, South Africa, (3)University of Duisburg Essen, Germany, (4)North-West University - Water Research Group, South Africa, (5)University of Duisburg-Essen, Germany, (6)North-West University - School of Biological Sciences, South Africa

Platinum (Pt) is a precious metal with unique chemical and physical properties, that makes it indispensable. It is primarily used in automotive catalytic converters, from where it is emitted, but mining and chemical facilities are also primary sources of Pt into the environment. Extensive research has been conducted on the fate and effects of Pt entering the environment via road dust resulting from mechanical and chemical abrasion of catalytic converters. However, limited studies have been conducted on Pt exposure from mining and production activities, while data on the occurrence of Pt in biota near production sites, is still lacking. Therefore, the aims of the present study were to determine the Pt concentrations in the aquatic environment, establish the transportation and bioavailability of Pt in the aquatic system, and subsequently establish the aquatic biota community structures to determine the effects and potential risk of Pt to biota and humans. Field surveys were completed, where water, sediment, macroinvertebrate

samples, three different fish species, as well as their associated parasites were collected for metal analysis. In all of the samples metal(loid)s that are normally associated with Pt mining activities were targeted, thus concentrations of As, Cd, Cr, Cu, Pb, Ni, Pt and Zn were determined. Dissolved concentrations of As, Ni, Cu and Pt, as well as concentrations of all the targeted metal(loid)s in the sediment were significantly higher after the influence of intensive mining activities. Macroinvertebrate community structures were significantly altered by the mining activities and changed from moderately sensitive taxa at the reference site to highly tolerant taxa at the impacted site, while both diversity and functional approaches indicating metals as the main drivers in community changes. Concentrations of As, Cr and Pt were significantly higher in fish collected from the impacted impoundment compared to the reference impoundment, whereas their associated cestodes and nematodes accumulated non-essential metals more readily compared to their hosts. These high metal(loid) loads also pose several carcinogenic and non-carcinogenic risks to humans who consume these contaminated fish. The present study provides valuable and missing data on the transformation and bioaccumulation of Pt and associated metal(loid)s from mining and production activities, as well as the negative effects it has on the aquatic ecosystem.

3.19.T-12 Distribution of Rare Earth Elements in the Food Web of Estuarine Ecosystems: The Case Study of the Loire Estuary

Julie Rétif¹, Aurore Zalouk-Vergnoux², Nicolas Briant³ and Laurence Poirier⁴, (1)Laboratoire Mer Molécules Santé (MMS), France, (2)Univeristé de Nantes, France, (3)IFREMER, RBE-BE-LBCM, France, (4)Nantes Université, France

Rare earth elements (REEs) regroup 17 metallic elements including the fifteen lanthanoids (from lanthanum to lutetium), yttrium and scandium. Their increasing use in many industrial sectors causes an increase of discharges into the environment and in particular in estuarine areas subject to strong anthropogenic pressures. This study focused on assessing the distribution of REEs along the food web of the Loire estuary (France). Several species (*Heteromastus filiformis*, *Nephtys hombergii*, *Nereis diversicolor*, *Coruphium volutator*, *Limecola balthica*, *Scrobicularia plana*, *Chelon ramada* and *Anguilla anguilla*) representative of different levels of the Loire estuary food web were sampled on different sites and their REE concentration was measured. Intra-species differences have been highlighted with much greater concentrations of light rare earth elements (LREE) than of medium (MREE) and heavy (HREE) ones for all species. LREE contribution was around 71%, whereas they were only 13 and 16% for the MREE and HREE. In addition, a higher REE accumulation was observed in lower trophic level species compared to organisms belonging to higher trophic levels (up to two times higher), demonstrating inter-species variations. Total mean REE concentration values were the highest for *C. volutator* (15 µg/g dw) and the lowest for *A. anguilla* (0.1 µg/g dw). Inter-phylum disparities were also noticeable. Among annelids, *H. filiformis* showed much higher concentrations than the two other annelid species. Among the two vertebrates, *C. ramada* presented five times higher concentrations than *A. anguilla*. European shale normalization allowed to highlight gadolinium positive anomalies in the REE patterns in most of the studied species. Only *C. volutator* stood out with a really diverging REE pattern preventing anomalies discrimination.

3.19.T-13 Effects of Different Forms of Gadolinium on Early LIFE Stages of Atlantic Cod (*Gadus morhua*)

Julia Farkas¹, Stefania Piarulli¹, Trond Nordtug², Pål Olsvik³, Christian Sonne⁴, Páll Leifsson⁵, Andy Booth⁶ and Bjørn Henrik Hansen¹, (1)SINTEF Ocean, Norway, (2)SINTEF Materials & Chemistry, Norway, (3)Nord University, Norway, (4)Aarhus Universitet, Denmark, (5)University of Copenhagen, Denmark, (6)Climate and Environment, SINTEF Ocean, Trondheim, Norway

The lanthanoid element gadolinium (Gd) is one of the rare earth elements (REY). Gd-chelate complexes are commonly used as contrast agents in medical diagnostics (gadolinium-based contrast agents; GBCA). Due to rapid and unmetabolized excretion and limited retention in wastewater treatment plants, GBCA are released into the aquatic environment. Here we studied the effects of different Gd compounds on early life stages of Atlantic cod (*Gadus morhua*), namely inorganic Gd as GdCl₃, and the contrast agent gadoterate (Gd-meglumin) obtained as pharmaceutical injection solution (Gd-Sol) and as off-the shelf chemical powder (Gd-Meg). Nominal exposure concentrations reached from 3 to 3000 µg L⁻¹. Our results show that, while GBCAs were fully soluble at all tested concentrations, GdCl₃ solubility was limited in seawater, with average dissolved Gd concentrations reaching only 122±48 µg L⁻¹ even at the two highest exposure concentrations. Despite the lower exposure concentrations, GdCl₃ was most available for uptake in both eggs and larvae. It was further the most toxic of the tested Gd forms, significantly reducing larvae viability and body area, and causing deformations at exposure concentrations >100 µg L⁻¹. At the highest exposure concentration (3000 µg L⁻¹) Gd-Meg caused deformation phenotypes similar to GdCl₃, i.e., larvae with craniofacial deformities, lordosis and reduced pigmentation. In contrast, Gd-Sol did not cause significant adverse effects, likely due to effective protective effects from the chelating agent. This highlights the needs to study the long-term stability of GBCA-complexes in the marine environment.

3.19.T-14 Probing the Role of Metal Speciation in Copper Nanoparticles As a Driver of Adverse Outcomes During Embryogenesis of Urchins *Paracentrotus lividus*, *Arbacia lixula* and *Sphaerechinus granularis*

Ivana Čarapar, Dijana Pavić¹, Hamer, Andrej Jaklin and Daniel Mark Lyons, Ružer Bošković Institute, Croatia

Copper and copper oxide nanoparticles (CuNPs) are widely used in a broad range of industrial applications encompassing biotechnology, medicine and health care, biomonitoring and environmental remediation. Their use in ship anti-fouling paints presents a direct route into marine environments where they can impact on a wide range of organisms at all life stages, from embryos to adults. Sea urchins have been widely used as a model in developmental biology and as a bioindicator for the marine environment. In this study, the effects of copper and copper oxide nanoparticles (CuO, Cu₂O) on fertilisation success and transmissible damage to offspring during embryogenesis of the sea urchins *Paracentrotus lividus*, *Arbacia lixula* and *Sphaerechinus granularis* were analysed. Subsequently, the ability of the exposed sperm to successfully fertilise untreated eggs, given as fertilization rate, was tested. After fertilisation, zygote growth to the pluteus larva stage was monitored over 72-96 h and these offspring of treated sperm were scored for developmental defects, developmental delays and death. While copper ions are

known to be toxic to organisms and are often used as a positive control in bioassays, copper and copper oxide nanoparticles showed values close to those of Cu²⁺ ions. Furthermore, zero-valent copper nanoparticles were found to be least toxic while the oxides of copper caused greater suppression of fertilisation. All plutei offspring showed increasing numbers and types of developmental defects as a function of copper concentration. The most common abnormalities were found to be delayed development, exogastrulation and skeletal defects and were present in plutei of all three urchin species. Exposure of sperm to copper nanoparticles may have significant negative consequences not only in their ability to successfully fertilise eggs but also in potentially causing transmissible damage to the subsequent offspring. Ultimately, the species of urchin must also be considered when investigating the toxicity of nanoparticles since not all species are equally sensitive.

3.19.T-15 Integrated Exposure and Effects Assessment of Three Trace Metals on a Marine Copepod *Tisbe battagliai*

Chloe Eastbrook¹, Emil Jarosz², Li Xie³, You Song⁴, Gary Caldwell¹, Hans-Christian Teien² and Knut Erik Tollefsen³,
(1)Newcastle University, United Kingdom, (2)Norwegian University of Life Sciences NMBU, Norway, (3)NIVA - Norwegian Institute for Water Research, Norway, (4)Norwegian Institute for Water Research (NIVA), Oslo, Norway

Some trace metals at low concentrations are essential for living organisms, yet they are environmentally ubiquitous and may bioaccumulate to become toxic at higher concentrations. Increasing coastal industrial development is driving a rise in effluent discharge (including metals) into coastal waters. These metals can exist as complex chemical mixtures, which may cause greater toxicity than predicted from single data. Metal speciation influences metal toxicity, as it can affect their bioavailability and uptake. An integrated exposure and effects assessment was conducted for a combined three metal study on an ecologically important coastal copepod *Tisbe battagliai*. Copper, nickel, and zinc are among the most common metals associated with toxicity in marine environments, making them good candidates for cumulative effects assessment. The experimental design used was Definitive Screening Design (DSD) that can determine main effect drivers and second-order effects. DSD uses LC₁₀, LC₅₀ and LC₈₀ values from single metal exposures to design 15 combined solutions. This study aimed to: (1) characterise the metal exposure solutions by size fraction; and (2) complete an acute, 24-hour combined effects assessment focusing on the metal-induced reactive oxygen species (ROS) – DNA damage – apoptosis toxicity pathway. This was achieved by measuring relevant endpoints and conducting size fractionation to determine each metal fraction's (particles, colloids, and low molecular mass – LMM) contribution to total concentration. Reduced survival after 24 hours was driven by copper, nickel, and zinc in the mixture, with significant interactions between copper*zinc and copper*nickel (P < 0.05). For cellular ROS formation and oxidative DNA damage, no particular metal was the main toxicity driver. For oxidative DNA damage, all paired metal combinations within the three-metal mixture had non-parallel interaction profiles, showing that the effect of each metal on DNA damage changed as other metal concentrations changed. Combined metal solutions were dominated by nickel in the LMM form, which is the most bioavailable, whereas copper and zinc were present in all three fractions. Copper was the only metal that did not have the highest contribution from LMM but remained a main effect driver for survival. An integrated exposure and effects approach allowed us to use metal fractionation data and interactions between copper, nickel, and zinc to better understand the observed toxicity.

3.19 Trace element biogeochemistry, exposure and impacts in ecosystems (Virtual Only)

3.19.V-01 Disclosing Short Time Scale Toxicokinetics and Toxicodynamics of Inorganic Mercury in the Saltmarsh Plant *Halimione portulacoides*

Ana Marques¹, Patrícia Pereira², Joana Luisa Pereira², Silja Frankenbach¹, Fernando J. M. Gonçalves², João Serôdio¹, Rita Menezes³, Rute Cesário⁴, Joao Canario⁵ and Mário Pacheco¹,
(1)University of Aveiro, Portugal, (2)CESAM & University of Aveiro, Portugal, (3)Centro de Química Estrutural, Instituto Superior Técnico, Universidade de Lisboa, Portugal, (4)IST, Portugal, (5)Instituto Superior Técnico, Portugal

Saltmarsh plants as *Halimione portulacoides* have a key role on the mercury (Hg) biogeochemical cycle, namely by accumulating high levels of this metal in the roots. Despite that, research on Hg toxicokinetics (uptake, accumulation, elimination) in those plants is scarce, while there is still a lack of knowledge on related toxicodynamics comprising biochemical responses. A short-term exposure (4 h; under hydroponic conditions) of *H. portulacoides* to realistic levels of inorganic Hg (iHg) (0.45 µg/L) was carried out, under light and dark conditions in order to clarify the influence of light-dependent activity on iHg toxicokinetics and toxicodynamics. Plants were collected in a coastal lagoon (Aveiro Lagoon, Portugal), namely at a highly contaminated site (Laranjo - LAR) and a reference site (REF), allowing an evaluation of the contamination background interference. Plants were acclimated to the lab for two months before exposure. Samples of leaves and roots were collected after 2 h (T2) and 4 h (T4) of exposure, as well as immediately before exposure (T0) for analysis of total Hg levels, antioxidant defences [catalase (CAT), ascorbate peroxidase (AP), glutathione peroxidase (GP), superoxide dismutase (SOD)] and oxidative damage [lipid peroxidation (LPO)]. Total Hg levels in the roots of *H. portulacoides* of both sites were similar at T0, suggesting elimination during the acclimation period and allowing a straightforward comparison of plant responses to the current Hg exposure. At T4, an enhancement of total Hg levels was recorded in roots of exposed plants from LAR at daylight, while at dark conditions no significant accumulation was found. No changes on antioxidants activities or LPO were recorded in LAR plant roots in T4 at daylight, suggesting a tolerance to Hg accumulation. An opposite pattern was found for REF plants at T4 with no significant Hg accumulation at daylight and a notorious enhancement in dark conditions. A concomitant decrease of AP activity was recorded in the roots of plants from REF. In general, no significant increases of Hg levels were found in the leaves of plants from both sites over time. Overall, the results highlight the rapid uptake of iHg by *H. portulacoides* roots (within 4 h) and a possible role of the plant Hg historical background on the toxicokinetics and toxicodynamics of iHg. Naïve plants seem to be more vulnerable to iHg toxicity than those from a chronically contaminated site.

3.19.V-02 Ecotoxicity and Human Risk Assessment of an Anthropogenic Contaminated Site

Omobolaji Oluwamuyiwa Afolabi¹, Sunday O. Eludoyin², Wali Elekwachi³ and Eze Ihunda², (1)University of Port Harcourt, Port Harcourt, Nigeria, (2)University of Port Harcourt, Nigeria, (3)UNIVERSITY OF NIGERIA, NSUKKA, Nigeria

One of the most common anthropogenically contaminated sites in developing country is landfill area. The pressure of urbanization has led to increased waste generation in major cities which are commonly deposited in landfill; hence, heavy metals contaminations are closer to human environment more than ever. The study examined the Ecotoxicity of Arsenic (As), Cadmium (Cd), Zinc (Zn), Manganese (Mn), Copper (Cu), Cobalt (Co), Chromium (Cr), Nickel (Ni) and Lead (Pb) and health-related risk from human activity of waste disposal using the ISSO methodology standard. The finding indicated that the concentration of the elements descended as follow; Mn>Zn>Cr>Pb>Cu>Ni>Co>As>Cd where all the element concentrations exceeded the WHO permissible limit. The Enrichment factor (EF) and potential ecological risk (ER) indicated no enrichment and low risk for all the elements except Cd (3.67, 426) with moderate enrichment and very high risk. The hazard index (HI) value of the elements indicated no significant risk of non-carcinogenic effect for both Adult and Children except for Mn in Children with value of 1.69×10^0 ; however the HI value of the elements descended as; Co>Mn>Zn>As>Cd>Cu>Pb>Ni>Cr for adult and Mn>Cd>Co>Cr>As>Zn>Pb>Cu>Ni for children. The total carcinogenic risk (TCR) value of the toxic metals descended as Ni>Cd>Cr>As>Pb for both Adult and Children while the metals showed no carcinogenic to acceptable risk to humans. Improving the method of waste disposal and management is needed to limit the potential human health risk and environmental contamination. Further studies on the bioaccumulation and availability to surrounding edible crops/plants are needed to fully understudy the environmental impact of the anthropogenic contamination action on plant.

3.19.V-03 Ecotoxicological Implications Due to Chronic Exposure to Relevant Concentrations of Rare Earth Elements

Melissa Diogo Faria¹, Juliette Bedrossiantz², Eva Prats³, Júlia Goyeneche⁴, Cristian Gómez-Canela⁵ and Maria Izquierdo¹, (1)Institute for Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (2)IDAEA CSIC, Spain, (3)Research and Development Centre (CID-CSIC), Spain, (4)School of Engineering, Institut Químic de Sarrià-Universitat Ramon Llull (IQS), Spain, (5)School of Engineering, Institut Químic de Sarrià-Universitat Ramon Llull, Spain

Rare Earth Elements (REE) are not as sparse in the environment as their name suggests. Currently, they play an essential role in a number of technological applications from electronics and fuel additives to agriculture and even environmental remediation. REE production spiked especially after 2010, and worldwide REEs anomalies have been observed in sediments, rivers, and lakes, estuaries and coastal waters, ground water and tap water as well as in aquatic species and humans. However, the potentially toxic effects resulting from exposure to REE in human health and the environment biota are not currently under the radar of lawmakers that legislate environmental quality standards for chemicals and for all ground and surface waters, where most of the legal efforts are focused on mine industry of these elements. This is also not helped by the existence of a generalized gap of synthesized information about REE environmental behaviors and impacts associated with biological effects including both Human and other animal species, especially considering more realistic scenarios and its ecological implications. REEs have been reported to induce neurotoxicity and oxidative damage in the central nervous system. However, due to limited underpinning experimental and field data, such effects are poorly documented. In this study, chronic waterborne exposure of zebrafish (*Danio rerio*) to two REE (Lanthanum (La) and Gadolinium (Gd)) at relevant concentrations altered fish key survival behaviors, such as social interactions dysfunction in shoaling formation. Furthermore, a clear unbalance between prooxidants and antioxidants was observed as a significant increase of oxidative damage and depleted defence activities, especially for La exposure. Metabolomics analysis of multiple fish neurochemical signaling profiles are also presented. However, despite the observed effects, the detection of these elements in fish tissues was indetermined.

3.19.V-04 Export of Mercury From Saltmarsh Vegetated Sediments During Flooding Period

Rita Menezes¹, Rute Cesário², Bárbara Ribeiro¹, Joana Luísa Pereira³, Mário Pacheco³, Henrique Zilhão¹, Carlos Eduardo S. S. Monteiro⁴ and Joao Canario⁵, (1)Centro de Química Estrutural, Instituto Superior Técnico, Universidade de Lisboa, Portugal, (2)IST, Portugal, (3)CESAM & University of Aveiro, Portugal, (4)Centro de Química Estrutural - IST-ID, Portugal, (5)Instituto Superior Técnico, Portugal

Several recent works indicated the elevated mercury (Hg) concentrations in saltmarsh sediments and its accumulation in the root-sediment system. During tidal flooding, the cycling of Hg between sediments and the water column is affected. To gain a better understanding of the export of Hg as well as the effect of water level fluctuations on the sediment-water exchange, overlying water (OW) and sediment cores (10-cm long) were sampled several times during the first 30 minutes of tidal flooding in one Hg contaminated saltmarsh in Ria de Aveiro. Immediately after sampling, OW were filtered and sediment cores sliced and stored in decontaminated plastic bags and centrifuged flasks. In the lab, separations were performed to obtain subsamples of sediments, pore waters (PW), and roots. Concentrations of reactive Hg [RHg] and total Hg [THg] were quantified in water samples and [THg] in solid sediments and belowground biomass. Physico-chemical parameters such as pH, temperature, salinity and conductivity were also determined in OW samples and humidity and organic matter (OM) in sediments. Dissolved [RHg] in OW increase in the first 4 minutes of tidal forcing due to flushing phenomena agreeing with the decrease of [RHg] in PW of all sediment layers from 0 to 2 minutes, suggesting a remobilization of Hg in the sediment. Overall [RHg] in PW increases on top layers after 2 minutes until it decreases significantly in the last 15 minutes, while in OW has a constant increase in the same time range implying a rapid export of Hg from sediments to the water column. Before flooding, [THg] in roots ranged between 9.34 mg/L (4-6cm) and 14.30 mg/L (6-8cm) in bottom layers, and increased to 16.42 mg/L (4-6cm) and 20.72 mg/L (6-8cm) in the first 2 minutes of inundation. The inlet of water that comes with the flooding increases the Hg concentration due to remobilization within the sediment. In the last 15 minutes, [THg] decreases in all root layers, which may suggest mobilization of Hg from the roots to the OW. Two peaks of [THg] were observed in roots and sediments in times 2 (20.7 mg/L in layer 6-8cm) and 15 minutes

(21.2 mg/L in 4-6cm layer), indicating a periodic trend for Hg remobilization between roots and sediments. The short-time variations registered in this study indicate a shift on the Hg equilibrium between PW, solid sediments and root surface. Moreover, as water floods the saltmarsh, Hg escape from sediments being potentially available to biota living in these ecosystems.

3.19.V-05 Long-Term Effects of Inorganic Mercury and Methylmercury in Naïve and Historically Exposed Saltmarsh Plants

Ana Marques¹, Joana Luisa Pereira², Patrícia Pereira², Silja Frankenbach¹, Fernando J. M. Gonçalves², João Serôdio¹, Rita Menezes³, Rute Cesário⁴, Joao Canario⁵ and Mário Pacheco¹, (1)University of Aveiro, Portugal, (2)CESAM & University of Aveiro, Portugal, (3)Centro de Química Estrutural, Instituto Superior Técnico, Universidade de Lisboa, Portugal, (4)IST, Portugal, (5)Instituto Superior Técnico, Portugal

Following the Minamata Convention on mercury (Hg), worldwide efforts to appropriately characterize and manage related contamination have been raising. Wetlands provide several highly relevant ecosystem services, including the regulation of biogeochemical cycles. Despite this relevance and the frequent contamination-driven threats to these ecosystems, much is still unknown in some fields such as the responses of salt-marsh plants to Hg species while those have a major role in their sequestration and cycling. This study aimed to assess the oxidative stress responses and photosynthetic activity of a salt-marsh plant (*Halimione portulacoides*) to inorganic divalent Hg (iHg) and monomethylmercury (MMHg), comparing between historically exposed and naïve plants to appraise putative adaptation mechanisms. Plants collected in one contaminated site and one reference site, both permanently under tidal influence, were kept under hydroponic conditions for exposure to environmentally relevant concentrations of iHg or MMHg and a blank control for 14 days, under different salinity levels (0 and 21 PSU). The activity of catalase (CAT), ascorbate peroxidase (AP), glutathione peroxidase (GP), superoxide dismutase (SOD), as well as the production of thiobarbituric acid reactive substances (TBARS) as a result of lipid peroxidation (LPO), was assessed in roots and leaves. Salinity levels have little to no interference in the responses of the leaves to iHg and MMHg exposure, while enzymatic activities and peroxidative damage tend to be higher in roots exposed under low salinity levels. No significant alterations in the photosynthetic activity of leaves were found. Previous adaptation to the metal contaminants apparently constrains the oxidative stress responses of both leaves and roots, but patterns are dependent on the endpoint and the Hg form. In spite of these differential responses, significant effects of iHg or MMHg dosed at environmentally relevant concentrations were not always identified. This suggests that large plasticity ranges are consistent with previous evidence on the potential of *H. portulacoides* to tolerate Hg, accumulate it, and drive important phases of its biogeochemical cycle, which should allow the plant to cope with possible future scenarios of change in tidal dynamics.

3.19.V-06 Rhodium Speciation Analysis in Environmental Matrices Combining Different Analytical Techniques

Carlos Eduardo S. S. Monteiro¹, Antonio Cobelo-García², Miguel Caetano³ and Margarida M. Correia dos Santos⁴, (1)Centro de Química Estrutural - IST-ID, Portugal, (2)CSIC, Spain, (3)Portuguese Institute of Sea and Atmosphere IPMA, Portugal, (4)Centro de Química Estrutural, Instituto Superior Técnico, Universidade de Lisboa, Portugal

Rhodium (Rh) is one of the platinum-group elements less-studied in the environment due to its low abundance, irrespective of its steadily increasing concentrations. Anthropogenic sources are responsible for releasing Rh to all environmental compartments, whose main contributions are from automotive catalytic converters and industrial catalysts. The forms in which Rh is released are not yet entirely elucidated, and analytical challenges in Rh determination make its speciation analysis and environmental fate poorly known. This study addresses the existence and discrimination of soluble/insoluble Rh species in the operationally dissolved phase (< 0.45 µm) and its particulate fraction as well, using a combination of analytical techniques. To this goal, leachates obtained from urban road dust experiments and water samples from an estuary were investigated in order to elaborate Rh speciation analysis schemes. In filtered (< 0.45 µm) solutions, concentrations of truly dissolved Rh were measured by adsorptive cathodic stripping voltammetry (AdCSV) using a second derivative transformation of the voltammograms to improve Rh ultra-trace signal. In the same solutions, Rh total concentrations (truly dissolved + nanoparticles) were determined by inductively coupled plasma mass spectrometry (ICP-MS). Total concentrations of Rh in the solid samples were determined by AdCSV after an acid-digestion step with *aqua regia*. In the road dust leachates truly dissolved species of Rh corresponded to a considerable fraction of total Rh (~40 %), resulting from the compounds already in the oxidized form present in the road dust particles. The % of Rh dissolution in the leachates was higher when determined by ICP-MS as compared with those measured by AdCSV. This confirms the presence of different Rh forms, i.e. colloidal species and/or (nano)particles, measured by ICP-MS besides the truly dissolved forms (AdCSV). Despite the success of this strategy with urban road dust leachates, Rh determination by ICP-MS in waters, especially saline, is still challenging due to interferences. The improvement and combination of analytical strategies, sensitive enough to tackle elements at ultra-trace concentrations, may provide further insight into the speciation analysis of other platinum-group elements, e.g. palladium. *Acknowledgement* - Project IST-1018P.04037.1.01.; FCT funding SFRH/BD/111087/2015, PTDC/REQ- EPR/1249/2014, CQE UIDB/00100/2020-UIDP/00100/2020; COST Action TD1407 NOTICE.

3.19 Trace element biogeochemistry, exposure and impacts in ecosystems (Poster)

3.19.P-We136 Total Mercury, Methylmercury, Phosphate, and Sulfate Inputs to a Bog Ecosystem From Herring Gull (*Larus smithsonianus*) Guano

Haley Geizer, Sara Klapstein, Mark Mallory and Nelson J O'Driscoll, Acadia University, Canada

Methylmercury is a form of mercury which is available for uptake by biota. It can magnify through trophic levels and leads to greater quantities within top consumers. The area of study, Brier Island Nova Scotia, receives upwards of 6000 herring gulls each

year in the spring during their nesting season. Previous research suggests that methylmercury hot spots are co-located with the highest density of the herring gull colony. This biovector mechanism has the potential to drastically alter the ecosystem through guano inputs. Samples were collected to analyze the temporal distribution of methylmercury within the guano. Samples were collected by installing five posts in the most populated area of the bog for birds to perch and excrete on. Collection of samples occurred every 2 weeks in the summer of 2018 and 2019 with a total of 43 samples. They were then taken back to Acadia University to measure total mercury (THg), methylmercury (MeHg), water-extractable phosphorous (PO_4^{3-}) and water-extractable sulphate (SO_4^{2-}) concentrations. THg concentrations significantly decreased throughout the nesting season (mean = 113.77 ± 50.22 ng/g, n=43) while %MeHg significantly increased (mean = 53.06 ± 24.94 %, n=40). This suggests a dietary switch because of gull nutritional needs or availability varies. PO_4^{3-} increased throughout the summer months (ranging from 2.8% to 4.4% of dry weight). Results suggested a variation in SO_4^{2-} as well (ranging from 0.1% to 0.8% of dry weight). These results are likely an underestimate as much higher concentrations can be found in feathers and carcasses. These data indicate that gulls are transporting considerable amounts of %MeHg, PO_4^{3-} and likely other contaminants that can alter environmental conditions of Big Meadow Bog.

3.19.P-We137 Examining Export and Bioaccumulation of Methyl Mercury in a Bog Habitat Impacted by Herring Gull Guano and WATER Table Restoration on Brier Island, Digby County, Nova Scotia

Nelson J O'Driscoll, Mia Doncaster, Brianna Bowes, Sara Klapstein and N Hillier, Acadia University, Canada

The processes controlling Hg accumulation in bogs and the confounding effects of both gull guano input and increased flooding are not well known. Big Meadow Bog (Brier Island, NS) underwent water table restoration which was completed in the summer of 2018. The bog is also host to 4000-6000 herring gulls clustered in a small area in the Northern Bog that feed at nearby mink farming and aquaculture sites. Previous research in our group has shown that bird biomass and waste products are increasing the trace metals and nutrients measured in groundwater. Gull guano analysis results have shown that gull guano is very high in water soluble PO_4^{3-} and that total mercury (THg) and methylmercury (MeHg) are low in guano. Research from various studies examining terrestrial freshwater catchment flooding indicated that export of methylmercury (MeHg) increases 3-6 times over a 3–9-year time span in otherwise undisturbed catchments. An examination of water quality and lower trophic level biota was initiated to set a baseline for methylmercury concentrations in the base of the food web. Outflow water samples showed a seasonal trend between 2018-2021 with highest concentrations and % MeHg occurring during the summer period for 2019 and remaining lower for 2020-2021 data. The % MeHg increases to >60% in July of 2019 and reduces to < 40% in the following years. Similar patterns were observed in DOC (mid summer highs of 40-60 ppm DOC) and total phosphorus (0.5-2 mg/L) with a large portion present as orthophosphate. A survey of invertebrate bioindicators of mercury bioaccumulation in the food web indicated a wide range in concentrations (~0.06 - 1778 ng/g MeHg dry weight). Highest median MeHg concentrations were observed in water striders, water boatmen, milky backswimmers. Other invertebrates also showed high maximum MeHg concentrations in some individuals such as ground beetles (max 721 ng/g), midges (705 ng/g), spiders (1779 ng/g) and predaceous diving beetles (1074 ng/g). An examination of MeHg versus THg results for a subset of samples shows 4 – 133% of the THg is present in a MeHg form. The top 3 families for MeHg content (Corixidae, Gerridae, Notonectidae) have >90% MeHg likely due to feeding ecology and specific habitat chemistry.

3.19.P-We138 Total Mercury Concentrations in Vulnerable Species Along the South African Coast: Sharks, Skates and Rays As CASE Study

Johannes Hendrik Erasmus¹, Nicholas J Smit², Ruan Gerber³, Bjoern Schaeffner³ and Victor Wepener⁴, (1)North-West University, South Africa, (2)NorthWest University, South Africa, (3)North-West University - Water Research Group, South Africa, (4)North-West University - School of Biological Sciences, South Africa

A global decline in elasmobranch populations resulting from targeted fisheries or overfishing via by-catch raises conservation concern. In addition to these stressors, apex predators like sharks bioaccumulate high concentrations of total mercury (THg), due to biomagnification through the food chain. Although South Africa is considered one of the top ten contributors of Hg emissions globally, information on Hg concentrations in elasmobranchs is insufficient. The aim of the present study was therefore to evaluate the THg concentrations in elasmobranchs along the coast of South Africa. Total mercury concentrations were determined in 22 species of elasmobranchs (16 shark, 2 skate and 4 ray species) consisting of 86 individuals. Six shark and two skate species were collected from the south coast, while 10 shark and four ray species were sampled from the east coast. Concentrations ranged between 0.22 mg/kg THg in *Haplobpharus pictus* (dark shyshark) and 5.8 mg/kg THg in *Rostroraja alba* (white skate) on the south coast, whereas on the east coast it ranged between 0.21 mg/kg THg in *Mobula kuhlii* (shortfin devil ray) and 17.8 mg/kg THg in *Sphyrna lewini* (scalloped hammerhead). Total Hg on the east coast from the present study were in the same range or higher compared to the same species sampled on the east coast of South Africa from 2005–2010. The results from the present study were also compared to THg concentrations from the same species sampled in other countries, with generally higher concentrations along the South African coast. This indicate an on-going cause of concern for the health of these vulnerable shark species along the South African coastline.

3.19.P-We139 Mercury Photochemistry and Speciation in the Jijuktu'kwejk (Cornwallis River) Estuary of the Minas Basin, Nova Scotia: Effects of Salinity/DOM Interactions and Tide

Rachel Clarke, Sara Klapstein and Nelson J O'Driscoll, Acadia University, Canada

The photochemistry and speciation of mercury (Hg) are important factors in the retention of Hg in estuarine ecosystems. Net photoreduction of divalent Hg (Hg(II)) and volatilization of photoreduction products (elemental Hg (Hg(0))/dissolved gaseous Hg (DGM)) can be a mechanism by which Hg burdens in ecosystems are decreased. Using natural surface water, the effects of

salinity were investigated while controlling the concentration of high molecular weight (>1 kDa) DOM through a tangential ultrafiltration-dilution technique, and Hg photoreduction was quantified. Surface water was collected every 0.5 hours during a daylight semi-diurnal tidal cycle in the Jijuktu'kwejk (Cornwallis River). Net Hg(0) was measured in unfiltered surface water while total mercury (THg), easily reducible Hg (ERM; in this study an estimation of photoreducible Hg in filtered water), and DOM were measured in filtered surface water. In lab experiments, pseudo first-order rate constants in estuarine dilutions ranged between 0.22 h⁻¹ and 0.73 h⁻¹. The amount of Hg available for photoreduction in the dilutions (Hg(II)_{RED}) ranged between 67.25 pg and 265.91 pg (~336–1329 pg L⁻¹). Gross photoreduction rate constants decreased with increasing salinity and lower salinities (< 13.5 g L⁻¹) incurred the most drastic change in rate constant. In addition, DOM concentration decreased after irradiation (>57% loss) in lower salinity dilutions (? 13.5 g L⁻¹), suggesting a loss of DOM reactivity at lower salinities. In natural surface water, concentrations of TSS followed a pattern related to tide height with lowest concentrations observed during the periods of high and low tide. In unfiltered surface water samples, Hg(0) concentration was mostly nondetectable (< 10 pg L⁻¹) throughout the day. In filtered water, approximate Hg(II)_{RED} concentrations (measured from ERM analysis) followed an inverse pattern to the tidal height with a maximum concentration of 381 pg L⁻¹. While ERM measurements may overestimate the photoreducible Hg(II) fraction, Hg(II) photoreduction is likely suppressed in the study system due to high TSS loads greatly limiting the amount of radiation penetration in the water column. This research demonstrates the importance of salinity and DOM interactions as well as estuarine processes in influencing Hg photoreactions, as well as the importance of complementary laboratory and field measurements in mercury photochemistry research.

3.19.P-We140 Release of Indium From In₂O₃ Nanoparticles

Kevin Rosales-Segovia¹, Encarna Companys², Jaume Puy² and Josep Galceran³, (1)Univ. de Lleida, (2)Universitat de Lleida and AGROTECNIO, Spain, (3)Chemistry, Universitat de Lleida, Lleida, Spain

In recent years, the use and demand for indium in technology industries around the world has increased dramatically. This metal is a Technology Critical Element, TCE, widely used in the production of Indium Oxide (In₂O₃) and ITO (Indium Tin Oxide) for the manufacture of electronic devices such as electrically conductive transparent thin films in LCD's displays and photovoltaic cells. These materials, sooner or later, will reach the different environmental compartments, like freshwaters, but their behaviour and fate is not yet sufficiently known. Therefore, it is timely to study the dissolution process of In₂O₃ nanoparticles, in order to understand the release of free indium into the environment. This can be suitably achieved by using the electroanalytical technique AGNES (Absence of Gradients and Nernstian Equilibrium Stripping). AGNES has been developed to determine the free concentration of metals such as Zn, Cd, Pb, Sn or In in aqueous samples. In the case of nanoparticles, there is no need of any previous separation from their dispersions. The general protocols for working with indium, such as the determination of the preconcentration factor or gain by calibration, have been developed in recent works. In addition, the use of the rotating disk electrode effectively reduces the required metal deposition times. Solutions of KNO₃ at different pH values and synthetic seawater (at pH 8.0) were prepared and put in contact with In₂O₃ nanoparticles and bulk In₂O₃ for months maintaining constant temperature and agitation. AGNES provided the dissolution curves, from whose final equilibrium concentrations the values of the solubility constants of these materials can be obtained. *Acknowledgement* - Support from the Spanish Ministry of Science and Innovation (Project PID2019-107033GB funded by MCIN/AEI/10.13039/501100011033) and from FISDUR-Generalitat de Catalunya (KRS).

3.19.P-We141 Influence of Organic, Inorganic and Absence of Phosphate on the Toxicity of Lanthanum and Gadolinium to *R. Subcapitata*

Marion Revel¹, Chantal Kimberley Eline van Drimmelen², Andrew Hursthouse³ and Susanne Heise⁴, (1)Hamburg University of Applied Sciences (HAW Hamburg), Germany, (2)HAW Hamburg, Germany, (3)University of the West of Scotland, United Kingdom, (4)Hamburg University of Applied Sciences, Hamburg, Germany

Lanthanides (Ln) are a group of 15 metals, ranging from lanthanum to lutetium. These elements are widely used because of their unique properties in modern technologies such as for electric cars, batteries, lasers, and smartphones. This has led to an increased risk for the environment. Lanthanides are now considered as emergent pollutants and studies of their impact on ecosystems has become an urgent issue. However, Ln toxicity experiments remain complicated due to the potential precipitation or complexation of these metals. This attributes to a strong affinity with several ligands such as phosphate. Phosphate is an essential element for algal growth and can easily interact with Ln. In the current study the impact of phosphate on La and Gd toxicity on the freshwater microalgae *Raphidocelis subcapitata* has been assessed. Four different test media were compared; (i) DIN media from the international guideline ISO (2012) containing inorganic phosphate, and two modified DIN media where phosphate was replaced with two different organic phosphates: (ii) glucose-1 phosphate (DIN-G1P) and (iii) cyclic adenosine monophosphate (DIN cAMP); (iv) and a fourth media without any phosphate (MHSM). *R. subcapitata* was exposed to La and Gd at five different nominal concentrations (0.01; 0.1; 1; 10 and 100 mg/L) for 72h. Growth inhibition was measured and EC50 values were compared for all media. According to first results, the presence of inorganic phosphate led to severe precipitation and complexation. For Gd, the EC50 measured for DIN was significantly lower than the EC50 measured for DIN-G1P and DIN cAMP. Notable is that the EC50 measured in the media with absence of phosphate (MHSM) was found to be lower than in the DIN media, but higher than the two media with organic phosphate (EC(DIN-G1P), EC(DIN cAMP) < EC(MHSM) < EC(DIN)). The lower toxicity of MHSM did not comply with our hypothesis, but could be explained by the incapacity of *R. subcapitata* to grow correctly in this media limiting the growth inhibition analysis. The first results also indicate that with La, toxicity seems to be significantly different to Gd. La tend to precipitate strongly which could explain why the EC50 measured were significantly higher than for Gd. More detailed toxicity and speciation results will be presented in the poster.

3.19.P-We142 The Influence of Sediment Geochemistry on Methylmercury Bioaccumulation in Coastal Invertebrates in the Minas Basin, Bay of Fundy

Molly Bradford¹, Mark Mallory² and Nelson J O'Driscoll², (1)Earth and Environmental Science, Acadia University, Canada, (2)Acadia University, Canada

Methylmercury (MeHg) is a toxic contaminant that readily bioaccumulates and biomagnifies in food webs, and negatively affects organism and ecosystem health. Impacts on ecosystem health from MeHg have been extensively studied in freshwater ecosystems however much less is known about MeHg retention and biomagnification in coastal ecosystems. Intertidal invertebrates are abundant in estuaries and are critical prey sources for migratory birds and marine fish, and thus determining the uptake of MeHg by intertidal invertebrates is essential for determining MeHg exposure in higher trophic level organisms in the food web. This research quantifies MeHg levels in invertebrates and relates bioaccumulation of MeHg to changes in sediment porewater concentrations of sulfate, dissolved organic matter, and mercury in five coastal estuarine locations in the Minas Basin, Bay of Fundy. The formation of MeHg by sulfate-reducing bacteria during the reduction of sulfate to sulfide suggests that systems with sulfate loading may have increased MeHg concentrations in sediments. However, binding of Hg with sulfide may reduce bioavailability of these complexes to methylating bacteria. Dissolved organic matter (DOM) may reduce the uptake of MeHg by invertebrates due to its size, however DOM may also increase MeHg production by acting as an energy source for methylating bacteria. To assess the effects of sediment geochemistry on MeHg bioavailability to invertebrates, organism MeHg concentrations were compared to total organic carbon (TOC), sulfur speciation, and mercury speciation in pore water and sediment. We found that bioaccumulation of MeHg in invertebrates (with a focus on *Corophium volutator*, *Ilyanassa obsoleta*, and Polychaete spp.) was not influenced by total mercury levels in sediments, or sulfate concentrations in pore water. However, a positive correlation between sediment total carbon content (measured as % Loss on Ignition) and total mercury was found. This research provides quantitative data on MeHg bioavailability in the Minas Basin which can be used to protect both ecosystem and human health. By identifying areas that are at greater risk for increased MeHg production this research sheds new insight on the health of ecosystems critical to migratory birds, coastal fisheries, and many industries in Atlantic Canada.

3.19.P-We143 Environmental Risks of Tungsten-Based Nanoparticles to Freshwater Ecosystem Using Indoor Aquatic Mesocosms

Amazigh Ouaksel¹, Andrea Carboni², Danielle Slomberg², Vladimir Vidal², Lenka Brousset³, Bernard Angeletti², Alain Thiery³, Jerome Rose⁴ and Mélanie Auffan¹, (1)CEREGE, France, (2)Aix-Marseille Université, France, (3)CNRS, Aix-Marseille Université, CNRS, IMBE, UMR 7263, Marseille, France, (4)CNRS, France

Tungsten (W) is a transition metal that has commonly been used in many industrial, and scientific, applications due to its unique physical and chemical properties (Koutsospyros *et al.*, 2006). Actual applications include the use of **tungsten nanoparticles** in different fields as wastewater treatment, hydrogen storage, biomedicine, as well as in solar cell and nuclear fusion reactors (ITER project). Due to its widespread use and its potential incidental release, the environmental exposure and hazards remains to be further understood (Strigul *et al.*, 2009). The aim of our works is to assess the environmental risk of W and WO₃ nanoparticles towards freshwater ecosystem, using indoor aquatic mesocosms which are considered as a robust experimental design to study the exposure and impact of nanomaterials. Experiments were conducted in twelve 16 L-mesocosms simulating a lentic ecosystem represented by natural picoplanktonic and picobenthic communities, one macro algae (*Chara vulgaris*, one macrophyte (*Ranunculus aquatilis*) and one benthic grazer (*Physella acuta*). A mesocosm is defined here as an enclosed and essentially self-sufficient (but not necessarily isolated) experimental environment or ecosystem with a number of interdependent system parameters. Tanks were chronically contaminated with the W and WO₃ nanoparticles during 4 weeks to reach nominal concentration of 2.5 m².L⁻¹ at the end of the experiment. The (bio)distribution and (bio)transformation were assessed by inductively coupled mass spectrometry and X-ray absorption spectroscopy. The biological impacts on the organisms were studied in term of mortality, growth and development. These results will be discussed in term of speciation-dependent biological effects of W-based nanoparticles, and trophic transfers under a realistic exposure scenario (chronic low-level additions of W, mid-term exposure).

3.19.P-We144 Platinum Partitioning and Effects in Aquatic Microcosms

AC Smit¹, Wynand Malherbe², Johannes Hendrik Erasmus³, Nicholas J Smit⁴, Sonja Zimmermann⁵, Victor Wepener⁶ and Ruan Gerber¹, (1)North-West University - Water Research Group, South Africa, (2)North-West University Potchefstroom Campus, South Africa, (3)North-West University, South Africa, (4)NorthWest University, South Africa, (5)University of Duisburg Essen, Germany, (6)North-West University - School of Biological Sciences, South Africa

Platinum is increasing in aquatic environments and therefore poses a risk to biological communities. Research studies (laboratory and field based) have indicated platinum bioavailability to biological communities is dependent on partitioning within environmental compartments. Therefore, the aim of this study was to investigate platinum partitioning and effects in semi-controlled aquatic microcosms. Microcosms were established for two months at the North-West University METSI facility. Following the establishment period, microcosms were exposed to a range of standard platinum concentrations (0.1, 1, 10, 100, and 500 µg/L) for eight weeks. Samples were collected at 48 hours, four weeks, and eight weeks. Water, sediment, macrophytes and artificial mussel samples were analysed for platinum. Platinum were quantified using an Atomic Absorption Spectrometer (AAS) and an Inductively Coupled Plasma-Mass Spectrometer (ICP-MS) to determine the different concentrations within each of the compartments. Platinum concentrations in the water column decreased over time, whereas the sediment, macrophytes and, artificial mussels (AM) showed higher initial accumulated platinum followed by a progressive decrease over time. The accumulation levels between the two macrophyte species varied, and *Frontalis* sp. had a higher accumulation level than the *Charophyta* sp. Diatom community assemblages were sampled at 48-hours (initial) and eight weeks (chronic) after exposure.

Initial samples (48 hours) indicated diatom communities showed little to no response; however, all the concentrations showed the presence of pollution tolerant taxa after the eight-week exposure. Diatom deformities were also observed at platinum levels higher than those present in the environment (500 µg/L). A total of 25 type 1 teratologies were identified from four 500 µg/L chronic exposure samples. Resulting in 1.025% of teratologies identified for the epiphytic diatom community and 1.875% of teratologies for the benthic diatom community. This teratology indicates a possible disruptive potential of increased platinum concentrations on aquatic communities. Overall, this study provided information that forms a valuable link between existing laboratory based platinum studies and various field based studies that have been implemented in South Africa. It is recommended to further investigate platinum effects in aquatic communities and to determine if teratologies seen in diatoms are found in field collected samples.

3.19.P-We145 The Use of Passive Samplers and Native Organisms to Monitor Platinum Exposure in a Freshwater Environment

Marelize Labuschagne¹, Johannes Hendrik Erasmus¹, Nicholas J Smit², Sonja Zimmermann³, Milen Nachev³, Bernd Sures³ and Victor Wepener⁴, (1)North-West University, South Africa, (2)NorthWest University, South Africa, (3)University of Duisburg Essen, Germany, (4)North-West University - School of Biological Sciences, South Africa

The artificial mussel (AM) is a passive sampling device that was originally developed for monitoring metal concentrations in the marine environment, but is also increasingly used in freshwater environments. The AM allows the determination of the dissolved, bioaccessible metal fraction in water bodies without killing organisms, as well as environments with unfavourable conditions for living bioindicators. The AM consists of a non-permeable Perspex tube, which is closed on both sides with a semi-permeable membrane. The main aim of this study was to compare the efficiency of the AM under field conditions to the Pt uptake by native organisms, and to comment on the appropriateness of the AM as an alternative to living organisms as indicators of metal exposure. Previous studies have shown that the AM accumulates Pt in a concentration dependant manner. To validate the AM in the field, the Pt accumulation of the AM was assessed together with that of freshwater clams (*Corbicula fluminalis africana*), muscle and liver tissue of three fish species; sharptooth catfish (*Clarias gariepinus*), common carp (*Cyprinus carpio*) and Mozambique tilapia (*Oreochromis mossambicus*), as well as water hyacinths (*Eichhornia crassipes*) at two sampling sites. The two impoundments studied are located in a Pt mining area in South Africa. In Olifantsnek Dam the Pt is from geogenic sources, while Bospoort Dam is located downstream from several anthropogenic activities such as intensive Pt mining and refining activities, as well as urban and industrial effluents. Results from the field exposures demonstrated that the AM is a promising tool for monitoring Pt in the freshwater environment. The AM only represents the dissolved bioavailable metal fraction and does not consider, e.g. particle bound metals, which can be taken up by living organisms via the food. Thus, it is recommended to combine active monitoring using living bioindicators together with AMs to obtain insight into the role of dissolved bioavailable metal fractions and particulate bound metals in metal exposure in aquatic ecosystems.

3.19.P-We146 Rare Earth Elements in Soil Samples Derived From Electronic Waste: Bioavailability in Soil

Martin Makombe and Vernon S Somerset, CPUT, South Africa

The dumping of waste electrical and electronic equipment (WEEE) and its recycling commonly known as “urban mining” has caused undesirable impacts on the environment. Many of these products are rich with rare earth and hazardous elements that end up in rubbish dumps and recycling centres. Harmful metals are exposed and leached into the environment. The fate of rare earth elements (REEs) through the disposal of electronic waste and urban mining into the environment has caused pollution and pose a threat to human health and the aquatic ecosystem. In this work, we report the results of several microcosm studies using conditioned soil to investigate the leaching of REEs in lab-scale experiments. The effective leaching of specific rare earth elements (La, Nd and Dy) were conducted under different experimental conditions. The effects of major variables on REE leaching were evaluated, which included lixiviant type and concentration, time, stirring speed, pH and solid to liquid ratio. The temperature was kept constant during all experiments at 23 ± 2 °C. The leaching efficiency of La, Nd and Dy was found to be significantly dependent on acid concentration and leaching time. The best leaching efficiency was obtained with 1 M HCl with a leaching time of 30 minutes, 300 rpm stirring, 50 g/L solid to liquid ratio. It was found that the leaching efficiency of 69%, 75% and 77% was achieved for La, Dy and Nd, respectively. In speciation studies, the results showed that 90% of REEs were obtained from acid-soluble fraction and residual fraction. The study is currently investigating the availability of the fractions, chemical behaviour in soil under environmental conditions, and the uptake of the REEs by biota.

3.19.P-We147 First Assessment of Rare Earth Elements Bioaccumulation in the Common Sole (*Solea solea*) Along a Continuum Between the Gironde Estuary and Its West Mud Patch (France)

Maeva Labassa¹, Jörg Schäfer², Younes HAN³, Clement Pereto², Cecile Bossy², Guillaume Bernard², Lise Latry², Nadège Bely⁴, Frédérique Pougnet², Antoine Lera², Magalie Baudrimont⁵, Pierre Labadie⁶, Bruno Deflandre² and Alexandra Coyne², (1)Université de Bordeaux, Pessac CEDEX, France, (2)Université de Bordeaux, France, (3)INERIS, France, (4)IFREMER, France, (5)Université de Bordeaux, France, (6)CNRS, France

Through their sedimentary and biogeochemical characteristics, the River-dominated Ocean MARGin (RIOMAR) systems constitute key components for the ecosystem functioning of coastal areas and are especially important for the delivery of ecosystem services to mankind. The West Gironde Mud Patch (WGMP) is a sedimentary body about 420 km² large in the Bay of Biscay supplied by the Gironde Estuary inputs. The WGMP is a key area for early life stages of many exploited marine species, especially the common sole (*Solea solea*), an emblematic specie highly dependent on this habitat. These marine species representing a strong economic interest for fisheries are increasingly exposed to emerging metallic contaminants, such as the Rare Earth Elements (REE). Growing consumption of REE has led to increasing transfer of these contaminants in the Gironde Estuary.

There is thus a real need for monitoring REE contamination in the common sole of the WGMP. This study aims to understand the spatial and temporal contamination patterns (sampling location and seasons) as well as the influence of intraspecific variations (length, weight, sex) of REE contamination in the common sole by comparing contamination between coastal and estuarine systems. The first data on REE concentrations in tissues of this species collected during two contrasting seasons at different locations in the WGMP (April and November 2021; MAGMA cruises, French Oceanographic Fleet) and in the Gironde Estuary (April 2015, April 2016 and October 2016; MOMBASAR cruises) are presented. Although data from coastal samples are still in process, our first results obtained for estuarine common sole showed the mean value of the sum of REE concentrations had a large variation range for small size/weight ($571 \pm 489 \mu\text{g}/\text{kg}$ d.w., $n=11$) corresponding to early life stages, whereas large fish had 3-fold lower values ($176 \pm 127 \mu\text{g}/\text{kg}$ d.w., $n=7$), probably attributed to weight dilution. Interestingly, three metals represent the majority of REE with Ce (40%), Nd (21%) and La (20%). This abundance corresponds to sea water composition and was previously observed in yellow eels in another French system (Loire Estuary). This study may greatly contribute to the future understanding of biogeochemical processes as a prerequisite for ecotoxicological risk assessment of emerging metals and subsequent regulations on metal exposure of marine species in the coastal domain.

3.19.P-We148 Spatiotemporal Biomonitoring of Rare Earth Elements and Yttrium Along the Norwegian Coast Using Cultivated Sugar Kelp *Saccharina latissima*

Stefania Piarulli¹, Silje Forbord¹, Tomasz Maciej Ciesielski², Juliane Riedel³, Bjørn Henrik Hansen¹, Andy Booth⁴ and Julia Farkas¹, (1)SINTEF Ocean, Norway, (2)Norwegian University of Science and Technology (NTNU), Norway, (3)Nord University, Norway, (4)Climate and Environment, SINTEF Ocean, Trondheim, Norway

The growing human population has led to an increased demand and use of raw materials including rare earth elements (the 15 lanthanoids and yttrium, REY). As technology critical elements, REY are used in a wide range of applications, including energy technology, electronics and lighting systems, metallurgical and automotive industries, and medical applications. In this study, we assessed the spatial and temporal patterns of REY in the sugar kelp *Saccharina latissima*, a key organism at ecological, economical and societal level. REY accumulation patterns were evaluated in relation to different local abiotic and biotic conditions and potential anthropogenic sources were identified. Cultivated *S. latissima* specimens were collected from 2 depths (1-2 m and 8-9 m) in 4 locations at 4 time points (from May to August) along the Norwegian coast over a germinating growth season REY concentrations were determined using ICP-MS in freeze dried samples ($n=96$), each comprising a pool of 10 specimens.

Relationships between element concentrations, algae growth (thallus length and frond width) and environmental parameters were evaluated. The results showed a high location-dependent variability in element concentrations and patterns. Specimens that were cultivated far from the freshwater riverine inputs exhibited higher growth over time, accompanied by increasing REY concentrations in function of their thallus length and frond width. Conversely, seaweeds from locations potentially affected by high fresh-water inputs reached their maximum growth earlier and exhibited different REY concentrations at different timepoints, irrespective of the dimensional growth trends. Cultivation depth did not appear to play a major role in REY concentration patterns. The results from this study provide information about spatial and temporal distribution of REY in marine environment along the Norwegian coast and elucidate the capacity of seaweeds to accumulate and sequester these potentially toxic elements from the environment.

3.19.P-We149 Sources and Fate of Metals and Metalloids in Wastewater Treatment PLANTS

Sean Comber¹, Genevieve Deviller², Graham Merrington³, Adam Peters⁴ and Iain A Wilson³, (1)Plymouth University, Plymouth, United Kingdom, (2)DERAC, France, (3)WCA Environment Limited, United Kingdom, (4)wca, United Kingdom

Sewage Treatment Plants (STPs) have been identified as significant sources of trace element emissions to aquatic environments. There is a need to gain a better understanding of the magnitude of the many sources of trace elements to STPs in order to be able to manage them in effluents if required. This study developed methods and applied them to derive an understanding of the proportions of inputs of aluminium, arsenic, cadmium, copper, nickel, molybdenum, silver, and zinc into wastewaters which are attributable to different urban sources. Furthermore, we have assessed the importance of ambient background levels of these metals/metalloids relative to anthropogenic sources in wastewaters as well as assessing the fate of metals during the wastewater treatment process. Of particular importance is to identify gaps in information and areas of uncertainty. Sources were split into domestic (mains tap water, faeces, urine and other sources including plumbing and activity related discharges), urban runoff (brake, tyre and road abrasion, exhaust emissions, oil loss and atmospheric deposition), service industry discharges, industrial emissions. Key specific sources included copper from brake lining abrasion and zinc in vehicle tyre abrasion. Significant variations were observed between countries depending on, for example, patterns of use of copper in plumbing and architecture and metals from industrial discharges tending to be more significant in eastern Europe. For many of the other elements the distribution of emissions between the sources was more evenly distributed reflecting their ubiquitous presence within the urban environment. Runoff sources were typically influenced by traffic density and degree of urbanisation. Background inputs were in most cases less than 25% of the overall contribution reflecting the current and historical use of these elements in urban environments. The removal of the elements from water within the sewage treatment process is generally efficient: cadmium, copper, zinc, aluminium and silver exhibit typically more than 70% removal to sludge for secondary treatment, with nickel and molybdenum over 50%. Only arsenic exhibited poor removal (< 10%) which may reflect a lack of data and/or the fact that it is the only element assessed that is an anion which may result in less sorption to particulates that themselves are often negatively charged. Significant uncertainty exists for many urban sources of aluminium, molybdenum, silver, and arsenic.

3.19.P-We150 The Impact of pH and Material Choice on the Toxicity of Elements

Jana Geuer, Viktor Sjöberg, Stefan Karlsson, Frederik Alexander Bussmann and Steffen Keiter, Orebro University, Sweden

Elements such as copper, zinc, cobalt and lithium can be essential for metabolic processes of many different organisms but are toxic in high concentrations. An increasing amount of modern industrial processes heavily influence the release of such elements to the environment. Mining and wastewater discharge are prominent examples of anthropogenic discharges into aquatic environments. Physico-chemical properties of the water, like temperature, pH, hardness, and conductivity control the speciation of such elements. This in turn influences their solubility, bioavailability, and consequently their toxicity. The toxic levels and effects of some elements like copper and lead to aquatic systems are quite well characterised. For other elements, such as lithium, this information is still scarce. To assess the toxicity of different elements, the zebrafish embryo toxicity test is a commonly used model. It is a very well described and widely used test systems in ecotoxicology. In addition to physico-chemical parameters, the material of the test vessel used influences element availability by affecting their adsorption to the vessel's surface. However, the interactions between the element tested and the material used to perform the fish embryo toxicity tests in have rarely been considered in the past. With this project, we want to fill some of these knowledge gaps by investigating, whether: (i) a decreasing pH impacts the toxicity of different elements and (ii) if the material used for the tests have an influence on metal availability and therefore toxicity. To address these aims, the zebrafish embryo tests using lithium, zinc, copper, and cobalt will be performed in standardised water. Afterwards, 120 hours after fertilisation, larval behaviour will be investigated. The test will be performed at pH 6 and at an unmodified pH 7.6. We will quantify the elements in the test solutions before and after performing the tests. Moreover, we will quantify their bioaccumulation in the larvae. With this data we aim at improving our understanding of element availability, their uptake, and toxicity under different test conditions and the importance of test vessel material choice.

3.19.P-We151 Accumulation and Effect of Cobalt in River Biofilms

Simon Colas¹, Mathieu Milhe-Poutingon², Benjamin MARIE³, Patrick Baldoni-andrey⁴, Amiel Boullemant⁵, Clementine Gelber⁶, Marie-Claire Lot⁴, Claude Fortin⁷ and Severine Le Faucheur¹, (1)Université de Pau et des Pays de l'Adour, France, (2)E2S-UPPA, CNRS, IPREM, Chaire Ecotox, France, (3)Muséum National d'Histoire Naturelle, France, (4)TOTALENERGIES, France, (5)Rio Tinto Aluminium Pechiney, France, (6)TOTAL ONE TECH S.E., France, (7)Institut national de la recherche scientifique (INRS), Canada

Cobalt (Co) is an essential trace element involved in several biomolecules. Over the last decade, industrial demand has led to an exponential increase of its extraction. Indeed, Co is intensively used in the energy storage technologies, such as in Co-lithium batteries found in electrical appliances and cars. An increase in dissolved Co concentrations is thus observed in aquatic environments, which might lead to negative impacts on living organisms such as river biofilms. These biofilms, at the base of the trophic network, are composed of bacteria, microalgae, fungi and microfauna. However, little is still known about Co accumulation and toxicity towards biofilms, which prevents adequate protection of freshwater environments. The objective of this study is to better understand the short- and long-term effects of Co on microalgal communities. To this end, mature biofilms were exposed to increasing concentrations of Co (0, 10^{-7} , 10^{-6} , $5 \cdot 10^{-6}$ and 10^{-5} M) for 7 days using outdoor microcosms (15 L) filled with the *Gave de Pau* water. Every day the exposure medium was sampled to analyse the concentrations of metals, cations, anions and dissolved organic carbon. Biofilms were also collected after 1, 3 and 7 days of exposure and were examined for different biological parameters. Firstly, the total and intracellular Co concentrations in biofilms were measured after an EDTA wash and acid digestion. This EDTA step allowed us distinguishing between total and intracellular content. The effect of Co will be evaluate at the subcellular levels using untargeted metabolomic analysis and the chlorophyll-a content while shift in microalgal community will be assessed using metabarcoding. In view of the first results obtained concerning the accumulation of Co by biofilms, bioaccumulated Co was mostly intracellular. Very good correlations between dissolved Co concentrations in the exposure medium and intracellular concentrations at each exposure time are observed (R^2_{adj} of 0.91, 0.95 and 0.97 respectively after 1, 3 and 7 days of exposure). The analysis of the various biological parameters could allow the characterisation of potential new biomarkers of exposure and the identification of bioindicator species within the exposed biofilms.

3.19.P-We152 Bioavailability and Colloidal Characterization of Heavy Metals and Radionuclides in Waterlogged, Contaminated Belgian Soils Via Diffusive Gradients in Thin Films

Francesc Xavier Dengra i Grau¹, Liesbeth Van Laer², Erik Smolders³ and Lieve Sweeck², (1)R&D Disposal, Belgian Nuclear Research Centre (SCK CEN), Belgium, (2)Belgian Nuclear Research Centre (SCK CEN), Belgium, (3)Katholieke Universiteit Leuven, Belgium

The "Sigmaplan" is a Belgian programme that aims to permanently flood different lands of Flanders to favour the downstream resilience against the flooding effects of climate change. Some of these areas involve the Grote Nete and the Winterbeek rivers, contaminated by heavy metals and also by radioactive materials, both naturally occurring (NORM) and coming from anthropogenic sources as a result of historical discharges from the phosphate and nuclear industries. However, the impact of this new waterlogged (anaerobic) state on the bioavailability, colloidal behavior, and fate of these elements of concern still remains unknown. This research intends to determine ex situ the labile pools of Cd, Zn, Ni, As, Pb, Cs, Ra and U in the Grote Nete and Winterbeek soils, both in oxic and anoxic conditions. To do so, we will deploy Diffusive Gradient in Thin Films (DGT) devices in both soils, under different simulated reducing conditions. This technique has recently seen large developments for concentration analysis of different elements in pore waters. We will consider DGTs piston-shaped devices containing two different commercially available binding gels (titanium oxide and styrene divinylbenzene) and one self-made gel (zirconium oxide). These binding gels will be further analysed through laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) and gamma spectrometry. We will place special attention to the challenging, low radionuclide concentrations of these soils, as well as the redox sensitive elements. We will present the results and discussion arising from this study and its influence in each element's solid-liquid distribution coefficient (K_D), which we intend to define as a radiological showcase for mixed contaminants.

3.19.P-We153 Evaluating the Protectiveness of the EQS for Zinc

*Adam Peters*¹, *Iain A Wilson*², *Dean Leverett*³, *Christopher Cooper*⁴, *Howard Winbow*⁴ and *Frank Van Assche*⁵, (1)wca, United Kingdom, (2)WCA Environment Limited, United Kingdom, (3)WCA-Environment Ltd, Faringdon, United Kingdom, (4)International Zinc Association, Belgium, (5)IZA, Belgium

Zinc is both naturally occurring and widely used within society for a variety of different purposes. The combination of these factors means that zinc is ubiquitous in surface waters and Environmental Quality Standards (EQS) have been established to regulate zinc levels in the freshwater environment in many countries. This study has evaluated the sensitivity of benthic invertebrate communities in England to zinc exposures in order to evaluate whether they are adequately protected by the EQS for zinc. The analyses considered the abundance of specific species, genera, or families of benthic macroinvertebrates in relation to bioavailable zinc exposures. The analyses focused on the most commonly recorded taxa at sites for which sufficient chemistry information was available to calculate bioavailable zinc concentrations, to maximise the amount of data that could be included in the analysis. Eight species were identified as being potentially responsive to zinc exposures, and another eight species were identified as being unresponsive to zinc exposures. Thresholds for a reduction in the abundance of several groups of zinc sensitive taxa were derived and indicate that the EQS for zinc is sufficiently protective of the abundance of these sensitive species.

3.19.P-We154 Seasonal and Spatial WATER Quality Variations in the Karst Riverine Ecosystem

*Sara Šariri*¹, *Tatjana Mijošek*¹, *Damir Vali*², *Tomislav Kralj*¹, *Zrinka Dragun*¹, *Želimira Cvetkovi*², *Zorana Kljakovi*²-*Gašpi*³, *Zuzana Redzovic*¹, *Ivana Karamati*², *Dušica Ivankovi*¹ and *Vlatka Filipovi*² *Mariji*¹, (1)Ruđer Boškovi Institute, Croatia, (2)Teaching Institute for Public Health Andrija Štampar, Croatia, (3)Institute for Medical Research and Occupational Health, Croatia

Karst rivers are characterized by complex and unpredictable variations in water quality due to the strong interaction between surface and groundwater, as well as high sensitivity to pollution. The present study aimed to evaluate the seasonal and spatial variations in physicochemical, organic (COD, TOC, DOC, mineral oils) and inorganic (total and dissolved Al, As, Ba, Ca, Cd, Co, Fe, Hg, K, Li, Mg, Mn, Mo, Na, Rb, Sb, Sr, U, V, Zn) parameters in the karst Krka River, Croatia. Although most of the Krka River watercourse is protected as a national park (NP), it is affected by improperly treated upstream wastewater discharges. The sampling was performed in four seasons of 2021 at eight sites: Krka River source (KRS, reference site), industrial wastewater from the screw factory (IWW), municipal sewage (MWW), tributaries Krpa (TKR, directly influences KRS), Orašnica (TOR, impacted by IWW), Kosovica (TKO, situated nearby gypsum factory), Butišnica (TBU, influenced by agricultural runoff) and Brljan Lake (KBL, located in the Krka NP). Water quality was more site than season dependent and, in all seasons, showed poor ecological status for IWW and moderate for MWW and TOR according to Directive on water quality status, especially for nutrients, TOC, DOC, and mineral oils. Compared to KRS, poorer values of some physicochemical water parameters were also recorded at TBU and TKO, as a result of agricultural and industrial activity, respectively. Dissolved and particulate metal(loid) forms showed comparable variations, with the highest levels at IWW, especially those used in industry (Sr, Fe, Zn, Mn, Ba, Al), but increase of many elements was also evident at MWW and TOR compared to KRS in all seasons. Seasonal variations of physicochemical water parameters were not obvious, especially at wastewater impacted sites which reflected discharge peaks. Concentrations of TOC, DOC, and mineral oils were higher during the wet season when transport from the catchment area and exchange between surface and groundwater were increased by the rainfall. However, phenol and metal(loid) levels were higher during the dry period, due to lower water levels and less effective purification processes in the river. Presented results pointed to deteriorated water quality near wastewater outlets, which also affect natural seasonal variations of the main ecological parameters. Proper purification of the wastewaters and monitoring plans are mandatory to protect this sensitive karst ecosystem.

3.19.P-We155 Cellular Mechanisms Involved in Cr(III) Uptake and Excretion : A Review

*Elsa Salles*¹, *Davide A.L. Vignati*² and *Vincent Normant*³, (1)LIEC (CNRS UMR 7360, Université de Lorraine), France, (2)CNRS, France, (3)LIEC - Université de Lorraine - CNRS, France

Chromium (Cr) exists in several oxidation states; the most common being hexavalent Cr (Cr(VI)) and trivalent Cr (Cr(III)). Various industrial activities (e.g. steel mills, tanneries) are associated with significant releases of Cr(III) or Cr(VI) into the environment. The toxicity of Cr(VI) is well established and the mechanisms involved in its cellular uptake and handling quite well documented. In particular, sulfate (SO₄²⁻) transporters import chromate (CrO₄²⁻) in prokaryotic and eukaryotic cells because of the structural homology between the two ions. Furthermore, in presence of CrO₄²⁻, bacteria and several ascomycetes express a plasma membrane protein involved in CrO₄²⁻ export from the cytoplasm to prevent Cr(VI) toxicity. The reduction of Cr(VI) is also associated with reactive oxygen species (ROS) production. The increase of ROS generates oxidative stress in cell and causes DNA and protein damage. At the opposite, Cr(III) is often considered as non-toxic despite increasing evidence to the contrary. The role of Cr(III) as an essential human micro-nutrient is also increasingly questioned. However, the understanding of the mechanisms of Cr(III) entry and action in cells remains fragmented. Several studies demonstrated a relationship between Cr(III) and Fe(III) metabolism and import. In yeast, a pretreatment with Fe(III) protected against Cr(III) toxicity, suggesting a competition between Cr(III) and Fe(III) transport in cells. This hypothesis is supported by observations in in vivo models where treatment with Cr(III) limited Fe(III) absorption. Cr(III) is also known to bind transferrin, the major iron transport protein in the blood. Finally, at physiological pH, Cr(III) precipitates and forms insoluble particles of Cr₂O₃ that can be taken up in cells by phagocytosis or endocytosis. The internalized Cr(III) may then be solubilized in lysosomes by acidification and released in cytoplasm. In this contribution, we review the mechanisms involved in Cr(III) uptake and intracellular release in various organisms. This information will provide valuable hints for an improved understanding of the toxicity mechanisms associated with the two most common oxidation states of chromium.

3.19.P-We156 Ecotoxicity of Cr (III) and Cr (VI) Mixture to Freshwater Algae

Elsa Salles¹, Antonin Ambiaud², Armand Maul³, Vincent Normant⁴, Maximilien Beuret⁵, Carole Cossu-Leguille⁵ and Davide A.L. Vignati⁶, (1)LIEC (CNRS UMR 7360, Université de Lorraine), France, (2)LIEC CNRS UMR Université de Lorraine, France, (3)Univeristy of Lorraine, France, (4)LIEC - Université de Lorraine - CNRS, France, (5)Universite de Lorraine, France, (6)CNRS, France

In the environment, Chromium (Cr) has two main redox states: Cr(VI) and Cr(III). Despite the consensus that Cr(VI) is more toxic than Cr(III), an increasing number of studies shows that both oxidation states are potentially toxic to organisms. In addition to this, Cr(VI) and Cr(III) often occur simultaneously in natural environments so that biota can be exposed to a mixture of the two forms. However, the ecotoxicity of Cr(VI) + Cr(III) mixtures is practically unknown. The present study evaluates the ecotoxicity of Cr (III)/Cr (VI) mixtures toward the model freshwater green algal *Raphidocelis subcapitata*. Algal tests were carried for individual Cr oxidation states and for their mixtures following the ISO standard 8692. Average EC₅₀ values were 0.099 ± 0.009 for Cr(VI) (n=40) and 0.059 ± 0.04 for Cr(III) (n=7). Mixture ecotoxicity was tested using binary combinations of the EC₅₀ and EC₁₀ of the two oxidation states. The corresponding experimental results were best described by a response addition model, suggesting different modes of actions for the two forms and no interactions between them. These observations agree with the known differences in the mode of action of Cr(III) and Cr(VI). Future studies should further examine the ecotoxicity of Cr(III) and Cr(VI) mixtures with real-world relative abundances in addition to the laboratory-based EC_x used for the present contribution.

3.19.P-We157 Cadmium Uptake and Its Effect on the Composition of Mineral Nutrients in Brassica Napus Grown Under Current and Future Climate Conditions

Austra Dikšaitytė¹, Jurate Zaltauskaite¹, Inesa Kniuipyte² and Romualdas Juknys¹, (1)Vytautas Magnus University, Lithuania, (2)Lithuanian Energy Institute, Lithuania

Increasing soil contamination by heavy metals is a global environmental concern as they endanger ecosystems and pose a threat to human health when entering the food chain. Of these toxic metals, cadmium (Cd) does not play any beneficial role in plants, while its toxicity in plants depends on the bioavailability of Cd in soils and the concentration of elements that can compete with Cd during plant uptake. Through competition with nutrients, Cd has a significant effect on their uptake and distribution in the plant. However, Cd-induced responses on the uptake of plant nutrients are not straightforward. The control of Cd accumulation in plants is complicated by the fact that most of the essential nutrient transporters could also facilitate Cd uptake. In this way, similarities in physicochemical properties between Cd and other cations may interfere with the uptake of the latter. The bioavailability of Cd in soil, and therefore its phytoextraction, is influenced by many environmental factors, including climate change factors, the most important of which are the increasing concentration of carbon dioxide (CO₂) in the atmosphere and temperature. Yet knowledge in regard to how these climate change-related factors interact with Cd exposure and downstream responses seems to be lacking. Therefore, the aim of this study is to elucidate if Cd affects plant uptake of essential elements from the soil in differential ways under current and future warmer climate conditions. For this purpose, we conducted the pot experiment with the rapeseed (*Brassica napus* L.) as the model plant in climate chambers under current climate (21/14 °C and 400 μmol mol⁻¹ CO₂) and future climate (25/18 °C and 800 μmol mol⁻¹ CO₂) conditions. Rapeseed is not only an important oilseed crop worldwide, but also an emerging biofuel crop and, like other *Brassica* species, has many features, like high biomass production, rapid growth rate, and ability to sequester Cd, suitable for the phytomanagement of Cd-contaminated soils. The content of Cd and mineral nutrients along with the interactions between Cd and nutrients in rapeseed were investigated. Acknowledgments: This research is funded by the European Social Fund under the No 09.3.3-LMT-K-712 “Development of Competences of Scientists, other Researchers and Students through Practical Research Activities” measure.

3.19.P-We158 An Integrated Analytical Approach Reveals the Distribution of Cadmium Uptake by Potato (*Solanum tuberosum*) Roots and the Effects on Root Viability and Plant Development

Enriqueta Antico¹, Dolores Company-Arumí¹, Katarina Vogel-Mikus², Eva Marguí¹, Monica Iglesias¹, Mercè Figueras¹ and Olga Serra³, (1)University of Girona, Spain, (2)University of Ljubljana, Slovenia, (3)Universitat de Girona, Spain

Potato (*Solanum tuberosum* L.) is the fourth most important crop in Europe and the third most important in the world, behind only rice and wheat. It is one of the main foods for humankind, consumed by more than one billion people worldwide due to its composition, gastronomic and technological versatility, as well as the low market price of tubers. Roots of potato plants develop protective tissue layers, endodermis and exodermis, which accumulate lignin (a phenolic polymer) and suberin (a fatty-acyl derived polymer) to regulate the uptake of nutrients and toxic elements [1]. Cadmium is toxic to plant cells, even at low concentrations. The roots of plants generally avoid Cd-enriched patches in soils. Shoot Cd concentrations are determined largely by Cd uptake by root, sequestration within root vacuoles, translocation into the xylem and phloem, transportation to other organs and dilution within the shoot through growth [2]. It has been described that potato is strongly affected by Cd toxicity, producing a reduction in biomass accumulation [3]. We have studied the effect of Cd in potato plants grown in hydroponic solution enriched with Cd (from 0 to 200 μM) at different exposure times. We have evaluated the effects on the shoot and root growth and their correlation with cell toxicity through vital staining of roots with propidium iodide/fluorescein diacetate, and lipid peroxidation analysis. As for metal accumulation, Cd in roots and shoots have been measured with ICP-MS after acid digestion. Other elements such as Ca, Fe, K, Mg, Cu, Mn, P, Zn, and Mo, have been included in the analysis to investigate in which extend the Cd uptake affects elemental concentration and translocation. Finally, micro-PIXE (proton induced X-ray emission) has been used to emphasize the differential distribution of metals in root sections [4]. **References** [1] Company-Arumí et al. *Phytochem Anal* 27 (2016) 326-335. 3.19.P-We159 Within Body Distribution of Metal Contaminants in Brown Trout (*Salmo trutta Fario*) and the Potential of Fish Blood As a Non-Lethal Monitoring Tool

Jules GIRAUD¹, Laurine Gouthier², Lisa JACQUIN³, Séverine JEAN⁴ and Sophia V. Hansson⁵, (1)Laboratoire écologie fonctionnelle et environnement, CNRS, Université de Toulouse, Toulouse, France, France, (2)Laboratoire écologie fonctionnelle et environnement, CNRS, Université de Toulouse, Toulouse, France; Laboratoire EDB, Université Toulouse 3 Paul Sabatier, Toulouse, France, France, (3)Laboratoire EDB, Université Toulouse 3 Paul Sabatier, Toulouse, France; Institut Universitaire de France IUF, Paris, France, France, (4)Laboratoire écologie fonctionnelle et environnement, INP, Université de Toulouse, Toulouse, France, France, (5)CNRS, CASTANET TOLOSAN Cedex, France

The use of fish as a monitoring tool of potential metal contamination in the surrounding environment is well established, and most often focus on internal tissues such as the liver and/or muscle tissues. Although successful, there are, however, clear disadvantages to this method. For example, not only does it require the sacrifice of a large number of fish but since it also requires dissection of each individual to extract the targeted tissues it can be rather time consuming. As such, there is a need to develop reliable and non-lethal methods for monitoring metal contamination loads in fish and other aquatic biota. Drawing on iCap TQ-ICP-MS-data, we explore blood as a potential (non-lethal) method to measure trace metal concentrations in brown trout (*Salmo trutta fario*) using small volumes of blood (< 0.5 mL). We also assess potential differences in contamination loads in different components of the blood (i.e. whole blood vs plasma vs red blood cells) and how these relate to each other. Finally, we also decipher the within individual distribution (i.e. blood, liver, kidney, bile, muscle and gonads) of metal contaminants (e.g. Pb, Cd, and Hg) and assess how these contamination loads relates to that of the surrounding environment (soil, sediment and biofilm). We will show that, based on initial results, even small quantities of fish blood appear to be a promising and reliable tool to monitor metal contamination in aquatic environments.

3.19.P-We160 Small Players in the Big League: Fish Parasites As Effect Indicators of Metal(Loid)S in the Marine Environment

Anja Erasmus¹, Victor Wepener¹, Sonja Zimmermann², Milen Nachev², Nicholas J Smit³ and Bernd Sures², (1)North-West University - School of Biological Sciences, South Africa, (2)University of Duisburg Essen, Germany, (3)NorthWest University, South Africa

Environmental parasitology has been used as an ecotoxicological assessment tool to determine the impact of anthropogenic activities on parasites, relating deviations to environmental health. Certain fish parasite taxa are known to accumulate metal(loid)s and to reduce the levels of toxic substances in infected hosts, thereby balancing the uptake and elimination rates more readily. In the present study, parasite taxa are considered as effect indicators, focussing on the effect of pollutants on changes in the parasite community structure of the marine fish host, *Clinus superciliosus* (Super klipfish) from various localities along the South African coast. The metazoan parasites of the selected host were sampled from four localities (two commercial harbours, west coast; and two relatively pristine localities, southeast coast). The parasite community structures of 55 klipfish were examined, and muscle and liver tissue were analysed to determine metal(loid) concentrations (As, Cd, Cu, Fe, Mn, Pb, Sn, Sb, Zn). Results from linear regression models comparing infection intensity with metal concentrations, indicate a decrease in metal(loid) concentrations with an increase in parasite load. From the redundancy analysis and general linear mixed models, helminths of the orders Acanthocephala and Cestoda associated with concentrations of As, Cu, Mn, Pb and Sn, as well as As, Cd, Cu, Fe, Mn and Zn, respectively, specifically at the two southeast coast sites. The results from the present study are supported by previous findings where concentrations of metal(loid)s measured in acanthocephalans and cestodes accumulated in a higher magnitude than its associated hosts. This is an important interdisciplinary approach, applicable to a wide range of systems but scarcely used on marine ecosystems, which can contribute to environmental monitoring programs.

3.19.P-We161 Assessment of Metal Bioconcentration in a Transboundary River: The Lower Olifants (South Africa) and Massingir Dam (Mozambique)

Artimisia MonJane-Mabuie¹, Victor Wepener² and Gordon O'Brien³, (1)North West University (Potchefstroom Campus), Potchefstroom, South Africa, (2)North-West University - School of Biological Sciences, South Africa, (3)University of Mpumalanga, South Africa

The Massingir Dam was built on the Olifants River, which is regarded as one of the most mineralized and polluted rivers in South Africa and has received considerable attention due to increased anthropogenic activities. Although the Olifants River is well studied in South Africa, there are limited studies on the exposure and effect of pollutants such as metals in the lower reaches of the river and no published studies at all on the ecotoxicological status of the Olifants River in Mozambique. The present study intends to determine the concentrations and distribution of selected metal on a spatial and temporal scale utilizing selected fishes from lower Olifants at Kruger National Park (KNP) and Massingir Dam. For this purpose, water, sediment and fish (*Oreochromis mossambicus*, *Clarias gariepinus* and *Hydrocynus vittatus*) samples were collected from three sites in the KNP (Mamba weir, Balule and Gorges) and Massingir Dam during low-flow periods of 2019 to 2020 for metals content analysis. The analysis of selected metals in different matrices of the two-sampling site revealed spatial and temporal variations and the first survey with highest bioconcentration, although the samples were collected at the same period, i.e., low flow. Zinc was the metal with highest concentration in water and fish and in Massingir Dam than KNP. For the sediment, Cr was the metal with highest concentrations. There was a clear bioaccumulative trend for Hg since it was lower in water followed by sediment, then fishes. The opposite was found for As, which was higher in water, sediment and finally fishes. All metals with the exception of Cr were higher in fishes from Massingir Dam. The sharptooth catfish, *C. gariepinus*, bioaccumulated more metals than the predatory tigerfish, *H. vittatus*, indicating that sediments are probably the main source of metals. Cadmium was the metal with lowest concentration for all samples in both surveys and sites. This study brings new, updated and important data on the metal pollution status of Olifants

River, indicating more surveys are needed in the transboundary regions to allow a better understanding of the pollution level on this system.

3.19.P-We162 Transfer of Lead From Ancient Shot Pellets to Sediments in a Mediterranean Floodplain

Claudia Santamaria Cervantes¹, Celia Laguna Mora¹, Pablo R. Camarero², Maximo Florín³, Silvia Lacorte⁴ and Rafael Mateo Soria⁵, (1)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (2)Instituto de Investigación en Recursos Cinegéticos, Spain, (3)Centro de Estudios del Agua (CREA), Spain, (4)IDAEA-CSIC, Spain, (5)IREC (CSIC- UCLM), Spain

The highest densities of lead shot pellets in sediment from Europe have been detected in waterfowl wintering areas in Mediterranean wetlands. Continued waterfowl hunting from the same hunting blinds originates high densities of shot pellets in sediment in the surrounding 250 m. Wetlands in Denmark, France and Spain show average densities of more than 100 pellets/m² in the top 20 cm of sediment. The persistence of pellets in sediment has been estimated around 30–300 years with the consequent risk of Pb poisoning, a significant cause of mortality for many waterbirds species. Lead pellets at the bottom of wetlands contaminate water and sediment due to mechanical corrosion and chemical reactions under specific conditions. In addition, contamination by other trace elements, such as mercury, antimony and arsenic, can be also associated with hunting in the past. Therefore, research that verifies levels of trace element pollution in wetlands where hunting has been practiced in the past is crucial. This study was carried out in Tablas de Daimiel National Park, a protected floodplain wetland from the Iberian Peninsula that suffered heavy hunting pressure during the late 19th and early 20th century. To determine the density of lead shot pellets (shot pellets/m²), sediment samples were taken along eight transects following the cardinal points around a historic hunting blind (Puesto del Rey). To evaluate the sediment contamination by lead and other elements, samples were collected randomly in NW and SE transects and in the vicinity of the hunting blind. Lead pellets in sediments were isolated by wet-sieving and sediment samples were acid-digested and Pb, As, Hg, Se, Sb concentration was measured by ICP-MS. Pellets in sediment ranged between total absence to a maximum of 707 pellets/m², with the highest density in the NW transect. Accordingly, sediment Pb concentrations in the NW transect were higher than in the SE transect and increased with the depth and number of pellets. Hg concentrations did not show significant differences between areas, but a slightly higher value was found close to the hunting blind. These results suggest that shot pellets can transfer lead to the surrounding sediment, creating a problem of metal pollution in wetlands that have suffered or are currently suffering a high hunting pressure.

3.19.P-We163 Photocatalytic Degradation of Rhodamine B Dye by Molybdenum-Doped ZnO Nanoparticles and Its Consequences for Danio rerio

Afshin Maleki¹, Mirco Bundschuh², Zakaria vahabzadeh³, Seyed Ali Johari⁴, Reza Rezaee¹, Behzad Shahmoradi¹, Shadi Kohzadi¹ and Nader Marzban⁵, (1)Kurdistan university of medical sciences, Iran (Islamic Republic of), (2)Swedish University of Agricultural Sciences, Sweden, (3)Kurdistan university of medical sciences, Iran, (4)University of Kurdistan, Iran, (5)Leibniz Institute of Agricultural Engineering and Bio-economy, Potsdam, Germany, Germany

The degradation of water pollutants with different photocatalysts are studied extensively in the last years, but potential impacts caused by degradation byproducts are still largely ignored. In this study Molybdenum doped Zinc oxide nanoparticles (Mo-ZnO NPs) were synthesized with the hydrothermal method and the NPs photocatalytic performance was assessed using the degradation of Rhodamine B (RhB) as proxy. Acute and sub-lethal toxicity of NPs, RhB and its (by)product were tested using *Danio rerio*. Fish were exposed for up to 4 and 15 days following OECD 203 and 204, respectively. Acute tests were done in triplicate with 21 fish in each group (i.e., with seven specimens per replicate) to determine the 96-hour median lethal concentration (LC50) of Mo-ZnO NPs, Rhodamine B and the photocatalytic degradation (by)product. The sub-lethal toxicity assessment was run with two replicates per treatment containing 10 specimen per replicate. The second test employed in total four treatments a control, a sublethal concentration of Mo-ZnO (100mg/l) or RhB (10mg/l) as well as the photocatalytic degradation (by)product diluted by 50 %. As endpoints changes in oxidative stress biomarkers such as total oxidant species (TOS), catalase activity (CAT), superoxide dismutase (SOD), glutathione content (GSH) malondialdehyde (MDA) in the liver, brain and ovary tissues were measured. The photocatalytic experiments indicated a removal efficiency of 95 % of the dye when applied at 5 mg/l together with a NPs concentration of 100 mg/l over 30 minutes under visible light. Acute tests indicated the 96 h LC50 of 482.71 + 0.56 mg/l and 23.176 + 0.147 mg/l for Mo-ZnO and RhB, respectively. For photocatalytic degradation (by)product no EC50 was calculated due to low mortality (only 1 at the highest concentration). In comparison to control group, mean CAT and GSH activity decreased but MDA which is known as a marker of oxidative stress and lipid peroxidation increased in all treatments. TOS was raised in presence of RhB and of photocatalytic degradation (by)products compared to control group while it decreased in the Mo-ZnO treatment. SOD activity was enhanced in Mo-ZnO and byproduct treatments but declined in RhB treatment. The results suggest that despite high removal efficiency of RhB by Mo-ZnO NPs, changes in oxidative stress markers induced by the (by)products did not significantly decrease compared to initial pollutant, accordingly further studies are needed for a better understanding of its ecological consequences.

3.19.P-We164 Microbiota-Mediated Transformations of Arsenic Species From Rice in Mammals

Teresa Chavez-Capilla¹, Mohana Mukherjee², Siegfried Hapfelmeier² and Adrien Mestrot², (1)University of Bern, Bern, Switzerland, (2)University of Bern, Switzerland

According to the World Health Organization, arsenic is one of the ten pollutants of major health concern, with more than 200 million people worldwide being at risk of arsenic exposure from their diet. In particular, rice accumulates up to 0.4 µg/g of arsenic, of which 85 – 90 % corresponds arsenous acid (AsIII) and arsenic acid (AsV); and the remaining to methylarsonic acid (MMAsV) and dimethylarsinic acid (DMAsV). Although all four arsenic species are classified as carcinogens by the IARC, their

specific modes of toxic action are strongly related to their metabolites once in the human body. In addition, interpopulation variability can influence arsenic metabolic products and excretion rates, which depend on human genetics and gut microbiome. Understanding the effect of gut microbial communities on arsenic biotransformations can help to prevent the adverse effects of chronic arsenic exposure in humans. This study aims to unveil the microbial-mediated transformations of AsIII, AsV, MMAsV, DMAsV from rice in the mammalian gut. Specific pathogen free (SPF) and germ free (GF) mice were fed rice-containing chow diets at varying concentrations of inorganic and organic arsenic species. After seven weeks of chronic arsenic exposure, mice were euthanized and all gut contents and key organs involved in arsenic metabolism were analysed for arsenic speciation using high performance liquid chromatography-inductively coupled plasma-mass spectrometry (HPLC-ICP-MS). Our findings show how the gut microbiome plays an important role in the methylation of arsenic from diet but also promotes the transformation of arsenic into the more toxic thiolated arsenic species. In addition, we identified differences on the specific arsenic excretion pathways in the absence and presence of gut microbiota. The results from this study provide valuable insights to effectively understand how the mammalian gut can help in mitigating the pernicious effects of dietary exposure to arsenic.

3.19.P-We165 Methylmercury Bioaccumulation in Coastal Invertebrates in the Minas Basin, Bay of Fundy

Molly Bradford¹, Mark Mallory² and Nelson J O'Driscoll², (1)Earth and Environmental Science, Acadia University, Canada, (2)Acadia University, Canada

Methylmercury (MeHg) is a neurotoxin produced in estuarine sediments that bioaccumulates and biomagnifies in ecosystems and has negative impacts on organism health. Studies on MeHg bioaccumulation in coastal invertebrates at the base of the food web in Eastern Canada are limited, and this data is necessary to determine risk for bioaccumulation in higher trophic level organisms like fish and migratory birds. Specifically, the Minas Basin in the Upper Bay of Fundy provides critical habitat for fish spawning, and is an important stopover site for over 30 species of shorebirds during their southern migration. Fourteen families of invertebrates were collected from 5 sites in the Minas Basin during summer 2021, and analysed for concentrations of MeHg and THg, and stable isotopes of ^{15}N and ^{13}C . Sites varied significantly in sediment THg (ANOVA $p < 0.001$), with mean concentrations ranging from 2.01 ng/g to 25.56 ng/g (dw). No clear relationship was seen between sediment THg and invertebrate THg or MeHg. Most invertebrate families had concentrations of MeHg below the Canadian tissue residue guideline for the protection of wildlife consumers of aquatic biota of 33 ng/g, but polychaete families (Goniadidae, Maldanidae, and Phyllodocidae) and mud snails (Nassaridae) had some individuals with MeHg levels above this guideline. Relative trophic position of invertebrates was determined using ^{15}N , and mean ^{15}N for families ranged from 6.72 (Corophiidae) to 14.14 (Goniadidae). A positive correlation was seen between MeHg levels and ^{15}N in invertebrate families, consistent with the bioaccumulative nature of MeHg in the food web.

3.20 Using measured concentrations of chemicals in environmental risk assessment: Improving the understanding of uncertainties (Poster)

3.20.P-We166 Evaluation of Component-Based Risk Metrics and Their Impact on Mixture Assessment Using 56 European WWTP Effluents As a CASE Study

Saskia Finckh¹, Liza-Marie Beckers², Wibke Busch³, Eric Carmona Martinez⁴, Martin Krauss³, Leo Posthuma⁵, Jaap Slootweg⁵, Tobias Schulze³ and Werner Brack⁶, (1)WANA, Helmholtz Center for Environmental Research - UFZ GmbH, Leipzig, Germany, (2)Federal Institute of Hydrology - BfG, Koblenz, Germany, (3)Helmholtz centre for environmental research - UFZ, Germany, (4)Helmholtz Center for Environmental Research - UFZ GmbH, Germany, (5)RIVM, Netherlands, (6)Helmholtz Centre for Environmental Research – UFZ, Germany

Chemical prioritization and mixture considerations are key elements of environmental risk assessment as a basis for effective management. While several different assessment approaches are frequently used for this purpose, systematic comparison and guidance for usage are currently lacking. Screening 56 European WWTP effluents for 499 typical water contaminants with LC-HRMS, we detected 366 pharmaceuticals, biocides, pesticides and industrial chemicals and applied three different risk metrics including the regulatory MEC/PNEC approach, an aquatic-community directed approach based on species sensitivity distributions and multi-substance potentially affected fractions (msPAF) of species and a Toxic Unit (TU) approach addressing algae, invertebrates and fish as major Biological Quality Elements. Concentrations of the detected target compounds range from less than 1 ng/L up to more than 10^5 ng/L. In agreement with regulatory requirements and precautionary principle, the MEC/PNEC provided most extensive exceedance of the threshold of concern at all sites varying from 58 to 13000fold with strong predominance of compounds with high assessment factors, thus prioritizing for uncertainty rather than for known toxicity. Although in our case none of the effluents could be evaluated as safe, MEC/PNEC can be useful as a tier-1 approach identifying samples that do not require further consideration. The higher tier approaches based on TUs and msPAF resulted in typically lower exceedances discriminating safe from non-safe effluents. WWTP effluents after ozonation or activated carbon treatment were evaluated as safe. Both higher-tier approaches prioritized primarily data-rich chemicals of known toxicity including pesticides, biocides and some pharmaceuticals. While mixture assessment can be performed as a tiered approach, a consensus approach for compound prioritization is proposed suggesting 55 compounds of concern prioritized by at least two approaches.

3.20.P-We167 Worst-Case Prioritisation Ranking of Organic Chemicals Detected in Groundwater and Surface Waters in England

David Spurgeon, Centre for Ecology & Hydrology, United Kingdom

The UK Environment Agency has been using GC-MS and LC-MS scans to semi-quantitatively measure organic substances in groundwater and surface waters. Here we present an analysis to generate a worst-case ecological hazard ranking of the detected

substances from these groundwater and surface water sample analyses. Water Framework Directive EQSs, NORMAN Network PNECs and chronic species sensitivity distribution (SSD) HC50s were collected for all chemicals measured in the two monitoring programs. These hazard values were then compared to the highest measured concentration for each chemical separately for ranking. Hazard ranks were then multiplied by the substance detection frequency ranking to calculate a detection corrected average hazard rank for each chemical measured for each analytical method, i.e. GC-MS and LC-MS in groundwater and surface water. The separate rankings in groundwater and surface water allowed comparisons of the nature of the highest ranked chemicals in each media. Pesticides present in the top 30 highest ranked chemicals included legacy pesticides (particularly in groundwater) and current use actives (particularly in surface water). Intentional monitoring of specific uses were responsible for certain substances appearing in the top 30 ranked. A number of industrial and plastics associated chemicals were ranked highly in groundwater, while more consumer goods, personal care products and pharmaceuticals were ranked highly in surface waters. The ranked lists of substances from the comparison of monitoring and hazard data for groundwater and surface water identify a set of potential priority substances that are putatively of higher risk. This list can inform on the relative importance of sources. The final ranked lists can act as a prompt to more detailed regulatory assessments and future research.

3.20.P-We168 Environmental Risk Assessment of Organic Micropollutants in Public Wastewater Treatment Plants in Flanders, Belgium

Warich Leekitratapanisan¹ and **Karel De Schampelaere²**, (1)*GhEnToxLab (Ghent University), Thailand*, (2)*Ghent University (UGent), Belgium*

The widespread occurrence of organic micropollutants (OMPs) is a growing concern due to potential adverse effects on aquatic wildlife. WWTP effluent is a major source of OMPs that have been found in the form of complex chemical mixtures. The prioritization of concerned OMPs and WWTPs is a useful approach for water quality management, which can be done by using environmental risk assessment (ERA). In this study, the ERA was performed using the Flanders Environment Agency database of measured environmental concentration (MEC) of OMPs in 38 Belgian WWTP effluents from 2000-2020. The effect data were annual average environmental quality standards (AA-EQS) and chronic species sensitivity distributions (SSD) to derive risk quotients (RQ) and multi-substance potentially affected fraction of species (msPAF), respectively. The 27 OMPs from the database included 14 pharmaceuticals, 4 personal care products, 9 herbicides, and 3 others, which had MECs ranging from 2.35 ng/L to 360 µg/L. Predicted ecological risks were mainly driven by the anti-inflammation drug diclofenac, the herbicides flufenacet and diuron, and the personal care product 4-nonylphenol. The 28 WWTP effluents were at high risk of mixture effects with the sum of RQs exceeding 10 and msPAF between 5 to more than 25%. RQs and msPAF of the herbicides dominated among these WWTP effluents. Based on this observation, we wanted to validate the prediction of the environmental risks from the database with ecotoxicity testing of real-world wastewater treatment plant effluents. WWTP effluents with high predicted risk were selected to perform whole effluent toxicity testing with freshwater green algae (*Raphidocelis subcapitata*) and cyanobacteria (*Microcystis aeruginosa*), which are sensitive test organisms to herbicides. Our study highlights the importance of using ERA for the selection of candidate compounds and toxicity test systems to focus on future effect-based monitoring campaigns.

3.20.P-We169 Analysis of Public Environmental Monitoring Datasets for the Listing and Delisting of Priority Substances

Gregory Hughes¹, **Liz Whitworth²**, **Michael Starp³** and **Jackie Atkinson⁴**, (1)*Cambridge Environmental Assessments, United Kingdom*, (2)*RSK ADAS Ltd, United Kingdom*, (3)*Elanco Animal Health, Germany*, (4)*Elanco Animal Health, UK*

The procedure for analysing public environmental monitoring data to assess the listing and delisting of substances as priority substances (PS) under the associated directive (2455/2001/EC amended by 2013/39/EU) draws on the Watch List approach (Carvalho *et al.*, 2016). This compounds a series of worst-case assumptions resulting in an unrealistic risk assessment, notably, the manner in which it (i) deals with outliers and non-detections; (ii) considers all available data to assess the current state of the environment whilst ignoring changes in policy and associated changes in product registrations/usage and their impact on environmental residues; (iv) compares a single worst case predicted no-effect concentration (PNEC) against the 95th percentile measured environmental concentration when deriving the hazard quotient ignoring associated Water Framework Directive guidance and the updated annual average (AA) and maximum acceptable concentration (MAC) environmental quality standards (EQS). This poster uses a surrogate dataset for an example compound, compiled using readily available and more recent public monitoring datasets (given the dataset used in the draft PS dossier preparation is not available owing to Member State data access restrictions). We outline key issues relating to (i) data quality and harmonisation, (ii) data processing e.g. outlier definition and dealing with non-detects, (iii) sample number for confidence in site/country exceedance results and (iv) continuity of data for assessment of trends. The method of analysis explores the implications of using the proposed methodology, for example, using the substitution approach for dealing with non-detections which is acknowledged to introduce bias/error (Helsel, 2005; 2012) instead of the Kaplan Meier, Robust Regression on Ordered Statistics and/or Maximum Likelihood Estimation (MLE) approaches, depending on the rate of left-censored data and sample size. The analysis presented demonstrates how compounding these overly precautionary assumptions may lead to an assessment of risk that will require many MS to invest precious resources monitoring for a compound that does not present a risk to their surface waterbodies. More dialogue between regulatory agencies, industry and data analysis experts is required to define an approach that makes the most of the public monitoring data available but that also acknowledges the inherent challenges when doing so.

3.20.P-We170 Evaluating Exposure Data for Reliability and Relevance: Time to Balance the Efforts in Chemical Risk Assessment?

Graham Merrington¹ and **Lisa Nowell²**, (1)*WCA Environment Limited, United Kingdom*, (2)*U.S. Geological Survey, United States*

Environmental risk assessment is routinely performed through the comparison of measured concentrations of a chemical in environmental matrices or biota with some hazard metric, often based on effects of the respective chemical on organisms tested in laboratories. The ratio of the measured environmental concentrations, or exposure, to the ‘no effect’ or ‘effect’ concentration is termed the risk quotient (or risk characterisation ratio). Clearly this simple ratio has two input parameters, but historically a great deal more effort and energy is expended in compiling data on the ‘effects’ half of the ratio than evaluating exposures. Indeed, regulatory jurisdictions across the globe responsible for performing chemical risk assessments have established prescriptive frameworks and process to assist in the evaluation of ecotoxicity data reliability and relevance. Such evaluation ensures consistency of approach in the derivation of hazard metrics, such as Water Quality Guidelines or Criteria, Environmental Quality Standards (EQS), Aquatic-Life Benchmarks, and Predicted No Effect Concentrations (PNEC). In addition, these frameworks and processes, also provide those generating ecotoxicology data with clear pathways to follow to ensure such data is useful for regulatory purposes. This presentation will outline ‘best practice’ for the evaluation of chemical exposure data reliability and relevance. This work will also be useful to the authors of chemical exposure studies, as it will address information that needs to be provided to ensure that the resulting chemical dataset will be useful in chemical exposure assessment. This work is part of a SETAC Technical Workshop; Using Environmental Concentration Exposure Datasets in Environmental Assessments: The Development of Criteria for Reporting and Evaluating Exposure Datasets (CREED), from which the full outcomes will be published in the autumn of 2022.

3.20.P-We171 Criteria for Assessing the Relevance of Exposure Datasets

Adam Peters¹ and Claus Svendsen², (1)wca, United Kingdom, (2)CEH, Wallingford, United Kingdom

This poster provides a summary of the preliminary findings of the relevancy aspects of a SETAC workshop on the development of criteria for the reporting and evaluation of exposure datasets. The workshop has been supported by the Metals Environmental Research Associations (MERA), Cefic LRI, Syngenta, ERM (Environmental Risk Management), Unilever, GSK, BASF, BAYER, Arcadis, and Concawe. The relevance of any given dataset depends intrinsically upon the purpose to which it is intended to be applied. A consequence of this is that it is necessary to define the purpose of the analysis that is to be conducted on the dataset prior to making any assessment of whether or not it is relevant. In this aspect the assessment of the reliability and relevance of exposure datasets may be somewhat different to the assessment of the reliability and relevance of environmental hazard data, such as Klimisch or CRED, that is routinely used for the derivation of environmental effects thresholds such as Predicted No Effect Concentrations or Environmental Quality Standards. The reason for this difference is because the potential scope of application appears to be somewhat broader. The assessment of the relevance of a dataset is also more closely linked to the assessment of reliability than for comparable assessments of environmental hazard data. Relevance in relation to chemical exposure data addresses the suitability of the data for the intended purpose of use. The key questions are around how the purpose for which the dataset is being applied affect the type and diversity of data that it is appropriate. This may need to consider the sampling programme design, and the spatial and temporal frequency of samples, as well as the handling of censored data and how data are summarised.

Track 4: Ecological risk assessment and human health risk assessment of chemicals, mixtures and stressors and risk mitigation strategies

4.01 Advancing the field of nano- and microplastic toxicity exposure scenarios to better support risk assessments

4.01.T-01 Behavioral and Growth Effects of Natural and Synthetic Microfibers in Two Estuarine Indicator Species

Samreen Siddiqui¹, John Dickens², Sara J. Hutton³, Emily Pederson², Stacey L Harper⁴ and Susanne M Brander, (she, her, hers)², (1)Oregon State University, United States, (2)Oregon State University, (3)Environmental and Molecular Toxicology, Oregon State University, Corvallis, OR, (4)Oregon State University, Corvallis, OR

Microfibers are increasing in environmental samples and need closer look to identify which size, shape and type can affect organisms. To identify this, we used three types of microfibers in this study from rope samples used in boats and coastal systems. To compare natural with synthetic microfibers, we used organic cotton, polyester, and polypropylene microfibers (80-150 µm in size). Early life stages of estuarine indicator species Inland Silverside (*Menidia beryllina*) and mysid shrimp (*Americamysis bahia*) (1 day pre-hatch – 4 days post hatch; 7-14 days post hatch, respectively) were exposed to these three microfibers at three concentrations (3,10,30 particles/ml) in 5-25 PSU salinity range to mimic estuarine conditions and identify climate change impacts. The cotton microfibers were not detected in silversides and mysids shrimps when looked through Zeiss microscope. Whereas both the polyester and polypropylene microfibers were detected in stomach and gut line of the silversides. When compared with behavioral variability and growth effects, cotton demonstrated least behavioral impacts and no growth effects in both the organisms. In contrast, polyester and polypropylene were identified to have a significant effect on mysid and silverside behavior as well as growth in at least one salinity. To improve our understanding, we mix microfibers with tire particles and next step is to identify its impact on organisms. This raises concerns for ecosystem health and policies required to limit the microfiber outfall in aquatic environment.

4.01.T-02 The Effect of Shape and Polymer Type on the Toxicity of Microplastics in *Daphnia magna*

Gabriël Olthof¹, Erik Hundstad², Johannes Völker³, Iurgi Salaberria⁴, Andy Booth⁵ and Martin Wagner², (1)Biology, Norwegian University of Science and Technology, Trondheim, Norway, (2)Norwegian University of Science and Technology, Norway, (3)NTNU University, Switzerland, (4)NTNU, Norway, (5)Climate and Environment, SINTEF Ocean, Trondheim, Norway

The impact of microplastics on the environment has been extensively studied in the past decade. A common criticism is that the polyethylene (PE) and polystyrene (PS) microbeads used in these studies do not reflect the secondary microplastics (fibers or fragments, other polymers) commonly found in the environment. Hence, existing literature might underestimate the impact of microplastics on the environment. This study aims at providing a comparative assessment of the toxicity of microplastics in freshwater invertebrates by investigating the reproductive effects of the different polymers and shapes on *Daphnia magna*. Daphnids were exposed for 21 d to polyamide (PA) and polyethylene terephthalate (PET) fibers and fragments. PS beads and wool fibers were used as reference material for other studies and as a natural reference, respectively. Animals were exposed to four concentrations ranging from 2 to 250 mg/L with 10 replicates for each treatment and 20 negative controls. A deviation from the standard OECD test setup was the use of plankton wheels to keep the microplastics in suspension and maintain a consistent exposure concentration. The number of neonates produced during the experiment was recorded during every water exchange (thrice a week). The reproductive toxicity of microplastics in daphnids varied with polymer type and particle shape. This shows that the common approach of using a single type of microplastic cannot sufficiently predict the impacts of microplastics in general. Furthermore, the data show that the dose metric (e.g., mass, number or volume per liter) used to present the plastic concentration can have significant impact on the results and conclusion. Lastly, the concentration of PS beads in the test medium decreased over time, demonstrating the importance of determining the actual exposure concentrations throughout the experiment.

4.01.T-03 Ecological Risk Assessment of Microplastics in the San Francisco Bay Using a Bayesian Network Relative Risk Model

Emma Sharpe¹, Skyler Elmstrom², Erika Whitney² and Wayne G. Landis¹, (1)Western Washington University, (2)Western Washington University, United States

There has been an increased interest in understanding and managing the impacts that microplastics may have on ecological systems, resulting in an increased need for a comprehensive risk assessment. The goal of this study was to conduct a spatially specific microplastic risk assessment for the San Francisco Bay. Additionally, we wanted to develop a framework that could be used for microplastic risk assessments in other regions. Microplastics are a complex, abundant contaminant and therefore require a risk assessment method that is able to consider the many variables that may impact overall risk. Using a Bayesian network relative risk model (BN-RRM), two models were produced based on likely differences in sources, transport, and toxicity: one model for tire wear particles and one model for other microplastics types. For this presentation, we will focus on the tire wear particle model. The model was parameterized with microplastic monitoring data from the San Francisco Estuary Institute and microplastic toxicity data from Oregon State University. These results can be used by regional stakeholder and decision makers to determine how concentrations of microplastics may affect important ecosystem endpoints. Desired outputs can also be selected, and the model will determine what the input must be to reach that goal. With the data that is currently available, a quantitative, spatially specific risk assessment is possible. Additionally, Bayesian networks are an excellent tool for modeling the complex and uncertain nature of microplastics in the environment. Bayesian networks can incorporate different types of data and easily be modified as new data becomes available, allowing for flexible and dynamic models to be created. Finally, we have noticed a significant lack of concentration-response data for microplastics and therefore this should be prioritized for microplastic toxicity testing.

4.01.T-04 First Steps Towards an Assessment of Plastic Risk to the Norwegian Environment (FARE)

Thomas Maes¹, Andy Booth², Amy Lusher³, Martin Wagner⁴ and Lisbet Sørensen⁵, (1)GRID-Arendal, United Kingdom, (2)Climate and Environment, SINTEF Ocean, Trondheim, Norway, (3)Norwegian Institute of Water Research, Norway, (4)Norwegian University of Science and Technology, Norway, (5)SINTEF Ocean, Norway

To understand the environmental effects of plastics it is necessary to set this within the context of risk. At its core, environmental risk is a function of the concentration of a pollutant in the environment (exposure level) and the effects that pollutant causes in organisms (hazard). To conduct a robust risk assessment of a particular pollutant it is necessary to have sufficient exposure and hazard data available. Recent studies have highlighted three critical limitations and knowledge gaps that are currently preventing risk assessment of plastic pollution in Norway and beyond, (i) an insufficient quantity of exposure and hazard data for macro- and microplastic [1], (ii) the variable quality of existing macro- and microplastic exposure and hazard data, and (iii) a lack of tools for assessing the quality. Regarding (ii) and (iii), the aim of this work was to develop and test a new toolbox specifically designed to assess the quality of existing macro- and microplastic exposure and effects data.

4.01.T-05 Bioaccumulation of Emerging Contaminants in Liver, Muscle and Plasma of Eel (*Anguilla anguilla*): Influence of Microplastics

Dyana Vitale¹, Rodrigo Alvarez-Ruiz¹, Yolanda Pico¹ and Julian Campo², (1)University of Valencia, Spain, (2)CIDE-CSIC, Spain

Emerging contaminants (ECs) are one of the most important indicators of the anthropic influence on the environment, and they have recently shown to interact with **microplastics (MPs)**, specially the pesticides, several PPCPs and a few PFASs contaminants. Several gaps remain on the accumulation and distribution of ECs in biota because only very partial data are available, as ecotoxicity studies rarely include tissue concentrations. Eels can be used as bioindicators of contamination, its **high protein and lipid content** (7-15% and 5-20% respectively in wet weight), pose a challenge for the extraction of organic pollutants, given their physiological and behavioral characteristics, which make them vulnerable and sensitive to the presence of emerging contaminants. The aim of this study is to assess the accumulation of a combination of ECs belonging to different chemical classes including pesticides, PFASs, PPCPs and MPs in visceral tissue of muscle and liver and plasma of eel (*Anguilla anguilla*). The validation of the method was carried out using **QuEChERS extraction** and a clean-up based on a new sorbent (**EMR-Lipid**) for the liver and muscle, and the solid phase extraction (**SPE**) for the plasma, and all of extracts were analyzed via **UHPLC-MS/MS**. For to evaluate the accumulation of ECs and the influence of MPs, eels were distributed into three groups:

control (B), exposed to ECs (C), and exposed to ECs and polyethylene MPs (C + M). The study was carried out during a 58 days period divided into two phases: (a) exposure phase (0-28 days), and (b) depuration phase (29-58 days). A total of 3 pesticides, 3 PFAS, and 2 PPCPs showed bioaccumulation in *eel muscle*, with bioaccumulation factors (BCFs), ranging between 1-342 L/kg, and 2 pesticides, 2 PFAS and 1PPCPs showed bioaccumulation in *liver samples*, with BCFs ranging between 1-295 L/Kg. Some ECs in plasma of *A. anguilla* have been determined, such as chlorpyrifos, chlorfenvinphos, etoricoxib, PFOA, PFOS, PFDA, PFBS, diclofenac, naproxen, triclosan e ibuprofen. The assessment of MPs influence in the bioaccumulation of organic contaminants requires deep knowledge about the sorption mechanisms of the contaminants to the different MPs in given environmental conditions. Acknowledement This work has been supported by Grant RTI2018-097158-B-C31 funded by MCIN/AEI/ 10.13039/501100011033 and by “ERDF A way of making Europe”

4.01 Advancing the field of nano,- and microplastic toxicity exposure scenarios to better support risk assessments (Virtual Only)

4.01.V-01 Developmental and EpiGenetic Toxicity of NanoPlastics Using Embryotoxicity Platforms: Human STEM Cell and Zebrafish Embryo

Jeongeun Im and Jinhee Choi, University of Seoul, Korea, South

Nanoplastics are high risk chemicals because they are small enough to pass through cell membranes as well as the chorion of fish embryos, yet our understanding of their effects on human safety and health remains in its infancy. In this study, by setting the experimental model to human embryonic stem cells (hESCs) and zebrafish embryos, a platform was established to analyze the developmental toxicity caused by nanoplastics exposure from the stem cell stage (embryoid body using hESCs, zebrafish embryo) to the embryonic stage through to the early stage of life (zebrafish from hatching to larvae). In addition, the role of DNA methylation changes in the mechanism of developmental toxicity caused by nanoplastics was studied. The cytotoxicity and pluripotency marker gene expression levels were analyzed by continuously exposing 100 nm of polystyrene nanoplastics (PSNPs) to the hESCs for 5 days. After forming the embryoid body using hESCs, PSNPs were exposed for 14 days to analyze the germline formation marker gene expression level. The zebrafish embryos were also continuously exposed from fertilization to hatching, and the oxidative stress gene expression levels were analyzed. In hatched zebrafish larvae, late developmental effects were studied by measuring malformation and locomotive behavior. At the end of exposure, DNA methylation changes due to PSNPs were screened through global DNA methylation analysis, and the results of global DNA methylation were supported by TET inhibitor assay using hESCs. The PSNPs cytotoxicity on hESCs was not observed, but germline marker gene expression in embryoid bodies was remarkably inhibited, and developmental toxicity, which was not observed in teratogenicity or survival rate in zebrafish, was shown in the locomotive behavior results. Through the results of TET inhibitor assay using hESCs, it was revealed that there is an effect of DNA methylation in the mechanism of developmental toxicity. This suggests the risk of exposure to PSNPs in the early development of life and suggests that the epigenetic effect played a role in the developmental toxicity mechanism of PSNPs.

4.01.V-02 Environmental Risk Assessment of Microplastics for Freshwater Benthic Species Using Strict Quality Criteria and Data Alignment

Paula Redondo Hasselerharm¹, Andreu Rico² and Albert Koelmans³, (1)Fundacion IMDEA Agua, Spain, (2)IMDEA Water Institute/University of Valencia, Spain, (3)Wageningen University, Netherlands

Although today we know that freshwater sediments can contain significantly higher microplastic (MP) concentrations compared to the water column, the risks of MP for benthic species have never been quantified. The aim of this study was to assess the environmental risks of MP for freshwater benthic species exposed via sediment using strict quality criteria and ecologically relevant dose metrics. An extensive literature search was first conducted to collect publications reporting measured environmental MP concentrations for freshwater sediments, as well as threshold-effect concentrations for freshwater benthic species exposed to MPs via sediment. The quality of the data was evaluated following published Quality Assurance/Quality Control Criteria (QA/QC). Effect data were rescaled to account for the polydispersity of environmental MPs, and exposure data were rescaled to the full MP size range (1 to 5000 μm). The threshold-effect concentration for each species was calculated for the toxicologically relevant dose metrics volume and surface area of bioavailable MP, assuming effect mechanisms triggered by food dilution or surface area-based particle toxicity upon translocation, respectively. After QA/QC screening and alignment of input data, species sensitivity distributions (SSDs) were constructed for both volume and area as quantitative drivers of effects using chronic no observed effect concentrations of 11 species. For both SSD, we calculated the HC₅, which is the value at which 5% of the species would be affected. Finally, the environmental risks of MP were characterized by comparing the aligned exposure and effects concentrations in a cumulative frequency distribution chart. The derived HC₅ values (95% CI) were 5.3×10^{10} ($6.1 \times 10^9 - 5.0 \times 10^{11}$) and 1.1×10^{10} ($3.0 \times 10^{11} - 5.0 \times 10^{12}$) microplastics/kg sediment dry weight, for volume and area, respectively. All minimum, mean, and maximum MP concentrations measured in freshwater sediments from 37 water bodies were lower than the HC₅ values. Our results demonstrate that after applying strict QA/QC and alignment of exposure and effect concentrations, environmental risks of MP are not likely to occur at current environmental concentrations. Future studies assessing the environmental risks of MP should consider the use of strict quality criteria for the selection of data to avoid biased results caused by poorly design studies. Moreover, aligning exposure and effect data will increase the ecological realism of the studies.

4.01.V-03 How to Investigate Additive-Related Effects From Microplastics?

Annegret Potthoff¹, Axel Müller-Köhn², Anita Jemec³ and Dana Kühnel⁴, (1)Fraunhofer IKTS, Dresden, Germany, (2)Fraunhofer Institute for Ceramic Technologies and Systems (IKTS), Germany, (3)University of Ljubljana, Biotechnical Fac., Slovenia,

(4)Helmholtz-Centre for Environmental Research- UFZ, Germany

When assessing potentially harmful ecotoxicological or toxicological effects of microplastics, researchers are in a quandary: To suit the requirements of interpretable experimental data, they wish well characterized small particles, ideally with a narrow particle size distribution and ideally doped with a well detectable element like Europium. But this scenario is far away from real plastic particles to whom people or environment might be exposed. Microplastic particles that are found in nature show a variety of sizes and shapes – and they do not only contain the polymer itself, but an unknown quantity of unidentified chemicals. Intentionally added chemicals, so-called additives include inorganic particles such as pigments or flame retardants and organic compounds acting as plasticizers or lubricants. Leaching of these unbound components may lead to an exposure of the surrounding environment and eventually cause toxic effects in environmental organisms. To cover both, a realistic testing scenario and the researcher's needs of testing well-known materials including additives, we here suggest the following approach: Based on an extrusion process, an additive loaded polymer of known composition is produced. In a second step, it is cryo-milled, and micron-scaled irregular shaped particles are formed and subjected to weathering and characterisation of additive release as well as ecotoxicity testing. This approach is applicable to both, inorganic and organic additives. To test the proposed approach, a study with Zinc oxide (ZnO) as a model additive has been conducted. Due to its promising properties, ZnO is often applied as flame retardant, heat stabilizer or inorganic pigment for example in low-density polyethylene (LDPE). In contact with water, ZnO dissolves within a short time, where the dissolution velocity increases with decreasing particle size. Moreover, it is assumed that Zinc ions are responsible for toxic effects in fish, daphnia, and others. In our study, a common amount (5 wt%) of a nanoscale ZnO (NanoTek) was homogeneously distributed in LDPE (DOW 410E). An additive-free polymer was processed in the same way. These particles are subjected to further testing with regard to changes in particle properties, the leaching behaviour of Zn depending on weathering, as well as their effects on daphnia and algae. Our results show that this approach is promising to distinguish the effects posed by microplastics and additives.

4.01.V-04 Multigenerational Study of Microplastics in *Folsomia candida*

Jin Il Kwak, Lia Kim and Prof. Youn-Joo An, Konkuk University, Korea, South

Microplastics are the widespread environmental contaminants which found on the mount Everest and in the deep sea. However, there are limited multigenerational study of microplastics though the number of research on soil ecotoxicity of microplastics have been increasing. The purpose of the present study was set to evaluate the multigenerational effects of microplastics in soil arthropods *Folsomia candida*. *F. candida* were exposed by 15.94 µm of HDPE fragments from F0 to F2 generation under maternal or continuous exposure scenario. As results, survival and reproduction rate of maternal and continuous exposed groups were not negatively affected by microplastics. Through the maternal exposure scenario, it was observed that damages in gut barrier were recovered in F1 and F2 generation. However, continuous exposure of microplastics to F2 generation caused inhibitions in adult growth and damages in digestive tract. These results indicated that *F. candida* was not tolerant to continuous exposure of microplastics. *Acknowledgement-This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT and future planning (2020R1A2B5B02001734, 2021R1C1C2012628)*

4.01.V-05 The Effect of Microplastics on the Interspecific Competition of *Daphnia*

Marcin Zebrowski¹, Ewa Babkiewicz², Aleksandra Błażejewska², Szymon Pukos², Julia Wawrzeńczak², Wojciech Wilczyński², Mirosław Ślusarczyk² and Piotr Maszczyk³, (1)Department of Hydrobiology, Uniwersytet Warszawski, Warsaw, Poland, (2)University of Warsaw, Faculty of Biology, Poland, (3)University of Warsaw Faculty of Biology, Poland

Microplastics (MP) pollution of aquatic environments is currently one of the most intensely studied issues in the field of ecology. Many studies have attempted to estimate the distribution and concentration of MP in various environments and have determined how MP affects their inhabitants. However, much less effort has been undertaken to assess the effect of MP on the inter- and intraspecific interactions between organisms, including interspecific competition in planktonic animals of the genus *Daphnia*. We assumed that the presence of MP could mitigate competition between different *Daphnia* species. To test this hypothesis, we performed 3 long-lasting (40 days) competitive experiments (i.e. each with varying population densities) in the absence (control) and the presence of different types of MP (polystyrene, high-density polyethylene and degradable polyhydroxybutyrate, each of 30 µm in diameter), at daily low algal food supplementation and 3 pairs of *Daphnia*, each pair consisting of a superior and inferior competitor respectively (*D. pulex* and *D. magna*, *D. magna* and *D. galeata* and *D. pulex* and *D. galeata*). In general, the results of our study did not support our predictions, since the negative effect of MP on the population density of competing species was similar to both superior and inferior competitors. The only exception was the effect of polyhydroxybutyrate in the case of *D. magna* and *D. pulex*, where its presence mitigated interspecific competition. This may be attributed to a greater ability of *D. magna* than *D. pulex* to benefit from the presence of additional bacterial food associated with degraded PHB.

4.01.V-06 Laboratory Tests of the Potential Effects of Plastic Leachate on Aquatic Organisms: A Literature Review

Susan B. Kane Driscoll and Konrad Kulacki, Exponent, United States

The release of chemicals from plastics is of concern due to the increasing global production of plastics and related increases in amounts of plastics waste in the environment. The potential effects of plastic additives or other weakly bound macromolecules that can leach into the aquatic environment are less well studied than physical effects of plastics on aquatic organisms. We conducted a review of the literature on the use of laboratory toxicity tests to assess the potential effects of plastic leachate on aquatic organisms. We identified, reviewed, and summarized 16 laboratory studies conducted on a variety of plastic types. Crustaceans were the most common taxonomic group tested; others included microalgae, fish, bivalves, snails, and sea urchins. Acute mortality was the most common endpoint examined; others included algal growth and photosynthesis, reproductive and

developmental effects, sublethal metabolic endpoints, and behavior. Concentrations of plastic used to prepare leachate were reported in various ways, including mass of plastics per volume (e.g., mg/L), number of particles per volume, and as area of plastic per volume (e.g., cm² plastic/L). All studies except one reported adverse toxic effects, with mass-based 48-h LC-50 (or EC-50) ranging from 5 g/L to > 250 g/L. Comparison of the results of laboratory tests to field conditions is complicated by differences in reported exposure metrics. For example, concentrations of microplastics (MP) in field-collected surface water samples are often reported as the number of particles per volume of water (e.g., number/L), the number of particles collected per surface area of water sampled by a towed net (e.g., number/m²), or less often as the mass of particles per volume of water (e.g., mg/L). Concentrations of plastics used to prepare leachates in these laboratory studies far exceeded mass-based concentrations of MP in field collected samples as reported in the literature, which contributes to the uncertainty in our understanding of whether the effects of plastic leachate observed in the laboratory are occurring or will occur in the aquatic environment.

4.01 Advancing the field of nano,- and microplastic toxicity exposure scenarios to better support risk assessments (Poster)

4.01.P-Mo198 The Capacity of MNP to Absorb Infochemicals As a Valuable Tool for Refining MNP Hazard Assessment

Matthias Schott¹, Magdalena M. Mair² and Christian Laforsch³, (1)Animal Ecology I, University of Bayreuth, Bayreuth, Germany, (2)Statistical Ecotoxicology, University of Bayreuth, Bayreuth, Germany, (3)University of Bayreuth, Germany

Micro- and nanoplastic particles are ubiquitous, their abundance is reported in all parts of the earth, in all bodies of water, all soils and in organisms. Several studies indicate effects of MNPs on organism and ecosystem level, but the modes of actions are not well understood. As most plastics are chemically inert the particle effect itself is discussed not to be the sole reason for affecting organisms. The vector effect - uptake of hazardous chemicals by MNP and the subsequent release in organisms – is also an area for debate. But models indicate that the carrying capacity of the small particles is limited and in combination of the prevalent concentrations in ecosystems, the concentrations transported by the vector effect could be negligible.

Another explanatory approach how MNP influence organisms and ecosystems is the distortion of chemical communication: infochemicals are absorbed by plastic particles and are thus removed from the system. Subtle changes in infochemical concentrations can alter or even distort the message. For example, a small change in hormonal titres can result in an up or down regulation of the biosynthesis of specific proteins; changes in neurotransmitter levels will impact cognitive and perceptive capabilities; changes in the availability of pheromones and predator cues will change an individual's reproductive success and survival probability. In the evaluation of the interaction of MNP with chemicals, the challenge is the immense variety of plastic types and their combination with sizes, shapes, ages, coatings and additives as this increases the numbers of necessary tests. For this reason we have developed an analytical high-throughput system that allows us to evaluate the degree to which MNP remove infochemicals from their surrounding medium.

We hypothesize that the degree of the adsorption depends on MNP-specific traits: For example, larger surface areas should lead to higher absorption rates and the formation of an eco-corona might affect the type of molecules that attach to the particles. To identify MNP traits associated with particularly high absorption abilities, we test various MNPs covering a large variety of MNP traits. MNPs showing high absorption capability with specific infochemicals will be tested in single species bioassays to mesocosms in further studies.

4.01.P-Mo199 Toxicity Interaction and prediction for combined toxicity of Microplastics and Heavy metals on daphnia magna

Joorim Na, Jinho Jung and Alisa LUANGRATH, Korea University, Korea, South

Biodegradable plastics have been emerged as alternatives of non biodegradable plastics, because of property for decomposition in consisted conditions such as light, temperature and microorganisms). Under natural conditions, the decomposition of biodegradable plastics is incomplete, and rather easily forms microplastics. In addition, biodegradable microplastics (BMPs) can easily adsorb more contaminants (e.g. heavy metals, additives) than conventional plastics due to their surface properties, leading more toxicity in aquatic organisms. However, positional effects in affecting the toxicity of BMPs are inadequately documented. In our study, the aim of this study was to investigate the toxic interaction between heavy metals and biodegradable plastics which were decomposed by UV in *Daphnia magna*. BMPs were manufactured by processes with and without process with UV decomposition using BP pellets, and their chronic toxicity to *D. magna* was investigated at lethal (mortality) and sublethal [oxidative stress including reactive oxygen species (ROS), total antioxidant capacity (TAC), and lipid peroxidation (LPO)] levels. As a result of this study, it is expected that microplastics were decomposed by UV will have more adverse effect on *daphnia magna* by adsorbing more heavy metals than conventional plastics (e.g. PE, PS, PET). This toxicity might be associated with the higher bioconcentration of heavy metal achieved by alteration of surface property in BMPs which was decomposed by UV condition than that by conventional microplastics. Overall, this study suggests a significant ecological risk of the toxic interaction between BMPs and heavy metals in aquatic organisms. Our results suggest that biodegradable microplastics can not apply as an alternative to conventional microplastics, and are not an absolute solution.

4.01.P-Mo200 Assessing the Impact of Polystyrene Microplastics on *X. Laevis* Using the Amphibian Metamorphosis Assay (AMA)

Maria Victoria Pablos¹, Eulalia María Beltrán², María Ángeles Jimenez³, Pilar Garcia Hortigüela¹, María Luisa De Saint-Germain¹ and Miguel Gonzalez-Doncel⁴, (1)Spanish National Institute for Agricultural and Food Research and Technology (INIA-CSIC), Spain, (2)Environment and Agronomy, INIA - National Institute for Agricultural and Food Research and Technology, Madrid, Spain, (3)The Complutense University. Faculty of Veterinary Medicine, Spain, (4)Environment and Agronomy, National Institute for Agricultural and Food Research and Technology (INIA-CSIC), Madrid, Spain

While there is no international consensus on the definition of microplastic (MP), these tiny particles are acknowledged as synthetic polymers with maximum sizes of 5 mm. Among them, polystyrene (PS) is one of the most produced. In the last years, the potential effects of MPs have become an environmental concern and are now considered as emerging contaminants. However, current data on their effects on amphibians is scarce, thus recommendations for increasing the ecotoxicological research in this topic are encouraged. For this purpose, a modified AMA test was developed to evaluate the effects of PS MPs (PMPs; $\leq 200 \mu\text{m}$) administered through the diet on *Xenopus laevis* tadpoles. Two concentrations were selected, 0.84 mg and 8.4 mg PMPs/g food, which corresponded to waterborne concentrations of about 50 (i.e. 1X) and 500 (i.e. 10X) μg PMPs/L, respectively. The 1X was considered as an environmentally relevant concentration, and the 10X a worst-case exposure scenario. The effects on tadpole development (developmental stage), apical endpoints such as whole length (WL), body weight (BW), snout to vent length (SVL), hind limb length (HLL) and histological alterations will be discussed. This work has been supported by Spanish Government Grant RTI2018-096046-B-C21 funded by the MCIN/AEI/ 10.13039/50110001103 and the ERDF.

4.01.P-Mo202 Transgenerational Toxicity of Polyethylene Microplastic Fragments Containing an Ultraviolet Stabilizer to *Daphnia magna*

Jinyoung Song¹, Changhae Kim¹, Joorim Na¹, Nüket Sivri² and Jinho Jung¹, (1)Korea University, Korea, South, (2)Istanbul University-Cerrahpasa, Turkey

Microplastics (MPs; $< 5 \text{ mm}$) are a growing concern due to their small size, wide distribution, and adverse effects. In addition, plastic additives (e.g. photostabilizer, antioxidant, and flame retardant) in MPs can cause additional toxicity to aquatic organisms. However, there are few studies on long-term effect of MPs containing chemical additives. In this study, transgenerational effects of polyethylene MP fragments ($17.35 \pm 5.50 \mu\text{m}$) containing benzophenone-23 (BP-3; $2.85 \pm 0.16\%$ w/w) ultraviolet stabilizer on *Daphnia magna* were investigated across four generations (F0 - F3 generations). Only *D. magna* in the F0 generation was exposed to MP fragments, MP/BP-3 fragments, and BP-3 leachate to identify the transgenerational effect on the F3 generation. Somatic growth (body length) of *D. magna* exposed to BP-3 leachate was recovered in the F3 generation, whereas reproduction (embryonic development and number of offspring per female) was significantly decreased ($p < 0.05$) compared with control. In addition, mortality of *D. magna* exposed to both MP and MP/BP-3 fragments was recovered in the F3 generation, but somatic growth and reproduction were significantly decreased ($p < 0.05$) compared with control. These findings confirmed the transgenerational effects of MP fragment and BP-3 additive on chronic toxicity in *D. magna* across four generations. However, there was no significant difference ($p > 0.05$) in global DNA methylation in *D. magna* among all treatment groups, requiring a gene-specific DNA methylation study to identify epigenetic transgenerational inheritance.

4.01.P-Mo203 Investigation of the Aquatic Hazard Potential of Biodegradable Plastics by Ecotoxicological Studies With Daphnids and Algae

Silja Denise Kroeger¹, Nicholas Johnson², Carolin Floeter³ and Gesine Wit⁴, (1)Hamburg University of Applied Sciences (HAW), Hamburg, Germany, (2)Hamburg University of Technology, Germany, (3)HAW Hamburg, Germany, (4)HAW Hamburg, Germany

Since 2021 single-use plastics are banned by the European Union. Therefore, the use and production of biodegradable plastics as an alternative to conventional plastics increases. Since the ecotoxicological impacts of bioplastics are still sparsely researched, bioassays of four new developed bioplastics within the project EU-Bioplastics were performed in this study. Two of the investigated materials are based on poly(lactic acid) (PLA) with a intended application as marine geomaterial and fish crates. In addition, one Poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) material applicable as fishing baits and a soft packing material based on poly(1,4-butylene succinate) (PBS) were examined. Acute and chronic leaching and contact tests with the crustacean *Daphnia magna* (OECD202; OECD211) and chronic leaching algae toxicity tests with the marine algae *Phaeodactylum tricorutum* (DIN EN ISO 10253:2006) were performed. The bioplastic concentration was maximum 50 g plastic in 1 L test medium. For chemical validation the test media were analysed by gas chromatography-mass spectroscopy (GC-MS) with regard to HOCs. In acute contact and leaching tests with *D. magna* no immobilisation was observed for PLA, PBS, and PHBV, respectively. During chronic contact tests a significant poor offspring for all materials compared to the negative control was observed. In chronic PLA leaching tests all adult daphnids died between day 7 and day 17 and no offspring was observed. GC-MS analysis of the material showed a contamination of PLA with 2-methylnaphthalene. Chronic PBS leaching tests had the highest amount of offspring with 27 neonates in 21 indicating endocrine effects. In leaching tests with *P. tricorutum* no growth inhibition was observed after 72 hours for PLA and PBS materials, respectively. For PHBV material a growth inhibition with an EC_{50} of 6.3 g plastic per L was observed. No HOC contamination of the media was detected. The results of this study showed that the tested bioplastics cause chronic but not acute toxicity to aquatic organisms. Since bioplastics remain long in the aquatic environment until degradation, the investigation of chronic effects to organisms contributes to the knowledge of bioplastic hazard potential. In addition, to bioassays chemical analysis can contribute to understand why a material cause toxic effects towards organisms, which can help producers to investigate bioplastics which are not harmful for aquatic organisms.

4.01.P-Mo205 Ecotoxicological and Biochemical Impacts of Polystyrene Single Exposure and Adsorbed to Copper on the Freshwater Microalgae *Raphidocelis subcapitata*

Mariana Rodrigues¹, Ana Marta Goncalves², Fernando J. M. Goncalves³ and Nelson Abrantes³, (1)University of Aveiro, CESAM - Centre for Environmental and Marine Studies, Portugal, (2)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Coimbra, Portugal, (3)CESAM & University of Aveiro, Portugal

The microplastics issue has become a global concern due to their variety of sources, ubiquity, isolated or combined toxicity to the environment and human health, persistence, and high densities specially in aquatic systems (i.e., freshwater systems).

Microplastics are small plastic particles (< 5 mm) that can adsorb chemical compounds from water or sediment compartments into their surface (e.g., metals, polycyclic aromatic hydrocarbons) and act as a vector of these contaminants. This issue has been more documented for marine environment, while for freshwater systems there is an immense gap in knowledge. For instance, the impacts of these micro-sized particles isolated or in combination with a chemical compound on primary producers are still scarce. Hence, the aim of the study was to evaluate the impacts of polystyrene isolated and adsorbed to copper on the freshwater microalgae *Raphidocelis subcapitata* by assessing the ecotoxicological effects on the growth and nutritional profile (i.e., fatty acids and carbohydrates abundance and composition). The bioassay includes one concentration of microplastics (0.5 p mL⁻¹) and four concentrations of copper (0.055 mg L⁻¹ – concentration below EC₁₀; 0.092 mg L⁻¹ – EC₁₀; 0.155 mg L⁻¹ – EC₂₀; and 0.378 mg L⁻¹ – EC₅₀). All the chosen concentrations are environmentally relevant and these EC_x values were determined in a previous study. Preliminary results suggested that the microplastic and the microplastic-metal combination did not affect the microalgae growth. In fact, when exposed to polystyrene isolated, combination 1 (0.055 mg Cu L⁻¹ + 0.5 p mL⁻¹) and combination 2 (0.092 mg Cu L⁻¹ + 0.5 p mL⁻¹) the microalgae growth was stimulated. Copper isolated bioassay showed a significant growth inhibition at concentration 0.378 mg Cu L⁻¹ (EC₅₀ value). The analysis of the fatty acids and carbohydrates abundance and composition are still ongoing.

4.01.P-Mo206 Effects of High-Density Polyethylene Fragment on the Acute Toxicity on Zebrafish Adults

Yunwi Heo¹, Jin-Soo Choi², Hakwon Yoon², kanghee kim², June Woo Park² and Hyejin Kim², (1)KIT, Korea, South, (2)Korea Institute of Toxicology, Korea, South

Microplastic leads to environmental contamination and causes health problems. Many studies have investigated the toxic effects of microplastic in various organisms, but most studied sphere microplastics. However, there is limited knowledge regarding the adverse effects of microplastics, particularly on fragments. We evaluated the effects of high-density polyethylene (HDPE) fragment which has no additive and Plasticizer, exposure on toxicity and behavior in adult zebrafish. Adult zebrafish were exposed to HDPE (< 25 μm) for seven days at a concentration of 50 ppm. HDPE accumulated in the gastrointestinal organs of the zebrafish. There was no significant behavior change in the exposed group. Significant HDPE exposure effects occurred in reactive oxygen species, acetylcholinesterase (Ache), tumor necrosis factor-α (TNF-α), interleukin 1-beta activity (IL-1β). In addition, gene expression of oxidative stress (Atp13a, Cat, SOD), immune response (TNF-α, IL-1β), neurotoxicity (Ache, Th) were changed significantly. The results of this study provide important insights into the impacts of environmentally relevant (fragmented) microplastics and the molecular mechanism of microplastic-induced toxicity in zebrafish.

4.01.P-Mo207 Toxicity Assessment of Micro-Sized PE in Human Caco-2 and HT-29 Cells

Mikko Herrala¹, Marjo Huovinen², Essi Järvelä², Pauliina Tolonen², Maija Lahtela-Kakkonen² and Jaana Rysä², (1)School of Pharmacy, University of Eastern Finland, Kuopio, Finland, (2)University of Eastern Finland, Finland

Microplastics are plastic particles (size < 5 μm) which are primarily a micro-size range or results from degeneration of larger plastic pieces in the environment. Plastics are inert materials, but degeneration can change plastic properties and they can adsorb different types of hazardous substances from the environment. In addition, compounds e.g., phthalates that are used in plastic to improve their properties can be released because of degeneration. However, only little is known how microplastics and plastic associated chemicals affect the human health. Majority of the human exposure to microplastics occurs via ingestion route, and polyethylene (PE) is one of the most abundant microplastics. Therefore, the aim of our study was to evaluate the ability of micro-sized PE to cause harmful effects in human colorectal adenocarcinoma cells. Raw ultra-high molecular-weight PE (Sigma-Aldrich, particle size 40-48 μm) was used. In addition, to investigate the effects of possible dissolved compounds from plastics, extraction with ethanol as solvent was studied. Ethanol-extracted PE samples (PE-EtOH) were prepared by extracting 0.5 g raw ultra-high molecular-weight PE in 10 ml of ethanol in shaker (+37 °C) for three days. After three days, the solution was filtrated and ethanol was evaporated, leaving a PE residue in a glass test tube. PE residue was mixed with 3 ml cell culture medium (100%) and diluted to 75%, 50%, 25% and 10% solutions. In the experiments, human colorectal adenocarcinoma Caco-2 and HT-29 cells were exposed to PE (0.25-1 mg/ml) or PE-EtOH (10-100%) for 48 h. After exposure, cell viability and cytotoxicity were assessed with MTT and lactate dehydrogenase (LDH) assay. Reactive oxygen species (ROS) production was measured with DCFDA (2',7'-dichlorofluorescein diacetate) and cytoplasmic production of superoxide (O₂^{•-}) with dihydroethidium and mitochondrial O₂^{•-} production with MitoSOX. The 48 h-exposure to PE or PE-EtOH decreased cell viability and increased cytotoxicity in both cell lines. Cell viability was decreased in a dose dependent manner with both types of PE used in this study. In addition, both exposures increased ROS production, especially mitochondrial superoxide levels were elevated in all doses in both cell lines. However, effects on cytosolic superoxide production were not observed. In conclusion, micro-sized PE and PE-EtOH decreased cell viability and increased cytotoxicity and mitochondrial superoxide levels on Caco-2 and HT-29 cells.

4.01.P-Mo208 Effect of Polyethylene Microplastic Fragments and Benzophenone-3 Additive on *Daphnia magna* Population

Changhae Kim, Jinyoung Song and Jinho Jung, Korea University, Korea, South

Most of the studies reporting toxicity of microplastic (MP) and various plastic additives have focused on adverse effects within individual test organisms. However, population studies of MP exposure are necessary for a more realistic, long-term risk assessment. Therefore, population-level microcosm studies were conducted to evaluate the effect of MPs on *Daphnia magna*. In this study, groups of 10 daphnids were exposed to polyethylene MP fragments (16.68 ± 7.04 μm) containing benzophenone-3 (BP-3; 2.89 ± 0.20% w/w), pristine MP fragment, and MP fragment leachate, respectively (n = 3). The populations were grown for 60 days and observations were made every three days. Somatic growth (body length), reproduction (number of offspring), population growth (biomass, population structure), and bioconcentration of MP and BP-3 were measured.

4.01.P-Mo209 Dependence of Polystyrene Size and Color on Embryonic Zebrafish Mortality

Brittany Cunningham¹, Bryan J. Harper², Susanne M Brander, (she, her, hers)² and Stacey L Harper², (1)Toxicology, Oregon State University, Corvallis, OR, (2)Oregon State University, United States

Hundreds of millions of tonnes of plastic are produced each year, over 80% of which is estimated to end up as pollution in the environment. In response to physical, chemical, and biological weathering these plastics breakdown into and shed micro and nano particles. The ubiquity of small plastic particles in ecosystems around the globe is well documented. The toxicity of plastic pollution cannot be evaluated as a single entity, but instead encompasses a diversity of chemical compositions, colors, morphologies, additive, and sizes. It is necessary to identify which of these features may be most important for toxicity and consequently risk assessment. The existing inconsistency of nanoplastic exposure conditions (e.g. polymer type, concentration, duration, organism) in the literature makes it difficult to draw conclusions about their contributions to toxicity. Overall, the role that particle size and other plastic additives (i.e. colorants), play in overall toxicity of micro and nanoplastic particles is not well understood. Therefore, we designed experiments to investigate the impacts of plastic particle size and color on embryonic zebrafish development and survival. Spherical polystyrene (PS) was selected for these experiments because it is the most widely available nanoplastics for laboratory studies, and is one of the only nanoplastic polymers available in a range of sizes and colors. Embryonic zebrafish were exposed to PS particles of 5 different sizes between 30 nm and 5 mm (n = 8). The colors of the PS nanoplastics included three types of red, as well as orange and blue. Exposures began at 8 hours post fertilization (hpf) and lasted a total of 5 days. Embryos were evaluated daily for mortality and hatching; evaluated at 24 hpf for: mortality, developmental progression, and spontaneous movement; and again at 120 hpf for: mortality, morphological abnormalities, and touch response. Exposure to nano PS resulted in hatch delays and mortality. LC₅₀ values between 167 and 496 mg/L were calculated. Overall, the differing sizes and colors of the PS nanoplastic exposures were found to impact the toxicity, with larger and non-red particles eliciting less toxicity. This suggests that nanoplastic colorant is an important feature and may help to explain contrasting trends in the literature about the effects of nanoplastic size on toxicity.

4.01.P-Mo210 Chemicals From Environmental Aged Plastics Are Toxic to Human Cells

Bettie Cormier¹, Florane Le Bihanic¹, Emilie Dassié², Justine Receveur³, Ronan Jezequel³, Stéphane Le Floch³, Jérôme Cachot¹, Bénédicte Morin¹ and Charlotte Lefebvre⁴, (1)University of Bordeaux, France, (2)Université Bordeaux, France, (3)CEDRE, France, (4)Environnements et Paléoenvironnements Océaniques et Continentaux, F-33600 Pessac, France

Humans are exposed to microplastics via ingestion, inhalation, and dermal exposure. Scientific community is working on understanding plastic effects on humans. However, most of the scientific literature study effects of industrial pristine plastics, which can be weakly representative of the environmental exposure. Therefore, in this study we focused on the chemical effects of naturally aged environmental plastics (HDPE, PP, PVC, PA, and PET) collected on the North Atlantic French coast. Chemicals associated to these plastics were chemically extracted from the plastics using the organic solvent dimethyl sulfoxide (DMSO). Organic and metallic compounds were analysed in DMSO extracts and quantified. The human hepatocyte carcinoma cell line HepG2 was selected for its suitability to model liver toxicity including a high ability to metabolize organic contaminants, while the human epithelial colorectal adenocarcinoma cell line Caco-2 was selected to model intestinal exposure. Both cell lines were exposed to DMSO extracts to investigate the effects of chemicals on cell viability, oxidative stress induction and genotoxicity. In addition, to evaluate ER activity, a human breast cancer cell line T47D-Kbluc, stably transfected with a triplet ERE (estrogen-responsive elements)-promoter-luciferase reporter gene construct, was selected. Chemical pattern was polymer-dependent, but PVC was highly contaminated with metals, followed by PA, HDPE/PET, while PP contained low concentrations of metals. For organic compounds, PAHs were mainly found in HDPE and PP, and PVC extracts, as well as organochlorine pesticides. Toxicological assays revealed that cell viability was altered by PVC extracts for both cell-lines, while ROS production increased with PA exposure and DNA damages increased with HDPE, PVC, and PA exposure. Toxicity level is linked to chemical contamination, revealing the importance of chemicals leaching (additives and/or pollutants adsorbed). Despite the increasing literature on the omnipresence of plastics in the environment, the risk of microplastics to human health is still difficult to apprehend. The effects from chemicals (contaminants and/or additives) associated to plastics must be distinguished from other environmental contaminants. Indeed, to evaluate the risk of plastic to human health, it is necessary to quantify the exposure and settle toxicity thresholds above whom risk is significant.

4.01.P-Mo211 Screening and Quantification of Plastic Additives in One-Use Household Items and Cytotoxic Effects in A549 and HepG2 Cell Lines

Katerina Savva¹, Xavier Borrell-Diaz², Ignacio Pérez³, Marta Llorca⁴, Teresa Moreno⁵, Carlos Barata Dr⁶ and Marinella Farre⁷, (1)IDAEA CSIC, Spain, (2)IDAEA-CSIC, Spain, (3)IQAC-CSIC, Spain, (4)IDAEA, CSIC, Spain, (5)Institute of Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC), Spain, (6)CSIC, Spain, (7)IDAEA- CSIC, Spain

Bioplastics derived from renewable biomass sources offering a greener solution for plastic production. However, limited information is still available about their potential environmental impact as well as the impact of related products such as plastic additives. Prospective studies indicated that the toxicity of additives in the new bioplastics may be even at superior levels than in conventional fuel based [1]. This work describes the application of a suspect screening approach to assess the plastic additives in different one-use household items made of bioplastics and petrochemical based plastics. Samples were collected in retail stores including three bags (made of polyhydroxyalkanoates-PHA), spoons, forks, straws, drinking glasses, and plates made of polylactic acid (PLA) and a tap made of polyethylene (PE). The extraction procedure consisted of ultrasonic-assisted extraction with toluene, methanol, and acetone, separately, followed by the suspected screening analysis. The analysis was performed by liquid chromatography coupled to high-resolution mass spectrometry using a heated electrospray ionization source operated in negative and positive conditions [2]. The acquisition was performed in full-scan (FS) and data-dependent acquisition (ddMS²) mode. The

tentative identification criteria were based on mass tolerance (± 2 ppm), the retention time ($\pm 2.5\%$ min), isotopic fit ($>90\%$), fragmentation and mass peak resolution and response [3]. The FS-ddMS² spectra were processed with Compound Discoverer 3.1 to obtain a list of candidates that was further filtered to level 2 matching the experimental fragmentation spectra and comparing them with theoretical patterns. Finally, identification at level 1 was possible for some compounds by means of pure standards confirmation. Cytotoxicity was individually estimated in vitro for MPLs in alveolar cell lines A549 with commonly used petrochemical polymers (PE, PS and PET) and biodegradable polymers PLA and PHB, and in liver cell lines HepG2 for the plastic additives extracted from straw (PLA), tap (PE) and a mix of additives of thirty-eight compounds obtained from available standards. Cells were exposed during 48h ranging from 1 mg/kg to 6.25 μ g/kg (from 100 μ L to 6.25 μ L for straw and tap extracts). The cell viability and the oxidative stress evaluating the Reactive Oxygen Species (ROS) effect were estimated. The first results confirm that the high quantities of plastic additives used in bioplastics to improve the performance of these materials could constitute an important environmental problem. In vitro assays confirmed the ROS effect and cell viability was more impacted by PLA than by common petrochemical plastics in A549 cells lines.

4.01.P-Mo212 Evaluating Direct and Indirect Effects of Nanoplastic Particles on *Daphnia magna* Under Environmental Conditions Using Artificial Wetland Mesocosms

Pierina I. Rivas-Comerlati¹, Franca Ståbile², Lars-Anders Hansson³, W. G. Chalani U. Soorasena³, Temitope Nwachukwu⁴, Julian Gallego-Urrea⁴ and Mikael T. Ekvall³, (1)Aquatic Ecology, Lund University, Lund, Sweden, (2)Department of Biology, Lund University, Lund, Sweden, (3)Lund University, Sweden, (4)University of Gothenburg, Sweden

Plastics pollution is increasing every year in aquatic ecosystems and with it, an ever-increasing number of micro- and nano-sized plastic particles. It has been shown that these particles find their way into the food-chain after being consumed by organisms at lower trophic levels, such as the zooplankton *Daphnia magna*. Previous studies have shown negative effects of nanoplastic particles (NPPs) on reproduction, development, and survival of *D. magna*. However, most studies have only evaluated the effects under small scale laboratory conditions and have not considered them under natural conditions, where different particle interactions may change their toxicity. For this, a mesocosm approach was used to evaluate the effects of NPPs on the behavioral responses and population dynamics of *D. magna*, as well as possible indirect effects through the food source (phytoplankton biomass). *D. magna* individuals were exposed to negatively charged polystyrene (PS) nanoparticles of 88 nm made with a gold core, at a concentration of 0.2 mg/l of PS, for a chronic exposure of 10 weeks under environmental conditions in artificial wetland mesocosms. The swimming behavior was evaluated as the immediate response to ultraviolet (UV) radiation exposure using a three-dimensional tracking method with an *in-vivo* labelling technique. The population dynamics were evaluated through a standardized sampling method from the 5th week of exposure. Lastly, the phytoplankton biomass was measured once a week from the 7th week of exposure. No direct effects from the exposure to NPPs were found on the behavioral responses and population dynamics of *D. magna*. Nonetheless, a trend was observed in the behavior where individuals treated with NPPs seemed to swim shallower during the UV exposure compared to non-treated individuals, resulting also in a reduced refuge demand. As well, the algae biomass was significantly reduced in the treated mesocosms in the last week of exposure compared to the controls. This could potentially lead to a possible indirect effect on *D. magna* in the long run, due to unavailability of the food source. The fluctuations in particle concentration and their interaction with the ecosystem might have played an important role in the toxicity levels observed. This study shows a first glimpse of what could be the effect of NPPs in wetland ecosystems and in key species like *D. magna*.

4.01.P-Mo213 Toxic Effects of Eugenol-Functionalised Silica Particles on the Nematode *Caenorhabditis elegans*

Cristina Fuentes¹, Samuel Verdu¹, Ana Fuentes¹, Jose Manuel Barat¹ and Maria-Jose Ruiz², (1)Universitat Politècnica de València, Spain, (2)Laboratory of Toxicology, Faculty of Pharmacy, University of Valencia, Burjassot, Spain

Functionalisation of silica particles with essential oils components has emerged as a useful strategy to increase these components antimicrobial activity and to overcome some of the limitations of their application to foods, such as high volatility, low solubility or marked sensory properties. These new antimicrobial particles have been proven to be effective preservatives when added to food matrices and as filtering materials for the cold pasteurisation of beverages; however, toxicological studies must be performed to identify possible hazards of their use for human health and the environment. In this work, the nematode *Caenorhabditis elegans* was used as an *in vivo* model to evaluate the toxicological effects deriving from the exposure to different eugenol-functionalised silica particles designed as antimicrobials systems for food applications. For this purpose, the effects of the acute and long-term exposure to three silica particle types (commercial synthetic amorphous silica (SAS), mesoporous silica (MCM-41) microparticles and MCM-41 nanoparticles) at three concentrations (0.2, 1 and 5 mg/mL), either bare or functionalised with eugenol, were evaluated on different biological parameters of *C. elegans*, such as survival, reproduction, locomotion behaviour or growth. Acute exposure to the bare and EOCs-functionalised silica particles did not affect nematode survival or reduced the locomotion behaviour, but affected worms' reproductive capacity. Specifically, 24 h exposure to eugenol-functionalised MCM-41 micro and MCM-41 nano at the two highest tested concentrations reduced the number of larvae laid per worm, and all the tested concentrations for the bare and eugenol-functionalised materials significantly reduced the egg number per worm. Moreover, long-term exposure to the different bare and EOCs-functionalised silica particles caused the inhibition of both, brood size and nematode growth. The multivariate analysis showed a positive correlation between the physico-chemical properties of particle's such concentration and functionalisation yield with different reproductive toxicity parameters in *C. elegans*. Our findings give an insight of the potential toxic effects deriving from the exposure to the eugenol-functionalised silica particles and may be useful for the design of safer new materials for consumers applications. **Acknowledgement:** Spanish Government (Project RTI2018-101599-B-C21 (MCUI/AEI/FEDER, EU)), the Generalitat Valenciana (grant agreement no. ACIF/2016/139) and the *Caenorhabditis elegans* Center (CGC) funded by the NIH Office of Research Infrastructure Programs (P40 OD010440).

4.01.P-Mo214 Challenges in Developing a Standardized Risk Assessment for Micro- and Nanoplastic Particles

Magdalena M. Mair¹ and **Christian Laforsch²**, (1)Statistical Ecotoxicology, University of Bayreuth, Bayreuth, Germany, (2)University of Bayreuth, Germany

Micro- and nanoplastic particles (MNPs) are highly complex pollutants. Each particle is characterized by a unique set of traits. These traits include the polymer type that forms the particle (e.g., poly ethylene, poly styrene, etc.), a set of particle-specific characteristics (e.g., shape, size, surface structure, surface charge etc.) and a variety of traits related to plastic-associated chemicals, each of which has its own molecular structure and properties. Furthermore, most of these traits can change over time through degradation processes and weathering. An eco-corona formed on the surface of the particles may additionally alter or influence all above mentioned properties, which in turn may affect the environmental behaviour of MNPs and their interaction with organisms. This complexity makes the development of a standardized hazard assessment scheme for MNPs challenging, because neither the one-substance-one-test approach currently used in regulatory hazard assessment of chemicals, nor an approach focussing solely on polymer or particle properties can represent this complexity sufficiently.

We discuss the difficulties that MNP complexity imposes on establishing a standardised hazard assessment scheme and argue that MNP hazard assessment needs to be guided by deconstructing MNPs into their traits and identifying those traits that are associated with particularly toxic outcomes. Using a sample dataset on MNP toxicity to *Daphnia* spp., we illustrate how the identification of traits and combinations of traits as toxicity drivers can be used to inform hazard assessment. Based on these considerations, we emphasize that the identification of traits associated with toxicity is similarly essential for guiding the focus and alignment of MNP exposure, and consequently, risk assessment.

4.01.P-Mo215 Ecotoxicological Impact of Microplastic Chemical Leachates From Common Consumer Products on the Early Life Stages of Atlantic Cod (*Gadus morhua*)

Stefania Piarulli¹, **Bjørn Henrik Hansen¹**, **Lisbet Sørensen¹**, **Mari Creese¹**, **Andy Booth²**, **Tania Gomes³** and **Julia Farkas¹**, (1)SINTEF Ocean, Norway, (2)Climate and Environment, SINTEF Ocean, Trondheim, Norway, (3)Norwegian Institute for Water Research (NIVA), Norway

Synthetic polymer-based materials are omnipresent in aquatic environments, where weathering and degradation processes can lead to their progressive fragmentation and the leaching of polymer-associated chemicals. The current study assessed chemical composition and toxicity of microplastic chemical leachates on early life stages of Atlantic cod (*Gadus morhua*). Microplastic particles derived from common consumer products such as balloons (BAL), car tire rubber (CTR) and dishwashing gloves (DG) were used to produce leachate stock solutions (100 g/L) which were then diluted with seawater to 5 different leachate exposure concentrations (from the highest to the lowest: C1-C5 where C1=100% and C5=6.3%). In addition, 2 CTR-specific chemical components, benzothiazole (BT) and 6PPD-quinone (6PPD-q) (degradation product of *N*-(1,3-dimethylbutyl)-*N'*-phenyl-*p*-phenylenediamine; 6PPD), were assessed, similarly to the plastic leachates, at 5 concentrations ranging from 15 mg/L (C1) to 0.2 mg/L (C5) for BT and from 50 µg/L (C1) to 0.08 50 µg/L (C5) for 6PPD-q. Considered endpoints included survival and mortality, hatching success and developmental alterations assessed by using morphometric measurements. Non-target GC-MS analyses combined with mass spectral library matching (>80% similarity) revealed a number of organic compounds in the leachates, representing antioxidants, antimicrobials and plasticizers. CTR and DG leachates had the highest content of tentatively identified organic additives. The DG and CTR leachate exposure led to lower hatching success and increased mortality from C3 to C1 compared to BAL leachates, which did not cause any significant effect. The hatching success and survival of embryos was significantly reduced after exposure to CTR leachates and benzothiazole (C2-C1), while no significant effect was observed in 6PPD-quinone treatments. Embryonic development was impacted by exposure to CTR and 6PPD-quinone at the highest concentrations for both treatments, resulting in smaller larvae at hatch. Larvae exposed to the highest 6PPD-quinone concentration exhibited a high degree of spinal deformation (scoliosis). This study indicates that microplastic leachates can affect survival and development of sensitive life stages in cod, where different chemicals caused different effects. Further research should be directed towards mechanistic-assessment of the toxicity driving components in microplastic leachates for a better understanding of the overall impact of plastic-associated chemicals on aquatic species and to identify key polymer-associated chemicals for possible mitigation measures.

4.01.P-Mo216 Microplastics Inhibiting Sediment Reworking ACTivity and Organic Matter Processing by Tubifex tubifex Bioturbators

Mohammad Wazne¹, **Florian Mermillod-Blondin²**, **Manon Vallier²**, **Laurent SIMON²** and **Stefan Krause³**, (1)Université Claude Bernard Lyon1, France, (2)UMR 5023 LEHNA, University of Lyon 1, France, (3)University of Birmingham, United Kingdom

The impact of microplastics on bioturbation activities and biogeochemical cycles are poorly acknowledged. Therefore, in an attempt to better understand this subject, we conducted two mesocosm experiments on deposit-feeders, *Tubifex tubifex*, to investigate the effects of sediment contamination with a heterogeneous mixture of variable sizes, morphologies, colors and different polymer types of microplastic on bioturbation activity of *tubificid* worms. In the first experiment, and after twenty-one days, the sediment reworking activity of *tubifex* bioturbators exposed to microplastics was reduced by almost 4 folds and a half in comparison to worms presented in the absence of microplastic. In the second experiment, after exposing the *tubifex* worms to the same concentration of microplastics as in the first experiment (100 mg.Kg⁻¹) but for longer-duration, for seventy-seven days, the biogeochemical cycles triggered by *tubificid* worms (CO₂ fluxes and NO₃⁻ efflux) were significantly reduced. Our results indicate that adverse impacts are caused on bioturbation level which reduce both bioturbator sediment reworking activity and their role in stimulating the biogeochemical cycles at the water-sediment interface.

4.02 Antimicrobials and antimicrobial resistance under the One Health Approach (Poster)

4.02.P-Mo217 Development of an Analytical Method for the Analysis of a Variety of Antimicrobials in Horse Manure and Earthworms

*Irantzu Vergara*¹, *Erik Urionabarrenetxea*¹, *Nerea Garcia-Velasco*², *Nestor Etxebarria*¹, *Olatz Zuloaga*¹, *Maitane Olivares*¹, *Manuel Soto*³ and *Ailette Prieto*¹, (1)University of the Basque Country, Spain, (2)Centre for Experimental Marine Biology and Biotechnology (PIE-UPV/EHU), Univ. of Basque Country, Spain, (3)Plentzia Marine Station, University of the Basque Country, Spain

The massive use of antimicrobials in veterinary treatments during the last decades has raised concerns regarding the occurrence of antimicrobials in the environment and the consequent proliferation of antimicrobial-resistant genes (ARG). The application of manure and slurry coming from treated livestock as fertilizers has contributed to the accumulation of these pharmaceuticals in agricultural soils, threatening the welfare of non-target organisms. Earthworms, representing the 60-80 % of the total soil biomass, have the ability to bioaccumulate soils contaminants via ingestion of contaminated organic matter as well as by dermal route, therefore, they may be the ideal organisms for identifying antimicrobials in the food web. Although toxicity studies of classical pollutants have been performed with these organisms, there is still scarce information regarding antimicrobial accumulation and toxicity. Within this context, in this work an accurate analytical method was developed for the analysis of tetracyclines and sulfonamides antimicrobial families in horse manure and earthworms. The method consists on a QuEChERS based extraction followed by a solid-phase extraction (SPE) clean-up step, using Oasis HLB sorbent, and the analysis was performed by liquid-chromatography-triple quadrupole tandem mass spectrometry (LC-QqQ-MS/MS). For method optimization, the loading sample volume was studied in the clean-up step for both matrices, as well as the quantity of the sample to be weighted in the case of the manure. The method was validated and applied to horse manure samples and *Eisenia fetida* earthworms that had been exposed to known (0, 5, 10, 50, 100, 500, 1000 mg/kg) sulfamethazine and tetracycline concentrations by different exposure pathways and times. Furthermore, possible toxic effects of antimicrobials in earthworms were evaluated by three different OECD Standard Toxicity Tests: a filter Paper Contact test (OECD-207), an Artificial Soil test (OECD-207) and a Reproduction test (OECD-222).

4.02.P-Mo218 Antibiotic Uptake by Spinach (*Spinacia oleracea*) and Radish (*Raphanus sativus*) - Distribution Between Above- and Belowground Plant Fractions, Soil, and Soil Pore-Water

*Inna Elina Nybom*¹, *van den Broek Sarah*², *Thomas Bucheli*³, *Christa McArdell*⁴ and *Gina Garland*², (1)University of Eastern Finland, Finland, (2)ETH Zurich, Switzerland, (3)Agroscope, Switzerland, (4)Eawag, Switzerland

Antibiotics are extensively used in animal husbandry for disease treatment, illness prevention and growth promotion. The major route for excreted antibiotics and their metabolites to croplands is via the application of animal manure fertilizers. Once applied onto agricultural soils, they can be taken up by plants and accumulate into edible tissues. The extent to which this process takes place depends on the physicochemical properties of the antibiotic compounds, soil sorption potential, crop species and environmental conditions. The objectives of this study were to evaluate the uptake of five antibiotics to spinach (*Spinacia oleracea*) and radish (*Raphanus sativus*) and their distribution between roots, leaves, soil and soil pore-water. A mixture of five antibiotics from different antibiotic classes; clarithromycin (macrolide), sulfamethoxazole (sulfonamide) and the co-applied trimethoprim, chlortetracycline (tetracycline) and enrofloxacin (fluoroquinolone), were applied to the soil in four concentrations ranging from 0 mg/kg to 10 mg/kg (dry weight). Following antibiotic addition, the crops were grown for 6 weeks under controlled environmental and climatic conditions, after which they were harvested, and samples were collected for soil and pore-water analysis. Soil and soil pore-water samples were collected at three additional time points (2 days, 1 week and 3 weeks) from the start of the experiment. Delayed sprouting and reduced biomass production were observed for radishes exposed to the highest antibiotic treatment. The antibiotic analysis, to be performed, will show the uptake of antibiotics to the plants, their distribution between above- and belowground plant fractions, soil, and soil pore-water.

4.02.P-Mo219 The Differential Effect of Triclosan Concentrations on the Emergence of Resistant Bacteria

*Borja Fernández Retuerto*¹ and *Blanca Sánchez*², (1)IMDEA Water Institute, Spain, (2)IMDEA Water Institute, Alcalá de Henares, Spain

The influence of antimicrobials (antibiotics and biocides) on antibiotic resistant has been broadly studied in the clinic settings, but not in the environmental surroundings. Antimicrobials can be found in many environments at different concentrations, such as wastewater, wastewater treatment plants (WWTPs) and surface water, because of their use. The objective of this work was to study the impact of triclosan on a model bacterium mimicking what could happen on those environments, carrying out an evolution assay. Triclosan, a biocide presents in household products, such as gels, soaps or toothpaste was assessed on a bacterial model *Escherichia coli* for 28 days to different quantities, 1/10 and 1/50 of the minimal inhibitory concentration (MIC) of *E. coli* and increasing concentrations above its MIC. Triclosan susceptibility phenotype analysis showed higher levels of resistance in populations evolved in the presence of high amount of triclosan, which appear early in time and gradually increase over time. The evolved population in the presence of low amount (1/50 MIC) did not show or showed low triclosan resistant phenotype (1/10 MIC), and longer time was required to acquire resistance without subsequently further changes. In both cases, evolved population displayed little or no increase in resistance to antibiotics (cross-resistant). Despite the difference in phenotype, the acquisition of resistance had a negative effect on the growth, being in both cases lower than in the wild type. Evolved populations were sequenced looking for the mutations responsible for the phenotype, finding different mutations as a function of the selective pressure exerted. Among the mutations found, mutations in *fabI* gene, described previously as the target of triclosan, and in *emrR* gene, transcriptional repressor of multidrug efflux transporter EmrAB, were identified under supra-inhibitory concentrations. Only mutations in *emrR* gene but not in *fabI* gene were found in evolved population under low biocide pressure. The low cross-

resistance to antibiotics and the fitness cost of evolved populations suggests a specific effect of triclosan and the prospect that it may not be maintained over time without selective pressure.

4.02.P-Mo220 Is the Current Lower-Tier Threshold Concentration for Veterinary Antibiotics Sufficiently Protective for Freshwater Biofilms?

Belen Gonzalez-Gaya¹, Blanca Sánchez², Elena Buelow³ and Andreu Rico⁴, (1)ESTACIÓN MARINA DE PLENTZIA. UPV/EHU, Spain, (2)IMDEA Water Institute, Alcalá de Henares, Spain, (3)Limoges University, France, (4)IMDEA Water Institute/University of Valencia, Spain

The current regulatory framework for antibiotics assumes that concentrations below 1 µg/L are not posing a risk to aquatic biodiversity and ecosystem functioning. Recent studies demonstrate that aquatic microorganisms (fungi, bacteria, archaea) forming freshwater biofilms may have a very high sensitivity to low concentrations of antibiotics. Furthermore, some studies demonstrate that concentrations below regulated thresholds can contribute to the development of bacterial resistance. The aim of this study was to evaluate whether the exposure to a realistic environmental concentration range of an antibiotic used in aquaculture (including the 1 µg/L threshold) may impact the bacterial community structure of freshwater biofilms and whether it can contribute to the selection of bacterial resistance. An evaluation of how the bacterial community and the resistome (identified genes for antibiotic resistance) may change/recover after the cessation of exposure was also performed. For that, a microcosm experiment was conducted under laboratory conditions where biofilm structures formed for a period of 14 days in a clean river (Sorbe River, Guadalajara, Spain) were exposed to 5 treatments with different flumequine concentrations (Control, 0.1, 1, 10 and 100 µg/L). The biofilms were exposed to the antibiotic for 7 days to evaluate the effects of the antibiotic and next, the biofilms were transferred to microcosms containing a clean water medium (river water without antibiotic) and cultivated for another 7 days to assess post-exposure biofilm changes and potential recovery. The analysis to assess the antibiotic impacts on the bacterial community composition was performed by DNA extraction and sequencing. For the resistome analysis, real-time PCR analysis was performed using a primer set targeting genes conferring resistance to antibiotics, heavy metals and genes encoding mobile genetic elements associated with ARGs. Analysis of Colony Forming Units (CFUs) was performed in R2A plates without and with 2 mg/L of flumequine by scraping the biofilms before and after exposure to antibiotics and after the recovery time. All results will be put in context with the 1 µg/L threshold established by the current VMP ERA regulations and the question as to what extent such concentration threshold is protective for the bacterial structure of the biofilm and its resistome will be explored.

4.02.P-Mo221 Chemical Stress As a Silent Driver of Climate Change? Antibiotics Increase Methane Production in Freshwater Sediments

Eric Bollinger¹, Jochen Zubrod¹, Foon Yin Lai², Lutz Ahrens³, Sabine Filker⁴, Andreas Lorke¹ and Mirco Bundschuh⁵, (1)University of Koblenz-Landau, Germany, (2)Swedish University of Agricultural Sciences (SLU), Sweden, (3)Swedish University of Agricultural Sciences, Sweden, (4)University of Technology Kaiserslautern, Germany, (5)Institute for Environmental Sciences University of Koblenz-Landau, Germany

The increasing concentration of atmospheric greenhouse gases is the main driver of current and projected climate change, and therewith of serious public concern for human health and the environment. Methane (CH₄) emissions from freshwater ecosystems (wetlands and inland waters), as the largest and most uncertain source of atmospheric CH₄, are rising, leading researchers to investigate environmental factors and climate change feedbacks to explain this increase. Despite their omnipresence in freshwaters, knowledge on the impact of anthropogenic chemical stressors (e.g., antibiotics) on methanogenesis is lacking. To tackle this knowledge gap, we examined the effects of antibiotics on CH₄ production and microbial communities in natural freshwater sediments. Samples were incubated under anaerobic conditions with a five-component antibiotic mixture at four levels (from 0 to 5000 µg/L sum concentration) for 42 days. Weekly measurements of CH₄ and CO₂, as well as their compound-specific ¹³C, showed that the rate of methanogenesis was increased by up to 94% at 5000 µg/L and up to 29% at the field-relevant concentration (i.e., 50 µg/L). Metabarcoding of the prokaryotic 16S rRNA region suggested that effects of antibiotics on prokaryotic community level (i.e., species composition) may partially explain the observed differences in CH₄ production rates. Despite the intricacy of transferring experimental CH₄ production rates to field conditions, our study showed a proof-of-concept that antibiotics can have adverse effects on greenhouse gas emissions by affecting methanogenesis in polluted freshwater ecosystems.

4.02.P-Mo222 Effects of erythromycin on juvenile rainbow trout microbiome and fitness

Phillip Ankley, Jonathan Challis, John Giesy and Markus Brinkmann, University of Saskatchewan, Canada

Small concentrations of antibiotics, such as erythromycin, are typically discharged continuously in effluents of WWTP. Erythromycin, which is a broad-spectrum macrolide antibiotic, is used to treat bacterial infections and is one of the antibiotics most commonly used in both human and veterinary medicine. These discharged antibiotics and their pseudo-persistence could potentially result in negative effects on ecosystem health, including condition and health of fishes. Fish serve important functions and roles in ecosystems and can be used as integrative, sentinels of aquatic ecosystems. Gut microbiomes of fish serve significant roles in overall condition of hosts, and dysbiosis could have important implications for health of host fishes. Results of the study reported here investigated responses of the gut microbiome to exposure to dietary erythromycin using 16S rDNA amplicon sequencing and quantitative PCR (qPCR). Profiles of short-chain fatty acids (SCFAs), which have essential roles in health of fish, were measured in blood serum of exposed fish using targeted metabolomics. Erythromycin was hypothesized to decrease abundances of microbes and shift gut microbiome community composition of exposed fish, relative to that of the unexposed control individuals. Due to declines in anaerobic microbe abundance and changes in gut microbial structure, absolute and relative concentrations of serum SCFAs or changes in SCFAs profiles were also expected. This could lead to adverse effects on host fish

due to changes in energy metabolism, decreased maintenance of gut and immune homeostasis, and fluctuations in neural signaling. Results of this study provide insight into potential effects of changes in microbiome communities and overall function due to antibiotic exposure, leading to altered fitness.

4.02.P-Mo223 Occurrence of Antibiotic and Ecotoxicological Risk Assessment From Three Hydrographic Basins Receiving Urban Wastewater Effluents

Belen Gonzalez-Gaya¹, Irene Beltran de Heredia², Teresa Acosta², Nestor Etxebarria² and Estilita Ruiz Romera², (1)ESTACIÓN MARINA DE PLENTZIA. UPV/EHU, Spain, (2)University of the Basque Country, Spain

The extensive use of antibiotics in the past decades have recently raised global public health concerns due to the growing problems of antimicrobial resistance proliferation. Wastewater treatment plants (WWTP) have been identified as one of the main sources of these active pharmaceuticals to the aquatic environment, as antibiotics have been reported to not get properly degraded in the most common water treatments implemented and are thus released in the environment. In this study, the occurrence of antibiotics was evaluated in three riverine basins of the Basque Country (NE of Spain) impacted by WWTP effluents gathering urban, industrial and hospital wastewater discharges. Four sampling campaigns were carried out in November 2019, January and September 2020 and January 2021. Water samples were taken in three sampling points established upstream and downstream WWTPs discharge and in the point directly affected by wastewater effluents. In addition, an integrated 24h sample from the WWTP effluent was analyzed in every campaign. Thirty-one antibiotics were screened in the water samples after a solid phase extraction and liquid chromatography coupled to high resolution mass spectrometry analysis (LC-HRMS qOrbitrap). A total of 18 antibiotics were detected in WWTP effluents and river water, including macrolides, fluoroquinolones, beta-lactams and sulfonamides. The environmental ecological risk of pharmaceuticals was assessed based on calculated Risk Quotients (RQ) in the wastewater effluents and surface water from the concentration data found in the samples. According to our data, four antibiotics (namely azithromycin, amoxicillin, norfloxacin and ciprofloxacin) posed a high risk on the aquatic environment in the studied areas. Temporal trends and possible consequences will be evaluated according to the reported data, willing to enhance the antibiotics assessment in fresh water ecosystems. *Acknowledgement:* This work was financially supported by the Spanish Ministry of Science and Innovation through the RTI2018-093989-B-I00 project.

4.02.P-Mo224 Persistent Carbapenemase-Producing *Escherichia coli* and *Klebsiella Oxytoca* in Wastewater and Associated River

Faisal Ahmad Khan¹, Bo Söderquist² and Jana Jass³, (1)The School of Science and Technology, Örebro University, Örebro, Sweden, (2)Örebro University, Sweden, (3)School of Science and Technology, Örebro University, Örebro, Sweden

Increasing resistance to carbapenem antibiotics in *Enterobacteriaceae* is threatening the ability to treat multidrug-resistant infections. Carbapenemase-producing *Enterobacteriaceae* (CPE) are increasingly reported in healthcare settings worldwide, however, their environmental distribution and persistence are unclear. The present study aimed to characterize CPE from a wastewater treatment plant (WWTP) and the recipient aquatic environment in central Sweden during 2015-2018 and to identify potential species as persistent reservoirs of carbapenemases genes. The bacterial isolates were recovered from wastewater and downstream river water samples using chromogenic media selective for carbapenem-resistant Gram-negative bacteria, identified by MALDI-TOF and carbapenemase production was confirmed using a hydrolysis assay. The genomes of CPE were sequenced and the genetic relatedness was determined using multi-locus sequence typing, average nucleotide identity (ANI) and core-genome phylogenetics. The isolates were clustered based on their genotypic and phenotypic resistance profiles. A total of 43 CPE recovered belonged to three different species; *Escherichia coli* (n=32), *Klebsiella oxytoca* (n=8) and *Raoultella ornitholytica* (n=3), all regarded as potential human pathogens based on genetic virulence markers. The majority of CPE were isolated from wastewater (n=37), while 6 were detected from the WWTP effluent recipient river. The most prevalent carbapenemase was *bla*_{OXA-48} (*E. coli*, n=20; *R. ornitholytica* n=3), followed by *bla*_{OXA-181} (*E. coli*, n=10) and *bla*_{VIM-1} (*K. oxytoca*, n=6). The results revealed that 6 *bla*_{VIM-1}-encoding *K. oxytoca* isolates from different years were genetically identical (ANI 99-100%) and belonged to the sequence type ST172. Similarly, some *bla*_{OXA-48}-harboring *E. coli* (ST38) isolated in 2015 were genetically identical to those detected in 2017 and 2018. Since most of these CPE were recovered from wastewaters, it is concluded that they are prevalent in the community and/or are successfully adapted for survival in the wastewater system. Furthermore, successful dissemination of CPE in aquatic environments of Sweden, a country with a low clinical prevalence of antibiotic resistance is present, therefore, advanced wastewater treatment is required to further reduce the global spread of CPE.

4.02.P-Mo225 The Profiles of Antibiotic Resistance in the Groundwater of Maozhou River Basin in Shenzhen, China

Dailing Wu¹, Paul van den Brink² and Guangguo Ying³, (1)Environmental Science group, Wageningen University & Research, Wageningen, Netherlands, (2)Wageningen Environmental Research, Netherlands, (3)South China Normal University, China

Groundwater has been affected dramatically by anthropogenic activities which leads to the increase of antimicrobial resistance bacteria (ARB) and antimicrobial resistance genes (ARGs). However, to a large extent the prevalence of those in groundwater is still not clear. Here, we investigated the antimicrobial resistance in groundwater from Maozhou River basin (Shenzhen, China). *E. coli* strains were selected as the representative bacteria species due to its close relationship with the intestinal health of human and animals. In total, 78 strains of *E. coli* were isolated from the investigated region (20 strains from 10 monitoring wells and 50 strains from 10 domestic wells). Their antibiotic resistance phenotypes and genotypes were analyzed. Antimicrobial susceptibility tests were performed by using 8 different classes of antibiotics and 18 ARGs subtypes and 3 mobile genetic elements (MGEs) were detected by PCR. The results showed that 71.8% of the isolated *E. coli* were antibiotic resistant strains, with the highest resistance rates to ampicillin (66.7%), followed by tetracycline (32.1%). Six strains of *E. coli* were multidrug-resistance bacteria (MDR) which showed resistance to more than 3 antibiotics. Nine ARG subtypes (*bla*_{TEM}, *aadA*, *cfr*, *ereA*, *qnrD*, *qnrS*, *sulI*, *sul2*,

tetC) and two MGEs (*Int1* and *Int2*) were detected. About 59.2% of these isolates carried at least one of the target ARG or MGE. The most frequently detected genes were *blaTEM* (28.2%) and *qnrD* (26.9%). The results from this study indicated that the prevalence of antibiotic resistance bacteria and antibiotic resistance genes is quite high in groundwater of this region which may pose a potential health risk to local people who use the water directly.

4.02 Antimicrobials and antimicrobial resistance under the One Health Approach (Poster Corner)

4.02.PC-Mo07 One Health Perspective: A Local Study on the Spread of Antibiotic-Resistant Pathogens in Aquatic Ecosystems

*Stefania Marcheggiani*¹, *Chaimae Shaimi*² and *Laura Mancini*³, (1)Italian Institute of Health ISS, Italy, (2)La Sapienza University, Italy, (3)Istituto Superiore di Sanità, Italy

The European rules for assessing the water quality of drinking and bathing water fixed mandatory requirements for the health of consumers and bathers. And they are highly precautionary. At the same time, the assessment of surface water is based on the analysis of biological elements expressed as an ecological quality ratio. It is not included parameters for assessing risk for human health. The presence and spread of pathogens and drug-resistant strains in the environmental sector are underestimated due to the lack of a dedicated surveillance system. Even if the last represents a crucial point in their transmission route to animals and humans. This lack of information and data from the environmental sector probably means the most significant gap in controlling and preventing infectious diseases from a One Health perspective. This work's objective was to search pathogenic microorganisms, antibiotic-resistant too, of sanitary and veterinary interest in surface waters. The study area was an urban area with highly impacted aquatic ecosystems. The pathogens searched were *Escherichia coli*, *Salmonella* spp, *Yersinia* spp. and *Staphylococcus* spp in raw water sampled in three sites chosen to represent the pollution gradient. In vitro tests were performed to detect the presence or absence of resistance of bacterial strains isolated against a set of common antibiotics used to treat human and animal infections. The results have highlighted the presence of target pathogens studied in the aquatic ecosystem and the presence of multi-resistant strains. The direct and indirect reuse of contaminated surface water, such as agriculture, fishing, breeding, and recreational activities, represents an unexplored or scarcely poorly known sector where pathogens escape to the control and prevention system. In conclusion, even if it is a local study, the results represent a promising environmental contribution in implementing the prevention actions plan according to the One-health perspective.

4.02.PC-Mo08 Bioaccumulation of Antibiotics and Resistance Genes in *L. Sativa* Leaves Under Manure and Digestate Application and Their Effects on Microbial Community

*Andrea Visca*¹, *Jasmin Raused*², *Francesca Spataro*², *Gian Luigi Garbini*³, *Ludovica Rolando*³, *Paola Grenni*⁴, *Valentina Mazzurco Miritana*⁵, *Giulia Massini*⁶, *Anna Barra Caracciolo*⁷ and *Luisa Patrolecco*², (1)National Research Council-Water Research Institute, Italy, (2)Institute of Polar Science- National Research Council (ISP-CNR), Italy, (3)National Research Council of Italy, Italy, (4)National Research Council of Italy (CNR), Italy, (5)Italian National Research Council, Italy, (6)ENEA-Italian Agency for New Technologies, Italy, (7)National Research Council - Water Research Institute, Italy

The frequent practice of employing zootechnical waste (e.g. manure) for soil fertilizer can be a source of antibiotics (ABs), antibiotic resistant bacteria (ARB) and antibiotic resistance genes (ARGs), such as sulfonamides and fluoroquinolones. ABs and ARGs from agroecosystems can be accumulated in plants and eventually pass through food chain to animals and humans which feed on fresh vegetables. Sulfamethoxazole (SMX), enrofloxacin (ENR) and ciprofloxacin (CIP) are commonly used in both human and veterinary medicine, and their residues are among the most commonly antibiotics found in the environment. The detection of antibiotic residues in crops amended with organic fertilizers has received increasing attention. In a review of the incidence and uptake of several antibiotics in edible crops, Pan and Chu reported that antibiotics can be taken up by plants through water transport and passive absorption. In this context, antibiotic plant uptake from soils spiked with fixed concentrations can improve knowledge on this issue. In this work, the bioaccumulation of spiked SMX, ENR and CIP (7.5 mg/kg) and ARG occurrence in *L. sativa* leaves grown on a soil amended with manure or digestate have been investigated. Moreover, the leaf microbial community was also evaluated sequencing its 16S rRNA gene. Interestingly, CIP and ENR were found to bioaccumulate in the leaves of *L. sativa*, while SMX was not bioaccumulated (BAF < 1). Moreover, *L. sativa* leaves grown on soil amended with manure significantly bioaccumulated more antibiotics than those grown on soil amended with digestate; in line with the latter result the highest values of ARGs were also found in this condition. The most abundant genes were *sul1* and *sul2*, although SMX concentrations were the lowest ones. Interestingly, in the leaves grown on amended manure soil, a correlation between the highest abundant genes (*sul1*, *sul2* and *int11*), all antibiotics and several bacterial genera were found. Among them *Escherichia*, *Shigella*, is known for carrying ARGs and including several human pathogens species. The presence of some potential human pathogens (i.e., *Nocardia*) has also been found in digestate. The presence of antibiotic residues and ARGs in *L. sativa* leaves, raises several concern because it is consumed by humans.

4.02.PC-Mo09 An Accurate Analytical Method for the Simultaneous Determination of Tetracyclines and Sulfonamides in a Variety of Vegetable Samples

*Irantzu Vergara*¹, *Inés Baciero*¹, *Belen Gonzalez-Gaya*², *Oskar Gonzalez*¹, *Nestor Etxebarria*¹, *Maitane Olivares*¹, *Olatz Zuloaga*¹ and *Ailette Prieto*¹, (1)University of the Basque Country, Spain, (2)ESTACIÓN MARINA DE PLENTZIA. UPV/EHU, Spain

The massive use of antibiotics in cattle industry has led them to reach the food chain through the accumulation in plants and vegetables of frequent human consumption, among others. Consequently, major concern has arisen in the last decades regarding food safety and human health, not only due to the possible effects after ingestion of contaminated food products, but also since transmission of antibiotic-resistant bacteria could occur. In this work, an accurate analytical method consisting of a QuEChERS

based extraction and detection by liquid-chromatography-triple quadrupole tandem mass spectrometry (LC–QqQ-MS/MS) was developed and validated for the simultaneous analysis of four tetracyclines (TCs) and five sulfonamides (SAs) in a variety of vegetables (lettuce, onion, tomato, and carrot). In the extraction, the effect of the addition of different extraction salts (Na_2SO_4 or MgSO_4) was evaluated, concluding that using Na_2SO_4 as dehydrating agent significantly improved the recoveries for TCs and SAs in lettuce and SAs in onion, while no significant differences were noticed in the rest of the matrices. Due to the lack of selectivity of QuEChERS, dispersive-solid phase extraction (dSPE) and solid phase extractions (SPE) clean-up approaches were also evaluated, concluding that Oasis HLB based SPE provided the best overall results in terms of analyte recovery and matrix effect suppression. The evaporation step and the injection solvent were thoroughly evaluated too and were eventually fixed at evaporation to 1 mL in glass test-tubes and acetonitrile:oxalic acid (aq, $0.01 \text{ mol}\cdot\text{L}^{-1}$, pH 2) 1:1 (v/v) mixture, respectively. Calculated apparent recoveries for most of the target analytes were over 60 % with adequate precision in all the matrices ($\text{RSD} < 30 \%$), while the procedural limits of quantification (LOQ_{PRO}) values remained below $4.7 \text{ }\mu\text{g}\cdot\text{Kg}^{-1}$ for TCs in all vegetables, except for lettuce (up to $12.8 \text{ }\mu\text{g}\cdot\text{Kg}^{-1}$), and $3.0 \text{ }\mu\text{g}\cdot\text{Kg}^{-1}$ for SAs in exception of SDZ ($8.0\text{-}9.4 \text{ }\mu\text{g}\cdot\text{Kg}^{-1}$). Finally, the method was applied to lettuce, onion, tomato, and carrot samples from both ecological and conventional agriculture for quantifying parent antibiotics and degradation products.

4.02.PC-Mo10 Antimicrobial Resistance Genes and Mobile Genetic Elements in River Sediments of Wastewater Effluent-Receiving Areas

*Irene Beltrán de Heredia*¹, *Julen Urra*¹, *Belen Gonzalez-Gaya*², *Teresa Acosta*¹, *Carlos Garbisu*³, *Nestor Etxebarria*¹ and *Estilita Ruiz-Romera*¹, (1)University of the Basque Country, Spain, (2)ESTACIÓN MARINA DE PLENTZIA. UPV/EHU, Spain, (3)NEIKER, Spain

There is a growing concern about the fate of antibiotics in the environment since recent studies have evidenced that sublethal concentrations of those products may act as a selective pressure for the acquisition of *antimicrobial resistance (AMR)* and dissemination of *antibiotic resistance genes (ARG)*. Moreover, those molecules do not appear individually but as complex mixtures with other chemical substances, as it is the case of metals which seem to promote co-selection between *metal resistance genes (MRG)* and ARGs. Here, we highlight the relevance of local inputs of wastewater treatment plants (WWTP) as important sources of these pollutants in aquatic systems. To do this, a systematic monitoring was conducted in three wastewater effluent-receiving rivers, where composite sediment samples and surface water samples were collected in non-impacted (basin headwaters) and impacted sites (downstream) during two monitoring campaigns: November 2019 (wet season, high water period) and September 2020 (dry season, low water period). Both relative (normalized to *16S rRNA* gene) and absolute abundance of 9 ARGs, 4 MRGs and 3 MGEs (*mobile genetic elements*) in sediment samples were quantified using quantitative PCR. In addition, physicochemical characteristics and pseudo-total metal contents were also measured in those river sediments samples and antibiotic concentrations were detected in both sediment and water matrices as well as in 24-h composite effluent samples taken in those facilities. Quantitative analysis revealed that correctly quantified genes appeared in all monitored sites regardless of sampling season, though absolute abundances were significantly higher in dry season as compared to wet season. Regarding spatial distribution patterns, significantly higher relative abundances of most quantified genes were generally found in downstream sites as compared to those in basin's headwaters. The relationship between target genes and environmental parameters evidenced significant correlations of most measured metals in surface sediments and antibiotics in water samples with relative abundances of some MGEs, thus indicating selective pressure of this pollutants can promote HGT. Moreover, correlations between antibiotics and particular ARGs were also observed, though not necessarily with paired antibiotics. Finally, MGEs showed significant correlations with ARGs and MRG suggesting that HGT may have enhanced resistance acquisition.

4.02.PC-Mo11 Multiple Tools for Antibiotics and AMR Characterisation in Aquatic Ecosystems - a 2-Year Monitoring Study

*Chloe Bonninau*¹, *Agnes Bouchez*², *Anais Charton*², *Teofana CHONOVA*², *Christophe Dago*³, *Marion Devers-Lamrani*⁴, *Margaux Gaschet*³, *Jerome Labanowski*⁵, *Emilie Lyautey*⁶, *Fabrice Martin-Laurent*⁴, *Leslie MONDAMERT*⁵ and *Stephane Pesce*², (1)UR RiverLy, INRAE Lyon, Villeurbanne, France, (2)INRAE Lyon, France, (3)Université de Limoges, France, (4)AgroSup Dijon, INRAE Agroécologie, Univ. Bourgogne, Univ. Bourgogne Franche-Comté, France, (5)Université de Poitiers, France, (6)Université de Savoie, France

The ubiquitous presence of antibiotics exerts a selective pressure on microbial communities leading to the acquisition and dissemination of antimicrobial resistance (AMR) in the environment. To better understand antibiotics & AMR dynamics in the aquatic environment and to identify hot spots of accumulation, we conducted a large field study consisting in 8 sampling campaigns over 2 years on 4 stations belonging to French regional observatories and presenting contrasting levels of pharmaceuticals: 2 on the Arve river belonging to Sipibel observatory and 2 on Lake Geneva belonging to the Observatory on Lakes. On each sampling campaign, the following parameters were determined: (i) antibiotics levels in water, sediments and periphyton; (ii) AMR in periphyton and sediments using various detection techniques: resistance genes & integrons quantification, evaluation of tolerance acquisition *via* a PICT (Pollution Induced Community Tolerance) approach; (iii) antibiotics biodegradation potential of microbial community from sediments (by radiorespirometric measurement); (iv) diversity of bacteria and diatoms in periphyton and sediments; (v) physico-chemical parameters. While microbial resistance to antibiotics is commonly assessed by quantifying resistance genes or isolating antibiotic resistant bacteria, AMR can also be estimated by measuring the acquisition of antibiotics tolerance at community level, following a PICT approach. In our study, periphytic microbial communities from the Arve river were found to have a higher tolerance to the tested antibiotics (ciprofloxacin, ofloxacin, sulfamethazine and erythromycin) than communities from Lake Geneva, in agreement with the expected levels of contamination. In addition, in some cases, a higher tolerance was also found at stations close to waste water treatment plants (WWTP) effluents

than in upstream/protected stations. For example, periphytic microbial communities collected downstream the WWTP on the Arve river were generally found to have a higher tolerance to ciprofloxacin than the upstream communities. Comparing whole community tolerance to other classical indicators of AMR and to antibiotics levels in the aquatic ecosystems allows us to better understand the interconnection between pharmaceutical exposure, *in situ* tolerance and genetic potential for A

4.02.PC-Mo12 Modelling the Distribution of Antibiotics in the Global River System

Heloisa Ehalt Macedo¹, Bernhard Lehner¹, Jim Nicell¹, Usman Khan¹, Eili Klein² and Günther Grill¹, (1)McGill University, Canada, (2)Center For Disease Dynamics, Economics & Policy, United States

Significant concentrations of antibiotics in rivers may lead to the gradual development of drug-resistant bacteria, among many other potential impacts. Still, there is a lack of observational data in the field since these substances are not typically included in routine monitoring programs, especially in developing regions. In this work, we developed a model to estimate the emission of various antibiotics and their subsequent transport in river networks at high spatial resolution (500 m) and global scale, enabling first-time estimates of the surface-water concentrations of these compounds for virtually any river in the world. A key component of this research is the integration of two novel datasets in the modeling approach: (1) the average levels of consumption of 84 different antibiotics for each country in the world, which are used to estimate the release of the antibiotics in each region; and (2) a global database of 58,502 wastewater treatment plants (WWTPs); which includes enough information to geo-locate point sources and estimate the emission of the contaminant discharges into river networks. To evaluate the model, we used 227 measurements of the antibiotic Sulfamethoxazole with good results (R-squared = 0.65). The high resolution (500-meter) predictions of the model can be used to identify specific areas in the river network where high concentrations (or 'hot-spots') will tend to be found. The results can then be used as support for decision-making on focusing and prioritizing field studies, policy and management efforts, and technology resources.

4.03 Bayesian Networks: Applications for Environmental Risk Assessment and Management (Virtual Only)

4.03 Bayesian Networks: Applications for Environmental Risk Assessment and Management (Poster)

4.03.P-We172 A Bayesian Network Model of Mercury Pollution in Canada's Mackenzie River Basin

Una Jermilova, Environmental and Life Sciences, Trent University, Peterborough, ON, Canada

High mercury concentrations in the Arctic Ocean are concerning for scientists and local communities. Methylmercury is a toxin that accumulates over time in living organisms, and exposure to mercury contaminated foods has been linked to developmental disorders in human fetuses. Fish consumption advisories impair Indigenous community access to affordable foods and infringe on inherent fishing and clean water rights. Mercury is a toxic heavy metal released through human activities such as fossil fuel burning and land disturbance, or through natural processes e.g., glacial melting releases mercury contaminants trapped in frozen soil and water. This study is the Canadian contribution to ARCRisk, a collaborative project between Canada, Russia, and Norway. The ARCRisk project aims to improve our understanding of the riverine contribution to Arctic mercury pollution. The Mackenzie River Basin was selected as the Canadian study site. The main objectives of the project are: 1) identify sources of mercury to land and water, 2) evaluate the associated risk for the environment and human health, and 3) develop an action plan to reduce environmental risk to the Arctic. To meet these objectives, I am developing a Bayesian-Network Relative Risk model (BN-RRM) capable of analyzing cause-and-effect relationships. BN-RRMs are used for risk assessment in large-scale systems and are depicted as webs connecting many stressors and outcomes. Bayesian Networks are visual representations of cause-and-effect relationships and facilitate communication of complex interactions to stakeholders. The model will identify risk factors and an action plan can be developed to target the influential source. This is an impactful and achievable master's project integrating existing datasets, human health assessment, traditional knowledge, and expert opinion.

4.03.P-We173 Bayesian Networks As a Tool for Predicting and Communicating Environmental Risks of Pharmaceuticals

Samuel Welch¹, Kristine Olsen², Jannicke Moe³, Mohammad Nouri Sharikabad², Knut Erik Tollefsen¹ and Merete Grung⁴, (1)NIVA - Norwegian Institute for Water Research, Norway, (2)Norwegian Institute of Public Health, Norway, (3)Norwegian Institute for Water Research (NIVA), Norway, (4)NIVA, Oslo, Norway

The ongoing COVID-19 pandemic has provided only the latest piece of evidence that communicating future risks to stakeholders and the public is a simultaneously vital and difficult task. Communicating the future risks of pollution in the environment builds on a broader, more nebulous, and less intuitive set of concepts, but is equally vital for safeguarding future human and environmental health. There will never be a single effective solution to a problem of this scale, but this by no means undermines the importance of developing tools that are simultaneously statistically rigorous and yet comprehensible to scientists, policymakers, and the public. We, then, present here our work on one item in the toolkit of risk characterisation and communication: a Bayesian network. Our more traditional approach to environmental risk assessment of pharmaceuticals is based on whole-sale data of pharmaceuticals in Norway for the years 2016-2019, which we have converted to predicted exposure concentrations for individual active pharmaceutical ingredients (APIs) (presented elsewhere). To make better use of this extensive dataset of exposure for environmental risk assessment, we are developing a prototype Bayesian network for the probabilistic calculation of risk quotients. The Bayesian network model will be used to assess the probability of exceeding regulatory threshold values (predicted no-effect concentrations - PNEC) for selected active APIs. The approach will be in accordance with the established process for the environmental risk assessment of pharmaceuticals in the EU, but with estimates of uncertainty retained throughout the process. Furthermore, we are expanding the model through the incorporation of predicted future conditions such as population growth and demographics, allowing for future environmental risk to be predicted under a variety of potential scenarios.

We are also developing a model version that will allow for the assessment of cumulative risk (probability of exceeding PNEC) for multiple pharmaceuticals with similar modes of action. With this Bayesian network, we hope to provide a case study in how Bayesian networks can be adapted to complex, real-world scenarios as a tool for prediction, communication, and explanation of environmental risks.

4.03.P-We174 Evaluating the Ecological Consequences of Altered Water Quality in South Africa Using Bayesian Networks *Victor Wepener¹ and Gordon O'Brien², (1)North-West University - School of Biological Sciences, South Africa, (2)University of Mpumalanga, South Africa*

Multiple water quality stressors derives from land use changes and formal anthropogenic sources including urban areas, agriculture, industries and mines have a legacy of impacting on receiving water resources. It is often very difficult to measure and predict the ecological consequences of these stressors on our socio-ecologically important rivers, lakes, wetlands and estuaries. It is also difficult to manage these stressors and as a result manage the sources from which they derive to achieve sustainable development. The management of water quality stressors and their sources are difficult because of the dynamism of the source-stressor-response relationships and multiple factors including lack of data, complex impact pathways and risks and uncertainties that are difficult to parameterise. Good scientific approaches that produce reliable impact projections of multiple water quality stressors are rarely applied to evaluate the ecological wellbeing of water resources, but Decision Analysis techniques commonly used in other fields have the potential to improve development decisions. This paper presents a Decision Analysis approach using a Bayesian Network (BN), risk based probability modelling approach to support decision makers manage multiple water quality stressors on multiple spatial scales. The BN probability modelling approach is widely applied in a range of disciplines, including medical sciences, genetics, environmental sciences and legal reasoning. It allows for the formal representation of causal models, such as risk probability modelling of multiple sources, stressors and receptors in the context of multiple ecological endpoints. This paper illustrates the use of BNs as a risk-based probability modelling approach to evaluate the probable ecological effects of altered water quality associated with multiple sources using the Vaal, Olifants, Inkomati, Thukela and uMvoti catchments in South Africa as examples. Available water quality, land use activity and ecotoxicology data were used to describe conceptual risk pathways, parameterise the BNs and model the probable consequences of multiple water quality stressors to water resources. Our models, based on available data, effectively represent the ecosystems considered in the case studies and using a scenario-based approach, predict the ecological consequences of altered water quality. This approach further identifies important, determining water quality constituents and associations to their sources so that the sources and their stressors can be managed to attain sustainable resource development.

4.03.P-We175 Bayesian Belief Networks As a Toolbox for the Creation of a Decision Support Framework for Plastic Clean-Up Technology Selection in Rivers and Estuaries

Giulia Leone¹, Ana I Catarino², Ine Pauwels³, Thomas Mani⁴, Michelle Tishler⁴, Matthias Egger⁴, Marie Forio⁵, Peter Goethals⁶ and Gert Everaert², (1)Ghent University Laboratory of Environmental Toxicology and Aquatic Ecology, Belgium, (2)Flanders Marine Institute, Belgium, (3)Research Institute for Nature and Forest (INBO), Belgium, (4)The Ocean Cleanup, Netherlands, (5)Ghent University (UGent), Belgium, (6)University of Ghent, Belgium

With plastic debris accumulating in the marine environment at high rates, the need for sustainable mitigation strategies is imperative. Currently, one of the most used end-of-pipe solutions to block the transport of litter to the coast and ocean is the deployment of clean-up technologies in rivers and estuaries. These crucial technologies prevent plastic litter from reaching the marine environment, where it would rapidly spread and become more difficult to extract. However, to date, there is a lack of published empirical data on the potential impact of these devices on riverine and estuarine biota. Therefore, in this study, we propose to evaluate observation-based trade-off data for plastic clean-up devices to weigh bycatch versus plastic removal by using Bayesian Belief Networks (BBNs). Thus, creating a tool to support stakeholders in the decision-making process. We have identified four clusters of parameters that may play a substantial role in the bycatch of clean-up technologies, and that will be used to feed a BBN model as a starting point of a decision support framework. A first factor that will be considered in the BBN is the initial environmental status of the river or estuary in which the device will be deployed. In fact, transport of litter, including plastic debris, is highly influenced by the river's hydrological conditions. A typical example of this factor is the river flow velocity. A second factor to integrate into the probabilistic model is related to the traits of the biota present in the system and with which the device might interact. Size, buoyancy, and adhesiveness are all characteristics that might influence the chances of biota being unintentionally caught. A third important parameter is the characteristics of plastics present in the river or estuary such as size and buoyancy. Lastly, the removal operation mechanism of the clean-up devices is considered. To maintain the efficient collection of plastic debris while mitigating unintentional bycatch, we advocate that this BBNs model will support policymakers in the decision-making process, prior to the selection and deployment of plastic clean-up devices in rivers or estuaries. Policymakers will be able to find an optimal trade-off between plastic removal and possible negative environmental effects due to unintentional organic bycatch.

4.03 Bayesian Networks: Applications for Environmental Risk Assessment and Management (Poster Corner)

4.03.PC-We01 A Spatial Bayesian Belief Network for Assessing Field-Level Pesticide Pollution Risk in a Small Drinking Water Catchment

Mads Trolborg, Zisis Gagkas, Andy Vinten, Allan Lilly and Miriam Glendell, The James Hutton Institute, United Kingdom
Pesticides continue to present a significant risk to the quality of raw water for drinking water supplies worldwide. While catchment management is considered a cost-effective alternative to costly drinking water treatment, the effectiveness of pollution

mitigation measures is uncertain and needs to consider the complex interaction of local biophysical and agronomic factors. We present a spatial Bayesian Belief Network (BBN) that simulates inherent pesticide leaching risk to ground- and surface water quality to inform field-level pesticide mitigation strategies in a small drinking water catchment with limited observational data. The BBN accounts for the spatial heterogeneity in soil properties, topographic connectivity, and agronomic practices; temporal variation in climatic and hydrological processes as well as uncertainties related to pesticide properties and the effectiveness of management interventions. The BBN was used to simulate pesticide loss via overland flow and leaching to groundwater as well as the resulting risk of exceeding the regulatory threshold for drinking water for five different active ingredients. The effectiveness of mitigation measures such as delayed timing of pesticide application; reduction in application rates; field buffers; and presence/absence of soil pan on risk reduction were also evaluated. Sensitivity analysis identified timing of application, land use, presence of buffers, field slope and distance as the most important risk factors, alongside several additional influential variables. Pesticide pollution risk from surface water runoff was found to vary spatially across the study catchment, while groundwater leaching risk in general was uniform and low. Combined interventions of 50% reduction in pesticide application rate, management of plough pan, delayed application timing and field buffer installation was found to notably reduce the probability of high-risk from overland runoff and groundwater leaching. The advantage of the developed BBN is that it allowed to integrate diverse data sources in a dynamic field-scale assessment of 'critical source areas' of pesticide pollution in time and space, with explicit representation of uncertainties. The graphical nature of the BBN furthermore facilitated interactive model development and evaluation with stakeholders to build model credibility.

4.03.PC-We02 A Multiple Stressor Bayesian Network Ecological Risk Assessment for the Upper San Francisco Estuary
Wayne G. Landis¹, Mikayla Bowers², Steven Eikenbary³, Skyler Elmstrom², Allie Johnson², Eric Lawrence⁴, Emma Sharpe¹ and Erika Whitney², (1)Western Washington University, (2)Western Washington University, United States, (3)Western Washington University, Institute of Environmental Toxicology and Chemistry, United States, (4)Texas State Department of State Health Services,, United States

The applications of the Bayesian network relative risk model (BN-RRM) recently have been recently reviewed. This report documents the application of these lessons learned to a risk assessment for the Upper San Francisco Estuary (USFE) in Northern California. The USFE is fed from a series of rivers that originate in the Sierra Nevada range and that form an extensive delta. Stressors include the inputs from agriculture, urbanization, industrial activity, and an extensive system of roads and other types of transportation. The region was divided into six risk regions capturing inputs from three major rivers, the different land uses, and urban areas. The Bayesian network identifies the inputs, the causal pathways, and the endpoints. The data are based on the SURF and CEDEN databases. We compiled an integrated database implementing extensive quality control measures to eliminate duplication, ensure the metadata, and organized by risk region. The models are built using Netica and followed the principles set forth in previous studies. Toxicity was documented using exposure-response curves as calculated using the drc package in R. Mixture toxicity was estimated using a novel additive curve fitting tool. The parameterized BN used to calculate the risk due to pesticides to overall fish mortality is an example of the overall process. The input concentration distributions for the pesticides were built using the observed amounts in that region. The concentrations for malathion, diazinon and chlorpyrifos are low but with long tails. Bifenthrin has a bimodal distribution with measurements at the higher concentrations. The risk calculation indicates that there is a 52 percent probability of the toxicity exceeding an EC₂₀ value in the Confluence risk region. We demonstrate that it is possible to generate a probabilistic Bayesian based risk assessment for multiple stressors to multiple endpoints even to a region as complex as the USFE. It is also possible to calculate the pesticide levels required to lower risk to acceptable levels. For the conference the interactions between the stressors and multiple other endpoints will be emphasized.

4.03.PC-We03 A Bayesian Network Tool for Predicting Fish Acute Toxicity Based on Fish Embryo Toxicity Test Data
Jannicke Moe¹, Anders Madsen², Thomas Braunbeck³, Kristin A Connors⁴, Michelle Embry⁵, Kristin Schirmer⁶, Stefan Scholz⁷, Raoul Wolf⁸ and Adam Lillicrap⁹, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Hugin Expert, Denmark, (3)University of Heidelberg, Germany, (4)Procter & Gamble Company, United States, (5)Health and Environmental Sciences Institute (HESI), United States, (6)Eawag, Switzerland, (7)Helmholtz Centre for Environmental Research, Leipzig, Germany, (8)Norwegian Geotechnical Institute (NGI), Oslo, Norway, (9)NIVA, Norway

Fish Embryo Toxicity (FET) testing has been proposed as an alternative to using juvenile or adult fish in acute toxicity testing, to reduce the number of live animals required for hazard assessments of chemicals. The European Chemicals Agency has recommended the development of a Weight-of-Evidence (WoE) approach for strengthening the evidence from FET testing. While WoE approaches in the past have been largely qualitative, we have developed a Bayesian network (BN) model for using FET data in a quantitative and probabilistic WoE approach. The purpose of this BN model is to predict fish acute toxicity of a given chemical from data on fish embryo toxicity in combination with other types of available information (lines of evidence): quantitative structure-activity relationships (QSARs), toxicity to other species (algae and daphnids), and fish gill cytotoxicity. This presentation will focus on the final step of the WoE approach: the integration of the multiple LoEs and the methodology for weighting the LoEs. We will also present approaches to evaluating the model performance and defining its applicability domain. We consider the model presented here as a promising step towards a probabilistic WoE approach, with potential for further refinement and evaluation during the final phase of the SWiFT project. The next step is to finalise the web-based user interface to the model. A preliminary version of the online tool is available for testing purposes, and demonstrations of this tool can be provided upon demand. We consider the model presented here as a promising step towards a probabilistic WoE approach, with potential for further refinement and evaluation during the final phase of the project. While the purpose of this model is to predict acute fish toxicity from fish embryo toxicity, the approach can be relevant more generally for evaluating animal alternatives in regulatory toxicity testing, or even more generally for other types of environmental assessments.

4.03.PC-We04 Using a Bayesian Network Model to Predict Effects of Pesticides on Aquatic Community Endpoints in a Rice Field - a Southern European CASE Study

Sophie Mentzel¹, Andreu Rico², Claudia Claudia Martínez², Merete Grung³, Knut Erik Tollefsen¹ and Jannicke Moe⁴, (1)NIVA - Norwegian Institute for Water Research, Norway, (2)IMDEA Water Institute, Spain, (3)NIVA, Oslo, Norway, (4)Norwegian Institute for Water Research (NIVA), Norway

Bayesian network models are becoming popular as a tool to support probabilistic environmental risk assessments. Compared to the deterministic approaches currently used in traditional risk assessment, Bayesian networks can better account for uncertainty. Our research focuses on the exposure of various pesticides in rice fields surrounding a Spanish Natural Park and their potential effect on the aquatic ecosystem. In this study, we use the Bayesian network as a meta-model that links the inputs and outputs for a process-based exposure model (RICEWQ) and a probabilistic case-based effect model (PERPEST). We run the exposure prediction model for various meteorological, hydrological and agricultural scenarios. The final developed Bayesian network enables the prediction of pesticide effects on several response classes of the taxonomic groups in an aquatic ecosystem. This approach also facilitates the communication of uncertainties associated with the risk calculation in a transparent way.

4.03.PC-We05 All That Glitters Is Not Gold - Should We Reconsider or Upgrade Bayesian Networks for Environmental Assessments?

Ulrika Sahlin, Lund University, Sweden

The many claims about the power and usefulness of Bayesian networks leave me with a spark of doubt – it sounds too good to be true! There are several things that make Bayesian networks fantastic. Bayesian networks are an icon of flexible modelling, allowing us to specify a probability model and integrate expert judgements with data, and query or update probabilities conditional on events. There are several challenges hampering the use of Bayesian networks for risk assessment. Bayesian networks can be used for different purposes and the models can be of different kinds. A Bayesian Belief network is a joint probability distribution over nodes representing states of the world or unique events, where the (subjective) probability distribution express uncertainty. A Bayesian network for multivariate data, can, e.g. as in machine learning, be trained to predict future data points or fill data gaps. Any risk assessment, concerned with variability in the system, as well as uncertainty about this variability, requires models able to separate these two things. Many applications of Bayesian networks mix variability and uncertainty (flat networks) or do not consider uncertainty (aleatory networks). This is partly driven by the availability of user-friendly Bayesian Belief network software, which has not been designed to make such a distinction. Bayesian models are agnostic to uncertainty and variability, and it is, therefore, a task for the assessors to attribute what parts of a model constitute variability, and make appropriate summaries to open up for communication of uncertainty in conclusions. Bayesian networks have gained a lot of attention as a promising method for risk assessment, but glorifying claims about these models are dangerous and may result in poor assessments. Instead, we must carefully reconsider what characteristics of Bayesian networks are desirable for each assessment, start with a clear conceptual understanding of the assessment model, use transparent and reproducible procedures to elicit expert judgments, integrate data and evidence, and consider uncertainties (including those outside the assessment model). Assessments need more use of complex statistical modelling relying on probabilistic graphical modelling and Bayesian inference. With some exceptions, it is only tradition that prevents the latter to be referred to as Bayesian networks. To ensure best practice in assessment, I recommend being precise about what we are modelling and upgrading our perception of what is a Bayesian network to include any probabilistic graphical model.

4.04 Contaminated sediment: an environmental compartment of concern

4.04.T-01 Recreation of Realistic Mixtures of Polycyclic Aromatic Hydrocarbons (PAHs) in Passive Dosing Bioassays

Anne Kreutzer¹, Sonja Faetsch², Susanne Heise³, Henner Hollert⁴ and Gesine Witt⁵, (1)Abteilung GBP/RA, BASF SE, Germany, (2)Hamburg University of Applied Sciences (HAW), Germany, (3)Hamburg University of Applied Sciences, Hamburg, Germany, (4)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (5)HAW Hamburg, Germany

Bioavailability is a key factor in ecotoxicological effects of contaminants and important for risk assessment approaches. However, total exhaustive extractions of contaminants do not consider the importance of the bioavailable fraction. Hydrophobic organic contaminants (HOCs), including polycyclic aromatic hydrocarbons (PAHs), are among the most common organic contaminants of concern. Due to their strong hydrophobicity, HOCs have their final destination in sediment, where their ecotoxicological effects are closely regulated by sorption and thus bioavailability. The North Sea is one of the most polluted marine regions in the world. The intensive use of this area leads to growing pollution of the ecosystem by chemicals. The mobility of HOCs, and consequently bioavailability, depends on their porewater concentrations. Currently, the freely dissolved concentration (C_{free}) is established as an important endpoint for sediment quality and risk assessment. In this study, solid-phase microextraction (SPME) was applied to examine the spatial and temporal distribution of C_{free} of PAHs in sediment cores sampled in the North Sea. The determined C_{free} were used to recreate realistic PAH mixtures found in North Sea sediments. These mixtures were then applied in miniaturized passive dosing bioassays to study their ecotoxicological effects on two species representing different trophic levels, namely *Raphidocelis subcapitata* as primary producer and *Daphnia magna* as primary consumer. Since nominal dosing often exhibits significant losses (e.g. due to sorption or volatilization), the passive dosing method was used to overcome these difficulties and to obtain stable exposure concentrations. The PAHs are released into the aqueous medium via passive diffusion from biocompatible polydimethylsiloxane (PDMS) O-rings, which serve as reservoirs for PAHs. The chemicals distribute between the silicone (C_{PDMS}) and medium (C_{free}) in the test vessels until thermodynamic equilibrium is reached. Bioassays with recreated PAH mixtures of North Sea pore water (C_{free}) were performed to assess their mixture toxicity. The field concentrations detected in the

sampled North Sea sediment cores inhibited the growth of *R. subcapitata* up to 95 %, whereas *D. magna* did not show a clear dose-response relationship when exposed to the same mixture concentrations. This suggests that *R. subcapitata* is the more sensitive species and that *D. magna* was not as susceptible to the exposure of realistic PAH mixtures.

4.04.T-02 Effect of Recent Mining Activities on Sediment Properties and Toxicity to Freshwater Organisms

Åsa Berglund¹, Johan Lidman², Carolina Olid¹ and Christian Bigler¹, (1)Umeå University, Sweden, (2)Department of biology and environmental science, Umeå university, Sweden

Active and closed mines are known to be a major threat to aquatic ecosystems, where metal inputs can result in decreased abundance and diversity of freshwater organisms. However, on a landscape level, metal exposure and environmental effects in mining impacted environments may vary over time and space. In addition, factors affecting the bioavailability and toxicity of metals, such as total organic carbon (TOC), may also vary over time due to mining activities. These temporal and spatial patterns are important to understand in order to assess the status, the potential recovery and the need for post-treatment in mining impacted environments. In this project we used the geochemical record preserved in lake sediment together with estimates of toxicity for aquatic organisms to examine the long-lasting effects of past, century-scale mining. We used sediment cores from three small lakes affected directly or indirectly by mine tailings from an abandoned mine. The lakes that had served as clearing ponds were more severely affected than the lake receiving indirect discharge from tailings. However, all lakes showed clear impact from the mine, with reduced TOC and increased input of metals (Pb and Zn) at levels that most probable caused negative biological effects. The peak in Pb accumulation differed in time, depending on when and how long the clearing ponds had been in use. Probable Effect Concentration Quotients (PEC-Q) indicated that although the risk for toxic effects became much reduced after mining ceased, there is still a high risk for biological effects in the old clearing ponds. This was also evident after PEC-Q were TOC-normalized. However, in the lake receiving no direct discharge from mine tailings, a biological recovery is expected within the near future. We conclude that even within the same catchment, the effect and recovery in metal contaminated lakes may differ and we further suggest that TOC-normalized PEC-Q, rather than PEC-Q should be used to assess the toxic risk of metal contaminated sediments.

4.04.T-03 Wastewater Treatment Plant Contaminant Profiles Affect Macroinvertebrate Sludge Degradation

Tom Vincent van der Meer¹, Piet Verdonschof², Lisa van Eck³, Dominique Mon-Coeur Narain-Ford³ and Michiel Kraak⁴, (1)Wageningen Environmental Research - WUR, Wageningen, Netherlands, (2)Wageningen Environmental Research, Netherlands, (3)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands, (4)University of Amsterdam, Netherlands

Disposal of excess sludge produced by wastewater treatment plants (WWTP) can make up 60% of the operational costs. Methods that may reduce the amount of excess sludge are therefore urgently required. As macroinvertebrate detritivores play an important role in the degradation of organic matter in the aquatic environment, they may also be capable to degrade WWTP sludge. Yet, interactions between detritivores as well as high contaminant concentrations in the sludge may affect the sludge degradation rate by macroinvertebrates. The aim of the present study was therefore to examine the degradation of sludge from WWTPs differing in contaminant profiles by three benthic macroinvertebrates, individually and in all possible species combinations, where we tried to link the observed macroinvertebrate sludge degradation to the WWTP specific contaminant profiles. Subsequently, we experimentally assessed the effect of contaminants on sludge degradation and biotic interactions, by spiking WWTP sludge with Cu. Our results showed that most macroinvertebrate (combination) treatments enhanced sludge degradation in a species and WWTP specific way. Positive biotic interactions were only observed at high contaminant loads, where sludge degradation rates were reduced. In the Cu spiked sludge, degradation decreased with increasing Cu concentrations, but the sludge degradation in the species combination treatment was higher than expected based on the degradation by the single species. Even though WWTPs differ in their contaminant profile and load, employing (combinations of) detritivorous macroinvertebrates offers a promising approach to reduce the amount of excess WWTP sludge, where the feasibility will depend on the possibilities of upscaling these methods.

4.04.T-04 Biotransformation of Benthic Invertebrates Impact Persistence and Bioaccumulation of Sediment-Associated Cyclic Volatile Methyl Siloxanes (D4, D5, D6)

Henriette Selck¹, Sara Nicoline Grønlund², Ronja Windfeld², Minh Vu² and Khuong V. Dinh³, (1)Roskilde University, Roskilde, Denmark, (2)Roskilde University, Denmark, (3)Department of Biosciences, Department of Biosciences, University of Oslo, Oslo, Norway

Regulatory frameworks generally assess risk of hydrophobic organic chemicals (HOCs) based on their persistence, bioaccumulation and toxicity using water-exposure setups and microbial degradation. However, this may misjudge the risk of HOCs, such as cyclic volatile methyl siloxanes (cVMS), due to their accumulation in the sediment compartment. We assessed the impact of dietary uptake (i.e., via sediment ingestion) and benthic invertebrate biotransformation for risk assessment of cVMSs in a number of studies. A radiotracer technique was employed to examine uptake- and depuration kinetics as well as biotransformation of sediment-associated cVMS (octamethylcyclotetrasiloxane, D4; decamethylcyclopentasiloxane, D5; dodecamethylcyclohexasiloxane, D6) by a freshwater oligochaete (*Tubifex tubifex*) and a marine polychaete (*Capitella teleta*). Overall, sediment-associated D4, D5 or D6 did not adversely affect the benthic invertebrates. Uptake, depuration and biotransformation was dependent on compound. BSAF was low due to biotransformation and fast elimination of parent and metabolites. Worm presence reduced sediment cVMSs (up to 95% for D4), especially in the estuarine system inhabited by *C. teleta*, to levels exceeding microbial degradation alone. It, thus, appears that cVMSs have little impact on sediment-dwelling

organisms at environmentally realistic concentrations. Our results highlight the importance of benthic invertebrate biotransformation in reducing uncertainty in B and P assessment of HOCs, like cVMSs.

4.04 Contaminated sediment: an environmental compartment of concern (Poster)

4.04.P-Th123 Assessing Sediment Status in Europe: Frameworks, Standards and Approaches, an Expanded Review

Sabine Elisabeth Apitz, SEA Environmental Decisions Ltd, United Kingdom

It is nearly two decades after passing the Water Framework Directive, which mandated catchment-wide approaches to managing waterways, and over a decade since the European Sediment Research Network (SedNet) published a series of books addressing the role of sediments in achieving this goal. In 2008, the European Commission published a directive on environmental quality standards in the field of water quality, but declined to specify or require sediment quality guidelines except under special circumstances, although it still required that Member States monitor sediment and biota for priority substances that accumulate in them. Subsequently, a significant body of work has addressed contaminant trends, drivers of toxicity and contaminants of emerging concern in European waters. While European approaches to sediment assessment and monitoring were reviewed by the SedNet, many national approaches have evolved since that time, or are under review. Documents on national approaches to freshwater and marine sediment assessment were reviewed for a range of European countries. An additional focus was on evaluating both national approaches to emerging contaminants not currently identified as priority pollutants, and how future attention on these might change sediment assessment frameworks in the near term. As far as was possible, national approaches were summarized in a common context. **1. 2.** Europe remains quite diverse in its approach to sediment standards and assessment. Approaches range from a complete absence of standards and guidelines to highly detailed frameworks; applications can be broad or narrow. The assumptions behind frameworks and policies are critical to their application; not all countries clearly distinguish between screening and action levels. Where specified, lists of potential contaminants to be monitored range from a handful to dozens, and differ for freshwater and marine systems. This paper will update a 2017 review and compare approaches to sediment chemical assessment in a much broader range of European countries and regions. Trends and changes, and the relationship between chemical and other assessments, will be discussed.

4.04.P-Th124 Investigations on the Risk Assessment of Soft Plastic Baits - Determination of the Content of Phthalic Acid Esters and Polycyclic Aromatic Hydrocarbons in Fishing Lures and Their Delivery to the Water Phase

Moritz Kielmann¹, Gesine Witt² and Mathias Reininghaus³, (1)Environmental Engineering, Hamburg University of Applied Sciences (HAW), Hamburg, Germany, (2)HAWHamburg, Germany, (3)RWTH Aachen, Germany

The offer of soft plastic baits (SPL) is large in the fishing stores. These baits are mostly made of soft PVC, which can contain about 70% plasticizer (i.a. phthalic acid esters) and also polycyclic aromatic hydrocarbons (PAH) as contaminants. These chemicals can be endocrine disruptors (phthalates) and toxic (PAHs). Lures are often lost when they get caught on the ground or torn off by the fish. But how many get lost and do they harm? The German city of Hamburg is a case in point. About 120,000 anglers are registered here. This high number of anglers meets only a small water area. Therefore, it is obvious that the load of torn baits can be locally high. To assess the risk of SPLs, the study investigated which plasticizers and contaminants are present in selected SPLs and how they enter the water phase. The analytes were extracted from the baits using solvents and measured by GC-MS technique. Selected baits were placed in water for several weeks. Water samples were extracted and measured regularly. It has been observed that some SPLs release attractants into the water. These consist of organic material and may have an influence on the release of pollutants. The most commonly detected phthalates were Diisononyl phthalate (DINP) and Diisodecyl phthalate (DIDP). The phthalates Dibutyl phthalate (DBP) and Benzyl butyl phthalate (BBP) were not found. The substance Di(2-ethylhexyl) phthalate (DEHP) was detected as an individual case in a single sample. PAHs were identified in some examined artificial baits. The concentrations of phthalates and PAHs are partly above the limits set on toys for young children. A risk for children can therefore not be excluded. For some phthalates and PAHs, a significant increase in concentration was observed in the water phase. In addition, a continuously increasing turbidity intensity was observed emanating from the attractants. The achieved concentrations of some phthalates clearly exceed the theoretical solubility. It can be discussed that the attractant release is a driving factor for the pollutant release. As a result, significantly more pollutants are released at higher rates. Thus, the use of SPLs increases the local risk of the pollutant release into the water. Therefore, it would be desirable to use either alternative degradable materials or alternative techniques. The awareness of the harmfulness of PVC baits is the driving force for this. It can be conveyed, for example, through the fishing license examination.

4.04.P-Th125 Derivation of Environmental Quality Standards for Sediments: Swiss Experience With Traditional and Emerging Sediment Contaminants

M. Carmen Casado-Martinez¹, Alexandra Kroll¹, Michel Wildi², Marion Junghans³ and Benoit J.D. Ferrari⁴, (1)Centre Ecotox, Switzerland, (2)Ecotox Centre CH, Switzerland, (3)Swiss Centre for Applied Ecotoxicology EAWAG - EPF, Switzerland, (4)Swiss Centre for Applied Ecotoxicology, Switzerland

The Swiss Centre for Applied Ecotoxicology (Ecotox Centre) has derived environmental quality criteria for surface waters for many substances, including pesticides, biocides, pharmaceuticals and industrial chemicals [1]. The derivation is largely based on the EU Technical Guidance for Deriving EQS (TGD for EQS; [2]), because the protection goals of the Swiss water protection law and ordinance and the Water Framework Directive (WFD) are comparable. In contrast to the WFD dossiers, sediment and human health via the consumption of fisheries products are not part of the EQS derivation in Switzerland. In the last years, the Ecotox Centre has been working on a sediment quality assessment strategy for Switzerland [3]. The objective is to harmonize and improve practices in sediment quality monitoring and assessment in Switzerland, which mainly addresses the chemical status so

far. The strategy proposes procedures for sediment sampling and analysis and a list of 20 substances for which information on measured environmental concentrations in sediments should be gathered to assess their occurrence at the national level. In this context, sediment EQS were derived. Here we report on the experience with deriving sediment EQS for 20 substances that include both, traditional sediment contaminants such as metals, PAHs or PCBs, and contaminants of emerging concern such as pesticides, pharmaceuticals or personal care product ingredients. We will present the derived values for each substance but will mainly focus on providing feedback from the derivation process, in particular on the availability of relevant ecotoxicological data and the quality and reliability of available data. We will also discuss the performance and potential issues with implementation of the derived EQS for sediments.. [1] Korkaric M, Junghans M, Pasanen-Kase R, Werner I. 2019. Revising environmental quality standards: lessons learned. *Integr Environ Assess Manag* 15: 948-960. [2] European Commission. 2011. Technical guidance for deriving environmental quality standards. Common implementation strategy for the Water Framework Directive (2000/60/EC). Guidance document No. 27. Prepared by EU, member states and stakeholders. Technical Report?2011?055. [3] Casado, C., Wildi, M., Ferrari, Benoit J.D., Werner, I. 2021. Strategie zur Beurteilung der Sedimentqualität in der Schweiz. Studie im Auftrag des Bundesamts für Umwelt. 4.04.P-Th126 Retrospective Screening Analysis for Biocides in Suspended Matter at Urban Locations

Susanne Schmidt¹, Ronja Paffrath¹, Christiane Meier², Korinna Ziegler¹, Georg Dierkes³ and Arne Wick³, (1)German Environment Agency (Umweltbundesamt), Germany, (2)Biocides, German Environment Agency (UBA), Dessau-Roßlau, Germany, (3)German Federal Institute of Hydrology, Germany

Biocidal substances enter the aquatic environment through numerous entry pathways. One main entry path is through the sewer system. Biocides entering the sewage treatment plants (STP) are often incompletely removed and thus the parent compounds as well as their transformation products are discharged into the water body. Moreover, a direct discharge of biocides into surface water can occur via rainwater discharges in separate sewers and in case of combined sewers also via the combined sewer overflow (CSO) during heavy rain events. In a recently finalized project, 29 STPs distributed all over Germany were investigated for selected biocides. It was shown that about 75 % of the 26 analyzed substances pass the STP. The results also confirmed relevant biocide concentrations in CSO released into the surface water. Due to their adsorption properties, it can be assumed that some of these biocides will also accumulate especially in suspended matter. Suspended solids are important structural and functional elements in aquatic ecosystems and also a suitable matrix for retrospective monitoring in order to assess temporal and regional trends. However, for many biocides data on concentrations in suspended matter are still scarce. Thus, the aim of the presented project is to expand the knowledge on biocides in suspended matter. For this purpose, 1) a retrospective quantitative analysis for selected biocides (e.g. quaternary ammonium compounds (QACs), azole fungicides, pyrethroids) is carried out at different urban locations over a period of 7-8 years and 2) a semi-quantitative analysis of further biocides via suspect screening is conducted. By focusing on urban locations, relevant biocides and their entry path should be traced. For this purpose, the new data are linked with existing findings of biocides in STP effluents in Germany. The extension of the monitoring to the particulate phase enables the detection of (strongly) sorptive substances even in low concentrations and thus a better knowledge of the distribution of these substances in surface waters. Finally, the results provide a time-dependent picture of the environmental pollution by biocides in Germany and also show possible fields of action for regulatory purposes. First results available so far confirm the wide spread occurrence of biocides in particular matter. Especially QACs such as Dimethyldidecylammonium were found to be ubiquitously present in high concentrations of up to 6 µg/g dry weight.

4.04.P-Th127 Uptake and Accumulation of Amitriptyline in the Polychaete, *Nereis Virens*, Exposed to Field-Collected Sediment Near a Wastewater Treatment Discharge Site in Norway

Jason Tyler Magnuson¹, Zoe Longenecker-Wright², Giovanna Monticelli², Hans Kristian Brekken², Daniel Schlenk³, Magne Sydnes² and Daniela Pampanin², (1)University of California, Riverside, Norway, (2)University of Stavanger, Norway, (3)University of California, Riverside, United States

An increase in the global consumption of pharmaceuticals and abundance of residues detected in the environment has raised concern to the health of aquatic organisms. Wastewater treatment plants (WWTPs) discharge represents a major source of pharmaceuticals to the aquatic environment due to an incomplete removal of compounds prior to release in freshwater and marine systems. Following sampling events in the surroundings of a WWTP outfall in Stavanger (Norway) in 2019 and 2020, sediment samples collected were comprised of several representative classes of pharmaceuticals. One compound in particular, a tricyclic antidepressant, amitriptyline, was detected in sediment samples and of particular interest as there is relatively little known regarding its capacity to accumulate in benthic organisms from contaminated sediment. To better understand the potential impact of amitriptyline in the marine environment and its ability to accumulate in biota, marine benthic polychaetes, *Nereis virens*, were exposed to field-collected sediment samples from Kvitsøy (reference), Boknafjord, and WWTP outfall, as well as 3.06 µg/g and 30.57 µg/g amitriptyline-spiked sediments for 28-days. The average amitriptyline concentration detected from sediment exposure samples were comprised of the following: Kvitsøy (12.7 ± 8.0 ng/g), Boknafjord (15.6 ± 12.7 ng/g), WWTP outfall (6.5 ± 3.9 ng/g), 3.06 µg/g amitriptyline-spiked sediment (423.83 ± 33.1 ng/g), and 30.57 µg/g amitriptyline-spiked sediment (763.2 ± 180.5 ng/g). *N. virens* had body burden concentrations of amitriptyline below the limit of detection (LOD; 3.5 mg/mL) following exposure to Kvitsøy and WWTP outfall sediments, whereas detectible concentrations were measured from Boknafjord (5.2 ± 2.8 ng/g) and those exposed to 3.06 µg/g (9.5 ± 0.2 ng/g) and 30.57 µg/g amitriptyline-spiked sediments (56.6 ± 2.2 ng/g). There was a positive correlation between the concentration of amitriptyline in sediment samples and body burden concentrations in *N. virens*, which suggests that amitriptyline has the potential for trophic transfer following exposure to contaminated sediments.

4.04.P-Th128 Toxicity Assessment of Dredged Sediments From the Lagoon of Venice Using the Clam *Ruditapes philippinarum*

*Davide Asnicar*¹, *Jacopo Fabrello*², *Maria Ciscato*³, *Filippo Basso*³, *Lea Magnifico*³, *Maria Gabriella Marin*⁴ and *Valerio Matozzo*², (1)Department of Biology, Università degli Studi di Padova, Padova, Italy, (2)University of Padova, Italy, (3)University of Padua, Italy, (4)Università degli Studi di Padova, Italy

The Lagoon of Venice is an important and complex coastal ecosystem of the Northern Adriatic Sea, the safeguard of which is fundamental for biodiversity protection and ecosystem services. Human activities caused the direct and indirect increase of inorganic and organic pollutants in seawater. The Lagoon of Venice often undergoes dredging of canals to allow the transit of ships and sediments can be dumped at other sites with unknown effects. Resuspension of sediments can allow toxicant release, making them available to filter-feeders, such as clams, with potential risk for consumers. Here, the toxicity of sediments from six sites of the Lagoon of Venice was assessed on the Manila clam, *Ruditapes philippinarum*. Five sampling sites were located between the city center of Venice and the industrial area of Porto Marghera. The sixth sampling site was selected far from the others, in an area with presumably low levels of contamination. Four sediment cores were collected at each sampling site. The clams were experimentally exposed to the sediments for 3 and 14 days and a battery of biomarkers was measured. The capability of sediments to induce oxidative stress and damage, as well as neurotoxicity, and to alter detoxification properties of clams was assessed both in gills and the digestive gland. The experiment was repeated in two seasons (winter and spring), in order to highlight a time-dependent toxicity of sediments and to reveal a different sensitivity of clams related to different periods of their biological cycle. For most of the biomarkers investigated there was a significant effect of the variables “exposure time”, “sampling site” and their interaction. The results revealed differences in the responses of the clams between the two experiments, with a possible influence of the clams’ reproductive phase. In general, a clear pattern could not be identified, and clams from the sixth site showed similar responses to those of bivalves from the other sites. Oxidative damage in clam tissues was low, suggesting the ability of the animals to cope with contaminants. A different pattern of contamination among sites is suspected. However, chemical analyses of sediment samples are still ongoing. Scientific activity performed in the Research Programme Venezia2021, coordinated by CORILA, with the contribution of the Provveditorato for the Public Works of Veneto, Trentino Alto Adige and Friuli Venezia Giulia.

4.04.P-Th129 Multidisciplinary Assessment of Estuarine Sediments Collected in the Bay of Biscay

*Nerea Garcia-Velasco*¹, *Jose Antonio Carrero*², *Erik Urionabarrenetxea*², *Beñat Zaldibar*², *Ainara Gredilla*², *Alberto De Diego*², *Urtzi Izagirre*² and *Manuel Soto*², (1)Centre for Experimental Marine Biology and Biotechnology (PIE-UPV/EHU), Univ. of Basque Country, Spain, (2)University of the Basque Country, Spain

In recent decades, pollution in estuaries has been one of the major environmental problems that affected waters but also sediments and organisms inhabiting them. Estuarine sediments accumulate high levels of discharged wastes, acting as a sink and source of pollution. Metals are the most studied and monitored pollutants in sediments chemical characterization. However, in order to perform a multidisciplinary assessment of polluted sediments biological effects in environmentally relevant species should be considered. The polychaete, *Hediste diversicolor*, was chosen as test organism since it is an endobenthic species, widespread in sediments. With this species, innovative *in vivo* and *in vitro* tests were performed to assess the toxicity of sediments collected in 4 estuaries of the Bay of Biscay. Sediments with different pollution inputs (present and past) were sampled in the Nerbioi-Ibaizabal (Udondo, Kadagua, Benedicta, Zorroza), Butroe (Plentzia-reference-), La Gironde (Plassac) and Charente (Rochefort) estuaries in October 2018 and March, July and October 2019. Physico-chemical characterization was done and the mERMq cumulative index was calculated according to the metal content. For *in vivo* assays, adult polychaetes were introduced into the sediments and after 7 d of exposure, metal accumulation, mortality, weight loss, histopathology and biochemical responses were measured and integrated in a Biological Response Index (IBR). Regarding *in vitro* approaches, immune cells (coelomocytes) were extruded from the coelom, exposed to sediment elutriates (DIN 38414-S4) and after 24 h their viability was recorded (Calcein-AM viability assay). In parallel the Sea Urchin Embryo Test with estuarine sediment elutriates was carried out (ICES, 2012). The characterization indicated that sediments collected at different estuaries and seasons were all loamy and high in OM (>3%), with the exception of Benedicta. mERMq and IBR values indicated that sediments from Udondo and Benedicta had the highest toxicity with a concomitant decrease in coelomocytes viability, lower growing capacity of sea urchin larvae and embryo malformations. The sediment toxicity bioassays implemented herein could be helpful for risk assessment, to define Sediment Quality Guidelines and for dredging operations management. *Acknowledgement*: Basque Gov. (IT1302-19, IT1213-19), U. Basque Country and MINECO (CTM2017-87766-R).

4.04.P-Th130 Multiple Stress Factors Affecting Sediments in the Estuaries of Elbe and Odra

*Safia El Touni*¹, *Inna Sokolova*² and *Susanne Heise*³, (1)Hamburg University of Applied Sciences (HAW), Germany, (2)University of Rostock, Germany, (3)Hamburg University of Applied Sciences, Hamburg, Germany

Estuaries are vulnerable to multiple human impacts threatening the long-term viability, ecological function and health of these important ecotones. Pollutant and nutrient inputs, increasing industrial pressure, habitat loss and climate change represent the most important stressors in estuaries. In this diverse range of pressures, scientifically sound sustainable management is a challenge. The preservation of healthy and viable estuaries therefore requires a detailed understanding of the essential characteristics and linkages in the estuarine systems, as well as novel measures to preserve these valuable coastal systems. The Blue Estuaries project (BluEs) aims to improve the understanding of the complex estuaries Elbe and Odra with regard to the interaction of different anthropogenic and natural process (e.g. hypoxia, eutrophication and chemical pollution) on the basis of a comparative analysis. One of the main objectives of our investigations within BluEs is the role of sediment bound contaminants in the Elbe and Odra estuaries. For this purpose, sediment and water samples will be collected over the course of 2 years along stress gradients. Their

ecotoxicological effects on organisms of different trophic levels (e.g. bacteria, microalgae and nematodes) will be investigated by applying various biotests such as bacterial contact test, algae growth inhibition test and the acute daphnia test. By analysing the toxic endpoints, undesirable effects of single and combined stressors on the biological community will be detected. The effects of new substances with specific modes of action, such as endocrine disruptors or herbicides, will be measured using reporter cell lines and pulse amplitude modulation (PAM) fluorometry. The concentrations of pollutants in the sediment and water samples will be analysed, and the Toxic Unit concept will be used to determine how much of the ecotoxicological effect can be attributed to the measured pollutants. The chemical and ecotoxicological data will be compared with the meiobenthic community data (Nema-SpeAR-Index) to assess the quality of the local biological communities. All results and relevant data collected in the project will be compiled and analysed, in form of a qualitative/quantitative model of complex cause-effect relationships, which will help to improve the understanding of the complex interactions in the estuaries. This poster will introduce the project and its first results.

4.04.P-Th131 Exploring Chemical and Biological Data to Understand the Impacts of the Pollutants in the Doce River, Brazil, After the Mining Dam Collapse

Flavia Yoshie Yamamoto¹, Andre Padial², Roma Tauler³ and Denis Abessa⁴, (1)UNIVERSIDADE ESTADUAL PAULISTA - UNESP, Brazil, (2)Universidade Federal do Paraná, Brazil, (3)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (4)São Paulo State University UNESP, Brazil

High levels of hazardous chemicals may be introduced into aquatic ecosystems and concentrate in bottom sediments during episodes of acute and chronic environmental contamination. The Fundão Dam failure in 2015 represented one of the worst environmental disasters in Brazil, discharging more than 43 million of m³ of iron-rich tailings wastes into the Doce River Basin (DRB), resuspending the chemicals deposited in the sediment and causing irreversible socio-environmental impacts. Although many studies initially reported the anomalous levels of metals in water, the longer-term impacts considering the influence of environmental factors and other pollution sources are yet to be determined, as well as potential effects on the exposed organisms. This study investigated the impacts of the pollutants from the Doce River four years after the mining dam collapse, considering the analysis of inorganic and organic chemicals in water and sediment, associated with biomarkers responses of wild fish and fish embryos exposed to elutriate solutions. The diagnostic indexes and multivariate analysis revealed that sampling sites at the Upper DRB, closest to the mining activities, showed the worst sediment quality, with the highest levels of trace elements, including the hazardous As and Hg, which exceeded the federal standards (CONAMA). Major stress responses were observed for fish from these sites, such as higher lipid peroxidation and metallothionein expression, and depleted GSH, as well as higher deformities rates of fish embryos. On the other hand, concentrations of PAHs in the sediments were higher in the Middle and Lower regions of the DRB. Benzo[a]anthracene exceeded legal limits, and fish exhibited higher DNA damage and increased AChE activity. In addition, PCA analysis showed the seasonal variation as an important factor influencing the distribution of chemicals, as the rainy season increases the levels of trace elements in water due to the higher resuspension of sediment. The integration of chemical analysis with biological responses allowed us to better understand the environmental impacts across the DRB, as a result of the historical ore exploration, combined with the dam failure disaster, which spread the inorganic contaminants along the DRB, and other contamination sources, such as those responsible of releasing organic chemicals. These sources have been historically neglected in the DRB, but their contributions, when summed to those from mining, result in complex mixtures of pollutants, increasing the ecological risks in the DRB.

4.04.P-Th132 Ecotoxicological Evaluation of a Floodplain Restoration Project Near an Industrial Plant

Nina Kuschik-Maczollek¹, Malte Glock², Sarah Johann³, Lena Müller², Sabrina Schiwy⁴, Markus Thomas Schmitz Student⁵, Werner Brack⁶, Henner Holler² and Jorg Oehlmann⁷, (1)Department of Aquatic Ecotoxicology, Goethe University, Frankfurt am Main, Germany, (2)Goethe University Frankfurt am Main, Germany, (3)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (4)Goethe University Frankfurt am Main, Frankfurt, Germany, (5)Evolutionary Ecology and Environmental Toxicology (E3T, Goethe University Frankfurt am Main, Frankfurt am Main, Germany, (6)Helmholtz Centre for Environmental Research – UFZ, Germany, (7)Johann Wolfgang Goethe-Universität Frankfurt, Germany

Floodplains are among the most species-rich ecosystems in Central Europe and are therefore of great importance for biodiversity conservation. In addition, they fulfill a variety of ecological services, such as water and air filtration, carbon fixation, or urban microclimate improvement. Over the past decades, however, rivers have been channelized and structurally degraded to allow navigation, gain land and protect against flooding. The European Water Framework Directive (EU-WFD) demands the implementation of several floodplain protection measures. Accordingly, the City of Frankfurt am Main (Hesse, Germany) has initiated the restoration of a 90 ha floodplain, which to date is the most extensive renaturation measure on the Hessian section of the river Main. The planning includes two tributaries and several oxbow ponds, bank flattening, meadows, and floodplain forests. Some of these structures have already been established between 2014 and 2019. About 1/3 of the area remains available for conventional agriculture. The project is particularly interesting from an ecotoxicological perspective because the plan area is located next to an industrial plant that discharges treated wastewater 1.5 km upstream of the inflow of the future tributary. Regarding the major flood events of the last decades, pollutants from the Main river and the effluents of the industrial plant, which had no wastewater treatment plant from 1870 to 1981, are hypothesized to have been deposited on the floodplain. Previous studies have shown that, in addition to hydromorphological restoration measures, good water and sediment quality is crucial to improve the ecological status of water bodies according to the EU-WFD. In the project, water and sediment samples from the Main river and the existing water bodies in the floodplain will be analysed, as well as soil samples from the future tributary. For an ecotoxicological evaluation of the restoration, the samples are tested for baseline toxicity (Microtox assay), mutagenicity (Ames

fluctuation test), endocrine and dioxin-like activities (yeast reporter gene assays, ?EROD- and CALUX® assay), neurotoxicity (AchE inhibition test), oxidative stress response (AREc32 assay) and *in vivo* fish embryo toxicity (FET). Additionally, a selection of samples will be chemically analysed for organic pollutants by the Helmholtz Centre for Environmental Research using liquid chromatography coupled with high resolution mass spectrometry (LC-HRMS).

4.04.P-Th133 Combined Chemical and Bioassay Analysis of Polycyclic Aromatic Hydrocarbons (PACs) in Sediment From the Coast of Gulf of Bothnia

Ulrika Eriksson¹, Louise Prost² and Maria Larsson³, (1)Örebro University School of Science and Technology, MTM Research centre, Örebro University, Örebro, Sweden, (2)MTM Research Centre, Örebro University, Sweden, (3)School of Science and Technology, Örebro university, Örebro, Sweden

The marine environment is a sink for polycyclic aromatic compounds (PACs) where their occurrence and levels are strongly affected by current and historic anthropogenic activities. Though the diversity of PAC spans over a multitude of different classes and compounds, only a limited number of PACs is usually assessed in current regulatory frameworks of sediments. Recent years, attention has increased towards PACs other than the priority PAH16, such as alkylated PAHs, heterocyclic PACs, and oxy-PAHs, due to their toxicity and environmental persistence. In this study, a wide range of PACs were analyzed in sediment samples from the coast of Gulf of Bothnia; PAHs, alkylated PAHs, oxy-PAHs, O-PACs, N-PACs, and S-PACs, in total 85 compounds.

Bioanalytical analysis was performed with three cell-based assays targeting aryl hydrocarbon receptor (AhR) activity, estrogenic activity and antagonistic androgenic activity; PAH CALUX, ER CALUX and anti-AR CALUX. Chemically derived benzo[a]pyrene (BaP) equivalents (chem-TEQs) were calculated from the relative response potency factors (REPs) specific to the PAH CALUX and compared to the derived bio-TEQ values. Extraction was performed with selective pressurized liquid extraction (SPLE) using basic silica and dichloromethane. The method was validated with spike and recovery experiment using low-contaminated sediment and showed good performance for all included analytes. The results showed ?PAC concentrations ranging from 2.8 – 12 ng/g d.w. Up to 67 PACs were found in the sediment samples. Comparison of the bioanalysis and the target PAC analysis revealed that chem-TEQ values of PAH16 could explain 12 – 84%, on average 34%, of the bioactivity in the PAH CALUX. Only a few samples showed significant activity in the ER CALUX and anti-AR CALUX.

4.04.P-Th134 Biotransformation of Cyclic Methyl Siloxanes by Benthic Invertebrates - a Proof of Concept Approach

Elettra D'Amico¹ and Henriette Selck², (1)INM, Roskilde University, Høje Taastrup, Denmark, (2)Roskilde University, Roskilde, Denmark

Hydrophobic organic contaminants (HOCs) will inevitably end up in the aquatic environment where they will settle out and accumulate in the sediment. The environmental fate of HOCs depends on several factors, including microbial degradation but also biotransformation by benthic macrofauna. Macrofaunal biotransformation have been reported to impact the persistence of sediment - associated HOCs to a higher extend than microbial degradation. Among the HOCs, cyclic volatile methyl siloxanes (cVMS) have a high hydrophobicity ($\log K_{ow} > 5$) and are defined as “superhydrophobic” (i.e., $\log K_{ow}$ approach or exceed 7) rendering them to bind particles in the water column and eventually accumulate in sediments to levels much higher than in the overlying water. The half-life of the most common cVMS in sediment is much longer than in water: D4 half-life is 3.9 days in water and 365 days in sediment; D5 half-life is 70.4 days in water and 3100 days in sediment. However, results from our laboratory demonstrate much lower half-lives in sediment inhabited by the estuarine polychaete, *Capitella teleta*, and the freshwater oligochaete, *Tubifex tubifex* due to a high biotransformation capacity. Deposit-feeding invertebrates, such as *C. teleta* and *T. tubifex*, colonize and thrive in organically polluted areas where they often reach high densities (e.g., >100.000 pr m^2). A high biotransformation capacity, as shown for several Persistent Organic Pollutants, may explain their ability to live in organically polluted areas. However, information on the mechanisms involved in biotransformation processes are limited. Our hypotheses are that *C. teleta* and *T. tubifex* biotransform cVMS through the induction of CYP450 enzymes and/or have a unique microbiome that metabolize the contaminants to more water-soluble compounds. In addition, methods to assess biotransformation of compounds with unknown metabolites is lacking. The aim of this study is to examine the mechanisms behind cVMSs biotransformation in *C. teleta* and *T. tubifex*. Here we suggest a conceptual approach to assess the biotransformation potential in benthic invertebrates using cVMS as model compounds. *Acknowledgement* - The authors acknowledge Centre European des Silicones (CES, Project no: 021444/5040/07/0226) for its financial support.

4.04.P-Th135 Organophosphate Esters Interactions With Microbial Assemblages in Coastal Sediments Under High Urban Pressure

Javier Castro-Jimenez¹, Philippe Cuny², Cecile Militon², Lea Sylvi², Florian Royer², Laure Papillon² and Richard Sempere², (1)Chemical Contamination of Marine Ecosystems, IFREMER, Nantes, France, (2)Aix-Marseille Université, France

The widely used and hazardous organophosphate esters (OPEs) flame retardants and plasticizers can effectively accumulate in marine sediments, and coastal sites may represent in some cases important sedimentary OPE stocks ^{[1][2]}. Open questions at present are on their field persistence and the capability of naturally occurring microbial communities in “contaminated sediments” from marine coastal areas to effectively degrade OPEs, enhancing their in-situ degradation, and on their potential impacts of these plastic additives on these communities. To address this issue, we applied an integrated chemical-microbiological approach on a sediment in the impacted area in the vicinity of the Marseilles’ WWTP outlet (NW Mediterranean) receiving constant OPE inputs. Immediately after sediment collection and homogenization, thirty-nine sub-samples (40 g of wet sediment) were spiked with an OPE mix to achieve environmental relevant concentrations and incubated in dark using a temperature-controlled chamber ($13 \pm 1^\circ\text{C}$) during one month. Two conditions (*i.e.* abiotic, biotic) were tested and samples were analyzed at T0 and after 7, 14 and 30 days corresponding to T1, T2 and T3, respectively. OPE were quantified by GC/MS after ultrasound extraction and clean-up, and

total sedimentary DNA was extracted in each treatment to quantify the number of bacterial 16S rRNA genes (proxy of bacterial abundance) and to characterize the structure and composition of the bacterial community (16S metabarcoding MiSeq Illumina) throughout the experiment. The degradation of seven OPEs, including non-chlorinated and chlorinated compounds was studied. Overall, OPE degradation proceeds faster under biotic conditions. For example, the $t_{1/2}$ for two alkyl-OPEs: the low molecular weight tri-n-butyl phosphate (TnBP) and the high molecular weight tris(2-ethylhexyl) phosphate (TEHP) were of 46 and 77 days (abiotic conditions) compared to 19 and 47 days in biotic conditions, respectively. However, chlorinated OPEs exhibited similar degradation rates under both conditions. The bacterial community of the Marseilles' WWTP outlet sediments are dominated by 4 bacterial phyla (*Proteobacteria*, *Bacteroidetes*, *Calditrichaeota* and *Epsilonbacteraeota*). OPEs didn't induce a significant effect on the structure of the prokaryotic community nor on the alpha diversity. There was however a stimulation of the growth of the bacterial community in the first days after the spiking with OPEs. Data treatment is still undergoing, and these results will be valuable data for the refinement of OPE chemical risks assessment methodologies

4.04.P-Th136 Structural Changes in Chironomus riparius Exposed to Iron Oxide Nanoparticles

Dimitrija Savic-Zdravkovic¹, Djuradj Milošević¹, Jelena Slavisa Stojanovic², Jelena Stankovic³ and Nikola Stankovič⁴, (1)Faculty of Sciences and Mathematics, University of Niš, Serbia, (2)Biology and Ecology, Faculty of Sciences and Mathematics, University of Niš, Nis, Serbia, (3)Faculty of Science and Mathematics, University of Niš, Serbia, (4)Department of biology and ecology, Faculty of Science and Mathematics, University of Niš, Serbia

In the last two decades, a large amount of data has emerged on the potential effects of factory-produced and processed nanomaterials on organisms living in freshwater, soil and sediments. The Organisation for Economic Co-operation and Development (OECD) and Widening Participation Medics Network (WPMN) point out that existing toxicological protocols can be used to test the toxicity of nanoparticles on chironomids, but with special reference to parameters that could affect the toxicity of the tested nanoparticles and the interpretation of the results. Through this research, the sensitivity and practicality of Geometric morphometry method for assessing the impact of iron oxide nanoparticles (nano-Fe₃O₄) was examined. Mouthparts of larvae (mentums and mandibles) and forewings of adults were analysed to determine all discrete differences in the size and shape of structures and associate the results with different nanoparticle concentrations in sediments. This method revealed differences in the structures of treated and untreated individuals, although no effect on standard life parameters was shown. Improving the testing methodology using chironomids as model organisms, can greatly improve the further monitoring of the state of aquatic ecosystems and the biomonitoring of nanoparticle pollution, and thus the possibility of early purification and remediation.

4.04.P-Th137 Testing Toxicological Sensitivity of Cultured Vs Newly Sampled Mud Shrimps, Corophium volutator

Sara Nicoline Grønlund¹, Monica Hamann Sandgaard², Tomas Brodin³ and Henriette Selck⁴, (1)Roskilde University, Denmark, (2)Department of Science and Environment, Roskilde University, Roskilde, Denmark, (3)Swedish University of Agricultural Sciences (SLU), Sweden, (4)Roskilde University, Roskilde, Denmark

When assessing the ecological effects of contaminants in the environment, well-studied test-organisms are a crucial tool when performing standard-tests (e.g. OECD guidelines). When conducting standard water-only tests, organisms used are in general well tested and documented (e.g. *Daphnia magna*), however, when assessing toxicity of sediment systems, organisms are in general less well described. OECD have previously suggested and many have used the mud shrimp, *Corophium volutator*, as a tests organism when assessing toxicity of estuarine- or marine sediment systems, based on *C. volutator* being a cosmopolitan species, thriving in a broad range of salinities (from fully saline to almost freshwater), having high sensitivity, and constitute a substantial part of the diet of many fish and shore birds. However, field collected specimens are often used, as laboratory cultivation of *C. volutator* may be challenging and as amphipods in general may decrease in sensitivity already after 15 days in culture. The aim of this study was to test how culture time (< 15 days, 1 month, >1 year) impact sensitivity of *C. volutator*. The mud shrimps were exposed to cadmium chloride (CdCl₂) in a concentration-response water-only setup to nominal concentrations of 1, 3, 7, 10 and 15 mg L⁻¹ CdCl₂ and a control assessing mortality after 72 and 96h. In general, organisms cultivated for < 15 days seemed to be more sensitive towards CdCl₂ after 72h of CdCl₂ exposure. However, after 96h exposure to CdCl₂ the differences between the groups was almost diminished. The results further suggests that it is merely when performing short-term exposures (less than 4 days), where it is important to use field-collected *C. volutator*. We suggest to use cultured *C. volutator* as test-species for toxicological testing in sediment systems for experimental time frames longer than 4 days, e.g. 10 day acute sediment tests. Lastly, would we like to emphasise the need for further studies to investigate the most optimal conditions for keeping *C. volutator* in culture.

4.04.P-Th138 Moving Towards Chemical Activity-Based Sediment Toxicity Tests

Sebastian Abel¹, Ann-Kristin Eriksson-Wiklund², Elena Gorokhova² and Anna Sobek², (1)Helmholtz-Zentrum für Umweltforschung GmbH - UFZ, Germany, (2)Stockholm University, Sweden

The chemical activity or effective concentration of hydrophobic organic contaminants (HOCs) can provide a highly relevant metric for the risk assessment of polluted sediments. Many HOCs can exert baseline toxicity to benthic organisms over a narrow but consistent range of activities. As chemical activities are additive, the approach works for both single compounds and HOC-mixtures. Furthermore, under equilibrium conditions, a compound's activity is equal in all compartments, including biota. This simplifies the prediction of adverse effects, as well as its communication to decision-makers. However, currently available data on activity-response relationships of HOCs are limited to a few species, and no additional environmental stressors are considered. Therefore, the primary goal of this study is to provide a reproducible laboratory test system consisting of microcosms with artificial sediment and applicable for various sediment-inhabiting species. The sediment is loaded with HOCs to a target activity by equilibrating the organic part of the sediment (peat) with HOC-saturated water (known activity). The water is kept at saturation throughout the loading process with a reservoir of crystalline HOCs closed with a water-permeable cap. The systems have been

pre-validated with PDMS-silicone as a proxy for organic matter and three PAHs (acenaphthene, fluorene and fluoranthene). We found that the organic phase can be brought into equilibrium with the saturated water within two weeks in this system. After this time, the concentration in the silicone was within 80-120 % of the values predicted with literature-obtained silicone-water partition ratios. In parallel, water concentrations were monitored during the equilibration process. As expected, the concentration in the water phase was initially low due to the presence of the silicone HOC-sink. However, with the silicone approaching equilibrium, the water concentration came back up to saturation levels. Thus, the tested loading method is promising for the preparation of sediments for long-term ecotoxicity testing of HOC mixtures.

4.04.P-Th139 Development of a Flow-Through Water-Sediment Test System for Studies According to OECD TG 219

Henry Krueger¹, Nanditha Billa², Jutta Hager³ and Eric Bruns³, (1)Eurofins Agrosience Services, United States, (2)Eurofins Agrosience Services / Science and Reg Affairs, United States, (3)Bayer Crop Science, Germany

The OECD TG 219 is the chronic water-sediment chironomid toxicity test with spiked water. Typically, the test is run as a static test with a single spike of a test item added to the overlying water at the beginning of the test. Five test concentrations and a control are normally used to evaluate effects on emergence, survival and growth (developmental rate). Samples of overlying water, pore water and sediment are collected at least at the beginning and end of test and optionally at intermediate time points. Following current guideline requirements, the nominal or initial measured test concentrations are to be used for endpoint derivation. However according to the "Recurring issue document" by EFSA (2019) the endpoint derivation should be based on geometric mean measured concentrations in case recovery over time is outside the 80 -120% range. In addition, a study is not considered valid in case no test item can be measured at study end. These requirements pose a problem for very instable compounds. When a test item is instable the exposure is short lived and the geometric mean for all time points results in a very low number that is not an accurate measure of exposure. This misleading low geometric mean can drive a risk assessment. A remedy to the problem of misleading low geometric concentrations is to run the test as a static renewal or flow-through test to maintain test concentrations over time. Other potential reasons for running chironomid studies under flow through conditions are variable exposure risk assessments as different exposure peaks can be tested. This allows to generate calibration and validation studies according to the EFSA TKTD scientific opinion. Testing in combination with modelling could result in the use of Tier 2C according to the EFSA AGD. Renewals are mentioned in the OECD TG 219, but the guideline does not provide methodology for how to run the test with renewals of test solutions. We have developed a flow through test system to replenish overlying water with continual additions of test solutions resulting in 5 turnovers per day. The system has been designed to minimize disturbance to the sediment and has been tested to show that the validity criteria of OECD TG 219 can be met. A test material that degrades very quickly was also tested in an abiotic system to show that test concentrations could be maintained during the test. Most aquatic labs have flow-through systems that can be easily modified to accommodate OECD TG 219 tests.

4.04 Contaminated sediment: an environmental compartment of concern (Virtual Only)

4.04.V-01 Identification of Potential Dioxin-Like Chemicals in Contaminated Sediments of the Bohai and Yellow Seas Using Effect-Directed Analysis and Non-Targeted Analysis

Junghyun Lee¹, Seongjin Hong², Hyo-Bang Moon³ and Jong Seong Khim⁴, (1)Seoul National University, Seoul, Korea, Republic of (South), (2)Chungnam National University, Korea, South, (3)Hanyang University, Korea, South, (4)Seoul National University, Korea, South

In this study, identification of dioxin-like chemicals (DLCs) in polluted coastal sediments in the Yellow and Bohai seas was conducted using a combination of effect-directed analysis (EDA) and full-scan screening analysis (FSA). Firstly, aryl hydrocarbon receptor (AhR) activity of the organic extracts of sediments from a large marine ecosystem scale was screened by use of H4IIE-*luc* bioassay. Great AhR-mediated potencies were observed in raw organic extracts, aromatic fraction (F2), and subfractions of F2 (F2.6–F2.9) in sediments from Nantong, Qinhuangdao, and Yancheng. AhR responses were significantly correlated with concentrations of traditional polycyclic aromatic carbons (PAHs). However, dioxin-like PAHs could explain only < 1% of the overall induced AhR potencies. Thus, highly potent fractions (F2.6–F2.9) were analyzed using GC-QTOFMS to investigate the presence of unknown dioxin-like chemicals, which likely contribute to the overall AhR activity. A five-step prioritization strategy was applied here; ninety-two candidate compounds satisfied all of the criteria. Among these chemicals, thirteen compounds considering commercial availability of standard materials were assessed for AhR activity. Six compounds, including benz[*b*]anthracene, 6-methylchrysene, 2-methylbenz[*a*]anthracene, 1-methylbenz[*a*]anthracene, 1,12-dimethylbenzo[*c*]phenanthrene, and indeno[1,2,3-*cd*]fluoranthene were shown to be significant AhR-mediated activities. 1,12-Dimethylbenzo[*c*]phenanthrene and indeno[1,2,3-*cd*]fluoranthene were identified as novel AhR agonists, and their relative potencies values were obtained. Results of potency balance analysis showed that the six newly identified AhR agonists explained 1.3% to 100% of the total induced potencies. Thus, these compounds should be included in the monitoring of toxic substances in the future, and their sources and fate should be elucidated. Overall, combining EDA and FSA applied in the current study demonstrated the benefits of assessing the potential toxic effects of DLCs contaminated sites.

4.05 Effect modelling for regulatory environmental risk assessment: So close, and yet so far away? (Part I)

4.05.T-01 Mechanistic Population Models for Decision Support: The Importance of Good Conceptual Model Diagrams

Valery Forbes¹, Chiara Accolla², Thomas Banitz³, Nika Galic⁴, Volker Grimm⁵, Sandy Raimondo⁶, Amelie Schmolke⁷ and Maxime Vaugeois⁸, (1)University of Minnesota, United States, (2)Waterborne Environmental, Inc, United States, (3)UFZ - Helmholtz Centre for Environmental Research, Germany, (4)Syngenta Crop Protection LLC, United States, (5)Ecological Modelling,

Helmholtz Centre for Environmental Research - UFZ, Leipzig, Germany, (6)U.S. Environmental Protection Agency, United States, (7)Waterborne Environmental, Inc., United States, (8)University of Minnesota, Twin Cities, United States

The use of mechanistic population models as research and decision-support tools in ecology and ecological risk assessment is increasing. This growth has been facilitated by advances in technology, allowing the simulation of more complex systems, as well as standardized approaches for model development (e.g., Population modeling Guidance, Use, Interpretation, and Development for Ecological risk assessment (PopGUIDE)), documentation (e.g., the Overview, Design concepts and Details (ODD) protocol; TRANSPARENT and Comprehensive Ecological modelling documentation (TRACE)), and evaluation (e.g., Pattern Oriented Modeling (POM)). Mechanistic population models are particularly useful for simulating complex systems, but the required model complexity can make them challenging to communicate. Conceptual diagrams that summarize key model elements can facilitate communication and understanding of complex models and increase their acceptance as decision-support tools. Currently, however, there are no consistent standards for creating or presenting conceptual diagrams, and both terminology and content vary widely. Here we argue that greater consistency in conceptual diagram development and presentation is an important component of good modeling practice, and we provide recommendations for achieving this.

4.05.T-02 Aquatic Risk Assessment of Sub-Lethal Effects With Deb-Tktd Modelling

Benoit Goussen¹, Marie Trijau¹, Roland Kuhl¹, Liubov Zakharova¹, Carmen Boerschig¹, Philipp Emnet¹, Anja Coors², Tjalling Jager³, Neil Sherborne⁴ and Roman Ashauer⁵, (1)IBACON GmbH, Germany, (2)ECT Oekotoxicologie GmbH, Germany, (3)DEBtox Research, Netherlands, (4)Syngenta, United Kingdom, (5)Syngenta Crop Protection AG, Switzerland

DEB-TKTD models are mechanistic models for the effects of constant and time-variable exposures on organisms. The EFSA provides guidance on the use of DEB-TKTD models for sub-lethal endpoints in a Tier-2 assessment, but also identified several knowledge gaps. Here we address these by (i) providing an automatised algorithm and well documented, freely available model code for a simplified DEB-TKTD model, (ii) demonstrating the fitting of all model parameters of the simplified DEB-TKTD model from data gathered from a GLP-compliant suite of experiments and an automated algorithm, (iii) providing bespoke empirical studies aimed at providing best parameter estimates while staying GLP-compliant and adhering to existing OECD guidance, (iv) state of the art case studies on three aquatic invertebrate species, and (v) example risk assessments using a moving time window approach. We show the calibration and validation of the model to bespoke experimental data on *Daphnia magna*, *Ceriodaphnia dubia* and *Hyalella azteca* under time variable exposure to azoxystrobin. The calibration experiments had long pulse exposures during the most sensitive life stages, and validation experiments followed EFSA recommendations whilst also exposing the most sensitive life-stages. The validated DEB-TKTD model was used to predict the effects of example FOCUS-SW exposure profiles on growth and reproduction. We employed a moving time-window approach and calculated the lowest multiplication factor (EP₁₀ value) from all moving time windows to identify the worst-case sections of the whole exposure profile. Our computational method ensured that sensitive life stages were exposed to whichever exposure sub-section is worst-case for them. Our method, illustrated with case studies on three aquatic invertebrate species, ensures that all life-stages are exposed to all parts of the FOCUS SW exposure profile *in silico*. Since no fixed duration can be determined as worst-case, the duration of these moving time windows was fixed to the respective OECD guideline test duration of each species. This aligns the Tier 2C1 approach with experimental Tier 2 methods. The model predictions can thus be interpreted as a range of *in silico* standardized laboratory tests, covering every possible part of the exposure profile. Efficient, open-source tools have been developed to assist the analyses; these have been largely automated but currently still require very long computation times.

4.05.T-03 Modelling Survival of Several Species Jointly in One GUTS to Reduce Animal Toxicity Testing

Alexander Singer¹, Dirk Nickisch² and Andre Gergs³, (1)RIFCON GmbH, Hirschberg, Germany, (2)Rifcon GmbH, Germany, (3)Bayer Crop Science, Germany

Toxicodynamic-toxicokinetic (TKTD) models have been suggested as a component of environmental risk assessment (ERA) of pesticide (EFSA Aquatic guidance 2013, EFSA Wildlife draft guidance 2021). In the acute aquatic risk assessment, the reduced version of the general unified threshold model of survival (GUTS-RED) can support the assessment of species sensitivities under time-variable exposure. For this purpose, species sensitivity distributions (SSD) are constructed from GUTS-RED survival predictions for several species (at least 8 invertebrate species) exposed to realistic exposure scenarios. However, application of GUTS-RED in ERA might practically be limited by additionally required empirical efforts. At least two non-standard tests are recommended for each species to validate a species-specific GUTS-RED (EFSA TKTD Opinion 2018), which amounts to an extra of 16 invertebrate tests for a GUTS-RED-based SSD. Here, we present a novel approach to jointly model species in the GUTS-RED framework. The joint model is based on recently established relations among TD-parameters that are shared across species, if these employ common receptors and pathways in their response to a toxic compound. Calibration of the joint GUTS-RED is eased compared to the taxa-specific models, as it exploits additional information on the TD-parameter relations shared in the taxonomic group. In particular, for 8 invertebrate species, the number of TD parameters that need to be calibrated reduces from 2 taxa-specific parameters for each of 8 species to 1 taxa-specific parameter per species + 1 joining parameter capturing information across the taxonomic group. We show that GUTS-RED-IT jointly calibrated to the taxonomic group match or outcompete species-specific GUTS-RED-IT in terms of parameter calibration and survival predictions. We suggest that the reduced degrees of freedom in the joint model provide the potential for more reliable model predictions. Further, as the joint GUTS-RED models taxa at the level of their taxonomic group, it can be validated from a representative subsample of the taxa, which reduces animal toxicity testing.

4.05.T-04 Predicting the Effect of Food Level on Individual and Mixture Toxicity of Prochloraz and Benzalkonium Chloride in *Caenorhabditis elegans*: Comparing Dynamic Energy Budget and Classic Concentration-Response Modelling

Approaches

Helena Bayat¹, Mafalda Castro² and Nina Cedergreen³, (1)Institute for Environmental Sciences University of Koblenz-Landau, Germany, (2)University of Copenhagen, Denmark, (3)Plant and Environmental Sciences, University of Copenhagen, Frederiksberg, Denmark

Simplified DEB models coupled with toxicokinetic and toxicodynamic (TKTD) modules are a powerful tool for understanding toxic effects of multiple endpoints over time. However they have not yet been implemented widely in risk assessment due to model complexity and data requirements. A recently updated DEBtox model was implemented to analyze sublethal toxicity data from experiments designed for dynamic modelling for two chemicals, prochloraz and benzalkonium chloride (BAC), and one environmental stressor (food stress) in the nematode model organism *Caenorhabditis elegans*. This study was conducted with three aims; to test performance of the experimental design, to compare interpretation of effects between the DEBtox and concentration-response analysis, and finally to analyze the predictive power of DEBtox extrapolations for single chemical and mixture toxicity under food stress. The 96 hour experimental design for growth and reproduction endpoints in *C. elegans* performed well in providing data for dynamic modelling. Growth and reproduction over time were successfully modelled using the DEBtox model. According to the best-fitting DEBtox model, the physiological modes of action (pMoA) were growth for prochloraz and maintenance for BAC, which is in accordance with known modes of action of prochloraz and BAC documented in the literature. Functional response decreased with decreasing food level, in line with DEB theory assumptions. The DEBtox model could predict effects of food level alone and in combination with prochloraz quite accurately, which was not possible with concentration-response analysis. Independent action could predict the mixture toxicity of prochloraz and BAC fairly well (IA prediction: 44% effect; measured mixture toxicity: $33.56 \pm 6.5\%$ effect), but not at low food level, when mixture effect increased to 75% (± 3.88). The DEBtox model predicted the effect of prochloraz at low food quite well (57.78% effect predicted compared to $46.76 \pm 11.33\%$ measured). However the DEBtox model underestimated the effect of BAC and the mixture prediction at low food was the same as for prochloraz alone. DEBtox models can be powerful tools to understand chemical stressors in combination with environmental ones, but they require further testing to make reliable predictions for multiple stressor interactions.

4.05.T-05 The Integrative Honeybee Colony Model BEEHAVE: Lessons Learned

Volker Grimm¹, Matthias Becher², Ming Wang³ and Juergen Groeneveld⁴, (1)Ecological Modelling, Helmholtz Centre for Environmental Research - UFZ, Leipzig, Germany, (2)University of Graz, United Kingdom, (3)Helmholtz Center for Environmental Research - UFZ, Germany, (4)Helmholtz centre for environmental research - UFZ, Germany

Honeybees play an important role in the environmental risk assessment of pesticides. While the effects of pesticides on honeybees have been intensively researched in terms of development, behaviour, and mortality of individual bees under controlled conditions, it is still largely unknown how these effects play out at the colony level in real landscapes. Since controlled field experiments at the landscape scale over one or more entire seasons are not possible, mechanistic modeling appears to be the only way to better understand and quantify colony-level impacts. The BEEHAVE model, published in 2014, includes a spatiotemporal representation of nectar and pollen availability in the landscape, foraging, inhive dynamics including brood care, consumption of nectar and pollen, and virus transmission by *Varroa* mites. Although the model does not include a pesticide module, it is the first to allow the study of multiple stressors and is based on first principles that can translate environmental conditions, including weather, into colony performance and survival. Beehave was published open-access and deliberately implemented in a programming language that is free, transparent, and easy to learn, so that all sectors involved, including academia, beekeepers, industry, and regulators, can use it as a tool that allows to integrate different questions, points of view, and results. Since 2014, 18 applications of BEEHAVE have been published. We examined these applications in terms of the issues addressed, potential additions to the model, and key lessons learned. BEEHAVE has been used to examine the effects of forage gaps and forage quality, lethal and sublethal effects of pesticides, development of thresholds for risk assessment, and the evaluation of multiple stressor interactions. While most early applications used stylized landscapes and hypothetical pesticide effects, more recent studies have focused on validating field studies. Specific pesticide modules have been developed, as well as a module for *Varroa* control. In a study conducted by EFSA, BEEHAVE was parameterized for different sites in Europe to generate reference dynamics for bee colonies that were not affected by pesticides. Although the complexity of factors affecting honey bee colonies makes it impossible to summarize the lessons learned in a concise manner, BEEHAVE has proven to be a valuable tool for better understanding and predicting honeybee colony dynamics and the impact of various stressors.

4.05 Effect modelling for regulatory environmental risk assessment: So close, and yet so far away? (Part II)

4.05.T-06 Assessing the Population Relevance of Adverse Effects of Endocrine Disrupting Chemicals on Individuals: A Practical Modelling Approach

Charles Hazlerigg¹, Kate Mintram², Charles Tyler³ and Pernille Thorbek⁴, (1)Enviresearch Ltd, Newcastle-upon-Tyne, United Kingdom, (2)Brunel University, United Kingdom, (3)University of Exeter, United Kingdom, (4)BASF SE, Germany

The presence of endocrine disruptors (EDs) in the environment continues to be a cause for concern for wildlife given some have been shown to cause adverse effects on organisms at low exposure concentrations. However, there is still a significant lack of understanding on the potential effects of EDs on populations and communities. This fundamental shortfall has real-world environmental management and regulatory implications, where the aim is to protect populations. The ECHA/EFSA 2018 guidance on performing an assessment for ED of chemicals states that any adverse effect on an individual recorded in a laboratory experiment (e.g. reduced fecundity) is assumed to be an adverse effect on a population unless additional evidence is provided, albeit that population level effects are established for very few EDs. Population modelling is proposed as one of these additional lines of supporting evidence, however, statements in the EFSA/ECHA ED guidance on the practicality of how to use population

models in this context are absent. Crane et al. (2019) suggested a hazard-based framework using population modelling within an adverse outcome pathway (AOP). We present a methodology to assess the population relevance of ED exposure using population modelling in line with this AOP framework. This includes critical decisions regarding model choice, data (effects and exposure) and how to integrate the two (hazard- or risk-based) approaches. We provide a case study with prochloraz, an imidazole fungicide that has been shown to have feminising effects in fish (acting as both an antioestrogen and an anti-androgen) to illustrate how this approach could be applied and evaluate how different decisions may alter the population response. Two fish population models for trout (inSTREAM) and stickleback that met requirements for development and validation were identified and used in the study. Effects data extracted from the literature was combined with exposure profiles generated with FOCUS SW. Population effects were observed in some scenarios (hazard-threshold) and not others (dose-response) demonstrating different outcomes that would then invoke making different decisions. The population responses of both species exposed to prochloraz was similar, indicating that for this compound the use of conservative effects / exposure decisions may over-ride differences in life-history and vulnerability to ED exposure. This study indicates that models can be used to effectively support the evaluation of the effects of EDs on fish populations and that the proposed method may be adapted for regulatory purposes. However, further work and consensus are required to ultimately establish an agreed approach for this.

4.05.T-07 Predicting Combined Effects of Chemical Stressors: Population Effects of Mixtures With Deb-Ibm

Karel Vlaeminck¹, Karel Viaene¹, Patrick Van Sprang¹ and Karel De Schampelaere², (1)ARCHE Consulting, Belgium, (2)Ghent University (UGent), Belgium

The current risk assessment framework contains discrepancies between protection goals and the information received from risk assessment. Uncertainty gaps exist when using lab test results as proxy for the complex environment. Mechanistic population models can bridge the gap between individuals and populations. Additionally, mixture toxicity can be included in mechanistic models to predict combined effects of chemical stressors. Our main research questions here are: in a multiple chemical stressor environment, which patterns of effects are observed on populations exposed to mixtures, and can we predict those patterns with DEB-IBM? We used an individual-based model implementation of the dynamic energy budget theory (DEB-IBM) for *Daphnia magna* to design a population experiment where we tested combinations of physiological modes of action (PMoAs). Our hypothesis is that combined effects emerge from the linking of DEB energy flows. Mixture combinations and concentrations were selected based on the DEB-IBM. We tested the effects of four organic compounds to *D. magna* populations: pyrene, dicofol, ?-HCH, and endosulfan. A 17-week experiment was conducted consisting of two phases: a constant-exposed period (first 11 weeks, exposure initiated after 1 week, lasting for 7 weeks, followed by 3 weeks recovery), and a pulse exposure period (last 6 weeks, including a 3-day acute pulse, and final recovery). We validated the DEB-IBM with the population data. With DEB-IBM, mixture effects at the population were predicted, in line with the observation of the population experiment. Moreover, these are blind predictions at the population level, with a calibration on single-substance, individual-level data only. The DEB-IBM accurately predicted the effects during the constant phase, the recovery phase, and the acute phase with great accuracy. After the acute pulse, the model became unreliable due to stochasticity in a population-level context. Synergisms were observed in the population data, which were accurately predicted by the DEB-IBM as well. This confirmed our initial hypothesis where mixture toxicity emerges from the linking of DEB energy flows. Moreover, the DEB-IBM performed better in predicting mixture toxicity than statistical models (such as the independent action [IA] model). To use IA, population data with single substances is required, whereas DEB-IBM predicts mixture population effects based on prior model calibration with single-substance individual-level data.

4.05.T-08 Inferring Chronic Pesticide Effects From Long-Term Daphnia Population Experiments With a Stochastic Population Model

Gian Marco Palamara¹, Nele Schuwirth², Stuart Dennis¹ and Peter Reichert³, (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Systems Analysis and Modelling, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland, (3)Eawag Swiss Federal Institute of Aquatic Science and Technology, Switzerland

Identifying sublethal pesticide effects on populations is challenging. Long-term population experiments can help to assess chronic toxicity. However, population experiments are laborious and subject to stochasticity (demographic, environmental, and genetic). Therefore, large variation among a limited number of replicates can lead to non-conclusive results based on classical statistical analysis. Model-based analysis can support the interpretation of such experimental data to quantify sublethal pesticide effects. The goal of such an analysis is to identify the most important processes that determine population dynamics and lead to stochasticity and describe them in the model. The main challenge for this task is choosing an adequate level of model complexity. Models should be as simple as possible and as complex as necessary for an adequate description of the system. In this study, we tackled this challenge by using a systematic model selection process based on a nested design of the model structure and Bayesian inference to identify mechanisms from population experiments. We used a stochastic, age structured population model applied to data from long-term population experiments with *Daphnia galeata* in 1L aquaria with and without chronic pesticide treatments (Diazinon and Diuron) at sublethal concentrations. We tested different formulations of fecundity and mortality and compared the inferred parameter estimates from the different treatments. Posterior analysis helped to choose an adequate model description for life-history characteristics under the specific experimental conditions: a zero-inflated negative binomial distribution for fecundity and mortality without density dependence. For the Diazinon treatments, a comparison of the inferred posterior parameter distributions indicated the need for a time-dependent mortality rate that increases with time, indicating cumulative chronic toxic effects of Diazinon on the *Daphnia* populations. With this study, we demonstrate how we can use stochastic models to infer mechanisms from population data to help identifying sublethal pesticide effects. The model-based analysis can also support the optimization of the experimental design of future studies.

4.05.T-09 Validating Models With Experiments, or Interpreting Experimental Data With Models - the Advantages of Using Ibm-Based Approaches to Modelling Aquatic Mesocosms

*Tido Strauss*¹, *Roman Ashauer*², *Nika Galic*³, *Jana Gerhard*⁴, *Josef Koch*⁵, *Jürgen Schmidt*⁶ and *Amelie Schmolke*⁷, (1)gaiaac Research Institute, Germany, (2)Syngenta Crop Protection AG, Switzerland, (3)Syngenta Crop Protection LLC, United States, (4)gaiaac - Research Institute for Ecosystem Analysis and Assessment, Germany, (5)gaiaac Research Institute, Aachen, Germany, (6)MESOCOSM GmbH Institut für Gewässerschutz, Germany, (7)Waterborne Environmental, Inc., United States

In recent years, individual-based population models (IBMs) have been increasingly used in ecological risk assessment, often coupled with TKTD effect models. Integrated within ecosystem models, they can be powerful tools for predicting species population dynamics for different environmental scenarios. This study is part of a larger ring study to compare four aquatic system models of different model structure and evaluate whether such model approaches can be used to simulate aquatic mesocosms, and thus might be acceptable in the regulatory context of pesticide risk assessment in the future. This ring study also provides an opportunity to further develop data sampling in aquatic mesocosms for the purpose of model development and testing. Here we used the ecosystem model framework StoLaM+, which is a coupling of the lake model StoLaM including IBMs for pelagic crustaceans, an IBM for *Chaoborus crystallinus*, and the aquatic stream community model STREAMcom also including a variety of IBMs for benthic macroinvertebrates. Data from seven outdoor aquatic mesocosm studies are available for the project. We exemplarily analysed mesocosm data with different levels of complexity (including either just one or multiple developmental stages) and methodology (with or without area reference to the entire mesocosm) for selected aquatic species from pelagic and benthic communities (copepods, *Chaoborus*, *Cloeon*, *Asellus*) using IBMs. Due to their individual-based organisation, IBMs are designed to easily provide multiple quantitative endpoints for a modelled population, e.g., the number of individuals at different life stages. Especially in cases where different experimental methods have been used for different life stages of the same species, this model approach can reveal gaps in the consistency of population field data. Additionally, conversion factors for abundance measurements can be estimated for extrapolation to the entire system using IBMs, as long as at least one endpoint has a quantitative relationship (e.g., per area or volume) to the investigated ecosystem. This study shows that a comparison of model results should not automatically lead to a unidirectional fit of the models to available complex data sets in every case, but should include the possibility of performing an alternating plausibility check between measurements and simulations, depending on the specific type of measured data and methods used.

4.05.T-10 Comparative Ecosystem Modeling Study for Assessing Pesticide Risks in Aquatic Mesocosms

*Amelie Schmolke*¹, *Nika Galic*², *Steven Bartell*³, *Yasemin Atalay*⁴, *Isabel O'Connor*⁵, *Simon Spycher*⁵, *Nele Schuwirth*⁶, *Tido Strauss*⁷, *Brandon Sackmann*⁸, *Damian Preziosi*⁹, *Robert Pastorok*¹⁰, *Peter Ebke*¹¹, *Jürgen Schmidt*¹¹, *Ann-Kathrin Loerracher*¹¹, *Farah Abiakar*¹, *Jennifer Collins*¹ and *Roman Ashauer*¹², (1)Waterborne Environmental, Inc., United States, (2)Syngenta Crop Protection LLC, United States, (3)Cardno Inc., United States, (4)Cardno, United States, (5)EBP Schweiz AG, Switzerland, (6)Systems Analysis and Modelling, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland, (7)gaiaac Research Institute, Germany, (8)GSI Environmental Inc., United States, (9)Integral Consulting Inc., United States, (10)Integral Consulting, Inc., United States, (11)MESOCOSM GmbH Institut für Gewässerschutz, Germany, (12)Syngenta Crop Protection AG, Switzerland

Outdoor aquatic mesocosms are artificial ecosystems used for higher-tier pesticide risk assessments to assess the effects of pesticides across a wide range of organisms and to capture indirect effects mediated by the food web. Mesocosms provide more realistic estimates of risks compared to single-species laboratory-based standard toxicity studies. Aquatic system models (ASMs) have been developed to simulate mesocosm systems and can extend pesticide risk assessment through applying scenarios corresponding to conditions untested in the empirical systems, including time-variable exposures. We are presenting a comparative modeling (“ring”) study with four previously published ASMs (Streambugs, AQUATOX, CASM, and StoLaM+StreamCom). With the ring study, we aim to assess whether the artificial mesocosm systems can be simulated with ASMs. In addition, the study is an opportunity to gain insight into and inform data collection from the mesocosms themselves and allow for comparison between available ASMs. The goal of the study is to calibrate and validate the models with the same set of available mesocosm data. Mesocosm data are available from untreated control mesocosms from seven studies conducted in four different years at the FNU Research Centre Neu-Ulrichstein, Germany. We reviewed these data for patterns and consistencies across studies, and derived calibration and validation criteria to compare with the model outputs. Four of the available control data sets were used for calibration by all models. The remaining three data sets were used for validation in a separate step. The ring study provides a unique opportunity to compare previously published ASMs and assess whether they can be used to simulate the transient ecosystem responses in mesocosms. The ring study attempts to develop and establish ASMs as virtual mesocosms acceptable in the regulatory context of pesticide risk assessment.

4.05 Effect modelling for regulatory environmental risk assessment: So close, and yet so far away? (Virtual Only)

4.05.V-02 Evaluating the Influence of Growth Rate in Macrophyte Risk Assessment

Johannes Witt and *Thomas Preuss*, Bayer Crop Science, Germany

The use of plant protection products can result in a variety of exposure profiles in edge-of-field water bodies. TKTD models allow to realistically assess the effect of this time-variable exposure on macrophytes. EFSA PPR Panel (2018) considers the *Lemna* TKTD model of Schmitt et al. ready to be used in regulatory risk assessment, paving the way for a broad use of this model in risk assessment. However, it has been argued that under time-variable exposure regimes, the *Lemna* model may not be representative for macrophyte species such as *Myriophyllum*, due to their slower growth: e.g., while a minimum doubling time of frond numbers of 2.5 days is required in a *Lemna* test, the minimum doubling time of total shoot length in a *Myriophyllum* test is 14 days. It has

been reasoned that fast *Lemna* growth would allow faster recovery during periods with low or no exposure. On the other hand, earlier research using global sensitivity analysis on the Lemna model (Klein et al., SETAC Europe 2021) has shown that for typical *Lemna* growth rates, growth rate inhibition is rather insensitive to changes in growth rate. To get a better understanding of the influence of the growth rate on macrophyte risk assessment, we perform simulations with the *Lemna* TKTD model under laboratory growth conditions and time variable exposure. We investigate the effect of different baseline growth rates on growth rate inhibition for different sets of parameters and exposure regimes. We discuss the mechanisms involved, the extent of effects, and the implications for macrophyte risk assessment.

4.05.V-03 Simple Debkiss-Based TKTD Model for Chironomids

*Tjalling Jager*¹, *Marie Trijau*², *Carlo Romoli*³, *Benoit Goussen*² and *Roman Ashauer*⁴, (1)DEBtox Research, Netherlands, (2)IBACON GmbH, Germany, (3)IBACON GmbH, Rossdorf, Germany, (4)Syngenta Crop Protection AG, Switzerland

Toxicokinetic-toxicodynamic (TKTD) modelling is receiving increasing interest in the regulatory risk assessment of pesticides. TKTD models explicitly consider the factor 'time', and are based on mechanistic principles, thereby allowing extrapolation across (time-varying) exposure scenarios. For sub-lethal effects, generic and practical TKTD models should be based on energy-budget considerations. Dynamic Energy Budget (DEB) theory is well established in this area, and practical, simplified frameworks such as DEBKiss are derived from it. Despite the obvious advantages of DEB-based TKTD modelling, there are species groups whose life histories do not fit well with the generic standard models. The insects are a particularly prominent group for which this is the case. These animals split up their life cycle into a growing, non-reproducing, phase (the larva) and a non-growing, reproducing, phase (the adult). For holometabolous insects, this split is accompanied by a dramatic morphological metamorphosis. In many species the adult does not even feed, or at least: does not have to feed to produce eggs. Several attempts at DEB modelling of insects have been made. However, these models are too complex to apply to risk assessment (at least, given the typical data sets that are available) and tend to yield unrealistic responses under stress (e.g., food limitation). In this study, we set out to develop a novel, simple, DEBKiss-based TKTD model for chironomids (nonbiting midges). The model should be simple enough to be parameterised from the limited data from standard experimental tests, extended with several length measurements in the larval phase. This implies sacrificing some mechanistic principles in favour of more pragmatic descriptive elements. However, the crucial test of the model will be to see whether it is able to extrapolate between different time-varying exposure scenarios. In this presentation, we will explain the model structure and report on the model testing against data from dedicated experimental tests.

4.05.V-04 The Importance of Confidence Limits for Ecotoxicological Endpoints

Zoe Leanne Jones, *Hanna Samantha Schuster*, *Marie Brown*, *Katie Smith* and *Nadine Taylor*, Cambridge Environmental Assessments, United Kingdom

In Europe, Tier I ecotoxicity tests using standard species are a regulatory risk assessment requirement for all chemicals prior to commercial use. The most common statistical endpoint used in acute and chronic ecotoxicological studies are Effect Concentration (EC_x) values. These describe the concentration at which the x percent of the organisms are affected for any given parameter, e.g. mortality, i.e. an EC₅₀ would be where 50% of all tested organisms had died. In recent years, there has been a requirement for the provision of both EC₁₀ and EC₂₀ values in addition to the traditional EC₅₀ values. Therefore, older study data is routinely re-analysed to generate these values to be submitted to the regulatory authorities for current environmental risk assessments. These re-analyses should also include an assessment of the reliability of each endpoint. This is usually carried out by investigating the corresponding confidence limits. Although confidence limits are a key indicator of the reliability of the data, they can sometimes be overlooked, or their importance misunderstood. Here, we provide an overview on the current guidance for calculating EC_x values, and their confidence limits, to provide an insight on how confidence limits can be used to identify a reliable EC_x endpoint. We will also highlight the standard species accepted endpoints detailed in the OECD test guidelines.

4.05 Effect modelling for regulatory environmental risk assessment: So close, and yet so far away? (Poster)

4.05.P-We176 Heart Rate As an Early Warning Parameter for Mortality in Fish Embryos Exposed to Ionisable Substances

*Peter Von der Ohe*¹, *Thomas Gräff*², *Mona Schweizer*³, *Heinz Köhler*⁴ and *Ute Kühnen*⁵, (1)Federal Environment Agency (Umweltbundesamt), Germany, (2)German Environment Agency (UBA), Dessau-Roßlau, Germany, (3)University of Tuebingen, Germany, (4)University of Tübingen, Germany, (5)German Environment Agency, Germany

Environmental risk assessment of organic chemicals usually does not consider pH as a key factor. Hence, most substances are tested at a single pH only, which may largely underestimate the toxicity of ionisable substances with a pK_a in the range of 4–10, with differences in toxicity between pH's of up to a factor of 2000. Thus, the ability to consider pH-dependent toxicity is essential for a more realistic assessment. We used *Danio rerio* embryos exposed to ten ionisable substances (the acids diclofenac, ibuprofen, naproxen and triclosan and the bases citalopram, fluoxetine, metoprolol, propranolol, tramadol and tetracaine) at four external pH levels, investigating the endpoints mortality (LC50) and heart rate (EC20). Dose-response curves were fitted with an ensemble-model to determine the true uncertainty and variation around the mean endpoints, and with relative model quality estimation based on the Akaike Information Criterion (AIC). This resulted in more robust EC_x estimates with lower 'standard errors' as compared to randomly selected individual models. We detected a high correlation between mortality (LC50) at 96 hpf and reduced heart rate (EC20) at 48 hpf for all compounds and all external pH levels (r=0.98). Moreover, the observed pH-dependent effects were strongly associated with log D and thus, likely driven by differences in uptake (toxicokinetic) rather than internal (toxicodynamic) processes. Prospectively, the *a priori* consideration of pH-dependent effects of ionisable substances might make testing at different pH levels redundant, by applying a respective safety factor, while the endpoint of mortality might

even be replaced by a reliable sublethal proxy that could reduce the exposure of the test species, while accelerating the evaluation process.

4.05.P-We177 Solitary Bees in Agricultural Landscapes: SolBeePop, a Population Modeling Approach

Amelie Schmolke¹, Nika Galic² and Silvia Hinarejos³, (1)Waterborne Environmental, Inc., United States, (2)Syngenta Crop Protection LLC, United States, (3)Sumitomo Chemical Agro Europe, France

With their large diversity of species, solitary bees are important pollinators of crops and native plant communities. In agricultural landscapes, they can potentially be exposed to pesticides, and thus, are considered explicitly in risk assessments of pesticides. The managed Western honey bee (*Apis mellifera*) is currently used as surrogate across bee species in these assessments. Fundamental ecological differences result from the social and solitary life styles, introducing uncertainty in the estimation of pesticide risk to solitary bee populations. We developed the model SolBeePop, a population model for solitary bees in agricultural landscapes. The model can simulate a variety of species by using species-specific traits as model parameterizations. Model parameterizations for the modeled species (*Osmia bicornis*, *O. cornifrons*, *O. cornuta*, *O. lignaria*, *Megachile rotundata*, *Nomia melanderi*, and *Eucera (Peponapis) pruinosa*) were compiled from the literature whereby data availability varied by species. The model can simulate the diverse life cycles of the species and can be used to explore the importance of uncertainties in data to the population dynamics. We calibrated and validated the model with control data from semi-field studies conducted with *O. bicornis* and *O. cornuta*. The model can successfully capture population dynamics observed in these studies. Further developments include the implementation of an exposure and effect module which will make it possible to simulate exposure and population-level effects in the context of realistic landscape scenarios. Thus, this model will become a valuable tool for higher-tier pesticide risk assessments of solitary bees in agricultural landscapes.

4.05.P-We178 An Environmental Risk Assessment Case Study on *Ceriodaphnia dubia* Analysed by 'DEB-TKTD'

Modelling

Benoit Goussen¹, Marie Trijau¹, Anja Coors², Neil Sherborne³, Tjalling Jager⁴ and Roman Ashauer⁵, (1)IBACON GmbH, Germany, (2)ECT Oekotoxicologie GmbH, Germany, (3)Syngenta, United Kingdom, (4)DEBtox Research, Netherlands, (5)Syngenta Crop Protection AG, Switzerland

Toxicokinetic-toxicodynamic (TKTD) modelling is receiving increasing interest in the regulatory environmental risk assessment of chemicals. This type of mechanistic model integrates all available data in a single framework. In particular, it allows performing refined risk assessment by extrapolating from laboratory results to relevant Tier 2C refined exposure scenarios, based for instance on FOCUS-sw predictions. Dynamic Energy Budget models coupled with TKTD modules (DEB-TKTD) are the leading approach to assess sublethal effects of chemicals on individual organisms. EFSA recognised, in its 2018 opinion, several strengths of DEB-TKTD modelling, but also highlighted some challenges. Particularly, EFSA stated that the “lack of published examples of DEBtox [DEB-TKTD] models for pesticides and aquatic organisms [...] results in the conclusion that these models are not yet ready for use in aquatic risk assessment for pesticides”. The aim of this study is to address this gap by providing a state-of-the-art example on a standard test species (*Ceriodaphnia dubia*) in aquatic risk assessment. This was achieved by following the framework proposed in the Scientific Opinion. In the first step, bespoke empirical studies based on OECD 211 guidelines were designed to allow obtaining the best estimate and identification of all relevant model parameters while staying GLP-compliant. A DEB-TKTD model, DEBtox2019, was then calibrated on these data and used to inform the design of the validation experiment. Once validated, the model was used to perform predictions for a refined exposure scenario based on FOCUS-sw exposure profiles. A moving time-window approach was used to perform the environmental risk assessment. This case study highlights and discusses how DEB-TKTD can be used in the aquatic environmental risk assessment of pesticides.

4.05.P-We179 Deb-Tktd Modelling for the Environmental Risk Assessment of Pesticides on Chironomids

Benoit Goussen¹, Marie Trijau¹, Carlo Romoli², Ullrich Seidel¹, Volker Wydra¹, Neil Sherborne³, Tjalling Jager⁴ and Roman Ashauer⁵, (1)IBACON GmbH, Germany, (2)IBACON GmbH, Rossdorf, Germany, (3)Syngenta, United Kingdom, (4)DEBtox Research, Netherlands, (5)Syngenta Crop Protection AG, Switzerland

The current regulatory environmental risk assessment of plant protection products (PPP) is often based on controlled laboratory experiments with constant or refined simple pulse exposure scenarios. While this approach has the benefits of simplicity, the tested exposure patterns are far from the real-world ones. In addition, the summary statistics derived from these traditional approaches do not allow, for instance, meaningful extrapolations to non-tested exposure patterns or to different exposure durations. Mechanistic modelling and, in particular, toxicokinetic - toxicodynamics (TKTD) models have the potential to overcome these challenges. These types of models make holistic use of all data available by integrating them into a unique framework. Dynamic Energy Budget models coupled with TKTD modules (DEB-TKTD) are the leading approach to assess sublethal effects of PPP on individuals. However, to date, no satisfactory DEB-TKTD-based model for use in regulatory risk assessment was available for chironomids. This challenge has now been overcome. We here present a case study with *Chironomus dilutus* exposed to a pesticide. Tailored OECD compliant life-cycle experiments were performed for both model calibration and model validation. A model based on a simplified DEB model was used to analyse these data according to the Scientific Opinion on TKTD modelling for EFSA. Ultimately, the validated model can be used to perform Tier 2C refined exposure environmental risk assessment.

4.05.P-We180 Can 'DEB-TKTD' Modelling Enhance Environmental Risk Assessment? - a Case Study With *Daphnia magna*

Benoit Goussen¹, Marie Trijau¹, Carmen Boerschig¹, Philipp Emnet¹, Neil Sherborne², Tjalling Jager³ and Roman Ashauer⁴,

(1)IBACON GmbH, Germany, (2)Syngenta, United Kingdom, (3)DEBtox Research, Netherlands, (4)Syngenta Crop Protection AG, Switzerland

Yes, it can! Traditional environmental risk assessment of plant protection products (PPP) is usually based on controlled laboratory experiments. These experiments are often conducted under constant or refined simple pulse exposure scenarios. These experimental conditions are often far removed from real conditions where complex time-variable exposure scenarios are the norm. Such challenges can be overcome thanks to mechanistic modelling. Mechanistic modelling is recently gaining interest in regulatory environmental risk assessment as it allows considering, within an integrated framework, more realistic environmental scenarios. In particular, toxicokinetic - toxicodynamic (TKTD) models make a holistic use of all data possible, by integrating them in a single framework. Dynamic Energy Budget models coupled with TKTD modules (DEB-TKTD) are the leading approach to assess sublethal effects of PPP on individuals. The EFSA Scientific Opinion on TKTD modelling recognises DEB-TKTD modelling as a potentially powerful tool for use in environmental risk assessment. It also identified that DEB-TKTD models are not yet ready for use in risk assessment as “sufficiently calibrated and validated DEBtox models for pesticide and aquatic organisms were not yet available in the open literature”. We here address this limitation by presenting a case study for *Daphnia magna* exposed to a pesticide. This case study followed the framework proposed by EFSA. A DEB-TKTD model was calibrated on bespoke studies based on the OECD 211 *D. magna* reproduction test. In a second step, the model was used to inform the design of the validation experiment with repeated pulsed exposure. The duration between pulses was varied across treatments to align with EFSA recommendations to validate toxicologically dependent and independent exposures. The model was then validated against the newly produced validation dataset. In a final step, the validated DEB-TKTD was used to perform an environmental risk assessment of relevant exposure profiles using a time-window approach. This case study showcases the advantages and challenges of using DEB-TKTD for risk assessments.

4.05.P-We181 On the Use of 'DEB-TKTD' Modelling for Regulatory Environmental Risk Assessment of Pesticides - a Case Study With H. Azteca

Benoît Goussen¹, Marie Trijau¹, Carlo Romoli², Anja Coors³, Neil Sherborne⁴, Tjalling Jager⁵ and Roman Ashauer⁶, (1)IBACON GmbH, Germany, (2)IBACON GmbH, Rossdorf, Germany, (3)ECT Oekotoxicologie GmbH, Germany, (4)Syngenta, United Kingdom, (5)DEBtox Research, Netherlands, (6)Syngenta Crop Protection AG, Switzerland

Mechanistic modelling and, in particular, toxicokinetic-toxicodynamic (TKTD) modelling, has received increasing interest in the regulatory environmental assessment for more than 10 years now. In its 2013 Aquatic Guidance document, EFSA already stated that TKTD models “may be used to predict the time course of effects of time-variable exposures”. This increased interest has culminated in the publication in 2018 of the “EFSA Scientific Opinion on the state of the art of Toxicokinetic / Toxicodynamic (TKTD) effect models for regulatory risk assessment of pesticides for aquatic organisms”. Traditional environmental risk assessment of chemicals is usually based on controlled laboratory experiments. These experiments are often conducted under constant or limited pulse exposure concentrations. These experimental conditions are often far removed from real conditions where complex time-variable exposure scenarios are the norm. Mechanistic modelling, and in particular TKTD modelling, allows considering within an integrated framework more realistic environmental scenarios. Despite its numerous strengths and advantages, EFSA considers that the use of TKTD modelling to analyse sub-lethal effects, i.e., dynamic energy budget models coupled with the TKTD module, is not yet ready for regulatory risk assessment. This conclusion mainly arises from the lack of published examples and case studies. In this study, we aimed at overcoming this challenge by presenting a case study for the standard test species *Hyalella azteca* exposed to a pesticide. We used a well-recognised DEB-based model, DEBtox2019, and designed bespoke empirical studies aimed at providing the best parameter estimates while staying GLP-compliant and adhering to existing guidance. Our study follows the recommendation of the EFSA scientific opinion on TKTD modelling and shows and discusses the advantages and challenges of using DEB-TKTD for risk assessments.

4.05.P-We182 DEBgen: A Generalised Model Formulation to Incorporate Common Deviations From the Standard Model of Dynamic Energy Budget Theory

Josef Koch¹ and Tido Strauss², (1)gaia Research Institute, Aachen, Germany, (2)gaia Research Institute, Germany

The Dynamic Energy Budget (DEB) theory has become a popular starting point when modelling the life history of individual organisms, e.g., as physiological units of an individual-based population model (IBM). Compared to other, often purely data-driven, *empirical* models, DEB models use a coherent framework of mechanistic rules – on the level of bioenergetic budgets – that respect the law of conservation of energy. As a result, these models are achieving increasingly high levels of trust, which is a key requirement for their potential use in environmental risk assessment. Another advantage of DEB models is their generic nature in the sense that theoretically any species can be modelled using the same set of bioenergetic rules and corresponding model equations, with only the deviations in parameter values accounting for inter-species differences. And while this appears to be true for many species, numerous exceptions, i.e., species that deviate from the standard DEB model, have been identified in recent years. This has led to the development of *typified models*, typically adding additional life stages (e.g., with an accelerated growth), in which they deviate from the standard model. While these typified models are relatively well documented, ready-to-use model implementations are scarce when compared to the standard model. Starting from a standard model and adapting it to a typified model is a rather error-prone task. Starting from a different typified model can be even more confusing since life-history events of the same name (specifically *metamorphosis*) can have different meanings (i.e., they trigger different rule changes) among the typified models. Here we argue, that the most commonly used typified models do not actually contradict the standard DEB model but can rather be seen as extensions. Conversely, one can think of a more general model formulation of which the standard DEB model and many typified models merely represent special cases. We present the model framework DEBgen, which so far covers the model types *std* (standard model), *abp*, *sbp*, *abj*, and *asj*. Further extensions (e.g., incorporating *hep* and *hex*

models) are also planned. A particularly useful application of DEBgen is its use as a building block in community models that incorporate multiple species described with different typified models. Thus, one would only need to implement a single DEB model structure instead of creating new code for each DEB model type.

4.05.P-We183 To Combine or Not to Combine Data Sets for GUTS Calibration

Andre Gergs¹, Barbara Bauer² and Alexander Singer³, (1)Bayer Crop Science, Germany, (2)Rifcon GmbH, Germany, (3)RIFCON GmbH, Hirschberg, Germany

Toxicokinetic-toxicodynamic (TK-TD) models allow for the integration of exposure and effects in an environmental risk assessment context. The General Unified Threshold Model of Survival (GUTS) is a particularly promising tool for predicting lethal effects under time variable exposure conditions. Before being used in risk assessment, GUTS models need to be parameterized and validated based on different toxicity data sets. The EFSA Scientific Option on TK-TD modelling (<https://doi.org/10.2903/j.efsa.2018.5377>) suggests that GUTS is calibrated on experimental data under constant and/or time variable exposure and preferably validated on data from different time variable exposure scenarios. The calibration data, but not the validation, will influence the parameter estimates and their uncertainty and thus the risk assessment endpoint calculated by GUTS (such as the Lethal Profile LPx). In particular, the parameter uncertainty will directly depend on the level of ‘information’ in the calibration data – generally speaking, the better the information, the better the parameter estimates. In most cases, calibrating GUTS based on a dataset from a single study will be sufficient for predicting risk assessment endpoint with an adequate confidence level. We will however illustrate, using data sets from toxicity tests with *Chironomus riparius* and the insecticide flupyradifurone as an example, that parameter uncertainty may decrease (rather than increase) when combining different types of toxicity studies for GUTS calibration.

4.05.P-We184 Can You Reduce Validation Effort When Jointly Calibrating GUTS Models for Multiple Species?

Hanna Samantha Schuster¹, Andre Gergs², Thomas Preuss² and Nadine Taylor¹, (1)Cambridge Environmental Assessments, United Kingdom, (2)Bayer Crop Science, Germany

In regulatory risk assessment of Plant Protection Products (PPP), an option for endpoint refinement using effect modelling has been included in guidance documents since 2013 (Tier IIC; EFSA Aquatic Guidance 2013). A detailed description on the type of models that are fit for the regulatory process, their application, and underlying data requirements were outlined and discussed in detail in the EFSA Opinion on TKTD modelling (2018). For lethal effects there is a clear recommendation for the parameterization of the (reduced) GUTS model. Although PPP notifiers are often very interested in the modelling approaches, in our experience, many are hesitant to ultimately choose an effect modelling approach to address their regulatory questions. This is mainly due to the uncertainty surrounding regulatory acceptance and the high costs associated with calibration and validation experiments, particularly if a large number of species are involved. Often, existing data sets from previous submissions do not include the necessary information to be re-used for model parameterization. The lack of information in some studies may be circumvented by calibrating GUTS jointly using multiple species data sets if parameters correlate. Here, we propose conducting a reduced number of non-standard higher tier experiments, for a set of key species to validate the multi-species GUTS parametrization. We highlight where the uncertainties of this approach within a risk assessment lie, as well as the potential advantages and knowledge gains.

4.05.P-We185 Refining Aquatic Risk Assessment With GUTS Modelling: The Right Tool for the Job?

Alice Tagliati¹, Charles Hazlerigg², Amy C. Brooks³, Hanna Samantha Schuster³ and Scott Hawley⁴, (1)Enviresearch, Newcastle upon Tyne, United Kingdom, (2)Enviresearch Ltd, Newcastle-upon-Tyne, United Kingdom, (3)Cambridge Environmental Assessments, United Kingdom, (4)Enviresearch Ltd, United Kingdom

In recent years toxicokinetic-toxicodynamic (TKTD) approaches have been developed to describe the effects of chemical substances on organisms over time. TKTD models represent real-world scenarios, such as time-variable pulsed exposure profiles, and hence overcome the limitation of conventional toxicity indicators which are commonly estimated at the end of an exposure period that assume constant exposure concentrations over time. Among the TKTD models, the General Unified Threshold model of Survival (GUTS) is considered ready-to-use in ERA by the European Food Safety Authority (EFSA 2018). In the tiered approach for pesticide risk assessment, GUTS is recommended as powerful Tier-2C refinement tools to assess the survival probabilities of aquatic organisms under realistic time-variable exposure profiles (i.e. by integrating the results from fate models). However, despite being structurally simple (TKTD models consist of three or four equations that link external concentrations to survival effects over time) and supported by easily accessible and user-friendly modelling tools (e.g. OpenGUTS and MOSAIC), the approach has seen limited use in regulatory environmental risk assessments. To determine the cause of this mismatch between their theoretical advantages and practical uses, we present an overview of the commercial viability of GUTS modelling in regulatory applications. In particular, GUTS approach is compared to the other options available to solve an aquatic risk assessment (e.g. multiple species testing approaches at Tier 2A and Tier 3 and Tier 2B pulsed exposure studies) in order to highlight the benefits of using a TKTD modelling approach as well its practical limitations in a pesticide dossier submission. For commercial viability, different risk assessment approaches can be combined if the potential use of TKTD is considered early on (as in Tier 1 testing and Tier 2B pulsed exposure studies). Here we present a case study where a TKTD approach was considered but not pursued due to cost implications. We thus define the characteristics of standard test studies that would make GUTS a routine part of regulatory submissions, whilst also identifying other refinement options that are appropriate in alternative situations.

4.05.P-We186 The Application and Limitations of Exposure Multiplication Factors in Sublethal Effect Modelling

Neil Sherborne¹, Tjalling Jager², Benoit Goussen³, Marie Trijau³ and Roman Ashauer⁴, (1)Syngenta, United Kingdom, (2)DEBtox Research, Netherlands, (3)IBACON GmbH, Germany, (4)Syngenta Crop Protection AG, Switzerland

Toxicokinetic-toxicodynamic (TKTD) models can be powerful tools in many areas of ecology, including environmental risk assessment (ERA) of substances such as plant protection products. To facilitate this use, exposure multiplication factors (EMFs, sometimes known as multiplicative margin of safety values) have been recommended by EFSA [1]. An EMF scales the whole exposure profile being assessed. The aim of the risk assessment is to find an EMF which - when applied to an exposure profile - results in some specified percentage effect relative to the control at the end of the exposure profile. This is known as the LP_x or EP_x (for sublethal effects). The core assumption of the approach is that increasing the scaling of a given exposure profile will always produce more extreme effects. Unlike experimental approaches, TKTD models offer an opportunity to interrogate this assumption in a mathematically rigorous manner. For the GUTS framework, and a chosen DEB-TKTD model we show the results of seeking a proof that LP_x or EP_x values exist and are unique for any x% effect and any non-zero exposure profile. We find necessary conditions for existence of these values and show that, in the majority of cases, the LP_x (EP_x) for an exposure profile is unique if it does exist. However, in DEB-TKTD models, there are certain model configurations where higher EMF values can have reduced effect, which also means that there may be more than one EP_x value for the profile. In other words, scaling up an exposure can reduce the effects observed at the end of the exposure profile. Assessing these modelling techniques with such rigour provides the utmost confidence in their use and their limitations. Most importantly, this work reveals both scientific and regulatory questions of great importance and interest. When non-uniqueness of the EP_x is a concern in ERA, algorithms may report a higher (but equally correct) value as the EP_x. Slower methods may need to be used to estimate the lowest EP_x. This unexpected key finding could naturally lead into many new investigations, for example attempts to replicate the modelling result *in vivo*.

4.05.P-We187 Exploring GUTS in the Environmental Risk Assessment of Pesticides: A Case Study

Alice Tagliati¹, Charles Hazlerigg² and Scott Hawley³, (1)Enviresearch, Newcastle upon Tyne, United Kingdom, (2)Enviresearch Ltd, Newcastle-upon-Tyne, United Kingdom, (3)Enviresearch Ltd, United Kingdom

Pesticide regulations are based on environmental risk assessment that incorporates information on the fate and transport (exposure) and ecotoxicological effects of a chemical on exposed organisms. At Tier 1, effects data are based on standardized laboratory studies (i.e. single active substance, constant concentration and few model organisms) which do not take into account the time-variable exposure profile of the chemicals. Toxicokinetic (TK) and toxicodynamic (TD) models have been developed to improve the environmental risk assessment of chemicals by describing the effects of chemical substances on organisms over time. Recently, the General Unified Threshold model for Survival (GUTS) has been judged to be “ready to be used in risk assessment” by the Panel on Plant Protection Products and their Residues (PPR) of the European Food Safety Authority (EFSA). However, despite the advantage of TKTD modeling, this approach is still underutilized within the context of environmental risk assessment. This presentation looks to answer the question of “why?” by presenting GUTS modelling for two active substances that relied on mesocosm data (Tier 3) for approval for use in the EU by EFSA. Our aim is to discuss the potential reasons for the applicability and common use of GUTS models in the EFSA tiered scheme for the aquatic invertebrates acute risk assessment, that may inform the selection of appropriate refinement methods in the future.

4.05.P-We188 Mixture Effects of Two Insecticides on the *Enchytraeus crypticus* Life Cycle Predicted With a Deb-Tktd Model

Sylvain Bart¹, Tjalling Jager², Alex Robinson³, David Spurgeon⁴ and Roman Ashauer⁵, (1)MOECO2, Paris, France, (2)DEBtox Research, Netherlands, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (4)Centre for Ecology & Hydrology, United Kingdom, (5)Syngenta Crop Protection AG, Switzerland

The Dynamic Energy Budget theory (DEB) enables modelling the effects of chemical stressors on the organism life cycle through the coupling with toxicokinetic-toxicodynamic (TK-TD) models. The DEB-TKTD framework also has the potential to predict effects in complex situations such as mixture effects. Hence, DEB-TKTD models are of great interest for pesticide risk assessment, but so far insufficient applied case studies are available in the scientific literature to assess their reliability. For soil organisms, these models are even scarcer, and currently, none can be found in the literature for enchytraeids, despite the fact that they are model organisms in soil ecotoxicology. We here present a DEB-TKTD model for the model species *Enchytraeus crypticus* that enables us to predict mixture effects of two insecticides. Hatchlings of *E. crypticus* were exposed in the standardized LUF_A 2.2 soil, to cypermethrin and imidacloprid, in single exposure and in mixture of both insecticides. Body length measurement and estimation of egg production were used as input for the calibration of a DEBkiss-TKTD model with the single exposures. The calibrated model was then used to predict the effects of the mixture, and these simulations compared with the observed effects. Results showed that the *E. crypticus* life cycle under chemical stress can be accurately simulated with a DEB-TKTD model. The physiological modes of action (pMoA) for cypermethrin and imidacloprid were an increase of the energy costs for growth, and an increase of maintenance cost, respectively. The DEB-TKTD model, calibrated with the single exposures, provided an accurate prediction of the mixture effects with r² values (predicted vs observed) of 0.95 and 0.96 for the body length and cumulative egg production. This study, with the development of the combined experimental and DEB-TKTD workflow, supports the robustness and reliability of DEB-TKTD models in their use in pesticide risk assessment.

4.05.P-We189 A User-Friendly Software Tool for Deb-Tktd Model Predictions

Oliver Jakob¹, Torben Wittwer¹, Thomas Martin², Neil Sherborne³ and Roman Ashauer⁴, (1)Rifcon GmbH, Germany, (2)The University of York, Germany, (3)Syngenta, United Kingdom, (4)Syngenta Crop Protection AG, Switzerland

Mechanistic effect models have a great potential to contribute more realism to the environmental risk assessment (ERA) of pesticides. In this context, toxicokinetic-toxicodynamic (TKTD) models have received particular attention and are now available for different applications. TKTD models based on dynamic energy budget theory (DEB-TKTD) have been developed to simulate sublethal effects, exploring the effects of toxicants on growth and reproduction over time. The EFSA scientific opinion on TKTD models for aquatic organisms (EFSA PPR 2018) recognises the great potential of DEB-TKTD models for a future use in prospective ERA for pesticides. However, the scientific opinion (EFSA PPR 2018) also concludes that these models are not yet ready for use. One main obstacle mentioned is the fact that no user-friendly DEB-TKTD modelling tools are currently available. To facilitate the use of DEB-TKTD models for ERA we are developing a user-friendly R-shiny application allowing users to conduct forward projections of defined DEB-TKTD models. Specifically, the tool will be based on the simplified DEB-TKTD models described by Jager (2020). The tool will allow calculating predictions for different exposure profiles and user-provided input parameter sets. It predicts the multiplication factor that would need to be applied to a given exposure profile in order for growth or reproduction to be reduced by X% (termed EP_x by EFSA PPR 2018). The results are then directly compiled in a basic report document. The publication of the software tool is envisaged for mid-2022. It will be freely available and comes along with a user manual. The code will be open source. We present the design and layout of the application and provides an overview of its functionality. 4.05.P-We190 Case Study for Mammal Risk Assessment of Pesticides Using the Deb-Tktd Model

David Heckmann, Andre Gergs and Thomas Preuss, Bayer Crop Science, Germany

The draft update to the EFSA guidance for bird and mammal risk assessment (EFSA 2021) emphasizes the great potential of toxicokinetic-toxicodynamic dynamic energy budget models (DEB-TKTD), for example for increasing realism of the risk assessment and reducing the use of test animals (EFSA 2021). Nevertheless, EFSA highlights the lack of published examples of DEB-TKTD modelling for mammals, especially in the assessment of reproductive effects. This lack of examples is currently seen as the major hurdle in the regulatory acceptance of these modelling approaches (EFSA 2021). We present a case study for the use of DEB-TKTD modelling in mammal risk assessment of insecticides. Starting from the published Add-My-Pet DEB model for the Wistar rat (Rakel et al. 2019), we adapted the model to describe the available toxicity data for an insecticide. We extended the existing DEB model (Rakel et al. 2019) to allow for an improved prediction of offspring body weight. Next, we added a TKTD module to the model and calibrated it to the available rat toxicity data, while holding out studies for model validation. Thus, this case study constitutes an example of the successful integration of a variety of studies into a single TKTD model parameterization, allowing for the prediction of realistic exposure scenarios and single endpoints that integrate the underlying toxicity data. 4.05.P-We191 Why a Lemna TKTD Model Can Also Be Applied to Sediment Rooted Macrophytes

Judith Klein¹, Udo Hommen², Thomas Preuss³ and Johannes Witt³, (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (2)Fraunhofer IME, Germany, (3)Bayer Crop Science, Germany

In the Scientific Opinion on TKTD modelling, the EFSA PPR panel (2018) has evaluated also models for primary producers and considered the *Lemna* model of Schmitt et al. (2013) as ready to use in risk assessment. A more complex model for *Myriophyllum spicatum* was found to need further refinements and testing. In this presentation we will show that the basic principles of the *Lemna* TKTD model can be applied not only to floating species like *Lemna* but also to model growth inhibition tests with sediment rooted macrophytes. The original TKTD model for *Lemna* uses six model parameters. Permeability through the cuticle, a plant-water partitioning coefficient to calculate the internal unbound concentration and a metabolisation rate describe the toxicokinetics while EC₅₀, a slope parameter and a maximum effect determine the response to the internal unbound concentration (toxicodynamics). However, a working group of the SETAC IG on effect modelling has recently evaluated the *Lemna* model and concluded that in most cases, the TKTD model can be simplified to a 3 parameter model (with permeability, EC₅₀ and slope). Despite that rooted macrophytes are physiologically different from small floating plants as *Lemna*, we argue that such a simple model is still applicable. Its complexity is similar to the one of the reduced GUTS model to describe lethal effect on e.g. invertebrates and fish. The usually slower growth of rooted macrophytes is just a matter of model parameterisation but not model structure. Growth inhibition tests with macrophytes aim to achieve exponential growth of the control plants and thus, this parameter can directly be taken from the observed control growth. If uptake from sediment pore water instead open water is the most relevant exposure path, the model allows to use measured pore water concentrations as the exposure measure. Modelling both paths simultaneously is not included yet. The model needs some species specific conversion factors between fresh and dry weight, volume and surface area. In addition, for rooted macrophytes the ratio of total shoot length (e.g. for *Myriophyllum spicatum*) or total leaf length (e.g. for *Glyceria maxima*) to dry weight instead of dry weight per frond are needed but are available from the usual tests. In a second poster we will give an example on the application of the model to *Myriophyllum spicatum* including calibration, validation and prediction.

4.05.P-We192 Virtual Refined Exposure Tests With Macrophytes - Using a Generic TKTD Growth Model to Predict the Effects of Time Variable Exposure on Myriophyllum spicatum

Udo Hommen¹, Judith Klein², Andreas Solga³, Johannes Witt⁴ and Thomas Preuss⁴, (1)Fraunhofer IME, Germany,

(2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (3)Ecotoxicology, Bayer Crop Science, Germany, (4)Bayer Crop Science, Germany

The use of herbicides can result in the exposure of macrophytes in edge-of-field water bodies. Depending on the properties of the active substance, the type of water body, and the soil and weather conditions, exposure models like FOCUS Step 3 predict a variety of time series of the environmental concentrations. Exposure events are often expected to be very dynamic, especially in ditches and streams. This can be addressed by refined exposure tests in contrast to the standard test with intended constant exposure. TKTD models in connection with such tests allow to address a large number of exposure profiles resulting from different uses of the plant protection product and the set of FOCUS scenarios. For the example of an ALS-inhibiting herbicide we tested whether a simple TKTD model already used for the duckweed *Lemna* can also describe the effects of dynamic exposure on the sediment rooted plant *Myriophyllum spicatum*, another standard test species. The model calculates a scaled internal concentration from the concentration in the medium and the permeability of the cuticle determining uptake and elimination. The inhibition of the growth rate is described by a 2-parameter log-logistic function of the scaled internal concentration. Thus, as for the GUTS model for lethal effects, three TKTD parameters have to be calibrated by means of growth inhibition tests. For this case study, the model could be calibrated very well by means of data from a standard test with constant exposure over 14 d and a test with short-term exposure. The model was highly conservative for the results obtained in two other refined exposure tests where the observed effects were smaller than to be expected. Thus, the model was considered suitable for conservative predictions of the effects of dynamic exposure of the herbicide on *Myriophyllum spicatum*. Therefore, the PECs of the worst-case 14 d time windows of FOCUS Step 3 exposure profiles were used as model inputs to simulate standard growth inhibition tests with time variable exposure. According to EFSA's Scientific Opinion on TKTD modelling, EP50, the multiplication factors applied to the FOCUS Step 3 PEC values which result in 50 % inhibition of the growth rate over the 14 d standard test duration (i.e. the Tier 1 assessment endpoint), will be presented.

4.05.P-We193 Applying Aquatic Ecosystem Models to Pesticide Risk Assessment: Data Needs and Lessons Learned

Robert Pastorok¹, Damian Preziosi², Brandon Sackmann³, Nika Galic⁴, Amelie Schmolke⁵ and Roman Ashauer⁶, (1)Integral Consulting, Inc., United States, (2)Integral Consulting Inc., United States, (3)GSI Environmental Inc., United States, (4)Syngenta Crop Protection LLC, United States, (5)Waterborne Environmental, Inc., United States, (6)Syngenta Crop Protection AG, Switzerland

Aquatic Systems Models (ASMs) are useful for extrapolating the organism-level effects of pesticides observed in laboratory toxicity tests to field-population, ecosystem, and landscape levels, thereby enhancing the ecological relevance of risk assessments. At the same time, aquatic mesocosms provide a complementary empirical approach for higher-tier risk assessments. Here, we address how these modelling and empirical approaches can complement each other in two ways. First, each can provide an independent line of evidence in a weight-of-evidence risk assessment framework. Second, ASMs can extend the value of data from mesocosm experiments by simulating their dynamic biological communities and physical-chemical environments under control conditions, then simulating scenarios corresponding to conditions untested in the empirical systems including series of multi-season exposures with time-variable pesticide concentrations. Lessons learned from our attempts to model pesticide effects in experimental aquatic mesocosms fall into several categories: 1) The availability of data and need to resolve potential mismatches between data generated by mesocosm experiments (e.g., cells/L or Chlorophyll-a for phytoplankton, and counts/sample of macroinvertebrates for some mesocosms) and the data input needs of an ASM (e.g., biomass of phytoplankton/L and biomass of macroinvertebrates/m² for some ASMs); 2) The appropriate level of taxonomic resolution in the models, and whether species or functional groups are modelled; 3) Calibration and validation approaches, especially the importance of Pattern Oriented Modelling and sensitivity analysis, and how to address substantial variability among replicate mesocosms; 4) How to handle lack of immigration/emigration data for some taxa in mesocosms; and 6) The importance of using standardized exposure scenarios and specific exposure concentrations from transport-fate modelling in regulatory programs (e.g., FOCUS profiles). Following the modelling cycle described by others, we recommend explicit definition of Data Quality Objectives for models (What questions are being asked? What data are available? What level of certainty is needed?); early communication between mesocosm study team and modelling team; and explicit characterization of key receptors and food web structure including how those relate to natural systems in agricultural landscapes of interest.

4.05.P-We194 Using a Dynamic Energy Budget Model to Unravel the Physiological Mode of Action of Lead (Pb) to *Lymnaea stagnalis*

Kristi Weighman¹, Karel Viaene², Josef Koch³, Karel Vlaeminck², Patrick Van Sprang² and Karel De Schamphelaere⁴, (1)Ghent University Laboratory of Environmental Toxicology and Aquatic Ecology, Belgium, (2)ARCHE Consulting, Belgium, (3)gaiaac Research Institute, Aachen, Germany, (4)Ghent University (UGent), Belgium

Lymnaea stagnalis is an especially sensitive species for a variety of metals, particularly lead (Pb). However, the observed sensitivity of *L. stagnalis* to lead (Pb) has been highly variable between studies. The exact mechanism of Pb toxicity to *L. stagnalis* currently remains unclear. Under dynamic energy budget (DEB) theory, different physiological modes of action (PMoAs) result in the emergence of distinct changes to the life histories of exposed organisms. DEB models provide a mathematical framework connecting chemical stress at the physiological level to individual-level effects. This work aims to better understand the PMoA of Pb toxicity to *L. stagnalis* by applying DEB modeling to previously published datasets. Two focal studies were selected in order to examine the impacts of Pb exposure on *L. stagnalis*. While initial difficulty in fitting the model to control data in one study led to a partial reparameterization of the model, satisfactory predictions of both growth and reproduction were ultimately achieved. Subsequently, the model (as calibrated to each of the two focal studies) was utilized to evaluate the relative likelihood of several PMoAs. Assuming decreased assimilation, the *L. stagnalis* DEB model was able to capture a variety of

trends in experimentally observed endpoints, including growth, reproduction, and food ingestion. Despite some difficulties experienced with calibrating the model to control data, the weight-of-evidence suggests that decreased assimilation via a decrease in food ingestion is the most plausible PMoA for chronic Pb toxicity in *L. stagnalis*.

4.05.P-We195 A Review of Modelling Approaches for Ecological Risk Assessment of Pesticides

Floriane Larras¹, Sandrine Charles², Arnaud Chaumot³, Celine Pelosi⁴, Morgane Le Gall⁵, Laure Mamy⁶ and Rémy Beaudouin⁷, (1)Helmholtz Center for Environmental Research - UFZ GmbH, France, (2)University Lyon 1, France, (3)Irstea, France, (4)INRA (Institut National de la Recherche Agronomique), France, (5)IFREMER, France, (6)INRAE, France, (7)INERIS, France

A wide diversity of pesticides are used for crop protection leading to the contamination of soil, water, and air, and can therefore have ecotoxicological effects on living organisms. It is inconceivable to study effects of each compound on each model species from each ecosystem compartment, experimental studies being time consuming and cost prohibitive, and animal testing having to be avoided. Therefore, numerous models have been developed to assess ecotoxicological effects of pesticides. In this context, our objective was to review modelling approaches enabling the assessment of the effects and the risk of pesticides, including biocontrol substances, on organisms, biodiversity, and ecosystems services. Several model categories were inventoried: QSAR, dose-response, TKTD, SSD, food web, population, community, landscape, and mixture models. These models were developed for various species (terrestrial and aquatic vertebrates and invertebrates, aerial organisms, terrestrial and aquatic primary producers, micro-organisms) and environmental compartments (soil, freshwater, seawater, air). These models are increasingly recognised for the regulatory risk assessment of pesticides but remain rarely used by regulatory bodies. The main limits of these models (for example, long-term effects and functional responses are hardly considered) will be discussed together with improvement avenues (multi-generational effects, multiple biotic and abiotic stressors...). This review will also underline that we are facing a lack of models tested from field data and a lack of sensitivity and uncertainty analyses. Our conclusion will be that accurate modelling of the effects of pesticides and other stressors on living organisms, from their application in the field to their functional consequences on the ecosystems at different scales of time and space, would help going towards a more sustainable management of natural resources.

4.05.P-We196 Scenario Development for Bee Risk Assessment and Health Modelling

Christopher M Holmes¹, Thorsten Schad², Sascha Bub³ and Thomas Preuss², (1)Applied Analysis Solutions, LLC, (2)Bayer Crop Science, Germany, (3)University of Koblenz-Landau, Germany

Bee effect modelling has become a core instrument in bee risk assessment (EFSA 2013 'Guidance Document on the risk assessment (RA) of plant protection products (PPP) on bees', EFSA 2018 'A systems-based approach to the environmental RA of multiple stressors in honey bees', EFSA 2021 'Outline of the revision of the Guidance on the RA of PPPs on bees'). Pesticide RA using such models is based on scenarios. In this project we (i) identified key conceptual elements of scenarios in regulatory RA, (ii) developed proposals for these elements, and (iii) generated scenarios for the BEEHAVE model to demonstrate these elements. The example assumed a RA for honeybees related to the use of a PPP in apples located in France. As apple cultivation density increases so does attractiveness of sites for honeybee keeping (occurrence) and exposure potential. Therefore scenario representativeness (level of conservatism) was mainly driven by regional apple cultivation density. Three regions were selected located in different climatic regions to account for weather variability. In these regions, local site selection (i.e., placing the beehive) was done in a combination of bee forage mapping at medium resolution and beekeeper preference. For each site, scenarios were constructed for a 9 km radius around the beehive. In view of a scenario development framework, we propose a tiered scenario development scheme to implement a well-defined level of complexity together with a targeted certainty evaluation. We developed structured bee forage information layers for transparent bee forage modelling: (i) Land use/cover, (ii) Vegetation, (iii) BeeForage. All information layers are spatially and temporally explicit. The transition from one information layer to the next was done by explicit modules, e.g., the BeeForage module represents an approach on how nectar and pollen provision is modelled for a given vegetation and its phenology. According to the tiered scenario scheme, simple modules can be replaced with more sophisticated ones if needed and available. In our example we start with simple representations of processes, e.g., bee forage (nectar and pollen) provision is modelled in five categories (0-4, 4=mass forage) represented in a lookup table defined from literature, by vegetation patches with a monthly resolution vegetation phenology. Due to current technical limitations of BEEHAVE, the spatiotemporally explicit BeeForage(x,t) information is aggregated into < 500 units.

4.05.P-We197 Connecting Heterogeneous Ecological Studies and Their Uncertainties Within a Modelling Framework for Ecological Risk Assessment

Virgile Baudrot¹, Thomas Kleiber², James Maino³, Rafael Schouten³ and Sandrine Charles⁴, (1)Université Lyon 1, France, (2)Qonfluens, France, (3)Cesar Australia, Australia, (4)University Lyon 1, France

Embedding laboratory or mesocosm studies within monitored landscape in order to assess the real impact of stressors at the ecosystem scale is a huge challenge for ecotoxicological modelling. Assessing the ecological risk of chemical compounds is critical to avoid the decline and potential extinction of some populations that may subsequently threaten other species for example in food chains. Simultaneously, being able to control population dynamics is also important when a population outbreak in specific time and space may compromise agricultural activities and human health. From marketing authorization of chemical products to control strategies, Ecological Risk Assessment studies have to deal with multiple stressors within multiple application contexts. In this talk, we propose a unified modelling framework for ecotoxicology, agroecology and eco-epidemiology. We used this framework under several different contexts and we will present results for two of them: (i) the first one focusing on Bt-maize impact on Non-Target Lepidoptera in Catalonia (Spain), and (ii) a second one on the outbreak of Fall Armyworm resistant population at the continental scale of Australia. We also performed a sensitivity analysis in both cases to identify the most

influential processes and provide recommendations toward ecosystem management practices. Our results illustrate that an appropriate and refined sensitivity analysis may help in identifying general trends in ecological parameters that have influence on population dynamics. Consequently, it can be assumed that an overall sensitivity analysis based on massive computing provides effective insights on the order of magnitude (e.g., the distance at risk to the nearest Bt-maize crop field) and allows to identify the most influential input parameters and variables to consider (e.g., influence of treatments on resistance outbreak depending on their Mode Of Action).

4.05.P-We198 Predicting Saltwater Toxicity From Freshwater Toxicity Using Species Sensitivity Distributions

Miina Yanagihara¹, Kyoshiro Hiki² and Yuichi Iwasaki³, (1)Ehime University, Japan, (2)National Institute for Environmental Studies (NIES), Japan, (3)National Institute of Advanced Industrial Science and Technology (AIST) Japan, Japan

In ecological risk assessment, species sensitivity distributions (SSDs) have played a crucial role. Estimating SSDs requires toxicity data for many species, but reports on saltwater species are often more limited than for freshwater species. This limitation can be a barrier to discussing the management of saltwater quality for protecting marine ecosystems, and the relationships between freshwater and saltwater SSDs have been investigated to consider the possibility of extrapolation. In order to determine how accurately saltwater toxicity could be estimated from freshwater toxicity test data, the present study aimed to examine the relationships between the parameters (i.e., mean and standard deviation (SD)) of freshwater and saltwater log-normal SSDs. Freshwater and saltwater SSDs for 104 chemicals were estimated with reported acute toxicity data, and their means, SDs, and hazardous concentrations for 5% of the species (HC5) were compared. As a result, standard major axis regression analyses generally showed that there were nearly 1:1 relationships between freshwater and saltwater SSD means, SDs, and HC5s. The squared correlation coefficients for the SSD means and HC5 values were high, and the ratios of freshwater-to-saltwater SSD means and HC5 values for most of the 104 chemicals fell within the range 0.1–10. Regarding SSD SDs, differences in values between freshwater and saltwater SSDs were relatively small though a strong correlation was not found. These results indicate that a saltwater SSD for a chemical can be reasonably estimated from the corresponding freshwater SSD, when the available ecotoxicity data for saltwater is not available or limited. In addition, differences in the means and SDs between freshwater and saltwater SSDs were larger when the number of test species used for SSD estimation was lower, which suggests that it will be a key to securing enough toxicity data for the prediction. Continuous data collection is required to capture the relationships between freshwater and saltwater SSDs for taking the best advantage of the freshwater toxicity data in saltwater ecological risk assessment.

4.05.P-We199 Applying a DEB Model to Multi-Stressor Exposures of Polyethylene Particles and Sodium Dodecyl Sulphate in *Daphnia magna*

Katie Reilly¹ and Iseult Lynch², (1)University of Birmingham, Birmingham, United Kingdom, (2)School of Geography, Earth and Environmental Sciences, University of Birmingham, Birmingham, United Kingdom

Daphnia magna are a well-established test organism in toxicity studies and regulatory testing. In addition to the acute 48-hour toxicity test (OECD 202) there is the 21-day chronic reproductive test (OECD 211) encompassing monitoring of growth (often measured as eye-tail length) and variations in reproduction (such as total offspring and time to first and subsequent broods). These test endpoints provide a good starting point for data collection and observations required for the application of a dynamic energy budget (DEB) model. A DEB model describes the rates at which an organism assimilates and utilises energy for maintenance, growth and reproduction, as a function of the state of the organism and of its environment. Data from chronic reproduction tests with *D. magna* exposed to a sublethal dose (25 mg/L) of spherical polyethylene particles (1-4 µm) was used in a BYOM DEB-KISS model to explore potential changes to the daphniid's energy budget in response to a particle-based toxicant. *Daphnia* were cultured and exposed in a high hardness salt medium (HH Combo) with the algae *Chlorella vulgaris* supplied as a daily food ration at *ad libitum* concentrations throughout the test. In addition to this, chronic data of a widely used surfactant, Sodium Dodecyl Sulphate (SDS), was used to establish a baseline response to a chemical based exposure in order to compare the variation in the energy budget due to the differing exposure routes and toxicant interactions i.e. adsorption compared to an ingestion-based pathway. The combined effects of a multi-stressor exposure of *D. magna* to SDS in combination with the polyethylene particles was also used to look at potential changes to the mode of toxicity within the DEB model based on the combined stress and exposure pathways. The DEB model outputs are then discussed in terms of the links to other sublethal indicators of stress, such as changes to the excreted proteins, variations in the concentration and distribution of lipid deposits, and morphological defects in the daphniids over the 21-day testing period, to further explore the links between these sublethal markers and toxicant impacts on the energy deviations from the controls. This raises interesting discussion points associated with the differences in toxicant responses induced in Daphniids' exposed to microplastic particles when compared to a chemical based toxicant response, and to the combined exposure response.

4.06 Environmental assessment and registration of polymers: scientific issues and implementation challenges

4.06.T-01 Improving Available Guidance for Persistence Assessment of Substances (CEFIC-LRI ECO52) - Framework for Polymer Persistence Assessment

Stefan Hahn¹, Dieter Hennecke², Graham Whale³ and Christopher Hughes⁴, (1)Fraunhofer ITEM, Hannover, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (3)SHELL, United Kingdom, (4)Ricardo Energy & Environment, Chester, United Kingdom

Chemical persistence plays a key role in the determination of environmental exposure making it an important component in risk assessment and regulation. However, existing frameworks under which persistence is assessed have shown some limitations. Chemical degradation rates are prone to wide variability depending on environmental conditions, which is difficult to address in a

weight of evidence approach. In addition, many substances are problematic, or fall outside the applicability domain of existing frameworks due to their specific characteristics. Finally, evaluating degradation half-lives using a compartment-by-compartment approach is overly simplistic, and neglects dynamic multimedia exchanges and degradation processes that may have an important bearing on the overall persistence of a substance in the environment. This CEFIC-LRI project aims to address these issues by improving available guidance for persistence assessment of substances, including those considered problematic to evaluate under the current frameworks. Is the concept for persistence assessment of substances applicable to plastic articles, for which persistence can be a beneficial property? As natural polymers are usually not regarded as a concern under real environmental conditions, better understanding is necessary to improve our methodology of polymer persistence assessment and to provide guidance to assess man-made polymers. The project aims to give information on essential elements to justify persistence assessment of polymers in a weight of evidence, and to give suggestions for future needs and research. Available literature was reviewed for polymer specific methodologies to identify influencing testing parameters, knowledge gaps and areas of improvement. Four major challenges have been identified for assessing polymer biodegradation by Albright and Chai (2021). Challenges have also been discussed in the ECETOC technical report No. 133-2, and a general outline for polymer (bio)degradation assessment has been presented. An overview and discussion is given about challenges of polymers with respect to the standard assessment scheme, and about suitable alternatives. A combination of all approaches seems to be most appropriate. Finally, a framework (workflow) is presented which includes the essential elements such as profiling of the polymer, scientific differences between natural and synthetic polymers, and on weathering for example by sunlight (UV) for the weight of evidence.

4.06.T-02 Modelling Cationic Polymers Aquatic Toxicity

Kristin A Connors¹, Scott Belanger², Kunal Roy³, Hans Sanderson⁴ and Pathan Moshin Khan³, (1)Procter & Gamble Company, United States, (2)The Procter & Gamble Company (retired), United States, (3)Jadavpur University, India, (4)Aarhus Universitet, Denmark

This presentation summarizes the CEFIC LRI study (ECO46 – iTAP) on how to improve the aquatic risk assessment of cationic polymers. The amount of publicly available, high quality environmental toxicity data on industrial polymers such as cationic polyquaterniums is however extremely limited. Given the large size of the materials traditional hydrophobicity driven toxicity is not expected. Other relevant descriptors for cationic polymers thus need to be identified. Molecular weight and charge density are well-known physical-chemical attributes that are suspected to be correlated with aquatic toxicity. Cationic polymers are polymers of potential environmental concern. They can be based on quaternary ammonium (PQ) used in personal care and household cleaning products as conditioners or softeners, and as flocculants in drinking water treatment plants. Developing (Q)SARs based on curated cationic data is challenging as the data availability, transparency and quality for the training set is limited and insufficient polymer descriptor information is available. We developed multivariate models for cationic polymers in accordance with the five principles of the *Guidance Document on the Validation of (Q)SAR Models* (OECD, 2007). Data was provided by Environment and Climate Change Canada (n = 242) and the USEPA (n = 73). The data was blinded in terms of full structural disclosure but contains information on key structural features allowing an analysis of the relative contribution of these to the overall toxicity. The data consisted of two fish species (*P. promelas* and *O. mykiss*), and green algae (*S. capricornutum*/*P. subcapitata*). It has been suggested by Boethling and Nabholz (1997) in that the aquatic toxicity of cationic polymers is primarily (solely) governed by the charge density. The table below reflects our results of a multivariate analysis of the contribution features of the compound have on the toxicity towards fish and green algae. The area of (Q)SAR modeling for the evaluation of toxicity of polymers has remained largely unexplored. Our study revealed that the presence of a cationic functional group in the pendant chain at positions; one, four and five enhances the toxicity. Similarly, higher charge density results in an increase in the toxicity towards fish and green algae and higher average molecular weight results in higher toxicity towards green algae. Presence of primary and secondary amines in the molecular building block result in a reduction in the toxicity, while the presence of quaternary amines in the molecular structures results in an increase in toxicity against green algae. Further work is needed to fully elucidate the toxicity contributions and validate regulatory applicable models for defined classes of polymers. Moreover, further work is needed to clarify the regulatory acceptance of multivariate models, as well as interspecies models for gap filling, as univariate models may not accurately predict toxicity as multiple descriptors affect the overall toxicity in addition to the charge density.

4.06.T-03 The ECETOC Conceptual Framework for Polymer Risk Assessment (CF4Polymers): Considerations & Examples for Grouping of Polymers

Jens C. Otte¹, Dawn Allan², Thiago Andrade³, Sylvie Barra-Thereux⁴, Emily EA Burns⁵, Christian Boegi¹, Michel Cassart⁶, Iain Davies⁷, Ming Fan⁸, Joe Frasca⁹, Philippe Gottis¹⁰, Heli Hollnagel¹¹, Joanna Klapacz¹², Isabel Krug¹, Tushar Mahale¹³, Stefan Moors¹, Mark Pemberton¹⁴, Véronique Poulsen¹⁵, Erik Rushton¹⁶, Gordon Sanders¹⁷, Hans Sanderson¹⁸, Ursula Sauer¹⁹, Diederik Schowanek²⁰, Len Sweet²¹, Nathalie Vallotton¹¹, Andreas Willing²² and Jonathan Zhang²³, (1)BASF SE, Germany, (2)Firmenich SA, United Kingdom, (3)ARKEMA France, France, (4)Solvay SA, Belgium, (5)PCPC (Personal Care Products Council), United States, (6)Plastics Europe, Belgium, (7)Personal Care Products Council, United States, (8)Procter & Gamble Company, United States, (9)Exxon-Mobil, United States, (10)Huntsman, Switzerland, (11)Dow Europe GmbH, Switzerland, (12)The Dow Chemical Company, United States, (13)Lubrizol, India, (14)Systox Ltd, United Kingdom, (15)l'OREAL, France, (16)LyondellBasell, Netherlands, (17)Givaudan International SA, Switzerland, (18)Aarhus Universitet, Denmark, (19)Scientific Consultancy – Animal Welfare, Germany, (20)Procter & Gamble Services Company NV, Belgium, (21)Lubrizol Corp., United States, (22)BASF Personal Care & Nutrition GmbH, Germany, (23)Corteva, United States

The building block nature of polymer chemistry and the corresponding definition of polymers in several jurisdiction globally demand for a targeted and dedicated strategy for polymer grouping when attempting for a systematic polymer evaluation under a

chemical risk assessment framework. Related polymers are often homologues manufactured from the same starting materials and similar processes, leading to a large number of similar structures. But even if few of the building blocks are different, such chemical variation in a small part of a macromolecule does usually not lead to differences in physico-chemical or biological properties. In the present contribution, the internationally agreed grouping concepts has been further advanced to better scope the complexity and versatility of polymers. Definitions going beyond the internationally agreed grouping concept have been introduced in the ECETOC Task Force report 133-3. A central role has been assigned to the term 'hazard similarity' that forms a central element of the grouping of polymers. It is the overarching aim of the polymer grouping approach to define 'hazard similarity' of different polymers and, consequently, the final group. Generally, polymer groups based on similar hazards can be expected to contain many more members than categories for non-polymer substances. The reason is the building block nature of polymer chemistry. Specifically, similarity is based upon three criteria to determine and to justify similarity: (Criterion 1) chemical nature; (Criterion 2) physico-chemical property/ies; and most importantly (Criterion 3). All three Criteria correspond with each other, and they are critical for the full description of the polymer group. The properties of each criterion also define the content and the boundary of the group. If the defined group is understood as one 'substance' (in a regulatory context), the content and boundaries of the three Criteria can serve as descriptors for substance identity. The polymer grouping approach was exemplified in three case studies, i.e. on BADGE polymers, Polyetheroles, and on surfactant polymers. The polymer grouping approach proposed here allows to significantly simplify and structure the data requirements for polymer hazard and risk assessment and gives rise to a pragmatic and reasonable description of the substance identity for polymers based on the newly introduced principle of hazard similarity.

4.06.T-04 Putting the ECETOC Conceptual Framework for Polymer Risk Assessment (CF4Polymers) Into Practice: Case Studies on Cationic Polymers

Nathalie Vallotton¹, Ming Fan², Tushar Mahale³, Hans Sanderson⁴, Ursula Sauer⁵ and Len Sweet⁶, (1)Dow Europe GmbH, Switzerland, (2)Procter & Gamble Company, United States, (3)Lubrizol, India, (4)Aarhus Universitet, Denmark, (5)Scientific Consultancy – Animal Welfare, Germany, (6)Lubrizol Corp., United States

Polymers are currently being reconsidered in the context of regulatory programmes, and this raises a number of technical and scientific challenges as polymers represent a diverse chemical space and are quite different from discrete mono-constituent substances. Against this background, the European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC) decided that a review of relevant scientific methods and knowledge applicable to the risk assessment of polymers would be helpful to provide a scientific perspective for the safety assessment of polymers. As an outcome of its work, the ECETOC Polymers TF has been preparing the ECETOC Technical Report (TR) No.133 series, of which this report is the third and final presents *Case Studies Putting the ECETOC CF4Polymers into practice*. The case study on cationic polymer is one of the seven case studies selected from the diverse universe of polymers to further evaluate (1) the usefulness of the CF4Polymers (ECETOC TR No. 133-1) for the safety assessment of different types of polymers and (2) the information on the applicability of tools, methods and models for the hazard and risk assessment of polymers presented ECETOC TR No. 133-2. It is important to make clear that the case studies were not intended to document a comprehensive risk assessment for any specific polymer. Rather, publicly available data and unpublished TF company data were collated and assigned to the eight steps of the CF4Polymers presented in ECETOC TR No. 133-1 to evaluate the scientific usefulness and comprehensiveness of the process through use of examples. The case study on cationic polymers served to illustrate how the CF4Polymers *can be used* for polymer hazard and risk assessment. Further, the collated data were used to assess the applicability of tools, methods and models for polymers in environmental and human health risk assessment.

4.06 Environmental assessment and registration of polymers: scientific issues and implementation challenges (Virtual Only)

4.06.V-01 Algal Toxicity of Cationic Polyquaternium Polymers

Kristin A Connors¹, Jessica Brill¹, Anna Magdalene Brun², Hans Sanderson² and Scott Belanger³, (1)Procter & Gamble Company, United States, (2)Aarhus Universitet, Denmark, (3)The Procter & Gamble Company (retired), United States

Cationic polymers, such as polyquaterniums (PQ), are widely used in water purification processes, wastewater treatment, and in personal care products. The flocculating ability of these materials is often leveraged to remove suspended solids from mining effluent or wastewater. It is therefore not surprising that algal clumping has been observed in some, but not all, cationic polymer standard toxicity tests. In this study, standard 72h OECD 201 algal toxicity tests with *Raphnidocelis subcapitata* were completed using several representative PQ materials (PQ6, PQ10, PQ16). Test materials were chosen to encompass a range of molecular weights and charge densities to determine the influence of test material characteristics on toxicity. Tests were conducted in two different laboratories to quantify inter-laboratory variation. Algal clumping was observed in some, but not all, polyquaterniums and was inconsistent within exposure concentrations. All concentrations were gently homogenized daily in order to improve growth estimation and repeatability of the assay. PQ6 toxicity was consistent between labs and across PQ6 materials with different molecular weights. Toxicity for PQ6 and PQ16 materials were correlated with charge density. This aligns with previous observations in the literature. Very steep dose response curves and low acute to chronic ratios (< 2) were observed for PQ6 and PQ16 materials, suggesting a physical MOA. PQ10 was several orders of magnitude less toxic than PQ6 and PQ16. Flat dose-response curves and significant clumping was observed. Mitigating factors like addition of organic carbon in the form of humic acid will also be presented.

4.06.V-02 Application of Standard Screening Biodegradation Tests to Water Soluble Polymers

Jennifer Menzies¹, Ashley Wilcox², Ken Casteel¹ and Kathleen McDonough³, (1)Procter & Gamble Company, United States, (2)Procter and Gamble Company, United States, (3)P&G, United States

The objectives of this research were to evaluate the biodegradation of a suite of water-soluble polyethylene glycol (PEG) materials ranging in average molecular weight (MW) from 4000-500,000 using activated sludge and river water inocula. The tests followed the OECD 301B, OECD 302B and OECD 301F guidelines. We wanted to probe the ability of regulatory accepted screening test methods to evaluate the biodegradability of water-soluble polymers with a wide range of MWs and use inocula from different environmental compartments. Further we were interested in gaining understanding of the time necessary for complete mineralization in these types of test systems for a range of polymer MWs. Additionally, we gained insight into test system viability and sensor stability as tests were extended well beyond traditional test durations. Finally, we wanted to evaluate the impact of the polymer endcap (due the changes in synthesis route from PEG to PEO) on biodegradability of polymers with similar MWs.

4.06.V-03 Cationic Polyquaternium Acute Toxicity and Toxicity Mitigation in *D. Magna*: Implications for Chronic Toxicity Testing and the ACR

Devrah Arndt¹, Jessica Brill², Anna Hansen³, Hope Woods⁴, Kristin A Connors², Hans Sanderson⁴ and Scott Belanger⁵, (1)P&G, United States, (2)Procter & Gamble Company, United States, (3)University of Copenhagen, Denmark, (4)Aarhus Universitet, Denmark, (5)The Procter & Gamble Company (retired), United States

Cationic polymers, such as polyquaterniums (PQs), are often used in shampoos and conditioners because of their anti-static properties. Cationic polymers have been shown induce toxicity to aquatic organisms, and these compounds have been flagged by chemical regulators as potential “polymers of concern” that are likely to receive additional regulatory scrutiny in the future. Cationic polymer toxicity has been shown to vary based on polymer physical/chemical properties, and previous studies have also shown that cationic polymer toxicity can be ameliorated in the presence of dissolved organic carbon. This toxicity mitigation may also impact chronic invertebrate testing, as chronic toxicity tests are done in the presence of food (algae). Therefore, this research first explores acute PQ toxicity to *Daphnia magna* as it relates to molecular weight (MW) and charge density (CD), followed by an investigation of PQ toxicity mitigation by humic acid (HA). The chronic toxicity of a subset of PQs was also conducted, coupled with an investigation of acute toxicity in the presence of food to explore how the addition of food may impact the toxicity outcome. Results of this work indicate that PQ toxicity is correlated with cationic CD but not with MW, and that PQ toxicity can be mitigated by environmentally relevant concentrations of HA. The presence of food in acute toxicity assays was also found to alter PQ toxicity. This work reveals that, due to the sensitivity of PQ toxicity to water quality parameters (e. g. TOC), special considerations should be given when applying standard toxicity extrapolation methods, like the acute to chronic ratio, for predicting chronic toxicity. More work is needed to characterize PQ toxicity mitigation relative to polymer characteristics and water quality parameters to aide in more accurate environmental hazard assessments of these materials.

4.06.V-04 Comparative Toxicity Assessment of 16 Different Polymers in *Daphnia magna*

Tim Steska¹, Carmen Wolf², Wendel Wohlleben, Dr.³ and Dana Kühnel⁴, (1)Helmholtz Centre for Environmental Research – UFZ, Germany, (2)Institute of Energy and Environmental Technology e.V. - IUTA, Germany, (3)Material Physics & Analytics AND Experimental Toxicology & Ecology, BASF SE, Germany, (4)Helmholtz-Centre for Environmental Research, Leipzig, Germany

Polymer materials are currently exempted from registration under REACH due to low concern for toxicity based on the high molecular weight (ECHA April 2012). However, with the increasing attention to the pollution of the environment with persistent plastic debris, research on the effects of microplastics in particular on environmental organisms intensified. The study presented here aims at adding to the knowledge on polymer toxicity by including various modifications of 6 different polymers and assessing their influence on *Daphnia magna* immobilisation. In total, micro-sized particles in 15 variations of TPU, PU, PMMA, LDPE, PE and PA were subjected to testing in the 48 h acute immobilisation assay, including a tire rubber particle positive control. For all polymer particles, dispersal in daphnia medium was facilitated by the addition of TWEEN-40. Non-toxicity of TWEEN-40 in the respective concentration was confirmed by pre-tests. The characteristics of the polymer particles differed not only in polymer type, but also with regard to size distribution, aromaticities, and crosslinking degree. All microplastic particles were tested in concentrations from 10 µg/L up to 1 g/L. Uptake of particles in the gut was assessed by microscopic inspection. None of the tested polymer microparticles exerted toxicity towards *Daphnia magna* during the time of observation. For some exposures, an attachment of particles to the carapaces (both before and after moulting and the antenna was observed. All tested microplastic particles were taken up by the organisms as visible by light or dark (in the case of tire rubber) coloration of the gut. Excretion of particles was observed as well. Surprisingly, also in the TWEEN-40 only exposures, a light coloration of the gut resembling those of particle exposed organisms was visible. It was confirmed by particle-only exposure of one selected polymer that uptake occurs also without the TWEEN-40 present, and that the coloration is indeed comparable. Overall, the results of our study demonstrate that no acute toxicity occurs irrespective of the various particle properties and irrespective of particle uptake and attachment to organisms. Neither particle size nor polymer type or the different polymer end groups had an influence on toxicity. Reference ECHA (April 2012). “Guidance for monomers and polymers Version 2.0, Guidance for the implementation of REACH.” [European Chemicals Agency ECHA-12-G-02-EN](#).

4.06.V-05 Understanding Ecotoxicological Responses of Fish Embryos to Cationic Polymers

Kristin A Connors¹, Jane Rawlings² and Scott Belanger³, (1)Procter & Gamble Company, United States, (2)Procter and Gamble Company, United States, (3)The Procter & Gamble Company (retired), United States

Cationic polymers have been highlighted as potential polymers of concern. Regulatory interest in polymers has been constrained on the assumption that polymer size will result in an inability to pass biological membranes and will therefore be likely to have limited interaction with man and the environment. In this presentation we describe a series of fish embryo toxicity (FET) assays used to establish a baseline understanding of several representative polyquaternium categories (PQ6, PQ10, PQ16). Materials were chosen to encompass a range of molecular weights and charge densities to determine the influence of test material characteristics on toxicity. Due to the ability for organic carbon to influence fish response to cationic polymers humic acid toxicity mitigation was also explored. Chorionated and dechorionated FET tests were comparable (z-test, $p=0.8962$). 96 h LC50 values for the four PQ-6 Merquat compounds, with charge densities of 6.2 mEq/g, ranged from 0.35 to 0.92 mg/L for chorionated and dechorionated tests which are comparable to the mean OECD FET validation PQ-6 Merquat 100 data. Existing SAR models for cationic polymers with carbon-based backbones attribute differences in polymer charge density. Toxicity in chorionated and dechorionated FET tests was correlated with charge density ($R^2=0.89$ and 0.94 , respectively), with the relationship following the same curve shape as the data from Boethling and Nabholz ($R^2=0.73$). Toxicity amelioration in the FET varied with HA source and concentration and with cationic polymer and concentration. Testing included dilution water controls, HA controls, and polymer concentrations at or above the 96 h LC50 values with and without HA. Amelioration by HA occurred in a dose dependent manner. These studies provide context for future testing of cationic polymers in an environmental risk assessment context. Characterization of polymers is of extremely high importance and needs exist for method standardization and regulatory prioritization. Production lots vary and chemicals given the same CASNO clearly can possess an array of potencies. Cationic polymer charge density clearly plays a role in toxic potency as does general water quality (organic carbon, water hardness, especially). As with test material characterization, the determination of water quality must accompany cationic polymer ecotoxicity data.

4.06 Environmental assessment and registration of polymers: scientific issues and implementation challenges (Poster)

4.06.P-We200 Critical Review of Methods to Determine Surface Tension and Solubility of Polymers

Joachim Venzmer, Research Interfacial Technology, Evonik Operations GmbH, Essen, Germany

The CESIO Working Group "Test Methods of Surfactants" (TMS) and the TEGEWA Working Group "Surface Active Substances" have identified the need to look into norms and guidelines concerning surface tension and solubility of surfactants and/or surface-active polymers. The motivation to care about this topic is that assignment of polymers as surface-active should be on account of their properties, but should not be caused by shortcomings of the analytical methodology. For example, the OECD Guideline 115 on surface activity is basically from the pre-computer era; the plate and ring method as described there are real classics (>100 years old!) and suffer from the general problem of ill-defined surface age, which could be especially problematic in case of surface-active polymers. Unfortunately, this is the only guideline on surface tension current (and hopefully not too many future!) regulations can refer to. In addition, it is unclear how the OECD guidelines 105 and 120 on solubility should be applied to surfactants and surface-active polymers, since (A) surfactants do not have a saturation concentration, and (B) surfactants form micelles which scatter light, and this Tyndall effect (i.e. the presence of micelles) – according to the guideline – invalidates the solubility test. So it needs to be discussed whether attaching a fatty acid chain of natural origin to a readily biodegradable water-soluble polymer like PEO should really yield an "insoluble polymer particle". Therefore, there is an urgent need to revisit outdated or unsuitable methods. In the case of surface tension, this should be relatively straight-forward, since today there is already a well established alternative method available: Advances in image processing/computing power during the past two decades have allowed drop shape analysis (Pendant Drop Tensiometry) to develop into a well-established, better alternative to determine surface tensions. Therefore, just the corresponding norm or guideline for the field of surfactants is missing. Respective activities within DIN NMP NA 62-5-63 and CEN TC 276 WG2 have been initiated.

4.06.P-We201 Polymers and Their Toxicity to Algae - Lessons Learned From a Comparative Study

Karsten Schlich¹, Ruben Schlinkert², Carmen Wolf³, Wendel Wohleben, Dr.⁴ and Kerstin Hund-Rinke², (1)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Fraunhofer IME, Germany, (3)Institute of Energy and Environmental Technology e.V. - IUTA, Germany, (4)Material Physics & Analytics AND Experimental Toxicology & Ecology, BASF SE, Germany

Due to the different areas of applications, polymers are a very heterogeneous group of chemicals. While the ecotoxicity of nanomaterials has been intensively investigated during the last years, the information on the toxicity of larger particles including polymers is still limited. To improve the knowledge, we investigated the ecotoxicity of eight polymers to algae (*Raphidocelis subcapitata*) in the growth test (OECD TG 201). The polymers differ in their chemical identity, polymer backbone, aromaticity, crosslinking degree, size distribution and dispersibility. None of the materials showed toxic effects. Size as the only reason for non-toxicity can be excluded since small (300 nm) and large materials (267 μm) were taken into account. The same applies for the state of the material, as at least one of the materials was available as a dispersion while others were powders. Furthermore, the surface areas as an influencing factor was discounted as this property differs for the various materials by a factor of 100. Six of the polymers could only be dispersed in the test medium using Tween 40 as dispersant. The use of dispersants in the toxicity testing of chemicals is limited and for nanomaterials it should be avoided. We included this approach to cover the range from no toxicity, due to no presence in water, to potential toxicity in the presence of a dispersant. Further experiments showed that a comparable dispersing effect can be achieved using a concentration of algae and their exudates which is similar to the conditions at the end of the test. We conclude that the missing ecotoxicity in the presence of Tween 40 should not be considered as a false-negative result. Tween 40 simulates a behaviour which can also occur in the environment. The advantage of Tween 40 over natural substances (algae exudates, humic acids) is the defined chemical composition. Heteroagglomeration has been identified as driving factor for

ecotoxicity to algae, at least for nanomaterials. Microscopic images of the test dispersions showed that there was no interaction between polymers and algae which agrees with the observed non-toxicity. Due to the large size and the lack of heteroagglomeration, the probability of polymers being toxic seems to be low, unless they contain bioavailable toxic components.

4.06.P-We202 Towards a Framework for Environmental Fate and Exposure Assessment of Polymers

Hattie Cerridwen Catherine Brunning¹, Jonathan Brett Sallach² and Alistair Boxall¹, (1)University of York, United Kingdom, (2)University of York, Heslington, United Kingdom

There is an emerging need to develop environmental risk assessment methodologies for polymers in order to prevent negative environmental impacts; however, existing environmental risk assessment approaches for low molecular weight chemicals will likely need to be adapted to account for the diversity and complexity of polymers as well as their unique properties. This poster will present key points from a literature review focussing on the challenges and opportunities for the fate and exposure assessment of polymers in the context of regulatory environmental risk assessment of low molecular weight chemicals. This includes a discussion of the applicability and adequacy of existing property and environmental fate parameters for polymers, along with proposed additional parameters which may be necessary to characterise polymer fate, such as attachment efficiency, particle size distribution, and hydrodynamic radius, among others. The implications of these parameters in various stages of an environmental exposure assessment framework will also be presented, with a distinction between solid polymers (such as microplastics) and dissolved polymers (including water-soluble polymers) being key for development of such a framework. Key considerations relating to: polymer identification, grouping and characterisation; polymer degradation and transformation in the environment; development and standardisation of analytical methods for characterisation of polymers and their fate properties; and exposure models for polymers, will also be presented, along with key knowledge gaps and research needs moving forward.

4.06.P-We203 Ecotoxicity and Biodegradability of Water-Soluble Polymers, Used in Cosmetics and Personal Care Products

Ula Rozman¹ and Gabriela Kalcikova², (1)Faculty of Chemistry and Chemical Technology, University of Ljubljana, Ljubljana, Slovenia, (2)University of Ljubljana, Slovenia

Although the research on microplastics is still growing exponentially, another form of plastics, such as water-soluble polymers (WSPs) have been greatly overlooked by scientists, society, and policy makers. They are used in many applications and their annual production in Europe is estimated at several million tonnes. However, their effects and fate in the environment remain unknown. In this context, the aim of our study was to evaluate the ecotoxicity and biodegradability of four WSPs (three of them in solid and one in liquid form) commonly used in cosmetics and personal care products. All four WSPs were polyacrylic acid-based polymers and further characterization revealed that the liquid WSP contained nanoparticles. Ecotoxicity was tested with several organisms, namely aquatic plant *Lemna minor*, microalga *Pseudokirchneriella subcapitata*, crustacean *Daphnia magna*, bacterium *Allivibrio fischeri*, and mixed bacterial culture (heterotrophic and nitrifying microorganisms of activated sludge). All four WSPs had low (10?40%) or moderate (41?60%) effects on the tested organisms at a concentration of 100 mg/L. However, the liquid WSP had a specific toxic effect on *A. fischeri* and nitrifying microorganisms of activated sludge. It caused $73 \pm 1\%$ inhibition of bioluminescence of *A. fischeri* and $88 \pm 17\%$ inhibition of the oxygen consumption by nitrifying microorganisms. The presence of this WSP in the wastewaters could have implications for the nitrification process in wastewater treatment plants. All four tested WSPs were not readily biodegradable, suggesting possible persistence in the natural environment.

4.06.P-We204 Case Studies Putting the ECETOC Conceptual Framework for Polymer Risk Assessment (CF4Polymers) Into Practice

Diederik Schowanek¹, Jens C. Otte², Dawn Allan³, Thiago Andrade⁴, Sylvie Barra-Thereux⁵, Emily EA Burns⁶, Christian Boegi², Michel Cassari⁷, Iain Davies⁸, Ming Fan⁹, Joe Frasca¹⁰, Philippe Gottis¹¹, Heli Hollnagel¹², Mark Pemberton¹³, Joanna Klapacz¹⁴, Isabel Krug¹⁵, Tushar Mahale¹⁶, Stefan Moors², Véronique Poulsen¹⁷, Erik Rushton¹⁸, Gordon Sanders¹⁹, Hans Sanderson²⁰, Ursula Sauer²¹, Len Sweet²², Nathalie Vallotton¹², Andreas Willing²³ and Jonathan Zhang²⁴, (1)Procter & Gamble Services Company NV, Belgium, (2)BASF SE, Germany, (3)Firmenich SA, United Kingdom, (4)ARKEMA France, France, (5)Solvay SA, Belgium, (6)PCPC (Personal Care Products Council), United States, (7)Plastics Europe, Belgium, (8)Personal Care Council, United States, (9)Procter & Gamble Company, United States, (10)Exxon-Mobil, United States, (11)Huntsman, Switzerland, (12)Dow Europe GmbH, Switzerland, (13)Systox Ltd, United Kingdom, (14)Dow Chemical Company, United States, (15)BASF AG, Germany, (16)Lubrizol, India, (17)l'OREAL, France, (18)LyondellBasell, Netherlands, (19)Givaudan International SA, Switzerland, (20)Aarhus Universitet, Denmark, (21)Scientific Consultancy – Animal Welfare, Germany, (22)Lubrizol Corp., United States, (23)BASF Personal Care & Nutrition GmbH, Germany, (24)Corteva, United States

An ECETOC Task Force entitled 'Assessing the human health and environmental safety of polymers' has been working on the topic of polymer safety assessment since January 2018, and has published three reports (ECETOC, 2019; ECETOC, 2020; ECETOC, 2021). In the third report (ECETOC, 2021) the ECETOC Task Force developed a series of case studies for a range of polymer types and applications. The case studies evaluated: (1) the usefulness of the CF4Polymers presented in ECETOC TR No. 133-1 (ECETOC, 2019) for the safety assessment of different types of polymers; and (2) the information on the applicability of tools, methods and models for the hazard and risk assessment of polymers presented in ECETOC TR No. 133-2 (ECETOC, 2020). The case studies were not intended to document a comprehensive risk assessment for any specific polymer. Rather, publicly available data and unpublished company data were collated and assigned to the eight steps of the CF4Polymers to evaluate the scientific usefulness and comprehensiveness of the process through use of examples. The case studies covered different types of polymers and/or different types of intended uses, and comprised the following: Case Study 1 – polycarboxylates, polyacrylates and polymethacrylates; Case Study 2 – cationic polymers; Case Study 3 – polyolefins; Case Study 4 – solid bisphenol-A

diglycidylether (BADGE) polymers (solid BADGE epoxy resins); Case Study 5 - polyetherols (PEOLs; or polyether polyols); Case Study 6 – surfactant polymers; Case Study 7 – selected professional and consumer uses of polyurethane and polyurea. Overall, the case studies confirmed the value of the CF4Polymers as a consistent framework for risk assessment of polymers whilst providing flexibility for applicability to different types of polymer as there is no “one size fits all” approach, thus highlighting the need for critical case-by-case assessments. Key highlights from each case study will be presented, along with overall learnings across the various case studies. ECETOC. 2019. The ECETOC conceptual framework for polymer risk assessment (CF4Polymers). May 2019. Technical Report No. 133-1. ECETOC. 2020. The applicability of analytical tools, test methods and models for polymer risk assessment. March 2020. Technical Report No. 133-2. ECETOC. 2021. Case Studies Putting the ECETOC Conceptual Framework for Polymer Risk Assessment (CF4Polymers) into Practice. September 2021. Technical Report No. 133-3.

4.06.P-We205 Polymer Registration Under EU REACH: Scientific Issues and Implementation Challenges

Warren Scott, CSI-Europe

Expanding REACH registration requirements to polymers is not as straightforward as it sounds. Due to the complexity of polymer chemistry with its vast array of building blocks and subsequent possible combinations, one size does not fit all in terms of using non-polymer registration data requirements. A more targeted approach is required, but in order to reduce the burden on industry and reduce animal testing, polymers requiring registration will be grouped based on chemical and physico-chemical parameters. This poster will look at the current EU REACH registration procedures for polymers and their monomers, and look ahead at how industry can identify their polymer substances. If grouped as a polymer requiring registration (PRR) substance, what data requirements will they be subject to? Additionally, this poster will look at complications due to Brexit, and how the UK Health & Safety Executive (HSE) plans to tackle polymers under UK REACH.

4.07 Environmental Risk Assessment of Organic and Inorganic UV filters (Virtual Only)

4.07.V-01 Eco-Epidemiology to Assess Potential Risks of Natural and Anthropogenic Factors, Including UV Filters, to Corals in Hawaii

Scott Dyer¹, Raghu Vamshi², Christopher M Holmes³, Nicholas Green⁴, Brenna Kent², Iain Davies⁵, Gerco Hoogeweg² and Amelie Schmolke², (1)LeTourneau University, United States, (2)Waterborne Environmental, Inc., United States, (3)Applied Analysis Solutions, LLC, (4)Kennesaw State University, United States, (5)Personal Care Products Council, United States

Recently questions have been raised regarding the environmental safety of some UV filters used in personal, skin care and beach products to corals. In some cases (Hawaii, Key West, Palau) regulatory actions have been precautionary, leading to bans. Eco-epidemiology is a methodology that considers impairments to environmental species and communities from complex combinations of multiple physical and chemical factors with the intent of developing weights of evidence for potential causal relationships. In this study a large set of natural and human influenced factors (including potential risks of measured UV filters and beach visitors) along with coral cover data were assembled to assess the potential adverse effects of UV filters on corals surrounding Oahu, Hawaii within the context of other factors. Principal component analyses simplified the coral data into two components: PC1 representing species diversity and PC2 representing abundance. These components along with all other factors were correlated against each other to determine if some factors could act as proxies for other factors via multiple linear regression and boosted regression tree analyses. Overall, there were good agreements between the two regression methods. The boosted regression tree for PC1 (diversity) showed that 90 percent of the variance were addressed by 3 factors: wave power, temperature (long-term mean) and benthic turf algae. The remaining 10 percent included 13 other factors including beach visitors and UV filters. The regression tree for PC2 (abundance) illustrated 3 factors (temperature long-term mean, latitude, and temperature long-term standard deviation) addressed 75% of the variance. Twelve other factors, including beach visitors and UV filters) were associated with the remaining 25 percent. Hence, it appears that UV filter hazards do not significantly address reduced coral diversity and abundance, suggesting that precautionary bans may not achieve their intended results.

4.07.V-02 Effects of Organic Uv-Filter on Development and Thyroid Endocrine System Using Dre-Mir-499-/- Zebrafish Embryo/Larvae

Yujin Ka¹ and Kyunghye Ji², (1)yongin university, Yongin-si, Gyeonggi-do, Korea, Republic of (South), (2)Yongin University, Korea, Republic of (South)

Homosalate (HS) and octisalate (OS) are widely used as organic UV filters and have been frequently detected in the water environment. Although their estrogenicity and androgenicity have been reported, the studies on thyroid endocrine disruption are limited. In the present study, the thyroid endocrine potential of HS and OS was investigated using wild-type and dre-miR-499 knockout (dre-miR-499^{-/-}) zebrafish embryo/larvae. Following 96 h exposure to HS and OS (0, 0.003, 0.03, 0.3, 3, 30 and 300 µg/L), embryo coagulation, hatchability, and developmental toxicity were observed. Levels of triiodothyronine (T3) and thyroxine (T4) and transcription of genes related to the hypothalamus-pituitary-thyroid (HPT) axis were measured in wild-type zebrafish exposed to target chemicals. To explain underlying mechanism related to miRNA, we applied dre-miR-499^{-/-} zebrafish and compared the larval mortality with wild-type. Body length and whole-body levels of T3 was tendency to increase. in fish exposed to HS and OS. In fish exposed to HS and OS, significant up-regulation of *tra*, *trfβ*, and *trh* genes and down-regulation of *crh*, *tshβ*, and *deio2* genes were observed. The results of significant decrease of larvae survival in dre-miR-499^{-/-} fish exposed to HS and OS, suggest that dre-miR-499 plays an important role in the toxicity of both chemicals.

Acknowledgement: This study was supported by National Research Foundation of Korea (NRF; Project no. 2019R1A2C1002712).

4.07.V-03 Evaluation of Environmental Stressors to Coral in the Florida Keys

Raghu Vamshi¹, Nikki Maples-Reynolds¹, W. Martin Williams², Scott Dyer³, Kurt Reynertson⁴, Jay Sirois⁵, Gerco Hoogeweg¹ and Amelie Schmolke¹, (1)Waterborne Environmental, Inc., United States, (2)Waterborne Environmental, Inc. Leesburg, USA, United States, (3)LeTourneau University, United States, (4)Johnson & Johnson, United States, (5)CHPA, United States

Coral decline has been observed worldwide including to reefs in Florida. Several global and local stressors have been implicated as contributors to the decline of coral populations. The most pervasive and deleterious stressor is the global event of rising atmospheric CO₂ levels which results in sea temperature changes and acidification. These global warming changes cause coral bleaching and ultimately coral death. Stony Coral Tissue Loss Diseases (SCTLD) is causing widespread devastation in the Florida Reef Tract. Expert coral biologists have identified the most important stressors to reefs in Florida – invasive species, unsustainable fishing practices, coastal development, untreated or poorly treated wastewater, urban and agricultural run-off, and tourism-related damage. Recently, questions have been raised about the potential for certain sunscreen active ingredients (UV filters) to contribute to the decline in coral ecological status. An investigation was conducted to evaluate environmental stressors to coral in the Florida Reef Tract with a focus on the Florida Keys through the lens of possible global and local factors. Stressors with potential to impact coral ecosystems in the Florida Keys were identified and prioritized. A weight-of-evidence did not verify sunscreens as a contributor to coral decline. Improving the ecological status of coral in the Florida Keys requires prioritizing efforts on the most significant stressors. Mitigation efforts to restore damaged coral have been successful to some extent but are labor and time intensive. Conservation efforts should focus on recreational practices such as educational efforts on boaters, divers, and other activities in and around the coral reef to reduce the spread of SCTLD and minimize structural damage to the reefs.

4.07 Environmental Risk Assessment of Organic and Inorganic UV filters (Poster Corner)

4.07.PC-Tu01 Freshwater Environmental Safety Assessment of Ethylhexyl Methoxycinnamate in the United States

Emily EA Burns¹ and Iain Davies², (1)PCPC (Personal Care Products Council), United States, (2)Personal Care Products Council, United States

Organic ultraviolet (UV) filters are used in cosmetic and personal care products (CPCPs), including sunscreens (considered over-the-counter drugs in the United States), due to their ability to absorb solar radiation. UV filters are released down-the-drain through cleansing, bathing, or rinsing of skin or through the laundering of clothing. The fraction of CPCPs that are washed-off down-the-drain enter wastewater treatment where they are removed to varying extents and discharged to effluent-receiving freshwater. It is therefore important to establish the environmentally safe use of UV filters entering the freshwater compartment. In this presentation, a freshwater environmental safety assessment is conducted for ethylhexyl methoxycinnamate (EHMC) in the United States. The environmental risk assessment (ERA) follows an established framework for CPCPs. For the exposure assessment, the spatially resolved aquatic exposure model, iSTREEM, is used. The iSTREEM model was specifically developed for chemicals disposed of down-the-drain and provides a comprehensive exposure assessment through the consideration of spatial variability in emissions, wastewater treatment, flow, and chemical loads transported from upstream to estimate CPCP concentrations in effluent-receiving freshwaters across the conterminous United States. The model output is a predicted environmental concentration (PEC) distribution representative of the spatial variability in conditions across the region. For the hazard assessment, a review of toxicity data from regulatory databases and the peer-reviewed literature was conducted. Data related to ecologically relevant endpoints for risk assessment (e.g., mortality, growth, reproduction) from studies conducted according to or similarly to standardized test guidelines were selected. From the suitable toxicity data, the most sensitive endpoint was selected to calculate the predicted no-effect concentration (PNEC). The PNEC was calculated by dividing the most sensitive endpoint by the appropriate assessment factor. A safety assessment was conducted by comparing the PEC distribution with the PNEC. The results indicate that freshwater exposure resulting from down-the-drain emissions of EHMC is of low concern as the PNEC does not exceed 90th percentile PEC. These results are instrumental in demonstrating the environmental safety of organic UV filters in the United States freshwater environment and will help prioritize future work.

4.07.PC-Tu02 Developing Standard Ecotoxicity Tests on Scleractinian Corals for UV Filters and Related Chemicals

Valentina Di Mauro¹, Ingo Miller², Matthias Kellermann², Samuel Nietzer², Mareen Moeller³, Elham Kamyab⁴, Laura Henriette Lütjens⁵, Sascha Pawlowski⁶, Mechtild Petersen-Thiery⁷ and Peter Schupp⁸, (1)Environmental Biochemistry, University of Oldenburg, ICBM, Wilhelmshaven, Germany, (2)ICBM, Carl-von-Ossietzky Universitaet Oldenburg, Germany, (3)ICBM, Universität Oldenburg, Germany, (4)University of Oldenburg, ICBM, Germany, (5)BASF SE, Germany, (6)GBP/RA, BASF SE, Germany, (7)BASF Personal Care & Nutrition GmbH, Germany, (8)University of Oldenburg, Germany

Coral reefs are marine hotspots of biodiversity and provide vital ecosystem services. Due to climate change and ocean acidification, reef building corals are declining at a dramatic pace. Not only global but also local stressors impact coral health. UV filters used in personal care products such as sunscreens are considered to be among those substances due to their direct release into the coastal marine environment. Some research findings indicate a possible impact on corals after exposure to certain UV filters such as bleaching or even mortality, whereas other scientific publications did not. Thus, the existing results are considered as controversial due to experimental deficiencies and require further investigation on corals. Using standardised and validated testing protocols would certainly help for a sound and scientifically based conclusion and will also support regulatory decision-making processes. Consequently, we currently develop short and long-term testing methods on corals of different live stages (e.g., larvae and adult stage) suitable for validation and standardisation within the DIN, ISO and/or OECD framework. So far, our

developed ecotoxicity assays for chemicals including those that are poorly water soluble (i.e., UV filters) on corals of different life stages showed reliable test results. As an example, our coral larval settlement assay presented an inverse correlation of the endpoints mortality and metamorphosis, whereas our adult coral bleaching assay displayed a positive correlation of the endpoint bleaching in a concentration-response relationship. As a next step, additional pre-validation work in collaboration with additional laboratories is needed to assess the interlab variability and reproducibility of our testing method and results.

4.07.PC-Tu03 Ecotoxicological Evaluation of Sunscreen Creams on Marine Plankton

María del Pilar González Muñoz¹, Alejandro Vilas da Fonseca², Clara Mendoza Segura³, Ricardo Beiras⁴ and Sara López Ibáñez², (1)University of Vigo, Spain, (2)University of Vigo, Vigo, Spain, (3)Marine Research Institute (CSIC), Spain, (4)University of Vigo, Afghanistan

In recent years, a large number of sunscreens have emerged to protect our skin from the damage caused by UV rays. Most of them are made up of simple or compound aromatic structures, sometimes conjugated, which can pose a threat to marine ecosystems. In order to understand their effects on the marine environment, different toxicity bioassays were carried out using two representative zooplankton organisms: sea urchin larvae (*Paracentrotus lividus*) and copepod nauplius larvae (*Acartia* sp.). In addition, a representative of phytoplankton, the microalgae *Tisochrysis lutea*, was chosen. The aim of these tests was to expose these three species with different dilutions of six sunscreen formulations. The endpoints to be evaluated were the larval length at 48 h of *Paracentrotus lividus*, the mortality at 72 h of *Acartia* sp. and growth inhibition at 72 h of *Tisochrysis lutea* cultures. Toxicity was estimated from the NOEC (no observed effect concentration), LOEC (lowest observed effect concentration) and EC₅₀ (median effective concentration). According to our results, none of the creams can be considered totally innocuous for plankton. All of them showed a great variability in toxicity on the different plankton organisms. The highest toxicity level was found in cream number 4 when tested on the sea urchin, exhibiting an EC₅₀ = 74.4 mg/L. In an attempt to identify the component causing the toxicity of cream 4, a UV-filter only present in this cream, 2-phenyl-5-benzimidazolesulfonic acid, was tested on sea urchin. This chemical was found to be more toxic when the sea urchin larvae were incubated with photoperiod 16:8 of light: darkness, obtaining an EC₅₀ = 2.7 g/L and requiring to be diluted 30 times in seawater to lose its toxicity. This study highlights the need to understand the toxic effects generated by solar protection products, as well as their components, on marine organisms.

4.08 Expert Knowledge Elicitation in environmental assessments - subjective, but scientific

4.08.T-01 The Quality of Judgements in Conservation Decision Making

Mark Burgman, CEP, Imperial College, London, United Kingdom

Conservation science is a crisis discipline in which scientists measure impacts in terms of species extinctions and ecosystem collapse, and practitioners typically seek solutions that preempt irreversible change. Present challenges such as global losses of biodiversity and social-ecological systems require efficient and timely action. Decisions need to be made quickly, yet the data and understanding necessary to assess problems and provide unequivocal solutions are typically unavailable, incomplete, dated, or biased. These issues are amplified by a suite surprisingly common procedures and actions that – without malicious intent – misuse or misrepresent data and analyses, generating spurious results and misleading advice. Here, I review the quality and reliability of expert opinion used to fill information gaps and assess the quality of scientific evidence, present some recent empirical results on the limits of ecological judgement, and discuss the prospects for improving expert judgement.

4.08.T-02 Assessing the Calibration of Expert Elicited Probabilities: The Good, the Bad, and the Ugly

Anca Hanea¹ and Tina Nane², (1)The University of Melbourne, Australia, (2)DIAM, TU Delft, Delft, Netherlands

Probabilistic predictions are frequently required in the context of risk analyses and decision making, including ecological risk assessments and human health risk assessments. The need of structured protocols to elicit expert predictions is well established. Such protocols ensure that the elicited judgements (a.k.a. the expert data) can be used as scientific data, since they are subjected to the scientific principles of review, critical appraisal, and repeatability. However, objectively evaluating the expert data, even though essential, is not a trivial task. Experts performance, and hence the quality of the elicited data should be evaluated by scoring experts on questions related to the elicitation questions, whose answers are known a priori, known as seed questions. Experts' performance on seed questions can be measured in terms of accuracy, calibration and informativeness. In this research we are concerned with calibration measures and the interpretation of their exact values. Calibration measures are random variables and their distribution plays an important role in such interpretations. Cooke (1991) proposed a calibration measure for probabilistic predictions (binary variables) that has an asymptotic distribution. In contrast, Hanea & Nane (2019) proposed a score with an exact distribution. Even though both these scores have attractive theoretical properties and proved comparable on real and simulated data, their behaviour is not fully understood. We will present new comparisons and evaluations of the two scores that will clarify the source of discrepancies. A better understanding of the separate scores is however necessary prior to engaging in these comparisons. Simulated and real data will be used to clarify the properties of these two calibration measures. This exercise will help define and refine what leads to a good vs. a poor calibration score and how important are the fine differences between the realisations of these scores (which are random variables). We also aim to identify those situations when neither score is either easy to interpret, nor reliable. **References** Cooke, R.M., 1991. Experts in Uncertainty: Opinion and Subjective Probability in Science. Environmental Ethics and Science Policy Series. Oxford University Press. A.M. Hanea, G.F. Nane, 2019, Calibrating experts' probabilistic assessments for improved probabilistic predictions, Safety Science, 118, 763-771, ISSN 0925-7535, <https://doi.org/10.1016/j.ssci.2019.05.048>.

4.08.T-03 Averaging Quantiles, Variance Shrinkage and Overconfidence

Roger Cooke¹ and Tina Nane², (1)*rresources for the future, United States*, (2)*DIAM, TU Delft, Delft, Netherlands*

Averaging quantiles as a way of combining experts' judgments is studied both mathematically and empirically. Quantile averaging is equivalent to harmonically weighting (HW) densities evaluated at quantile points (Bamber et al 2016, Colson and Cooke 2017). Although not attested in any guidance of which the author is aware, HW is often employed as a way of summarizing expert judgment data without introducing additional assumptions. It has been adopted by the COVID-19 ForecastHub (<https://covid19forecasthub.org/doc/ensemble/>) (Ray et al 2020, Cremer et al 2021). Examples of others using quantile averaging include (Christensen et al 2018, De Gooijer and Zerom (2019), De Vries and de Wal 2015, Flandoli et al 2011, Sayedi et al 2020, Kim et al 2021). It has been promoted as an alternative to equal weighting (Lichtendahl et al 2013). A variance shrinkage law is established between equal weighting (EW) and HW. Letting $AveVar$ be the mean variance of the empanelled experts based on elicited (or imputed) distributions, one can show that $Var(EW) \geq AveVar \geq Var(HW)$. Equality holds for the first inequality iff experts all have the same best guesses and holds for the second if and only if the experts have the same variance and their distributions are completely correlated. Variance shrinkage raises the question whether HW invites overconfidence. The TU Delft expert judgment data base [1] contains the 49 studies since 2006 involving 530 experts assessing, in addition to the variables of interest, 580 calibration variables from their field to which true values were known. Of these, 140 experts (26%) would not be rejected as statistical hypotheses at the traditional 5% level (Cooke et al 2020). The previous analysis has been extended to include HW combinations for each study. The following picture emerges: Whereas PW and EW as statistical hypotheses would be rejected at the 5% level on 3 resp 2 of the 49 studies, HW is rejected on 31 studies. On 19 studies rejection is at the 0.1% level. HW's informativeness on average is 50% greater than that of PW, which in turn is twice that of EW. [1] available from <http://rogermcooke.net/> This site also contains pre 2006 data with 45 studies involving 446 experts and 778 calibration variables. The earlier studies are of less uniform design.

4.08.T-04 The Assessment of Overall Uncertainty in Risk Assessments

Ullrika Sahlin¹ and Andy Hart², (1)*Lund University, Sweden*, (2)*Newcastle University, United Kingdom*

Uncertainty analysis is the process to identify and assess the combined impact of sources of uncertainty on uncertainty in the conclusion. This is called "overall uncertainty" and must be assessed by expert judgement because it should consider all sources of uncertainty, i.e. not only those that are addressed by the assessment model or statistical analysis. The assessment of overall uncertainty is a key requirement of the European Food Safety Authority's guidance on uncertainty analysis, because overall uncertainty is what matters most for decision-making. The outcomes of interest for risk management will always be uncertain to some degree. Qualitative expressions of uncertainty, such as likely or unlikely, are ambiguous and mean different things to different people. Therefore, EFSA's approach is to recommend that assessors *always try* to quantify the overall uncertainty using probability. This should always be possible, provided the outcome of interest is well defined, but can be challenging for those unfamiliar with the approach. This presentation shares experience and lessons learned from implementing overall uncertainty assessment, which may be helpful when applying it in other areas. There are well-established methods for eliciting expert judgements to quantify uncertainty using probability, but this will be new for many assessors and requires some training and familiarisation. Existing guidance refers mostly to eliciting probability distributions for parameters, but assessment conclusions are often framed as binary statements which require only a single probability. Experience suggests that experts find it easier to give a range of probabilities for overall uncertainty. Documenting the methods, evidence and reasoning for the assessment of overall uncertainty is essential for the transparency and credibility of the results. Care is needed to present and explain the results, specifying clearly the outcome of interest and its probability, and to avoid confusion with other uses of probability to express frequency, incidence or risk. For this reason, EFSA's Guidance on the communication of uncertainty has suggested expressing probabilities that quantify overall uncertainty for a conclusion as % certainty for the more probable outcome. Though developed in the area of food safety, the Chief Scientific Advisors to the European Commission have commended the approach to assess overall uncertainty as suitable for use in other fields.

4.08.T-05 Application of Data Analysis Based Expert Knowledge Elicitation in Deriving In Vitro Point of Departure of DNA Damage With Uncertainty From Three In Vitro Assays

Dawei Tang¹, Andrew White², Andrew Scott³ and Mona Delagrangé³, (1)*Unilever SEAC*, (2)*Unilever, United Kingdom*, (3)*Unilever/Safety and Environmental Assurance Centre SEAC, United Kingdom*

DNA damage can be caused by exposure to certain genotoxic chemicals. Traditionally, genotoxicity data has not been used for risk assessment, and recently, quantitative methods have been developed to estimate threshold concentrations which could potentially be used in genotoxic risk assessment. However, the methods do not adequately address the mechanism causing the adverse effect, nor do they characterise the uncertainty in the estimate. Based on the outcome of three previously reported *in vitro* assays relevant to DNA damage mechanisms following exposure of p53-positive HT1080 cell line to quercetin, this study aimed to derive a Point of Departure (PoD) for DNA damage - the Lowest Observed Effective Level to cause saturation of endogenous DNA repair capacity in HT1080 cells, using both data analysis and Expert Knowledge Elicitation (EKE). The assays were: 1) microarray (MA) assay, aiming to determine the concentration of quercetin above which, both global transcriptional changes and those related to DNA Damage Response (DDR) in the HT1080 cells were induced, 2) DNA Repair Centre (RC) assay, measuring fold change of DNA RCs in HT1080 cells at different concentrations of quercetin and 3) Micronuclei (MN) assay, measuring fold change of MN in the HT1080 cells at different concentrations of quercetin. Based on the assays' outcome, a Bayesian method was used to generate distributions of PoD for the DNA RC assay and MN assay, i.e., the concentration above which, DNA RCs and MNs were formed. For the MA assay, the concentration above which DNA damage-related gene transcription were induced can be revealed. Whilst the induction of DDR differential gene expression, the formation of DNA RCs and MNs are closely related to

DNA damage, none of them directly measure the PoD for DNA Damage. However, knowledge exists on the relationship between the assay outcomes and DNA damage. Therefore, the Sheffield framework based EKE was used to estimate PoD of DNA Damage from the assay outcomes and this existing knowledge. In summary, this work used data analysis and EKE to generate a distribution of PoD for DNA damage induced by exposing HT1080 cells to quercetin based on three *in vitro* assays' outcome. The principles outlined in the work can be applied in many areas, e.g., toxicological and environmental risk assessment, where expert knowledge can be elicited and analyzed to derive a probabilistic distribution of a quantity of interest when there is a lack of direct data or knowledge.

4.08 Expert Knowledge Elicitation in environmental assessments - subjective, but scientific (Poster)

4.08.P-Mo226 Aggregation of Bounded Probabilities From Judgements by Experts in a Food Safety Assessment

Ullrika Sahlin¹, Matthias Troffaes² and Andy Hart³, (1)Lund University, Sweden, (2)Durham university, UK, (3)Newcastle University, United Kingdom

In expert elicitation, experts are asked to make probabilistic judgements. Several organisations producing scientific advice are accepting judgements made with probabilities that are bounded (also called “imprecise” or “approximate”). Bounded probabilities can be easier to obtain when resources to perform elicitation are limited, or help to reach a consensus judgement among multiple experts (behavioural aggregation). Mathematical aggregation of bounded probability judgments from multiple experts poses, compared to aggregation of precise probabilities, an extra challenge for assessment. What approach to use depends on the purpose of aggregation, and to what extent it is desirable to allow the aggregated judgement to retain information about disagreement amongst members in the group. We review methods to aggregate bounded probabilities and demonstrate their applicability and differences, using an example based on a recent assessment in the area of food safety. In this example, multiple experts assess multiple endpoints that are then combined in an assessment to quantify uncertainty about the threshold dose for the most sensitive endpoint. Aggregation of bounded probabilities can be done by taking the convex hull, pooling of the bounds, aggregation that requires a higher order measure over probability, or updating of judgments per expert considering the judgments by all others (which requires a model for updating judgements). We show that these approaches for aggregation give different ranges between the bounds and that approaches requiring additional information usually result in smaller ranges. Current guidelines for expert knowledge elicitation lack instructions on how to aggregate bounded probabilities. Methods to aggregate bounded probabilities deserve more attention as they play a vital role in assessments using expert judgements where experts provide their judgements with bounds on probabilities.

4.08.P-Mo227 Encoding and Updating Uncertain Judgements Using Hybrid Elicitation and Quantile-Parametrized Distributions

Dmytro Perepolkin¹ and Ullrika Sahlin², (1)Lund University, Lund, Sweden, (2)Lund University, Sweden

Bayesian parametric inference is about updating the prior beliefs on parameters in light of the new data. *Elicitation of parameters* require that the expert understands the model and the role a particular parameter plays in it. An alternative is to elicit *predictions* about the “next observation”. Predictive elicitation makes no distinction between the randomness explained by the model (variability) and uncertainty about the parameters within the model. This makes it difficult to update the expert predictions with the data coming from the new observations. We propose a *hybrid elicitation* approach, where elicitation of the observable quantities is accompanied by the elicitation of the uncertainty around them. Hybrid elicitation, combining features of predictive and parametric elicitation, can be used to define the prior distribution for a model defined by a quantile-parametrized distribution. In this talk we present an example of the expert-elicited foods consumption distribution used for exposure assessment, and update it with the observations of actual consumption obtained from the food consumption database. Asking experts to provide their uncertainty about the elicited quantile-probability pairs is enough to quantify the uncertainty about the food consumption distribution, which can be particularly useful when food consumption data is sparse.

4.08.P-Mo228 Global Approaches to Identifying and Managing Apparent Emerging Chemical Issues

Olivia Lin Tran¹, Graham Merrington², Adam Peters³, Therese Manning⁴, Anna Ramarosandratana⁵, Julie Cattle⁶ and Janina Beyer⁷, (1)wca, Faringdon, United Kingdom, (2)WCA Environment Limited, United Kingdom, (3)wca, United Kingdom, (4)Enriska, Australia, (5)NSW Environmental Protection Authority, Australia, (6)NSW Environment Protection Authority, Australia, (7)NSW DPE, Australia

The chemicals management regulatory systems have evolved over the last century, as different aspects have been modified in response to scientific developments. Chemicals are managed under international, national and state-level legislative instruments, usually on the basis of use (e.g. industrial chemicals, pharmaceuticals, pesticides and biocides, cosmetics), exposure (e.g. occupational health, contaminated land) or intrinsic properties (e.g. hazardous substances, persistent organic pollutants). Nevertheless, chemical issues may arise even within these developed regulatory systems that present potential risks to human or environmental health. These chemical issues may arise from previously unknown hazardous properties or environmental exposure profiles, or from unexpected changes to the exposure profile from new uses. Such issues may be identified through existing regulatory frameworks or can be triggered from scientific research or real-world events, reported in scientific journals or by mass media outlets. This poster summarises approaches taken by various regulatory jurisdictions across the world to identify and manage apparent emerging chemical issues. Information was gathered from discussions with regulatory scientists and reports from regulators and authoritative bodies. Several jurisdictions use quantitative approaches to identify emerging chemical issues, including biomonitoring, environmental monitoring and *in silico* modelling. Furthermore, a small number of jurisdictions have developed qualitative approaches in the recent years to supplement already robust chemical management programmes. These

range from surveys of expert panels to systematic monitoring of websites and published information. Many of the data-driven qualitative and quantitative approaches can be quite resource-intensive. Varying degrees of structure are seen in the use of expert panels to identify emerging chemical issues, ranging from ad-hoc discussions to systematic surveys utilising the Delphi method. Overall, there is no 'ideal' approach to identifying emerging chemical issues. Bespoke approaches to identifying emerging chemical issues are dependent on the available resources (i.e. time and budget), expertise and remit of the risk management organisation.

4.08.P-Mo229 Proxies for Uncertainty Quantification - Are Best Estimates Enough?

Tina Nane¹ and Roger Cooke², (1)DIAM, TU Delft, Delft, Netherlands, (2)resources for the future, United States

The Classical Model for structured expert judgment (SEJ) is an established method to elicit, validate and aggregate experts' uncertainty assessments. The Classical Model proposes performance-based mathematical aggregation of experts' distributions, using statistical accuracy and informativeness to objectively evaluate experts assessments. Along with individual expert performance, the model therefore enables the evaluation of the aggregated distributions, by using the same performance measures that were used to evaluate individual assessments. The Classical Model has been employed in numerous professional applications, and expert data is continuously documented by Roger Cooke[1], which enables a meta-analysis of the performance of various weighting schemes to aggregate experts uncertainty distributions or quantiles. A ample body of research demonstrated the superiority of performance-based aggregation in terms of overall performance, cross-validation analysis and forecasting performance. Nonetheless, many published expert judgment studies elicit only best guesses. Further, very large studies often employ SEJ only for the most important variables, other variables are assigned 'nominal values' or averaged best guesses from experts. Best guesses will remain part of the expert judgment repertoire. Here we address the question whether it is possible to leverage the above-mentioned validation research to obtain proxies for uncertainty quantification based only on best guesses. We propose several such proxies and investigate, using the collected expert data, the performance of those proxies with respect to statistical accuracy and a proxy measure for informativeness, and compare their performance to equal weighted aggregation of experts distributions. [1] <http://rogermcooke.net/>

4.09 Implementing Ecosystem Functions and Services Approaches into ERA to Improve Decision Making: What else is needed? (Virtual Only)

4.09 Implementing Ecosystem Functions and Services Approaches into ERA to Improve Decision Making: What else is needed? (Poster)

4.09.P-Tu202 Feasibility of Applying Ecosystem Services Principles to the Derivation of Environmental Quality Standards

Lorraine Maltby¹, Andrew Ross Brown² and Helen Wilkinson³, (1)The University of Sheffield, United Kingdom, (2)Exeter University, UK, (3)Environment Agency, England, United Kingdom

Environmental Quality Standards (EQSs) are key tools in the assessment and control of hazardous chemicals in the environment in order to protect biodiversity and ecosystems. To maximise their effectiveness, we need to ensure that EQSs are scientifically defensible and relevant. Currently EQSs used to protect freshwater ecosystems from the adverse impacts of chemicals are based on toxicity data generated from single species toxicity tests and are typically driven by the most sensitive species, irrespective of its functional role. The current approach takes no account of species interactions or ecosystem processes and hence the links between EQS, biodiversity and ecosystem functioning are uncertain. We describe the principles involved in adopting an ecosystem services approach to setting EQS values and then describe the technical steps involved. Two exemplar chemicals are used to illustrate the proposed approach. The regulatory implications for using ecosystem service-based EQSs in practice are outlined, their key benefits are highlighted and the technical requirements for their derivation and implementation are identified.

4.09.P-Tu203 Linking Individual Level Effects and Ecosystem Functioning Through Invertebrate Feeding: What Do We Know About Feeding Responses to Stressors in the Lab?

Niamh O'Connor¹, Philip Warren² and Lorraine Maltby¹, (1)The University of Sheffield, United Kingdom, (2)University of Sheffield, United Kingdom

For effective environmental protection, it is critical to understand how effects observed in the Laboratory toxicity tests translate into changes in ecosystem processes and functioning in the field. In freshwaters, invertebrates play a key role in the trophic transfer of energy, decomposition, and nutrient cycling. Impacts of stressors on invertebrates are likely to result in ecosystem level responses and changes in ecosystem service delivery. Changes in feeding rate is a general stress response and has been found to be a sensitive toxicity endpoint. It may also provide a link between toxicity effects at the individual and ecosystem level, using energy as currency. However, feeding rate is not a standard toxicity endpoint. A systematic review of studies examining freshwater invertebrate feeding rate responses to stressors was conducted to establish 1) the species in which this had been tested 2) the mechanisms by which stressors affect feeding rates 3) the variation in responses between species and contaminants 4) the sensitivity of feeding, compared to lethality, as an endpoint. A total of 395 laboratory feeding assays were found in 214 studies, observing the effects of 165 different contaminants across 7 Phyla (235 Arthropoda, 92 Mollusca, 29 Rotifera, 18 Cnidaria, 11 Platyhelminthes, 6 Annelida, 4 Nematoda). Most assays were conducted on only a few standard genera (Daphnia 97, Gammarus 56, Dressienia 20, Brachionus 18, Hydra 18). Fewer data were available for Insecta. Trichoptera and Odonata were the most studied but little, or no, information was available for other orders. About 80% of assays reported negative effects of contaminants on feeding rate and behaviour. No single mechanism was identified leading to reduced feeding but the mechanisms by which chemicals affect feeding are largely contaminant specific. Spearman's rank correlation was performed to compare the sensitivity

of the feeding endpoint to lethality ($r = 0.41$, $p < 0.01$). When grouping by mode of action, strong relationships were found for AChE inhibition ($r = 0.81$, $n = 80$) and polar narcosis ($r = 0.77$, $n = 20$) suggesting that species sensitivity of feeding response is positively related to sensitivity to mortality. This was not so strong for metals ($r = 0.24$, $n = 140$). These results suggest that, in the absence of feeding endpoints, lethality data may be used to predict feeding sensitivity for particular modes of action.

4.09 Implementing Ecosystem Functions and Services Approaches into ERA to Improve Decision Making: What else is needed? (Poster Corner)

4.09.PC-Tu13 Biodiversity Assessment Request Under Regulation EC No. 1107/2009 Approaches, Challenges and Limitations

Elena Alonso¹ and Miriam De Roman Martinez², (1)Knoell Iberia S.L., Madrid, Spain, (2)Dr.Knoell Consult GmbH, Germany
The legal framework that regulates the placing of Plant Protection Products (PPP) on the market (Regulation EC No. 1107/2009 and Regulations EC No. 283/2013 and EC No. 284/2013) includes the requirement to consider *the potential impact of the active substance on biodiversity and the ecosystem, including potential indirect effects via alteration of the food web*. Besides, the *EU Green Deal, Farm to Fork and Biodiversity Strategies*, recently adopted by the European Commission, display objectives for reducing the loss of biodiversity and present quantitative targets by 2030 on pesticide uses, namely the reduction by 50% of the overall use of – and risk from – chemical PPP. However, at the time being, there is no methodology “fit for use” to satisfy the legal request of the biodiversity assessment within the PPP environmental risk assessment (ERA) scheme. Therefore in the present work, a review of currently available scientific reports and regulatory guidance has been conducted with the objective of identifying workable approaches to link available ecotoxicological data provided during the PPP authorization process with the assessment of biodiversity. According to this review, the Ecosystem Services (ES) concept is an existing available approach to identify Specific Protection Goals to support the biodiversity assessment, but it is still a conceptual idea without a clear methodology to be integrated into the PPP regulatory process. The ES concept, as well as the groups of organisms that provide these ES, are not clearly described in any guidance or publication and thus, limiting its direct link to standard Tier 1 toxicity data or even higher tier approaches. An additional challenging topic identified during this review is the lack of figures for discerning the effects on biodiversity caused by the use of PPPs from those caused by agricultural practices themselves, regardless of PPP application. This knowledge would be essential to propose appropriate mitigation measures that complement current ERA practices. Overall, this review provides a synthesis of the available conceptual approaches proposed by different stakeholders to address the impact of PPP on biodiversity. Based on that, it can be concluded that there are still many challenges and limitations before a workable regulatory ERA scheme for addressing biodiversity can be implemented.

4.09.PC-Tu14 PPP Precision-Application As Part of the Farm-To-Fork Strategy: Using Ecosystem Service Approaches to Assess Risks to In-Soil Organisms?

Steven Droge¹, Louise Wipfler² and Bas Buddendorff³, (1)Wageningen Environmental Research (Alterra), Netherlands, (2)Wageningen Environmental Research, Netherlands, (3)Wageningen UR, Nederland

The Farm to Fork (F2F) Strategy is a multi-level action plan as part of the EU Green Deal, addressing the challenges of sustainable food systems. Part of F2F is a targeted 50% reduction of the overall use and risk of chemical pesticides by 2030. Precision-farming can contribute to this target, supported by technical innovations, improving access to fast internet in rural areas and satellite technology. Precision-application of plant protection products (PPPs) can, besides reducing the amount applied, result in a lower risk of protection-targets. It will also introduce in-field spatial variability in exposure concentrations, particularly in a spot treatment. Taking these effects into consideration, precision-applications for crop protection could play a role in the environmental risk assessment (ERA) of PPPs. This presentation explores several key issues with implementing precision application as part of the ERA for in-soil organisms under the current regulations. Currently, the Tier 1 ERA for PPP regulation is based on negligible chronic effects on reproduction of three key species (earthworm, collembola, predatory mite), based on the local in-field maximum soil concentration (PECs). Yet, even for spot treatment applications (use on < 10% of the total field), PECs are based on the advised application dose considering the low dispersal capacity of in-soil meso- and microfauna. EFSA is currently revising Guidance documents on Persistence (9188/VI/97 rev.8) and Terrestrial Ecotoxicology (SANCO/10329/2002). Additionally, an EFSA Scientific Opinion on the science behind the soil RA was published in 2017. This Scientific Opinion addressed the implementation of specific protection goals for Ecosystem Services (ES) provided by agricultural soils, and provides arguments to better include external recovery (dispersal) and internal recovery (e.g. reproduction). Based on recovery rates, small effects up to a period of months may be tolerable for most service providing units. In case of precision-application, external recovery may occur from “unimpacted” patches to impacted field hot spots. The increased level of realism in ERA via an ES approach should also account for multiple stressors (e.g. including the full PPP treatment scheme per crop) and should be supported by adequate population modelling. Several examples of precision application are presented with options for recovery with considerations for spatial and temporal variability.

4.09.PC-Tu15 A Review of Environmental Protection Goals: What Are the Options for the UK?

Amy C. Brooks and Helena Crosland, Cambridge Environmental Assessments, United Kingdom

Protection goals are key to the environmental assessment of pesticides. Without them it is not clear what is being protected and whether it is appropriate to authorise or refuse a plant protection product. Protection goals must be clear regarding what is acceptable in terms of size/magnitude of effects in the environment of the substances being used and, furthermore, indicate what level of uncertainty is acceptable. General protection goals for the environmental risk assessment (ERA) of plant protection products are stated in relevant legislation but specific protection goals (SPGs) are not defined. However, as these are crucial for

carrying out a regulatory risk assessment and for making a decision, in certain circumstances they have been defined in guidance documents. The UK regulatory authority (HSE CRD) is funding a project to establish what “approaches” are currently available that will help with the definition of specific protection goals in the UK. This poster will present a summary of all the currently available approaches, including ecosystem services, for determining, and hence establishing, environmental protection goals for non-target organisms. An assessment of the main pros and cons of the approaches will also be presented. An opinion will be provided regarding the best methodology for establishing environmental protection goals for non-target organisms in the UK. The setting of specific protection goals will be part of a future project and won't be addressed here.

4.09.PC-Tu16 Functional Measures As Potential Indicators of Down-The-Drain Chemical Stress in Freshwater Ecological Risk Assessment

Claudia Rivetti¹, Laura Harrison², Katie Pearson³, Christopher Wheatley², Jane Hill², Lorraine Maltby⁴, Lucy Speirs⁵ and Piran White², (1)Unilever, Sharnbrook, United Kingdom, (2)University of York, United Kingdom, (3)Environment & Geography, University of York, York, United Kingdom, (4)The University of Sheffield, United Kingdom, (5)Unilever, United Kingdom

Conventional Ecological Risk Assessment (ERA) predominantly evaluates the impact of individual chemical stressors on a limited range of taxa, which are assumed to act as proxies predicting impacts on freshwater ecosystem function. However, it is recognised that this approach has limited ecological relevance. Here, we reviewed published literature to identify measures that could be considered as functional indicators of down-the-drain chemical stress as a potential approach to build more ecological relevance into ERA. Overall, we found wide variation in the use of the term ‘ecosystem function’, and conclude that it is important to distinguish between measures of processes (i.e. the interactions between biotic and abiotic components of the ecosystem) and measures of the capacity for processes (i.e. the status and composition of functional traits underlying processes). We present a classification of potential functional indicators and suggest that including indicators directly connected with processes will improve the detection of chemical stress impacts on ecosystem functioning. The rate of leaf litter breakdown, oxygen production, carbon dioxide consumption and biomass production show high potential to be used as functional indicators in ERA. However, the limited supporting evidence means that further studies are needed before these measures can be fully implemented and interpreted within ERA and with regulatory context. Sensitivity to chemical stress is likely to vary among functional indicators depending on the stressor and ecosystem dynamics context. Therefore, we recommend that ERA incorporates a variety of indicators relevant to each aspect of the function of interest, such as a direct measure of a process (e.g. rate of leaf litter breakdown) and a capacity for a process (e.g. functional composition of macroinvertebrates), alongside structural indicators (e.g. taxonomic diversity of macroinvertebrates). Overall, we believe that the consideration of functional indicators can add value to ERA by providing greater ecological relevance, particularly in relation to indirect effects, functional compensation, interactions of multiple stressors and the importance of ecosystem context.

4.09.PC-Tu17 Leaf Litter Decomposition As a Functional Indicator of Chemical Stress in Ecological Risk Assessment

Katie Pearson¹, Piran White², Jane Hill², Lorraine Maltby³, Claudia Rivetti⁴ and Geoffrey Hodges⁵, (1)Environment & Geography, University of York, York, United Kingdom, (2)University of York, United Kingdom, (3)The University of Sheffield, United Kingdom, (4)Unilever, Sharnbrook, United Kingdom, (5)Unilever, United Kingdom

Using toxicity data from one or a few selected species to understand chemical impacts on whole ecosystems in ecological risk assessment is an approach based on the concept of protection from, rather than prediction of, chemical effects. As a result, it does not consider all potential impacts of chemicals on the complex processes and interspecies interactions present in ecosystems. Varying responses of different species to chemical exposure, and cascading ecological effects make outcomes difficult to predict at the community level. Measuring change in rates of ecosystem functioning provides an alternative approach and may make ecological risk assessment more representative of ecosystem-level responses. Leaf litter decomposition is a key ecosystem function which regulates carbon and cycles nutrients via feeding behaviour of detritivore species, which can be impacted by chemical exposure, making decomposition sensitive to the effects of chemicals. Using decomposition as a functional indicator of stress requires a good understanding of its underlying drivers, especially relationships between function and biodiversity. Utilizing an overview of published reviews, we examined whether a general consensus exists in the relationship between freshwater community biodiversity and leaf litter decomposition rate, by quantifying the reported presence and type (i.e. positive, negative, inconsistent) of the relationship. Our overview: 1) collated systematic reviews on the relationship between freshwater community biodiversity and decomposition, 2) assessed the methodological quality of reviews, and 3) determined the consensus on the decomposition-biodiversity relationships. We found a total of 7 systematic reviews containing 242 independent papers, with 5 out of 7 reviews reporting a positive relationship between biodiversity and the rate of decomposition, showing a consensus. The AMSTAR2 tool was used to assess methodological quality, revealing common gaps in review methods. For example, no reviews clearly reported a priori methods or reported that study selection and data extraction was performed in duplicate. Our findings will inform future work on evaluating the usefulness of leaf litter decomposition as an indicator of community responses to chemical exposure, by assessing whether rate of decomposition changes consistently with chemical exposure. This will inform development of decomposition as a robust functional indicator for use in environmental risk assessment.

4.09.PC-Tu18 Ecosystem Service Delivery in Freshwater Catchments: A Review of Current Tools and Methods and Their Potential Application in Risk Assessment

Susanna Mølkänen¹, Lorraine Maltby² and Philip Warren³, (1)The University of Sheffield, Sheffield, United Kingdom, (2)The University of Sheffield, United Kingdom, (3)University of Sheffield, United Kingdom

Several challenges exist when applying an ecosystem services approach to ecological risk assessment. These include questions regarding the availability of methods and tools for applying an ecosystem services approach to chemical risk assessment and the

spatial and temporal scale of these approaches. Freshwater ecosystems and their catchments provide a wide range of ecosystem services (i.e. drinking water, fisheries, and recreation). However, they are exposed to both diffuse and point source pollution, which may adversely affect ecosystem service delivery. We conducted a literature review to identify approaches used in studies for ecosystem service quantification both within freshwater ecosystems and in the wider catchment. This review aimed to investigate: (1) Which freshwater ecosystem services are currently assessed? (2) What spatial and temporal scales are current tools capable of assessing? (3) Are there tools which can readily assess the effect of chemical stressors on ecosystem service delivery? The search returned 289 relevant studies with 117 unique mentions of models or tools on ecosystem service assessment. The approaches for ecosystem service assessment covered lentic and lotic freshwater ecosystems and catchments, as well as standalone wetland ecosystems. Results indicate that nearly all freshwater services were assessed with the majority of studies investigating regulatory & maintenance services (55%) such as water cycle and flow regulation. Concerning the spatial and temporal scale of studies, catchment-level assessments made up most (59%) of the studies whilst lentic and lotic systems were considered in about 20% of the studies. Multiple stressor types appeared within the studies including land use, climate change, and pollution. Pollution was assessed in about 16% of studies for different pollutants including nutrient loading, wastewater, and chemicals. Chemical stressors were not as widely acknowledged in literature as opposed to other stressors, making up a total of 9 studies from the search. In these studies, methods often employed several models and tools in order to assess chemical effects on ecosystem service delivery. This review has resulted in a database of ecosystem service tools and models for catchments as well as highlighting the need for model-based approaches to determine chemical stressor impact on ecosystem service delivery.

4.10 Linking soil ecology, ecotoxicology and risk assessment to the impact of multiple stressors on soil organism communities in the field (Part I)

4.10.T-01 ERAMYC - the Need of a Test System With Arbuscular Mycorrhizal Fungi Including Pre-Symbiotic and Symbiotic Phases for Environmental Risk Assessment

Tiago Luz¹, Luís Oliveira Filho², Mari Moora³, Patrícia Ferreira⁴, Pia Kotschik⁵, Silvia Pieper⁶, Sonia Purin da Cruz⁷, Susana Rodríguez-Echeverría⁸, Susanne Walter-Rohde⁶, Tanel Vahter³, Matthias Rillig⁹, Osmar Klauber-Filho¹⁰ and José Paulo Sousa⁸, (1)University of Coimbra, Coimbra, Portugal, (2)Santa Catarina State University, Brazil, (3)University of Tartu, Estonia, (4)CloverStrategy Lda, Portugal, (5)Umweltbundesamt / Federal Agency of Environment, Dessau, Germany, (6)German Federal Environment Agency (UBA), Germany, (7)Federal University of Santa Catarina, Brazil, (8)University of Coimbra, Portugal, (9)Freie Universität Berlin, Germany, (10)Universidade do Estado de Santa Catarina, Brazil

Arbuscular Mycorrhizal Fungi (AMF) are recognized as ecologically relevant in supporting key soil functions, providing important ecosystem services (e.g. increasing resistance of host plant to several stressors, acquiring nutrients from soil for host plants, stabilizing soil structure and increasing soil carbon stocks). AMF have been indicated by the European Food Safety Authority as a potential group of non-target organisms for the risk assessment of Plant Protection Products. The existing ISO protocol 10832, which aims to evaluate effects of pollutants on AMF, considers the pre-symbiotic phase, only. Spore germination, germ tube formation, and asymbiotic hyphal growth are important phases of the fungal life cycle and are essential for establishing symbiosis. Some other processes like root colonization could be affected by pollutants and are not addressed by existing test protocols. Some studies have also analysed how stressors can influence AMF colonization, but at the moment, there is no standardized test protocol available which includes effects of soil contaminants on AMF species during the symbiotic phase. ERAMYC is a project which integrates a consortium of experts and aims to i) improve the existing protocol for the pre-symbiotic phase by including additional AMF species, test conditions and procedures embracing the symbiotic phase of AMF species; ii) standardize the developed advanced protocol through a ring-test with different chemicals; iii) develop a draft OECD Test Guideline and evaluate experimental results compared to the existing framework for the risk assessment of soil organisms exposed to chemicals. ERAMYC project is structured in four work packages (WPs): WP1 comprises a literature review; WP2 integrates two clusters of experiments to evaluate the performance/suitability of the selected AMF species in selected soils under specific test conditions and to assess how the different AMF species and parameters measured react to the selected chemicals; WP3 comprises a ring-test and WP4 aims at developing a draft OECD Test Guideline and a validation report for testing AMFs exposed to chemical substances. The literature review evidenced that sensitivity of test parameters can be species and substance dependent. The first phase of WP2 is ongoing and some preliminary results on performance/suitability of the selected AMF species in selected soils under specific test conditions (environmental conditions and selected host plants) will be presented.

4.10.T-02 How Is the Nitrogen Cycling Function of the Soil Affected by Copper Pollution in Two Contrasting Soils?

Ingrid Rijk¹, Christopher Jones², Alf Ekblad³, Linn Berkelund², Sara Hallin², Astrid Taylor⁴, Maria Viketoff⁴ and Dan Kleja⁵, (1)MTM Research Centre, Örebro University, Sweden, (2)Swedish University of Agricultural Sciences, Sweden, (3)MTM Research centre Örebro University, Sweden, (4)Swedish University of Agricultural Sciences SLU, Sweden, (5)Swedish Geotechnical Institute, Sweden

Soil is a complex and dynamic ecosystem which holds a tremendous diversity of life forms that perform important processes. Nitrogen (N) is one of the most important macronutrients for plants that is cycled in soils via various microbial-driven processes. Site-specific studies have shown that stressors such as pollutants may affect the abundance of specific functional groups of N-cycling organisms. However, it is unknown if these effects are generalizable among soils with different properties. Moreover, the microbial abundance only reflects potential functioning, but actual activity under field conditions and its link to plant productivity is hard to reveal. The present study addresses this complexity by assessing effects of copper (Cu), a common heavy metal pollutant, on the N cycle in two different soils with highly contrasting properties. Microbial parameters are studied in concert with plant parameters so that changes in communities of N transforming microorganisms may be linked to plant quality and quantity. A

lysimeter experiment was performed in 2015-2017 as part of the APPLICERA project. Two pasture soils, one acidic sandy soil and one slightly alkaline sandy loam soil were spiked with a CuCl_2 solution and aged six months before mixing with untreated soil of the same origin until target concentrations (resp. 0, 200, 430 and 1100 mg/kg Cu). The soils were placed in lysimeters and sown with a grass mixture of *Festuca rubra* and *Poa pratensis*. Plants and soils were sampled in the second growing season (2017). Abundances of the microbial N-cycling functional guilds ammonia-oxidizing archaea and bacteria (AOA and AOB), nitrite-oxidizing bacteria *Nitrobacter* (NIB) and *Nitrospira* (NIS), and denitrifiers were determined by real-time quantitative PCR (qPCR), and then compared to measurements of plant shoot- and root biomass, C (carbon), N and stable isotopes ^{13}C , ^{15}N , and ^{18}O . Negative effects on the microbial communities and plant biomass were much more pronounced in the acidic sandy soil. Remarkably, the effects on plant N, C/N and ^{15}N were similar between soils, while the abundance of microbial communities had very distinct soil-specific patterns. This may speak against generalizing microbial community responses to pollution stressors across soil types. Also, plant parameters did not correlate well with microbial abundances, which shows that other pathways and communities may also play large roles in the soil N cycle under stressed conditions.

4.10.T-03 Investigating the Effects of Pesticides on Soil Microbial Communities Using rRNA Amplicon Sequencing

Martin Siedt¹, Andreas Schaeffer², Martina Roß-Nickoll³, Kilian Smith⁴ and Joost van Dongen³, (1)Zentraler Rechnungseingang, RWTH Aachen University, Aachen, Germany, (2)Institute Environmental Research, RWTH Aachen University, Aachen, Germany, (3)RWTH Aachen University, Germany, (4)Magdeburg-Stendal University of Applied Sciences, Germany

It should be ensured that the application of pesticides to agricultural soils does not harm these communities. Potential effects comprise structural as well as functional change. However, soil microbial communities naturally have a high variation of these traits. This complex and chaotic network is far from being fully understood. Luckily, next-generation amplicon sequencing allows scientists to drastically improve their insight into the genetic structure of soil microbial communities in the last decade. Can this technology help us regarding the environmental risk assessment of pesticides? Analyses of the soil bacterial community of soils will be presented showing that the herbicide MCPA and fungicide Metalaxyl-M did not have clear and dose-related effects. Also, data on the response of fungi will be presented (data are currently processed). Structural and functional investigations both are required for evaluating the effect of pesticides on communities. Additionally, the talk will cover the possibilities, limitations, and biases during the different stages of laboratory and computational work. Finally, the suitability and value of amplicon sequencing data for evaluating the environmental risk of pesticides for soil microbial communities in the regulatory context is discussed.

Acknowledgement This work was funded by the Federal Agency for Nature Conservation, Bonn, Germany, within the SAMPL project (3518 84 0800) with Funds of the Federal Ministry for Environment and Nuclear Safety (BMU).

4.10.T-04 Determination of Soil Invertebrate Diversity Using Morphological and Dna-Based Methods at 25 Sites in Germany

Stephan Jänsch¹, Paul Henning Krogh², Daniela Alves³, Tiago Natal-da-Luz³, Verónica Rojo⁴, Adam Scheffczyk⁵, Rüdiger Schmelz⁶, José Paulo Sousa⁷, Joaquín Vierna⁴, Anton Vizcaino⁴ and Jörg Römbke⁵, (1)ECT Oekotoxikologie GmbH, Flörsheim, Germany, (2)Aarhus Universitet, Denmark, (3)CloverStrategy Lda, Portugal, (4)AllGenetics & Biology SL, Spain, (5)ECT Oekotoxikologie GmbH, Germany, (6)Freelance Researcher, Spain, (7)University of Coimbra, Portugal

The recording and evaluation of the diversity of soil organism communities have made considerable progress within the last decade (see, e.g., the results of the European FP7-project „EcoFINDERS“). In particular, the large influence of these organisms on the ecological functions of the soil has been highlighted (e.g., maintenance of soil structure and organic matter decomposition). Equally important, it was shown that not only flagship species such as the deep-burrowing earthworm *Lumbricus terrestris*, but also the highly diverse meso- and microfauna have to be considered. However, in Germany no regional coverage and comprehensive information regarding the biodiversity of soil invertebrates is available. Reasons for ignoring them are the lack of trained taxonomists, lack of sampling methodology standards (released only recently by ISO) as well as the general lack of interest in these often small and inconspicuous species. In order to improve this situation, the German Federal Environmental Agency (UBA) started a project in 2018, aiming to develop a standardized, comprehensive and efficient programme to monitor selected soil invertebrate groups all over Germany, representing different soils, land use forms (i.e., meadows, crop sites and forests) and regions. Sampling was performed at 25 Permanent Soil Monitoring Sites (PSMS), looking in particular at earthworms (Lumbricidae), springtails (Collembola) and potworms (Enchytraeidae), using ISO standard sampling methodology. Species belonging to these groups were determined by classical morphological methods but also by using modern genetical methods such as DNA-metabarcoding of a mixture of soil invertebrate communities (comDNA) as well as metabarcoding of environmental DNA (eDNA) extracted from soil. The final aim of the project is to develop an efficient, cost-effective, and routinely applicable soil invertebrate monitoring system, as a tool for the evaluation of soil invertebrate biodiversity under stress. A pilot study was conducted in autumn of 2018 at one meadow, one crop site and one forest in order to test the experimental approach and decide on the sampling design for the remaining 22 sites. The project progress was severely slowed due to the Covid pandemic. The sampling programme was completed in autumn of 2021 and the final samples are currently being processed. Selected results from the project will be presented.

4.10.T-05 Chemical Sensitivity of Earthworms: Effects of Morphology, Phylogeny and Habitat

Tomás Duque¹, Rufat Nuriyev², Jörg Römbke³, Ralf Bernhard Schaefer² and Martin Entling², (1)Institute for Environmental Sciences University of Koblenz-Landau, Germany, (2)University of Koblenz-Landau, Germany, (3)ECT Oekotoxikologie GmbH, Germany

The chemical risk assessment (RA) of plant protection products on non-target soil macro-organisms has mainly been done by testing the acute, chronic and sublethal responses on the compost earthworm *Eisenia fetida*. Although *E. fetida* meets the basic

requirements for being a RA standard test organism, its use as the only earthworm representative has often been criticized as being only to a limited extent representative for other species found in the field. In this context, it has been proposed to include additional species covering the three main ecological groups of earthworms in the RA process (i.e. endogeic, anecic and epigeic). As toxicity data for other earthworm species is scarce, the aim of this research was to provide information on the chemical sensitivity of multiple earthworm species. Hence, acute single-species tests of earthworms sampled from different habitats (i.e. forest, wetland and grassland) and covering the major ecological groups were performed based on the artificial soil test described in the OECD 207. The median lethal concentrations (LC₅₀) of a copper-based fungicide and the insecticide imidacloprid were derived. Additionally, species sensitivity distributions were fitted together with the hazardous concentration affecting 5% of the species (HC₅). In both pesticide assessments, laboratory-raised *E. fetida* mortality responses were less sensitive than most of other earthworm species, including *E. fetida* collected in the field. Additionally, the HC₅s calculated for copper and imidacloprid were 173.36 and 0.58 mg a.i. / kg d.w., respectively. Preliminary results suggest that the chemical sensitivity of earthworms is linked with environmental variables such as soil pH, where earthworms sampled from acidic soils were more resistant to both substances. Experiments covering a wider range of species is required to confirm and understand the relationship between habitat variables and chemical sensitivity.

4.10 Linking soil ecology, ecotoxicology and risk assessment to the impact of multiple stressors on soil organism communities in the field (Part II)

4.10.T-06 Carbon Dioxide Effects on the Soil Invertebrate *Enchytraeus crypticus* Exposed to Metal(Loid) Contamination

Rita Silva¹, Catarina Correia de Lemos Malheiro², Carla Quintaneiro³, Marija Prodana¹, Janine Mariën⁴, Cornelis A.M. van Gestel⁴, Dick Roelofs⁵, Susana Loureiro⁶ and M. Nazaret Gonzalez-Alcaraz⁷, (1)University of Aveiro, Portugal, (2)Department of Biology, University of Aveiro, Portugal, (3)CESAM & University of Aveiro, Portugal, (4)Vrije Universiteit Amsterdam, Netherlands, (5)KeyGene, Netherlands, (6)Universidade de Aveiro, Portugal, (7)Technical University of Cartagena, Spain

Greenhouse gas emissions (e.g., CO₂) by human activities are causing serious environmental impacts worldwide. Atmospheric CO₂ levels are predicted to reach 800-1000 ppm by 2100, which might exacerbate global warming. The impact of global climate changes might be aggravated in environments affected by metal(loid) contamination where soil living organisms have to deal with multiple stressors. Thus, the aim of the present study was to evaluate the effects of increased levels of atmospheric CO₂ on the soil invertebrate *Enchytraeus crypticus* exposed to a metal(loid)-contaminated soil, from sub-organism to population level. *E. crypticus* was exposed for 48h (short-term exposure) and 21d (long-term exposure) to a metal(loid)-contaminated soil from central-northern Portugal under different CO₂ levels based on the IPCC predictions for 2100. The scenarios tested were: standard climate conditions as recommended by OECD/ISO guidelines, 20°C+50% soil water holding capacity (WHC)+400-500 ppm CO₂; low exposure CO₂ level: 20°C+50% WHC+600 ppm CO₂; intermediate exposure level: 20°C+50% WHC+800 ppm CO₂; high exposure level: 20°C+50% WHC+1000 ppm CO₂. After the short-term exposure, surviving *E. crypticus* were analysed for body As and Pb concentrations, RNA content, expression of target genes related to stress conditions (metallothionein-1 -MT1-, catalase-1 -CAT1-, and heat shock protein-70 -Hsp70-), and biochemical markers related to stress conditions (activity of the enzymes cholinesterase -ChE-, catalase -CAT- and glutathione-S-transferase -GST- and of the electron transport system -ETS-, and lipid peroxidation levels -LPO-). After the long-term exposure, *E. crypticus* survival and reproduction were assessed. Soil pH, electrical conductivity, and water-extractable metal(loid) concentrations were also analysed. Short-term exposure to metal(loid) soil contamination and increased levels of atmospheric CO₂ favoured the bioaccumulation of metal(loid)s in *E. crypticus*, which was accompanied by significant changes in the expression of some target genes related to stress conditions (mostly MT1 and CAT1), but less changes in biochemical markers were observed. Despite this, when exposed to this multi-stressed scenario for a longer period, few effects at population level (survival and reproduction) were noticed. This study emphasises the relevance of considering future climate changes under real contamination scenarios.

4.10.T-07 Soil Moisture Interferes With Uptake and Effects of Phenanthrene in Springtails

Yang Wang¹, Liyan Xie², Stine Slotsbo³ and Martin Holmstrup³, (1)Ecoscience department, Aarhus Universitet, Denmark, (2)Ecoscience, Aarhus Universitet, Denmark, (3)Aarhus Universitet, Denmark

Drought is one of the most important environmental factors influencing the physiology of soil invertebrates. Springtails (*Collembola*) are a species rich group of invertebrates inhabiting soil, litter or vegetation of most terrestrial ecosystems. The springtail, *Folsomia candida*, is often used in standardized ecotoxicity testing. The drought physiology of *F. candida* is well known and therefore *F. candida* ideally suitable for both drought stress and soil toxicity tests. Here, we employed a long-term exposure to phenanthrene (PHE) and a series of soil water contents to study the combined effects of these stressors/factors to survival, reproduction and biomass in a full factorial experiment. Our results showed that the used concentrations of PHE had no significant effect on adult survival rate ($p > 0.05$) whereas very dry soil (soil water content at 4% of dry weight) caused a significant decrease of survival rate. Growth of springtails was significantly lower at PHE 60 mg/kg dry soil than in uncontaminated soil ($p < 0.05$), and growth was very low when soil water content was at or below 6% of dry weight. Reproduction of springtails was susceptible to drought and PHE and their combinations in this study. Juvenile counts significantly decreased with soil water content decreasing ($p < 2e-16$) and PHE increasing ($p < 2e-16$). Moreover, we observed a synergistic interaction of these two stressors significantly impacting juvenile counts ($p < 2e-16$). Bioaccumulation factor (BAF) decreased significantly with soil water content increasing at PHE 10 mg/kg dry weight, 20, 30, 40 and 60, corresponding to p values 0.0004128, 1.4e-05, 8.26e-10, 0.00632 and 5.35e-06, respectively. Soil water content has significantly impacted BAF that increased almost 3-fold from 22% to 5% soil water content. Taking the final concentration of PHE in soil into account, we found that bioaccumulation (BAF) decreased significantly with moisture increasing at PHE 30 mg/kg dw. The results show synergistic

interaction of soil water content and PHE for reproduction after 28 days. Moisture levels can interfere with the PHE concentrations in animals, indicating that drought could weaken PHE detoxification, but strengthen PHE accumulation in animals.

4.10.T-08 Intermediate Tier-Based Approach in the Environmental Risk Assessment by Using a Set of Natural Reference Soils in OECD 222 Earthworm Reproduction Test

Eva Aderjan¹, Eiko Wagenhoff², Thomas Moser² and Andreas Duffner³, (1)Terrestrial Ecotoxicology (Lab), Eurofins Agroscience Services Ecotox GmbH, Niefern-Öschelbronn, Germany, (2)Eurofins Agroscience Services Ecotox GmbH, Germany, (3)Eurofins Agroscience Services Ecotox GmbH, Niefern-Öschelbronn, Germany

One of the most used laboratory tests at lower tier for soil organisms in the environmental risk assessment is the earthworm reproduction test OECD 222 with *Eisenia fetida/andrei* in artificial soil. By using a unique artificial soil, test system criteria such as reproducibility and comparability are met. However, one artificial substrate cannot represent the diversity of natural soils, nor is it representative of arable soils to which plant protection products are applied. Moreover, the sorption properties of a soil can influence the bioavailability of chemical substances and consequently their toxicity for soil organisms. If soil parameters are not included in the examinations, it can lead to a bias in the results. If a potential risk for the soil organisms is expected from extrapolations of the laboratory results to field conditions, higher-tier studies are carried out. In these earthworm field studies performed according to ISO 11268-3 (1999), it is recommended to avoid the use of extremely sandy or clayey soils. Further criteria for the soil parameters are not set. This lack of consideration of soil parameters represents a gap in the environmental risk assessment of chemicals that is currently neither covered by laboratory studies conducted with artificial OECD substrate, nor by field studies usually performed only on one of many possible arable soils on one site. To fill this gap, a set of natural agricultural reference soils (RefeSols, Fraunhofer) with a broad spectrum of soil properties that can be found in agricultural soils in mid-latitudes were evaluated in the lab with the reference substance carbendazim in the OECD 222 test system and compared to the OECD substrate. A successful, valid and reproducible implementation of a set of natural agricultural reference soils in the OECD 222 test system was possible. The use of field soils in extended-laboratory tests with various properties provides a more realistic application-oriented approach, and can help in refining the risk assessment and eventually avoid field trials. The study results provide to estimate a spectrum of possible risks that may occur in diverse agricultural soils rather than a single toxic endpoint on OECD soil with uncertainties.

4.10.T-09 Multiple Pesticide Residues Across the European Terrestrial Ecosystems: Risks and Challenges

Violette Geissen¹, Dennis Knuth², Vera da Silva³, Paula Harkes³, Esperanza Huerta³, Coen Ritsema⁴, Jakub Hofman⁵ and Shiva Sabvezari⁶, (1)Alterra Wageningen University and Research Centre, Netherlands, (2)Wageningen University and Research, Netherland, (3)Wageningen University, Netherlands, (4)Wageningen University & Research, Netherlands, (5)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (6)Masaryk University | Faculty of Science RECETOX, Czech Republic

Farming systems in Europe rely strongly on the use of Plant Protection Products (PPPs) to secure yields and food safety in plant production and animal husbandry, using an average 340,000-370,000 tons of active substances per year. Multiple PPP residues are then commonly found in soil, water, crops, food and feed, animals and humans. Of the 487 substances currently approved in the EU market and combined in several thousand different commercial PPPs, almost 50% are bioaccumulative and 25% are persistent in soil (PPDB, 2019). According to the Classification, Labelling and Packaging Regulation (CLP), 30% have a high acute aquatic toxicity and 28 are suspected carcinogens. These properties, among others, are potentially harmful to ecosystem, plant, animal and human health. However, data on the distribution of PPPs across European agricultural landscapes, that account for ecological and environmental variability, are scarce and fragmented (Silva et al. 2019). There is a need to harmonise data collection approaches across Europe and collect the critical data necessary to deliver integrated approaches to fully assess overall risks and impacts of PPP formulations, residues and their metabolites. The overall aim of SPRINT project (SPRINT-h2020.eu) is to develop, test, validate and deliver a Global Health Risk Assessment Toolbox for the integrated assessment of the impacts of PPPs [formulations (F), active substances (a.S.), metabolites (Me) and mixtures (Mi)] on terrestrial and aquatic ecosystems (E), plant (P), animal (A) and human (H) health. Three main attributes for the health status will be examined: resilience, reproduction/productivity and manifestation of diseases, while transition pathways towards sustainable use of PPPs will be identified in a multi-actor approach. In this study we present first results on (multiple) pesticide distribution in the terrestrial environment based on a harmonised data collection conducted in the growing season 2021 in 10 representative Case Study Sites (CSS) across Europe covering the main EU cropping systems. We correlate the measured pesticide concentrations in the soil with recorded application data per crop and farming system. These field data can be used as a verification for the EFSA predictions (predicted environmental concentrations in soil), and as a basis for new terrestrial ecotoxicological tests.

4.10.T-10 Influence of Plant Protection Products on Beneficial Soil Life

Judith Riedo, Thomas Bucheli, Florian Walder and Marcel Van der Heijden, Agroscope, Switzerland

Plant protection products (PPPs) are indispensable in today's agriculture. However, the contamination of soils with PPP raises concerns about effects on beneficial soil life. So far, few reports are available on PPP residues in agricultural soils with regular pesticide applications and almost no data can be found on residues in organically managed soils or grassland where they are not or no longer applied. However, knowledge about these areas is of utmost interest, as these as these soils are considered particularly vital and ecologically valuable and may serve as ecological sanctuary for soil organisms. We assessed the occurrence of 45 PPPs or metabolites in 120 agricultural soils. We specifically tested whether the occurrence of pesticides differed between organic and conventional management and whether it is dependent on the landuse type (vegetable farming, arable farming and grassland). Furthermore, it was investigated whether the occurrence of residues is linked to important indicators of soil life. In a follow up greenhouse study, the effect of the bioavailable fraction of three fungicides on soil microorganisms was assessed. Residues were

found in all sites, pointing towards a consistent background contamination of soils no matter the management practice. Also after 20 years of organic farming without application of synthetic PPPs, up to 16 different residues were found. Various biological endpoints, including the abundance of beneficial arbuscular mycorrhizal fungi, were significantly negatively linked to the amount of residues in soil, indicating that PPPs are a key factor determining microbial soil life. The greenhouse setup showed that the bioavailability of the three different fungicides was similar between the tested soils, independent of their soil properties. Furthermore, some of the examined microbial genes reacted to the bioavailable fraction of the fungicides, thus being sensitive enough for changes to be evident within the observed time period. The results of the field study demonstrated that PPP are a hidden reality in agricultural soils and suggest that they have harmful effects on beneficial soil life. This widespread contamination of PPP in all soils raises the question of how bioavailable these PPPs are in these sites and whether they still influence important soil organisms and functions. Future analysis from the greenhouse study, including the assessment of functional gene abundance will clarify this.

4.10 Linking soil ecology, ecotoxicology and risk assessment to the impact of multiple stressors on soil organism communities in the field (Virtual Only)

4.1.V-01 A Field Study on Soil Ecological Risk Assessment Based on TRIAD Approach

Dokyung Kim, Jin Il Kwak, Tae-yang Lee, Lia Kim, Rongxue Cui, Haemi Kim, Sang A Kim, An Sanghee and Prof. Youn-Joo An, Konkuk University, Korea, South

In 2017, International Standard Organization (ISO) published the guideline for site-specific ecological risk assessment (SERA) based on TRIAD approach. The TRIAD approach is required three lines of evidence (LoE); chemical-LoE (Chem-LoE), ecotoxicological-LoE (Ecotox-LoE), and ecological-LoE (Eco-LoE) and integrate them as one risk number; integrated ecological risk (IR) on scales of 0-1. This study performed site-specific SERA of metal contaminated area based on TRIAD approach. This study attempted to minimize uncertainty in the estimation of IR by constructing far more assays than previous studies. The aim of this study is to suggest priority of assays representing ecological risk. For Chem-LoE, total concentrations and extractable concentrations of heavy metal was measured. Six soil bioassays (including two plants, earthworm, collembola, soil nematode, and soil algae) and five soil extract bioassays (including fish embryo, waterflea, nematode, algae, and microorganism) were conducted for Ecotox-LoE. In Eco-LoE, bait-lamina test, collembola abundance, vegetation survey was performed. The IR was estimated by assigning the equal weight to the three-LoEs. As a result, it was confirmed that despite the high chemical risk, it may appear differently from the actual ecological risk through mutual supplementation with Ecotox- and Eco-LoE. The results of this study emphasized the validity of TRIAD approach for site-specific SERA by confirming the harmony of three LoEs. This study provides useful information on future policies for SERA assessment and risk management in that it suggested the priority of tools in SERA by presenting assay that can represent ecological risk. *Acknowledgement-This study was funded by the National Institute of Environment Research (NIER) of the Republic of Korea (NIER-SP2020-223).*

4.1.V-02 A Multiparametric Comparison of the Toxicity of Non-Encapsulated and Microencapsulated Forms of Esfenvalerate in *Caenorhabditis elegans*

Libânia Queirós¹, Carlos Marques², Fernando J. M. Gonçalves², Joana Luisa Pereira², Michael Aschner³, Mário Pacheco² and Patrícia Pereira², (1)CESAM & DeBio, University of Aveiro, Portugal, (2)CESAM & University of Aveiro, Portugal, (3)Albert Einstein College of Medicine, United States

The agrochemical industry has aimed to develop environmentally and user-friendly pesticide products, namely, new types of formulations such as the suspensions of microcapsules. The encapsulation of the active ingredients (AIs) has been described as a feasible approach to improve the targeting and delivery of these substances to the target pests/weeds, thus decreasing the quantity required for their intended pesticidal activity. However, there is a gap in the literature regarding the comparative health and environmental effects of encapsulated and non-encapsulated pesticides. In this context, the laboratorial model organism *Caenorhabditis elegans* was used to comparatively assess the effects of non-encapsulated and microencapsulated esfenvalerate (analytical standard vs. commercial formulation *Onslaught*) regarding different parameters. Specifically, the post-exposure reproductive capacity (brood size) and lethality were measured after 1-h exposure in aqueous medium to recommended application rates of this insecticide (0.025 % and 0.050 % AI), with subsequent change to OP50 *Escherichia coli*-seeded nematode growth medium plates for a recovery period. Additionally, the chemotaxis to *E. coli* – i.e. clean and contaminated by esfenvalerate in both forms at these same application rates – was comparatively assessed at 1 h, 3 h and 24 h of exposure. The effects of a microencapsulated pesticide on chemotaxis behavior in the nematode *C. elegans* were addressed for the first-time. We found that *C. elegans* was highly tolerant to both non-encapsulated and microencapsulated esfenvalerate with respect to lethality and reproduction, but its chemosensation response to bacterial food was similarly negatively affected by exposure to esfenvalerate in both forms. These results suggest that encapsulated formulations may not be environmentally safer options as argued by agrochemical industry. Given that chemotaxis behavior plays an important role in the survival of nematodes and other soil organisms (e.g. linked to the search for food and avoidance of toxic substances), a more profound understanding on the comparative effects of microencapsulated and non-encapsulated formulations to non-target organisms is of key relevance and should be addressed in future studies.

4.1.V-03 Assessment of Adverse Effects of Olive Mill Waste WATER and Olive Mill Waste Contaminated Soil on Springtail *Folsomia candida*

Marija Kovacevic¹, Nikolina Stjepanović², Salsabil Trigui³, Davorka Hackenberger², Olga Jovanović Glavaš², Amjad Kallel³ and Branimir Hackenberger², (1)Department of biology, University of Osijek, Osijek, Croatia, (2)University of Osijek, Croatia,

(3)University of Sfax, Tunisia

The olive oil industry generates considerable amounts of olive mill wastewater (OMW) which is treated and used in agriculture, energy production, or discharged into evaporating ponds where OMW contaminated soil (OMWS) is formed. Due to the extremely high phenol content, untreated OMWS is not suitable for plants and soil organisms. Collembolans are an extremely important group of non-target soil organisms that are frequently used in ecotoxicological research. However, information on the impact of OMW on the collembolan species *F. candida* is scarce. Therefore, this study aimed to determine the effects of OMW and OMWS on survival, reproduction, neurotoxicity, oxidative stress, and available energy in springtail *F. candida*. Exposure to different ratios of OMW and OMWS showed a higher toxicity of OMWS in terms of survival ($LC_{50}=32.34$ % of OMW; $LC_{50}=45.36$ % of OMWS) and reproduction ($EC_{50}=10.10$ % of OMW; $EC_{50}=19.44$ % of OMWS). The number of juveniles gradually decreased as the ratio of OMW increased. In contrast, exposure to OMWS enhanced the reproduction rates in a lower ratio. However, complete inhibition of reproduction was observed after exposure to the highest ratio of OMWS (50%). Furthermore, neurotoxicity (AChE induction), oxidative stress (SOD, GST and MDA induction), and changes in available energy (decrease in lipid and carbohydrate content) have been observed. These negative effects are probably consequences of the high phenol content specific for OMW and OMWS at higher tested ratios. Namely, at lower ratios, OMW and OMWS served as a food source and had a positive effect on reproduction. Consumption of energy for reproduction, defense against neurotoxicity and oxidative stress has led to metabolism imbalance and consequently to long-term consequences visible at the population level. Obtained results indicate that for the ecotoxicological assessment of different wastes, the incorporation of ecotoxicological tests with non-target soil organisms is crucial. Moreover, it is essential to use different endpoints to gain insight into the exact mechanism of action. Furthermore, the application of OMW and OMWS in small ratios can have a positive effect on non-target soil organisms and consequently cause better quality of the soil. Therefore, more research is needed to monitor the impact of lower concentrations of OMW and OMWS over several generations to allow its safe application.

4.1.V-04 Biomarker Responses of *Enchytraeus Albidus* to Fungicide Azoxystrobin: Differences Between Active Ingredient and Commercial Product

*Marija Kovacevic*¹, *Nikolina Stjepanović*², *Davorka Hackenberger*², *Željka Lončarić*² and *Branimir Hackenberger*²,

(1)Department of biology, University of Osijek, Osijek, Croatia, (2)University of Osijek, Croatia

Strobilurin fungicides (SFs) are a group of new fungicides produced by strobilurin A as a lead compound. Azoxystrobin, the best-selling SF, is a highly efficient broad-spectrum fungicide with relatively high-water solubility, which can lead to accumulation in water, sediments, and soil. Due to its wide application and impact on non-target soil organisms, azoxystrobin has attracted attention. Soil dwelling organisms are among the first in line of exposure to pesticides. However, their risks are often based on the pure active ingredient (AI) and not on the commercial products (CPs) actually applied in the field. *Enchytraeus albidus* is a model species in soil ecotoxicology used for the assessment of environmental risk. Due to their important role in proper soil functioning, it is essential to investigate the toxicity and adverse effects of fungicides used in agriculture on enchytraeids. Previous research has demonstrated a negative impact of azoxystrobin on the reproduction and oxidative status of earthworms, and the survival, reproduction, and hatching success in enchytraeids. However, most studies have assessed the effect of AI, while only a few use a CP. Therefore, we investigated the effects of pure AI, azoxystrobin, and CP Quadris on survival, reproduction, MXR activity and oxidative stress biomarkers in *E. albidus*. The results showed that CP exhibited higher toxicity in terms of survival ($LC_{50}CP = 16.7$ mg/kg soil, $LC_{50}AI = 15.3$ mg/kg soil), while reproduction was affected only by CP ($EC_{50} = 3$ mg/kg soil). Furthermore, while AI caused induction of the multixenobiotic resistance system, CP caused inhibition. Moreover, although both tested substances caused oxidative stress, the toxicity of the CP was higher and long term impact in form of lipid peroxidation was observed. These results suggest the importance of evaluating the effect of AI and CP. Furthermore, to obtain more accurate information on the mode of action, access is required through different endpoints. These findings highlight the need to further explore the toxicity of CPs compared to AIs, in order to predict a more realistic environmental hazard of fungicides.

4.1.V-05 Field-Realistic Doses of the Neonicotinoid Acetamiprid Impact Natural Soil Arthropod Community Diversity and Structure

*Michella Ligtelijn*¹, *Henrik Barmantlo*² and *Cornelis A.M. van Gestel*³, (1)Rijksuniversiteit Groningen, Netherlands, (2)University of Amsterdam, Netherlands, (3)Vrije Universiteit Amsterdam, Netherlands

The neonicotinoid acetamiprid is used as a foliar spray, this results in direct exposure of the soil and the organisms that maintain the soil health. It is already shown in lab tests that acetamiprid is toxic to the Collembola (springtails) species *Folsomia candida*, but Acari (mites), on the other hand, seem to be insensitive to neonicotinoids. This study determined: (i) if field-realistic doses acetamiprid affect the abundance and diversity of soil arthropod communities, and (ii) whether or not potential effects are short-term or persist after degradation of acetamiprid. Intact soil cores were taken from an untreated grassland field in Wageningen, the Netherlands, and placed in the CLIMECS (a standardized and controlled mesocosm set up). Thereafter, the naturally sourced communities were exposed to a control and different field-realistic doses (0, 0.05, 0.2, 0.8 mg a.s./kg dry soil) of acetamiprid were applied. After 10 and 56 days the abundance of mites and springtails was assessed. Simultaneously, for the springtails, diversity was assessed by identifying them to the lowest possible level. This data was, among others, used to analyse the effect of acetamiprid application on abundance over time, but also to analyse the changes in Alfa and Beta-diversity (PERMANOVA) as well as community structure. Springtails and mites abundances were more or less equal at the start of the experiment. After 10 days increasing doses of acetamiprid significantly lowered springtail abundance and increased mite abundance. At the highest dose, springtails decreased by 53% on average while mites increased by 26%. This effect was no longer clearly visible after 56 days, this might indicate a recovery of the springtail community. The relative proportion of mites in the total soil fauna actually significantly increased because of these strong declines in springtails, due to a lowering of interspecific competition (i.a. food or

living space). The community composition was significantly changed by acetamiprid and time. Shortly after application, communities diverged, from the control in terms of structure (Beta dispersion), while later, communities converged again, probably due to recovery of species that were not filtered out by the treatment and by the hatching of eggs. With this experiment, we are the first to show that field-realistic applications of neonicotinoids negatively impact natural soil fauna, both in terms of abundances as well as diversity and community structure.

4.1.V-06 Increased Temperature Enhances Toxicity From Contaminant Stress in a Widespread Collembola With Different Thermal Adaptation

Silje Marie Kristiansen¹, Hans Petter Leinaas², Cornelis A.M. van Gestel³ and Katrine Borga⁴, (1)Department of Biosciences, University of Oslo, Oslo, Norway, (2)University of Oslo, Norway, (3)Vrije Universiteit Amsterdam, Netherlands, (4)UiO, Norway

Springtails (Collembola) are important components of soil ecosystems worldwide, and may be exposed long-term to anthropogenic contaminants. As global air temperature continues to increase, it is likely that it will affect ectotherm responses to contaminant stress. Populations inhabiting different climates may respond differently to higher temperature, as their adaptation to utilize ambient heat likely differ. Our aim was to document whether sub-lethal effects on Collembola exposed to an insecticide depend on the ambient temperature. Additionally, we aimed to determine effect from the thermal adaptation of the study organisms on their response. One temperate and one arctic originated population of *Hypogastrura viatica* (Collembola) were exposed dietary to two sub-lethal concentrations of imidacloprid in addition to control, at 10, 15, 20 or 25°C. The exposure lasted from 0 to 1500 day-degrees (days*temperature), allowing comparisons between temperatures. Each experimental unit contained 25 juveniles, and each treatment had 12 replicates, of which 4 were harvested at three different life stages. We studied among other the traits survival, growth (body size) and egg production. Dietary exposure to imidacloprid resulted in sub-lethal effects for both populations at 10 and 15°C (>85% survival), while the highest concentration of 0.16 mg/kg dry bark was lethal at 20°C and 25°C (approx. 50-70% survival). The effect was stronger for the temperate population. The growth pattern for both populations showed little or no effect on the body size at an early age, but a strong reduction in body size at a high adult age, which was increasing with increasing temperature. A decrease in egg production in arctic *H. viatica* was caused by imidacloprid exposure of the highest concentration, but without any apparent interaction from ambient temperature. Contrastingly, the toxic effect on egg production was temperature-dependent for temperate *H. viatica*, for which higher temperature resulted in a stronger decrease in number of eggs laid. The temperate population is adapted to efficiently utilizing a warm summer climate by increasing egg production at increasing temperature, unlike the arctic population. The energy cost of high egg production might cause the temperate population to be more sensitive to other stressors when the temperature is high. Knowledge on how other factors affect toxicity from contaminant stress can contribute to a more relevant risk assessment in the future.

4.1.V-07 Linking Scavengers and Decomposers in the Anthropocene: Vertebrate Guilds Drive Soil Ecosystem Processes

Minerva García-Carmona¹, José Sánchez-Zapata², Fuensanta García-Orenes², Jorge Mataix-Solera², Esther Sebastián-González³, Marcos Moleón⁴ and Zebensui Morales-Reyes², (1)University Miguel Hernández, Spain, (2)Miguel Hernández University of Elche, Spain, (3)UNIVERSITY OF ALICANTE, Spain, (4)University of Granada, Spain

Currently, rewilding in Mediterranean ecosystems is driving the expansion of both native and exotic ungulates which are an important source of carcasses for scavenger vertebrate guilds. Carrion is an ephemeral resource of great quality that drives relevant ecosystem processes. Carrion consumption rates are influenced by scavenger communities, particularly species richness and the presence of key species such as vultures and top-predators. In this way, the heterogeneity derived from vertebrate communities, environmental factors and the type of carrion resource can significantly influence the interactions between scavengers, decomposers and soil properties. These interactions have not been addressed to date despite their potential regulatory role of key ecosystem processes. We evaluated some physicochemical and biochemical soil properties and the abundance of soil microbial communities before and after the consumption process of carcasses of Barbary sheep (*Ammotragus lervia*), an exotic invasive ungulate in the Regional Park of Sierra Espuña (SE Spain). Our results suggest that there are important differences in the soil properties studied and the activity of decomposing microorganisms related to the consumption rates and the richness of scavenging vertebrates in Mediterranean ecosystems. Particularly, carcasses influenced available phosphorus in the soil, basal soil respiration and microbial soil communities, especially the group of bacteria. The use of ungulate carcasses by vultures modulated the effects on soil ecosystem processes by enhancing carcass consumption rates.

4.1.V-08 Nature-Based Approaches for Oil-Impacted Ecosystem Restoration Using Microbes

Eno Williams Abang, Chioma Blaise Chikere and Phillip Okerentugba, University of Port Harcourt, Nigeria

Petroleum hydrocarbon degradation potentials of bacteria isolated from crude oil-polluted site in Igbuduya IV (Lat N 5° 2' 57.2964" Long E 6°35' 5.7192) in Rivers State, Nigeria were investigated. Polluted soil samples were collected from four coordinate points using soil auger at depths of 0-15cm (surface) and 15-30cm (subsurface) soil while unpolluted control was taken 80m away from the polluted site. Physicochemical parameters of the soil sample were determined using APHA standard methods, while culture-based enrichment methods were used in bacterial isolation. Hydrocarbon degradation potentials of the bacterial isolates were determined by screening in Bushnell Haas broth amended with 1% crude oil and monitored weekly over 28 days. Optical density readings were taken on days 0, 7, 14, 21 and 28 using a calibrated spectrophotometer (at 580nm wavelength) to measure microbial growth and pollutant degradation. Three isolates with high degradation abilities were identified as *Lysinibacillus fusiformis*, *Bacillus thuringiensis* and *Micrococcus luteus* by amplification and sequencing of the 16S rRNA genes. The percentage degradation of crude oil by *Lysinibacillus fusiformis*, *Bacillus thuringiensis* and *Micrococcus luteus* were 97.93%, 97.44% and 97.69% respectively. Paraffin oil degradation was highest for *Lysinibacillus fusiformis* 97.56% followed by *Bacillus thuringiensis* 95.19% and *Micrococcus luteus* 94.85%. In conclusion, members of the indigenous microbial community in the

polluted soil have the capacity to utilize petroleum hydrocarbons and hence could be further stimulated by external nature-based nutrient addition for enhanced decontamination.

4.1.V-09 Organic Matter Decomposition - a New Microbial Laboratory Test Standard

Stephanie Kvas, Ajith Dias Samarajewa, Lee Beaudette, Rick Scroggins and Juliska Princz, Environment and Climate Change Canada, Canada

The soil microbial community is critical in maintaining a healthy ecosystem through processes such as nutrient cycling and organic matter decomposition. Soil microorganisms serve as valuable indicators of soil health, and therefore, their contribution needs to be included within environmental risk assessments. One way to measure changes to soil microbial activity in the presence of contaminants is an assessment of their ability to decompose organic matter. Here, we present a simplified laboratory scale method, derived from the field-based litterbag technique, which can be used to assess the effects of soil contaminants on soil organic matter decomposition or to compare the organic matter decomposition rate among different soils. The organic matter decomposition (OMD) test is based on the mass loss of pre-weighed filter papers, a representative material for organic matter, wherein the mass loss over time is correlated to organic matter decomposition. This method can be applied to most soils including field-collected (reference and contaminated,) or those amended with a chemical substance for risk assessment purposes by which a quantitative measure of toxicity (e.g., EC50) can be derived. The method is currently being validated as part of a new International Organization for Standardization (ISO) standard for Soil Quality: ISO 23265 “Soil Quality – test for estimating organic matter decomposition in contaminated soil”. As part of the standardization process, an international ring test was conducted with the participation of up to 14 laboratories from across Canada, South Korea, and Europe. Our most recent phase involved using LUFA 2.3 soil amended with silver nitrate (AgNO₃), as a representative soil contaminant, along a concentration-response gradient. We will highlight the OMD method along with results from the different phases of the inter-laboratory study, demonstrating the efficacy, validation and standardization of this method. The method contributes to a current gap for the inclusion of microbial studies in risk-based assessments, as well as applicability to derive apical toxicity endpoints.

4.1.V-10 The Influence of Soil Organic Matter Content on the Acute and Chronic Toxicity of Pesticides to *Eisenia andrei*

Bart Gerrit van Hall¹, Cornelis A.M. van Gestel², Christopher Sweeney³ and Melanie Bottoms⁴, (1)Vrije Universiteit Amsterdam, Nederland, (2)Vrije Universiteit Amsterdam, Netherlands, (3)Syngenta, Bracknell, United Kingdom, (4)Syngenta, United Kingdom

Lipophilic pesticides can bind to soil organic matter (OM) reducing their bioavailability to soil invertebrates. Therefore, the risk assessment for lipophilic pesticides (Log K_{ow} > 2) divides toxicity endpoints derived from tests using OECD artificial soil (~10% OM) by a factor of 2 to correct for the lower OM content in agricultural field soils (~5% OM). The application of this assessment factor (AF), however, is questionable, as it is based on results from acute earthworm toxicity tests focussing on mortality, instead of chronic toxicity tests focussing on reproduction. Additionally, the AF assumes that the relationship between bioavailability (and thus toxicity) and OM content is similar for all lipophilic pesticides, which might not be true. To develop a more accurate AF, the relationship between chronic pesticide toxicity and soil OM content for pesticides with different lipophilic characteristics needs to be elucidated. The aim of this study was to investigate the influence of soil OM content on the acute and chronic toxicity of different pesticides to earthworms. Chronic earthworm toxicity tests were performed using *Eisenia andrei*, using growth, mortality, and reproduction as endpoints. Adult earthworms were exposed to five persistent pesticides with a range of lipophilic properties in four soils with different OM contents. Three soils were artificially constructed by mixing quartz sand, kaolinite clay, and varying amounts of sphagnum peat, one soil was a standard agricultural test soil. The data were used to determine LC₅₀ and EC₅₀ values, and the relationships between acute and chronic pesticide toxicity and soil OM content were analysed by linear regression analysis. The results show that acute and chronic pesticide toxicity to earthworms is influenced by soil OM content, and that soil OM influences lethal effects more than sub-lethal effects. Additionally, the results indicate that toxicity-OM relationships differ between pesticides, and that the soil OM content also influences the toxicity of pesticides which are considered non-lipophilic under current legislation (i.e. imidacloprid). Overall, the results from this research will help to provide regulators with a sound basis for increasing the accuracy and ecological relevance of chemical risk assessments.

4.10 Linking soil ecology, ecotoxicology and risk assessment to the impact of multiple stressors on soil organism communities in the field (Poster)

4.10.P-Tu204 MICROSOIL - Correctly Assessing Risks for Microorganisms in Agricultural Soils - Identifying Meaningful Endpoints Under Field-Relevant Pesticide, Biocide and Pharmaceutical Exposures

Karsten Schlich¹, Cecilia Andrea Diaz Navarrete², Kerstin Derz², Bodo Philipp², Udo Hommen², Marie Winter², Kerstin Hund-Rinke², Bjoern Scholz-Starke³, Frank Zielinski⁴, Jens Schoenfeld⁵, Pia Kotschik⁶ and Silvia Pieper⁷, (1)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Fraunhofer IME, Germany, (3)darwin statistics, Aachen, Germany, (4)Federal Environment Agency Umweltbundesamt, Germany, (5)Federal Environment Agency, Germany, (6)German Federal Environment Agency UBA, Dessau, Germany, (7)German Federal Environment Agency (UBA), Germany

Soil health is an important driver for sustainable agriculture and must be maintained and strengthened. For the regulatory risk assessment of plant protection products (PPPs), biocides or pharmaceuticals, effects on the nitrogen transformation (OECD 216) are considered. This process is an important overarching soil function. However, by focussing on one central function of the microbial community, other effects can be overseen. The aim of the project MicroSoil is the identification of meaningful endpoints under field-relevant exposure of PPPs, biocides and pharmaceuticals. It will be investigated whether additional

endpoints relevant for the environmental risk assessment of microorganisms exposed to chemicals in soils should be proposed. By an literature search through various search engines 23 suitable methods were identified covering six methodological groups: Determining (i) the activity of aerobic and anaerobic heterotrophic microorganisms, (ii) nitrifying and denitrifying bacteria, (iii) the activity of exo- and endoenzymes, (iv) the effect on arbuscular mycorrhizal fungi, (v) functional genes and structural changes in soils and (vi) effects on carbon cycling and sequestration. The identified test methods were evaluated according to various criteria such as practicability in the laboratory, costs, replicability/reproducibility and regulatory relevance. For the identification of the most suitable methods, a traffic light system was developed. Based on the evaluation of the test methods, five methods with the highest score for aerobic heterotrophic soil microorganisms (MicroResp™), nitrifiers (ISO 15685), enzyme activity (ISO 20130), arbuscular mycorrhizal fungi (ISO 10832) and structural microbial diversity (ARISA) were proposed as potential test strategy. The sensitivity of the selected test methods will be investigated for six model substances (PPPs, biocides and antibiotics) in three soils varying in their physico-chemical properties. In addition, uncertainties in the risk assessment due to the current consideration of exposure to single substances will also be investigated by determining the influence of repeated applications of e.g. PPPs on processes driven by soil microorganisms. Acknowledgement - The authors thank the German Environment Agency for granting the project (FKZ: 3720 64 411 0).

4.10.P-Tu205 MICROSOIL - Investigation of Alternative Test Methods to Correctly Assess the Impact of Plant Protection Products, Biocides and Pharmaceuticals on Soil Microorganisms

Marie Winter¹, Frank Zielinski², Jens Schoenfeld³, Pia Kotschik⁴, Silvia Pieper⁵, Gabriele Broll⁶ and Karsten Schlich⁷, (1)Fraunhofer IME, Germany, (2)Federal Environment Agency Umweltbundesamt, Germany, (3)Federal Environment Agency, Germany, (4)German Federal Environment Agency UBA, Dessau, Germany, (5)German Federal Environment Agency (UBA), Germany, (6)University of Osnabrueck, Germany, (7)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmollenberg, Germany

Agricultural land use profits from a sound relationship between microbes and soil minerals resulting in stable mechanical and fertility properties. For the risk assessment of plant protection products (PPP), biocides and antibiotics only the effects on N-transformation (OECD 216) are considered. This process is an important overarching soil function. However, by focussing on one central function of the microbial community, other effects can be overseen. One part of the project 'Microsoil' is to investigate the sensitivity of three alternative test methods, which can be used to determine effects on nutrient cycles (MicroResp™), enzymatic activities (ISO 20130) and specialists (ammonium oxidizing bacteria, ISO 15685). To gather information about the sensitivity of the methods, the fungicide tebuconazole, the herbicide ethofumesate and the antibiotic tiamulin hydrogen fumarate will be used as model substances besides three other test substances. The tests will be performed in three different soils (LUFA 2.1, RefeSol 02A and RefeSol 04A). LUFA 2.1 with a high amount of sand and a low pH value will be used as worst-case soil. Three nominal test concentrations will be investigated based on the specific predicted environmental concentration. In addition, a control treatment will be prepared. Due to the low solubility in water, the substances will be dissolved in acetone and applied via quartz sand as suggested by OECD 216. At each measurement, the effect on the activity of ammonium oxidizing bacteria, the enzyme activity patterns of arylamidase, arylsulfatase, β -glucosidase, phosphatase and urease as well as the basal and substrate-induced respiration (SIR) will be observed. Measurements will be performed at test start and after 14 and 28 days. If effects above 25% occur, the test duration will be extended up to 100 days. The 1st test with ethofumesate in LUFA 2.1 soil was initiated, using test concentrations of 5.0, 10.0 and 20.0 mg a.s./kg per soil dry weight. The described test methods were performed to observe short-term effects. The results showed that no effect above 25% occurred using the three test systems. Therefore, there is no indication for a short-term effect due to the tested concentrations of ethofumesate in LUFA 2.1 soil. Further data for the other test substances and at different time points will be collected and presented at the conference. Acknowledgement - The study was funded by the German Environment Agency FKZ 3720 64 4110.

4.10.P-Tu206 Effects of Tembotrione Herbicide on the Soil Bacterial, Hppd Communities and on Antibiotic Resistance Indicators: A Microcosm Study

Hugo Terol¹, Laetitia Fournier², Christophe Calvayrac³ and Lise Barthelmebs⁴, (1)BAE-LBBM USR 3579, Université de Perpignan, France, (2)Laboratoire BAE-LBBM, USR 3579, Université de Perpignan, France, (3)University of perpignan, France, (4)BAE, University of Perpignan, Perpignan, France

Soil is known as a (microbial) biodiversity reservoir, whose microbial communities are essential to the functions of this ecosystem. Indeed, microorganisms in soil play an important role in maintenance of ecosystem services, like nutrient cycling, soil structure or crop yield and are recognized as key organisms by the European Union. Herbicides used in agriculture to maintain high yield in crop production, aim to prevent weed growth, but are known to end up in contact with soil microorganisms, that are defined as non-target organisms. One question that microbial ecotoxicologists raise is do the herbicides have toxic effects on soil microorganisms, and does it disturb soil microbial community dynamic and structure? More broadly, short- and long-term impacts on abundance, diversity and functions of these communities need to be investigated. Moreover, an emergent question linked to adaptation behaviors of soil microorganisms exposed to herbicides is the possible co-selection of resistance mechanisms to antimicrobial and to antibiotics. Resistance mechanisms that can thus be shared within microbial communities exposed *via* horizontal gene transfer (HGT). Our study focuses on tembotrione, a recently developed β -triketone herbicide, used in maize crops. This molecule is known to inhibit the 4-HydroxyPhenylPyruvateDioxygenase (4-HPPD) in targeted plants, enzyme also found in numerous soil microorganisms. Thus, our study aims to characterize the potential effects of tembotrione on soil microbial communities, taking also into account the evolution of antibiotic resistance indicators after herbicide application. Soil microcosm approach was performed using 1-fold or 10-fold the recommended agronomical dose of tembotrione, or none for controls, under controlled conditions (temperature and humidity). Soil samples were then collected at day 0 and after 3, 7, 14, 24, 40, and 55 days

to determine the listed endpoints: · The dissipation of the molecule · Viable bacterial abundance with standard culture method, associated to antibiotic resistance analysis · Bacterial diversity of the total bacterial community, and of the *hppd* bacterial community with high throughput sequencing of the 16S rDNA. · Antibiotic resistance genes (ARGs) and HGT genes “dynamics” with PCR and qPCR. Results analyses are still ongoing at the time of writing this abstract but should be available by March 2022.

4.10.P-Tu207 Soil Microbial Composition and Replication Directly Respond to the Presence of Biocides From Building Materials

Fabienne Reiß¹, Nadine Kiefer², Prof. Stefan Kalkhof³ and Matthias Noll⁴, (1)Microbiology, Coburg University of applied sciences and arts, Coburg, Germany, (2)Coburg University of applied sciences and arts, Coburg, Germany, (3)University of Applied Sciences Coburg, Germany, (4)Coburg University of applied sciences and arts, Germany

Biocides are used in building materials to protect the building against microbial colonization and biodeterioration. However, these biocides are introduced by gradual leaching into soils in proximity of the buildings. The effects of biocides frequently used in facade renders and paints on the soil microbiome are still unknown. Therefore, the study aimed to elucidate the effect of three individual biocides (terbutryn, isoproturon, octylisothiazolinone) and its four combinations of two or three biocides on the bacterial and fungal community composition and proliferation activity. Moreover, soil chemical parameters (soil respiration, pH, anion concentrations, ignition loss), biocide (in realistic concentrations between 0.4 to 6 µg g⁻¹ soil), and biocidal degradation product concentrations were determined at the beginning and after 28 d of incubation and compared to the control (incubation with water). Bromodeoxyuridine (BrdU) immunocapture technique was used in combination with pair-end Illumina sequencing to differentiate the total and active bacterial and fungal microbiomes. In addition, bacterial and fungal gene copy number were quantified via Real-Time PCR analysis. The biocidal treatment did not alter the soil's chemical properties significantly. In turn, the biocidal treatment significantly decreased the total gene copy numbers of both fungal and bacterial community composition. At the same time total bacterial and fungal microbiomes did not significantly change between the biocidal treatments, but the active microbiomes of both bacteria and fungi. While *Desulfotomaculum*, and *Methyloversatilis* decreased, well-known herbicide degraders such as members of the genus *Arthrobacter* increased. Similarly, shifts were found in the fungal community composition, which will be shown in detail by an indicator species analysis. Our results show that biocides as preservatives of facade renders and paints lead to a significant alteration in the active soil microbial community without dramatic shifts in the soil's chemical properties. Therefore, the addition of even low biocide concentration led to a distortion in the activity patterns, which should be characterized with the run-off of façades in future.

4.10.P-Tu208 Measurement and Simulation of Distribution, Degradation, Maximal Soil Concentrations and Ecotoxic Effects of Biocides Being Released From Building Facades

Nadine Kiefer¹, Fabienne Reiß², Judith Klein³, Karlheinz Weinfurter⁴, Michael Klein⁵, Matthias Noll⁶ and Prof. Stefan Kalkhof⁶, (1)Coburg University of applied sciences and arts, Coburg, Germany, (2)Microbiology, Coburg University of applied sciences and arts, Coburg, Germany, (3)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Germany, (5)Fraunhofer IME, Germany, (6)Coburg University of applied sciences and arts, Germany

Biocides are applied to increase the durability of building materials and to protect buildings from microbial colonization and biodegradation. However, biocides are released by gradual leaching and can thus reach soils and ultimately groundwater close to the building. A deeper understanding of this multiparametric process and the development of comprehensive characterization methods remain essential to allow a realistic assessment of the environmental impact of biocides used in building materials. Therefore, facades which formulations contained three in-can preservatives MIT, CMIT and BIT and encapsulated film preservatives zinc phyrithione, terbutryn, OIT as well as zinc oxide in different concentrations in renders and paints were investigated. We conducted two artificial weathering experiments, namely a DIN 16105 laboratory testing (without UV irradiation), and an artificial weathering protocol by a weathering chamber, with controlled UV irradiation. Additionally a real weathering experiment were performed. Biocides and their degradation products were quantified by UHPLC with UV and MS detectors. The observed maximum concentration of BIT was 6.0±0.5 mg per immersion cycle of DIN testing and 5.9±2 mg per rain event of the real weathering test. Eluates were diluted according to local weathering data to reflect realistic dilution by rain, and toxicological effects were evaluated in several soil and sediment toxicity tests for sediment worm, *Lumbriculus* as well as total nitrogen and total carbon transformations. In addition, aquatic toxicity was tested on green algae, daphnia, zebrafish luminescent bacteria, and *Arthrobacter globiformis*. Based on the leaching, weathering, degradation, and adsorption data, the depth-resolved soil distribution was modelled with PELMO considering discontinuous rainfall and biocide input. The predicted biocide concentrations were experimentally validated for different soil horizons. In summary, biocide-containing facade eluates showed toxic effects at early sampling times, but not at later sampling times after application. Biocide distribution in soil was simulated considering discontinuous input and experimentally validated to predict maximum concentration and correlation to acute effects in the ecotoxicological tests. The combination of the prediction of the biocide concentration in soil and further knowledge on the ecotoxicological effects on soil organisms will be presented.

4.10.P-Tu209 Arbuscular Mycorrhizal Fungi and the Need for a Meaningful Regulatory Plant Protection Product Testing Strategy

Christopher Sweeney¹, Melanie Bottoms², Sian Ellis³, Gregor Ernst⁴, Stefan Kimmel⁵, Stefania Loutseti⁶, Agnes Schimera⁷, Leticia Scopel Carniel⁸, Amanda Sharples⁹, Frank Staab¹⁰ and Michael Marx⁴, (1)Syngenta, Bracknell, United Kingdom, (2)Syngenta, United Kingdom, (3)Corteva Agriscience, United Kingdom, (4)Bayer Crop Science, Germany, (5)Corteva Agriscience, Germany, (6)Syngenta Hellas Single Member S.A.C.I., Greece, (7)ADAMA Deutschland GmbH, Germany,

(8)Regulatory Sciences - APS, BASF SA, São Paulo, Brazil, (9)FMC, United Kingdom, (10)BASF SE, Germany

Arbuscular mycorrhizal fungi perform key soil ecosystem services and due to their symbiotic relationship with plant roots, may be exposed to the plant protection products (PPPs) applied either to soils or crops. In 2017, the European Food Safety Authority (EFSA) released a Scientific Opinion on Soil Organisms recommending the inclusion of AMF ecotoxicological testing in the PPP regulatory process. In particular, the use of the ISO 10832 spore germination test was proposed. However, it is not clear how this can be implemented in a tiered, robust and ecologically relevant manner. Therefore, a critical review of current literature was conducted to examine the recommendations made within the EFSA Scientific Opinion on Soil Organisms and the methodologies available to integrate AMF into the PPP risk assessment. After assessing potential tier 1 methodologies it was concluded that AMF spore germination testing may be a potential option for the lowest tier of AMF risk assessment, providing that the considerable unknowns, regarding reliability, variability, reproducibility of such lab studies, fungicidal versus fungistatic outcomes, intraspecific diversity and how these study outcomes relate to in-field data, can be appropriately addressed. No recommendations for higher tier studies on AMF were made in the EFSA Scientific Opinion on Soil Organisms. This review concludes that the development of agronomically relevant intermediate and higher tier studies will face significant challenges stemming from the difficulties associated with including an obligate symbiont within the PPP risk assessment, particularly when testing herbicidal products which may be intended to kill the symbiotic plant partner. Finally, the suggestion in the EFSA Scientific Opinion on Soil Organisms proposing that AMF could be protected through the measurement of community metrics such as composition and diversity was considered, but ultimately cautioned against. Instead, there is a need to further the collective understanding of the linkages between the phylogenetic and functional diversity of AMF to ensure any risk assessment scheme is ecologically sound. Overall, this work highlights critical knowledge gaps; significant further research is required to enable the development of relevant, reliable, and robust scientific tests alongside pragmatic and scientifically sound guidance to ensure that any future risk assessment is adequately protective of the ecosystem services it aims to preserve.

4.10.P-Tu210 Chronic Effects of an Insect Growth Regulator - Teflubenzuron - on the Full LIFE Cycle of *Folsomia candida* Via Food Exposure

*Liyang Xie*¹, *Stine Slotsbo*² and *Martin Holmstrup*², (1)Ecoscience, Aarhus Universitet, Denmark, (2)Aarhus Universitet, Denmark

Current standardized toxicity tests using soil invertebrates mainly focus on the survival and reproduction of adults. Such results limited to one developmental stage of soil invertebrates are likely insufficient to predict the effects on higher organizational levels. Toxic effects may vary from life-stage to life-stage within the same species. Moreover, the adverse effect may be transferred to the next generation, affecting the offspring but not the exposed adult. The present study evaluates the effects of the insect growth regulator, teflubenzuron (TBF), on the full life cycle of a soil invertebrate aiming to understand the long-term effect of TBF on the life history of springtails. Insect growth regulators such as teflubenzuron inhibit the synthesis of chitin and thereby interfere with the moulting processes. TBF contaminated baker's yeast suspension was provided as the only food source to springtails throughout the experiment. The growth of individual springtails (*Folsomia candida*) was traced from hatching (one day old) and until animals were 2.5 months old. Survival, growth, time to first egg-laying, number of eggs and hatchability were recorded. Concentrations of 4.0, 2.7, 1.8, 1.2, 0.8, 0.5 and 0 mg/L yeast suspension were used. Survival was reduced after two weeks at the high concentrations (4.0, 2.7 and 1.8 mg/L) and reached 0%, 9% and 56% at 40 days. Springtails had good survival at low concentrations, more than 80%, till the end of the experiment. However, negative impacts on growth were detected at all tested concentrations in both juvenile and adult stages. Time to first egg-laying tended to increase as concentrations increased. The accumulated number of eggs was significantly reduced for concentrations of 0.8 mg/L and above compared to controls. The hatching rate was significantly affected at all tested concentrations. Our results show that the toxic effects of TFB are long-term, including slow growth, reduced number of eggs and reduced hatchability. However, such subtle effects are not captured in current standard acute or reproduction tests. Growth and hatchability are more sensitive than survival and they are also important indicators in extrapolating the effects at the organismic level to the population level. Toxicity testing would benefit from the inclusion of such life-history parameters that can be used for mechanistic models to unmask the contribution of growth, reproduction, hatchability to the ecological effects of TFB.

4.10.P-Tu211 Successful Implementation of a Natural Reference Soil Set in OECD 222 Earthworm Reproduction Testing Using Comparable pF Units for Soil Moisture

*Eva Aderjan*¹, *Eiko Wagenhoff*², *Thomas Moser*² and *Andreas Duffner*³, (1)Terrestrial Ecotoxicology (Lab), Eurofins Agroscience Services Ecotox GmbH, Niefern-Öschelbronn, Germany, (2)Eurofins Agroscience Services Ecotox GmbH, Germany, (3)Eurofins Agroscience Services Ecotox GmbH, Niefern-Öschelbronn, Germany

According to the current guidelines for ecotoxicological risk assessment of plant protection products for non-target soil organisms, standardized laboratory tests are carried out with artificial soil that meets criteria such as reproducibility and comparability. One of the most used test with standardised artificial substrate is the earthworm reproduction test OECD 222 with *Eisenia fetida/andrei*. Sorption properties like soil organic matter can influence the bioavailability of chemical substances and consequently the toxicity of the exposed organisms. If soils with different properties are not included in the investigations, it can lead to a bias in the results. The artificial OECD substrate has limitations in representing the spectrum of toxicity that could occur in natural soils. To fill this gap, a set of natural agricultural reference soils (RefeSols, Fraunhofer) with a broad spectrum of soil properties that can be found in agricultural soils in mid-latitudes were evaluated in the laboratory with OECD test system 222 and compared to the OECD substrate. A literature review showed that not only the toxicity of some chemicals can vary between natural soils, but also the number of earthworm juveniles produced in the untreated controls can vary greatly between different soil types. Beside food quality, temperature, and pH, soil moisture has a direct influence on the number of juveniles produced. However, the optimal moisture in natural soils for reproduction is poorly understood and previous studies with natural soils and *E.*

fetida/andrei were performed using percentage of WHC_{max} as recommended unit for water content for standard OECD studies. This common method leads to disadvantages in the comparability between soils: the same percentage value of WHC_{max} may mean different actual water availability for the earthworms in different soil types. This is because available water is determined by the soil water matrix potential (often specified as unit pF), a force strongly related to pore sizes and texture. With adjustments in the test performance and the implementation the unit pF, a successful, valid and reproducible implementation of natural agricultural reference soils in the OECD test system 222 is possible. Moreover, mean values for the number of juveniles in the controls of all natural reference soils used were above average when compared to the long-term mean in the OECD 222 substrate.

4.10.P-Tu212 Moisture Level, a Key Parameter in the Earthworm Sensitivity That Is Important to Consider in the Waste and Enrichment Product Risk Assessment. a User Feedbacks

Julien Bertin¹, Aline Jourdan² and Célie DUPUY³, (1)Ecotoxicology, SGS France laboratoire de Rouen, Saint Etienne du Rouvray, France, (2)SGS Multilab, France, (3)SGS France - Laboratoire de Rouen, France

The guidelines to evaluate the Waste Hazard Property 14 “ecotoxic” (HP14) include test with Earthworms (acute testing (ISO 11268-1) or avoidance testing (ISO 17512-1)), in some European member states. A proposal for a new French regulation on soil enrichment matter include the earthworm reproduction testing (ISO 11268-2) to evaluate the toxicity of enrichment matter before using on soil. Soil moisture is a decisive factor for earthworm survival and growth. Studies suggest that earthworm’s sensitivity and behavior can be influenced by the moisture level in the soils. Moreover, the earthworms used in normalized guidance are not typical soil species and few studies have been performed to characterize the moisture requirements of *Eisenia fetida* in soil or other substrate. According to the wide range of waste and enrichment matter and their influence on soil holding water, it is crucial to better understand the effect of moisture level on the sensitivity of earthworm. Although documented in the test guidelines as a rate of the maximum holding water, these guidelines don’t consider the very specific characteristics of waste and soil enrichment matters. In this study, the sensitivity of *Eisenia fetida* was evaluated at different moisture levels. For example, the mortality of worms was measured with 3g/l of boric acid in soils at different water contents. The result demonstrates a linear relationship between the moisture level and the mortality: below 50% of water holding capacity, 100% of worms died, whereas over 70% of water holding capacity, only 10% of worms died. This study is a user feedback on the earthworm ecotox testing in the waste and enrichment product risk assessment context and a contribution for a better use of earthworm in ecotox lab testing.

4.10.P-Tu214 Towards a Toxicokinetic-Toxicodynamic Model for Earthworms: Integrating Movement and LIFE Histories

Andre Gergs¹, Kim Rakel, MSc Ecotoxicology RWTH University², Dino Bussen², Yvan Capowiez³, Gregor Ernst¹ and Vanessa Roeben¹, (1)Bayer Crop Science, Germany, (2)Research Institute gaiac, Germany, (3)INRAE, UMR EMMAH, France

The environmental risk assessment of plant protection products aims at the prevention of any adverse effects on the environment including soil health. Therefore, the risk assessment for in-soil organisms, such as earthworms, is based on two key elements: the effect assessment and the exposure assessment. In the current regulatory frameworks toxicity endpoints and predicted environmental concentrations are compared to derive risk quotients for the characterization of risks. This procedure, however, largely ignores that environmental exposure concentrations are variable in space and time, and the exposure of moving organisms will vary in time too. In turn, the movement of earthworms can be affected by a number of abiotic factors as is their growth and reproduction. These factors include the moisture level, temperature, and the organic matter content. In laboratory experiments, earthworms showed a decrease in burrowing activity with decreasing moisture levels and even avoidance behavior of these unfavorable moisture environments. Furthermore, experimental results indicate that earthworm movement ceases completely at low moisture levels. At these conditions, individuals enter an inactive state, also described as diapause or aestivation. Moreover, the burrowing activity of earthworms is affected by temperature, for which the number of casts produced per earthworm was used as a proxy in laboratory experiments. Finally, the organic matter content plays a significant role for the burrowing and movement of earthworms. In this poster, we present a Dynamic Energy Budget model for the endogeic earthworm *Aporrectodea caliginosa* to integrate the effect of the abiotic factors on earthworm movement and life-history. This development is a major step towards a toxicokinetic-toxicodynamic model for earthworms.

4.10.P-Tu215 Phytoremediation of Pesticide Contaminated Soils and the Transformation of Chlorinated Pesticides in PLANTS

Marigona Morina - Gashi¹, Gerd Hamscher² and Rolf-Alexander During³, (1)Justus-Liebig-Universität Gießen, Germany, (2)Justus-Liebig-University Giessen, Germany, (3)Justus Liebig University Giessen, Germany

Soil is presumed a risk matrix in terms of the transfer of pollutants into the food chain. Pesticide residues in the soil are of big interest in agricultural pollution. Due to their properties, such as slow degradation and accumulation in living organisms, the removal of chlorinated pesticide (OCP) residues in the soil is considered pivotal. Knowing the limitations of conventional treatment such as high cost or the disturbance of soil flora and fauna, phytoremediation is assessed as a sustainable approach for soil reclamation. The identified fundamental processes of the plants used for remediation make this environmental friendly clean-up method a promising approach for OCP contaminated soil. This study’s goal is to establish a phytoremediation method for OCP contaminated farmland by an enhanced transformation of OCPs accumulated in plants and aims to evaluate the ability of different adjuvants such as distinct fungi (i.e. white rot or brown rot fungi) and of the use of mobilizing agents to boost phytoremediation efficiency. First experiments for the optimization of the OCP uptake from contaminated soil into the plant are being conducted in greenhouse experiments by closely observing plant health parameters. By this, a suitable, strong growing plant with the ability for OCP uptake should be identified. The study design of the first experiment contained different replicates of contaminated and uncontaminated soil and the studied plants were *Miscanthus x giganteus* and *Ricinus communis* L. The first preliminary results show that both studied plants have the capability for OCP uptake. These first results are being used for planning the next

greenhouse research, during which mobilizing agents will be added and the increase of OCP uptake will be evaluated. Afterwards, the fate of OCP accumulated in plants under conditions in the fermenter will be extensively studied in laboratory experiments with sophisticated analytical methods (GC-MS and LC-HRMS) with regard to emerging transformation products.

4.10.P-Tu216 Genome Sequencing Reveals Active Functionalities in Petroleum Degrading Consortium From Impacted Soil

Chioma Blaise Chikere¹ and Memory Tekere², (1)University of Port Harcourt, Nigeria, (2)University of South Africa, South Africa

Crude oil pollution is a major environmental problem in the Niger Delta region, Nigeria which has destroyed both biodiversity and ecosystem services severely. Functional attributes of a petroleum degrading consortium developed from bacteria isolated from crude oil-polluted soil with 4923-51780 mg/kg of total petroleum hydrocarbons (TPH) in Igbuduya, Niger Delta region, were investigated using deep sequencing to ascertain the site's amenability to nature-based reclamation. Enrichment in 1% crude oil- and naphthalene-Bushnell Haas (BH) broth was used to select for isolates with enhanced degrading potentials. Axenic cultures that decolorized 1% 2,6-Dichlorophenolindophenol (DCPIP) redox dye in hydrocarbon-BH broth degradation assay within 24h were sub-cultured and extracted genomic DNA was further analyzed with the ZymoBIOMICS shotgun metagenomic sequencing for microbiome analysis. Sequencing libraries were prepared with the KAPA HyperPlus library preparation kit while final library was sequenced on the Illumina NovaSeq platform. Genome analysis by composition barplots at strain level revealed the presence of *Micrococcus luteus* (83.54%), *Micrococcus aleoverae* (14.64%), *Micrococcus luteus* Mu201 (0.72%) and *Sphingobium barthaii* (0.1%). Functional pathways for nucleotide biosynthesis and hydrocarbon degradation very prominent and dominant in the consortium were most affiliated with *M. luteus*. This deep sequencing insight established that the indigenous microbes in the oil-impacted site have the genetic capacity to obtain carbon and energy sources from the contaminant during biodegradation and thus could be further stimulated for enhanced bioremediation of the polluted site.

4.10.P-Tu217 Agricultural Waste Recycling, Sustainable Food Production and Ecosystem Services: Circularity in a Case Study of Tomato Production

Catarina Correia de Lemos Malheiro¹, Marija Prodana², Diogo Filipe Nunes Cardoso³, Sara Cristiana Lopes Peixoto², Rita Silva², Fábio Campos², Pedro Sarmiento⁴, Daniel Murta⁵, Amadeu Soares⁶, Rui Morgado² and Susana Loureiro⁶, (1)Department of Biology, University of Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)CESAM & University of Aveiro, Portugal, (4)Escola Profissional de Agricultura e Desenvolvimento Rural de Vagos, Portugal, (5)Ingredient Odyssey, Portugal, (6)Universidade de Aveiro, Portugal

In the mid-20th century, advances in scientific knowledge helped the development of the Green Revolution, characterized by a fast increase of agricultural production, essential for a flourishing world population. Still, this intensification in agricultural production has been responsible for ecosystem deterioration, which is imperilling the delivery of ecosystem services. As global food demands continue to grow, crop yields show signs of stagnation adding further pressure to agriculture. A new revolution is urgent to ensure food security, one that is rooted in novel sustainability paradigms such as efficiency and circularity. Technological innovations focus on the use, transformation, and valorisation of agroindustrial wastes into innovative products aimed to ameliorate soil properties, reducing fertilizer dependence, and maintaining ecosystems integrity. Special attention is being given to integrated strategies that promote nutrients' circularity, such as agro-waste based fertilizers (AWBF). The present study used an ecosystem services approach to evaluate the effectiveness and environmental impact of an AWBF derived from the digestion of vegetable residues by *Hermetia illucens* larvae (product at the developmental stage). In a greenhouse, a randomized block experiment was set with four fertilization treatments: 1) reference (no fertilization), 2) NPK plus horse manure (conventional fertilization), 3) NPK plus AWBF, and 4) AWBF alone. An integrated assessment included: tomato productivity and quality (provisioning services), soil biodiversity (regulating services), functionality of microbial communities (supporting services), *in situ* feeding activity of soil organisms (supporting services) and soil retention function (regulating services). Overall, the incorporation of AWBF, alone or in combination, did not impact supporting services, such as the activity of extracellular soil enzymes involved in nutrient cycling (dehydrogenase, urease, alkaline and acid phosphatase, aryl sulfatase and beta-glucosidase), and feeding activity of soil organisms; still, low consumption rate was observed in all treatments. In addition, soil elutriates did not impact the growth of *Raphidocellis subcapitata* and *Lemna minor*, nor *Daphnia magna* mobility. This holistic perspective demonstrated that AWBF can be considered an adequate alternative to conventional fertilization treatments, which may improve the sustainability of ecosystems.

4.10.P-Tu218 Triticum Aestivum Bioaccumulation and Physiological Responses to Copper Nano-Formulations and Ionic Copper: An Indoor Mesocosms Approach

Marija Prodana¹, Rui Morgado², Diogo Filipe Nunes Cardoso³, Catarina Correia de Lemos Malheiro⁴, Pedro Monteiro², Sara Cristiana Lopes Peixoto², Joana Neves⁵, Zahra Khodaparast², Maria D Pavlaki², Sandra Rodrigues², Isabel Henriques⁶, Sónia Rodrigues⁵, Gloria Pinto² and Susana Loureiro⁵, (1)University of Aveiro & CESAM, Portugal, (2)University of Aveiro, Portugal, (3)CESAM & University of Aveiro, Portugal, (4)Department of Biology, University of Aveiro, Portugal, (5)Universidade de Aveiro, Portugal, (6)University of Coimbra, Portugal

Nano-based copper (Cu) formulations are getting more attention in the recent years. Key property of these novel pesticides is a gradual release of Cu ions resulting in higher efficacy than in the case of conventional formulations. Lower application rates of nano-pesticides may bring economic and environmental benefits. Yet, to assure sustainability, it is crucial to understand their behaviour, fate, and toxicity in soil ecosystems. We performed an indoor mesocosms study to understand how nano and non-nano Cu formulations affect soil functions and health, while assessing their bioavailability and bioaccumulation potential. A model

community in each soil core contained: wheat *Triticum aestivum*, earthworms *Eisenia andrei*, isopods *Porcellionides pruinosus*, mealworms *Tenebrio molitor*, plus soil microbiome. Four compounds were tested, at 50 mg Cu/kg of LUFA 2.2 soil: ionic form as $\text{Cu}(\text{OH})_2$, and nano-formulations - Kocide 3000®, $\text{nCu}(\text{OH})_2$, and nCuO . LUFA 2.2 represented a negative control. Destructive sampling was conducted in triplicates, on day 14 and 28 (and day 0 and 6 for plant bioaccumulation), collecting the soil for microbiome analysis, Cu quantification (dissolved and total), and the organisms for biomass and biomarker assessment. Part of this work addressing plant responses is presented here. We hypothesized that plant bioaccumulation patterns and physiological responses depended on the Cu form. $\text{Cu}(\text{OH})_2$ had the highest effects on root and shoot fresh weight, and shoot length. No statistically significant differences were found for the nano-formulations. Effects of $\text{Cu}(\text{OH})_2$ on biomass were more pronounced in the aerial part. For all the treatments, total Cu concentrations in the roots were 10-fold those in the aerial part. The highest Cu content was in the roots exposed to $\text{Cu}(\text{OH})_2$. Cu toxicokinetics for the roots and for the aerial part was described using the classic one-compartment model. The highest uptake rate constant in the roots was observed for $\text{Cu}(\text{OH})_2$. The uptake pattern was similar among nano-formulations. Substantially lower uptake rate was observed in all the treatments for the aerial part. Pigment contents did not differ, and there was no treatment-induced lipid peroxidation. Total phenolic content in *T. aestivum* shoot was significantly increased as response to $\text{Cu}(\text{OH})_2$. The largest overall impact of the ionic Cu form in this study is aligned with the higher bioavailability observed during the experiment compared to nano-formulations.

4.10.P-Tu219 Response of Ginger Growth and Soil Phosphorus Availability to the Different Years of Chloropicrin Fumigation

Yan Wang¹, Xiaomei Yang², Minggang Xu³ and Violette Geissen⁴, (1)Wageningen University, Nederland, (2)Wageningen University, Netherlands, (3)Chinese Academy of Agricultural Sciences, China, (4)Alterra Wageningen University and Research Centre, Netherlands

Although chloropicrin (CP) fumigation is widely used to control soil-borne pathogens, it can also change the cycle of soil nutrients by affecting soil beneficial functional microorganisms. However, the effect of repeated use of CP fumigation on soil phosphorus (P) availability is still largely unclear, which is the main problem we want to solve in this study. A field experiment was conducted in ginger fields with 0, 3 and 7 years (F0, F3 and F7, 3 replicates of each) of annual CP fumigation history in Shandong Province of China. Soil samples (0-20 cm) were collected at four different times in 2019: Before fumigation (05/03/2019), After fumigation (28/03/2019), Middle growth period (24/08/2019) and Harvest (23/10/2019). Ginger yield, soil phosphatase (acid and alkaline) activity and soil P fractions from different sampling periods were measured and compared with three experimental replicated plots. Results showed that ginger rhizome yield was similar in F0 and F3 (70.0 t ha⁻¹), but significantly lower in F7 (37.5 t ha⁻¹). The acid phosphatase (AiP) activity was significantly higher in F0, while alkaline phosphatase (AIP) activity was the highest in F3. There was no significant difference in the available P (Resin-P+NaHCO₃-P+NaOH-P) between F0 and F7, with 33.6% to 57.5% of total P (TP), while the available P was significantly lower in F3, being less than 30% of TP. Redundancy analysis (RDA) showed that pH values were significantly negatively, while AiP activity was significantly positively, correlated with the proportions of soil available P to total P. The results showed, although the yield of ginger rhizomes was similar between F0 and F3, the significantly lower proportion of soil available P in F3 may be a key limiting factor for higher ginger yield. After 7 years of repeated CP fumigation, soil-borne pathogens may be resistant to CP fumigation. At this time, the serious death of ginger has become the main limiting factor for ginger production, and we should first consider finding another effective method instead of sole CP fumigation to prevent soil-borne diseases. The high proportion of soil labile P fractions in F7 may further cause serious environmental problem such as water eutrophication. Decreased phosphatase activity after repeated CP fumigation is also evidence of reduced soil P availability, which highlights the necessity of further research on soil P solubilizing microorganisms to reveal the microbial mechanism.

4.10.P-Tu220 Response of Soil Phosphorus Availability and Ginger P Uptake to the Combined Application of Chloropicrin and Azoxystrobin

Yan Wang¹, Xiaomei Yang², Minggang Xu³ and Violette Geissen⁴, (1)Wageningen University, Nederland, (2)Wageningen University, Netherlands, (3)Chinese Academy of Agricultural Sciences, China, (4)Alterra Wageningen University and Research Centre, Netherlands

Although chloropicrin (CP) and azoxystrobin (AZO) are widely used to control soil-borne pathogens, they can also change the cycle of soil nutrients by affecting soil beneficial microbes. However, the effect of the combined application of CP and AZO on soil phosphorus (P) availability and plant P uptake is still largely unclear, which is the main problem we want to solve in this study. A 28-week greenhouse experiment was set up with six treatments: CK (Control), AZO1 (A single application of AZO), AZO2 (Two applications of AZO), CP (CP fumigated with no AZO), CP+AZO1 (CP combined with AZO1) and CP+AZO2 (CP combined with AZO2). Ginger was used as the model plant. Field recommended amounts of 37.1 g m⁻² of CP and 47.1 mg m⁻² of AZO were used for each application. Soil was sampled four times at different growth period and ginger plants were sampled at harvest. Basic soil chemical properties, phosphatases activity, soil P fractions, and ginger P uptake were tested. Results showed that soil acid (AiP) and alkaline (AIP) phosphatase activity were significantly lower in CP-treated soil than in CK during the entire growth period, while AZO did not have significant inhibitory effects on soil phosphatases activity until 17 weeks after plant (WAP). The proportions of labile P (Resin-P, NaHCO₃-Pi and NaHCO₃-Po) to total P (TP) were significantly higher in AZO1 and CP (29.3% to 35.5% of TP) than in CK (20.5% of TP) at 9 WAP. Only CP-treated soil had significantly higher proportions of labile P (31.3% to 36.5% of TP) than CK (21% of TP) at 17 WAP. Soil inorganic P fractions and organic P (NaHCO₃-Po) fractions were highly negatively correlated with soil pH and phosphatases activity, respectively. The height and total P content of ginger plant were significantly higher in CP (height 86.0 cm, total P content: 43.6 mg) and CP+AZO2 (height 72.1 cm, total P content: 42.0 mg) as compared to CK (height 53.2 cm, total P content: 20.0 mg). The rhizome P content was significantly highly

in CP+AZO2 (18.3 mg) than in CK (6.1 mg). The ginger physiological P use efficiency decreased from CK (1799.8 g DM g⁻¹P) to CP+AZO2 (589.0 g DM g⁻¹P). From the result, we could conclude that CP fumigation increased the proportions of soil in organic P proportions and ginger total P uptake, but no synergistic effects were observed after the combined application of CP and AZO. Therefore, ginger planting farmers may avoid the unnecessary AZO application in soils with CP fumigation.

4.10.P-Tu221 Evaluating the Compounded Effect of Environmental Disturbances and Pesticide Mixtures on Soil Microbes

Camilla Drocco¹, Anja Coors², Marion Devers-Lamrani³, Fabrice Martin-Laurent³, Nadine Rouard³ and Aymé Spor³, (1)INRA Dijon, France, (2)ECT Oekotoxicologie GmbH, Germany, (3)AgroSup Dijon, INRAE Agroécologie, Univ. Bourgogne, Univ. Bourgogne Franche-Comté, France

Pesticides are widely used in conventional agriculture, either applied separately or in combination, and often in serial application during the culture cycle. Due to their occurrence and persistence in soils, pesticides may have an impact on soil microbial communities and on supported ecosystem services. In this regard, the EFSA (European Food Safety Authority) recently published a scientific opinion inciting to include more soil microbe-mediated processes in pesticide risk assessment. Climate change is another major concern for microbial community stability. Extreme climatic events, such as droughts or heavy rainfalls, are becoming more and more frequent and their impact on soil microbial diversity and functioning have already been demonstrated. The objective of this study is, therefore, to evaluate the compounded effect of global change related environmental disturbances and pesticides on soil microbial community structure and functioning. To this end, 270 soil microcosms were exposed to either a heat disturbance, heavy rainfall conditions, or no environmental disturbance (control). After a 3 days recovery period, the active ingredients clopyralid, cypermethrin and pyraclostrobin that are commonly used as herbicide, insecticide and fungicide, respectively, were applied either in single application or combined at 1X or 10X of the agronomical application rate. Control and treated microcosms were then kept under controlled conditions for 42 days. The ecotoxicological impact of pesticides' application scenario conditionally to the prior environmental disturbance will be evaluated on total bacterial community diversity and structure using sequencing of 16S rDNA gene amplicons. We will focus specifically on the effects of treatments on the abundance of ammonia-oxidizing archaea and bacteria via q-PCR, and on the subsequent changes in mineral nitrogen pools. We hypothesize that climate change related environmental disturbances and pesticides' mixtures application may have compounded effects on the structure and functioning of some key microbial community members as compared to single pesticide applications. The results from this work will provide new knowledge and insights for the scientific community and may help fill the regulatory gaps on pesticide risk assessment.

4.10.P-Tu222 Chronic Copper Exposure Shifts the Thermal Performance Curves and Temperature Preference in the Springtail *Folsomia candida*

Jian Ge¹, Stine Slotsbo², Jesper Sørensen² and Martin Holmstrup², (1)Department of Ecoscience, Aarhus University, Denmark, (2)Aarhus Universitet, Denmark

Toxic effects of chronic exposure to low-dose contaminants in animals has been continuously drawing attention due to their occurrence and persistence in the soil of urban, rural, industrial, and natural environments. The aim of this study was to investigate the chronic effects of copper contamination on thermal performance and behavioural temperature preference in a typical soil invertebrate, *Folsomia candida*. We hypothesize that bioaccumulation of copper alters the position and shape of thermal performance curve and changes temperature preference in springtails. Soils contaminated with three copper levels (approx. 40, 400 and 1500 mg/kg dry weight soil) were collected from a former timber preservation industry at Hygum, Denmark. Age-synchronized springtails (12-14 d) were exposed to the three exposure levels in Hygum soil and distributed to 10 temperatures (0, 2.5, 5, 10, 15, 20, 22, 24, 26 and 30 °C) with 6 replicates (n=10). After a three-week exposure, springtails were weighed and the numbers of the animals and their offspring were counted to draw thermal performance curves regarding survival, growth and reproduction. A temperature preference experiment was conducted using rectangular arenas (75.8 cm length × 4.7 cm width) with a temperature gradient from approximately 5 to 35 °C. After copper-exposure for 3 weeks, 50 springtails were placed in the middle of the panel (approx. 20 °C) with and without temperature gradient, respectively. The distribution of animals was recorded every 10 minutes in the total period of 1 hour in order to estimate the temperature preference distribution. The results of this research demonstrated the toxic effects of copper contaminations on thermal performance and temperature preference in springtails, which is essential for evaluating the individual plasticity and population resilience as well as their ecological function and service.

4.10.P-Tu223 The Response of Earthworm *Eisenia fetida* to Triclosan Exposure Under Drought Stress

Diana Miškelytė and Jurate Zaltauskaitė, Vytautas Magnus University, Lithuania

Antimicrobials are essential for the maintenance of public health and life quality. Triclosan (TCS), widely used as an antimicrobial agent, is usually introduced into soil by sewage sludge application and may present potential risks in the terrestrial ecosystem. Recently, large numbers of studies carried out on TCS-induced physiological and biochemical effects on soil biota. Nevertheless, these studies did not consider the co-occurrence of different stress sources in soils related to ongoing global warming. Changing climate conditions might alter both physical and chemical soil properties. Due to higher temperatures and increasing evapotranspiration rates, a general decrease in soil moisture content is expected. This threatens many soil organisms that rely on these moist environments for their survival as well as is likely to change the toxicity of various soil pollutants. Earthworms *Eisenia fetida* are directly exposed to soil pollutants with their thin epithelium and their feeding, thus, they are highly relevant for the assessment of the toxicity of inorganic and organic contaminants to soil biota. The main objective of this study was to evaluate the influence of decreased soil moisture on TCS-induced changes in *E. fetida* growth, mortality, and oxidative stress levels. 4-weeks triclosan-contaminated soil (10 - 750 mg TCS kg⁻¹) experiments with *E. fetida* were performed at different

soil moisture contents (60% and 30% of the soil volumetric content). Earthworm growth, survival rate, biochemical indicators (the activity of enzymes) and the damage of oxidative stress (lipid peroxidation) were detected.

4.10.P-Tu224 Effects of Increased Atmospheric CO₂ Levels With WATER Stress Situations on the Avoidance Behaviour of Soil Invertebrates Towards Metal(Loid)-Contaminated Soils

Rita Silva¹, Sara Tavares², Daniela Gomes², Inês Vieira², Maria João Ferreira², Marija Prodana¹, Catarina Correia de Lemos Malheiro³, Susana Loureiro⁴ and M. Nazaret Gonzalez-Alcaraz⁵, (1)University of Aveiro, Portugal, (2)CESAM & University of Aveiro, Portugal, (3)Department of Biology, University of Aveiro, Portugal, (4)Universidade de Aveiro, Portugal, (5)Technical University of Cartagena, Spain

Across the globe, different areas are known to be affected by anthropogenic metal(loid) contamination. In addition, climate changes are leading to increased atmospheric CO₂ levels and air temperature along with variations in the precipitation patterns, with a higher incidence-severity of extreme events such as droughts and floods. In the terrestrial environment, soil organisms are surrounded by a complex matrix, in which climate factors can modify the bioavailability of metal(loid)s, due to changes in some edaphic parameters, but also alter the performance of soil invertebrates and/or their susceptibility to contaminants. Although the effects of increased temperature have been explored, the possible impacts of rising atmospheric CO₂ levels have received less attention. Considering all the above mentioned, the aim of the present study was to evaluate the effects of combining high atmospheric CO₂ levels with water stress situations on the avoidance behaviour of the invertebrate species *Enchytraeus crypticus* towards metal(loid)-contaminated soils. With that purpose, two historically metal(loid)-contaminated soils were collected in central-northern Portugal: a soil from a former agricultural area near an industrial chemical complex, and a soil from a former metal mining district. Avoidance tests with *E. crypticus* were performed under different climate scenarios based on the IPCC predictions for 2100: 1) standard conditions – climate conditions recommended by OECD guidelines (20 °C + 50% soil water holding capacity -WHC- + 400-500 ppm atm. CO₂); 2) high atmospheric CO₂ levels with soil drought conditions (20 °C + 25% soil WHC + 1000 ppm atm. CO₂); 3) high atmospheric CO₂ levels with soil flood conditions (20 °C + 25% soil WHC + 1000 ppm atm. CO₂). As previously observed for standard conditions, *E. crypticus* significantly avoided the metal(loid)-contaminated soils tested. Though, when exposed to high atmospheric CO₂ levels combined with water stress situations, enchytraeids lost their ability to avoid metal(loid) contamination. This pattern was clearer in the drought scenario probably due to the susceptibility of these soft-bodied oligochaetes to desiccation. Understanding the response of soil invertebrates in the given context is of utmost relevance since multiple stress conditions are the most common situations for natural populations.

4.10.P-Tu225 The WARMET Project: An Interdisciplinary Approach to Evaluate the Response to Climate Change of Abandoned Mine Wastes Colonized by Vegetation vs. Restored in Semiarid Areas

M. Nazaret Gonzalez-Alcaraz¹, Héctor M. Conesa Alcaraz², Juan J. Martínez-Sánchez¹, José Álvarez-Rogel³ and Matías Ceacero Moreno⁴, (1)Technical University of Cartagena, Spain, (2)Technical University of Cartagena, Spain, (3)Escuela Técnica Superior de Ingeniería Agronómica. Universidad Politécnica de Cartagena, Spain, (4)Department of Agricultural Engineering of the E.T.S.I.A. & Soil Ecology and Biotechnology Unit of the Institute of Plant Biotechnology, Technical University of Cartagena, Spain

WARMET is a research project funded by the Spanish Ministry of Science and Innovation (PID2020-118941RA-I00) that began in September 2021 and will last for three years. Metal mine wastes are often deposited in open-air piles (mine tailings). Classic-restoration approaches (technical reclamation) usually involve topsoil capping aiming to create a new soil above wastes and then afforestation. These options have been questioned in semiarid regions due to ecosystem inability to be self-sustaining. An alternative is to promote the growth of plants in mine wastes (phytomanagement by phytostabilization). This contributes to create vegetated patches that may promote plant-soil feedbacks and ecosystem functioning. If tailings pose immediate risks, the necessary measures should be made available for immediate technical restoration. However, if conditions are not so extreme, the spontaneous succession of plants directly growing in wastes has some advantages (e.g., plants adaptation to local climate, improved long-term sustainability). Previous works showed that the direct grow of native plants in tailings can provide functional soil-vegetation systems with attenuated ecotoxicity, but functional and ecotoxicological aspects of conventionally restored tailings are scarce or even lack. Furthermore, how systems will respond to climate change is still an open question. Answering these questions is core for evaluating the suitability of phytomanagement vs. conventional techniques for mine tailings restoration in semiarid regions. WARMET aims to assess whether spontaneously-colonized and conventional technically-reclaimed (capping and afforestation) metal mine tailings soils of Mediterranean semiarid regions differ in their response to climate change in terms of functionality and ecotoxicity. To achieve this an interdisciplinary study is being carried out in tailings from SE Spain: i) field work (evaluation of the functionality and ecotoxicity of the soil-plant system from different types of mine tailings, considering areas with vegetation and adjacent bare soils); ii) lab-experimental work (subjecting tailing soils to different climate change scenarios according to IPCC predictions). Physical, physico-chemical and biological soil parameters related to systems functionality and ecotoxicity are being considered. Soil ecotoxicity is being assessed through a battery of bioassays (microorganisms, invertebrates and plants). The poster presents the outline of the project.

4.10.P-Tu226 Combined Effects of Chlorpyrifos and Microplastics Derived From Conventional and Biodegradable Mulch Film on Earthworm (*Lumbricus terrestris*) and Their Fate in Soil

Hui Ju¹, Xiaomei Yang² and Violette Geissen³, (1)Environmental science group, Wageningen University & Research, Wageningen, Netherlands, (2)Wageningen University, Netherlands, (3)Alterra Wageningen University and Research Centre, Netherlands

In this study, we investigated the combined effects of low-density polyethylene (LDPE-MP) and PBAT/PLA (Bio-MP)

microplastics, and insecticide chlorpyrifos (CPF) on growth, reproduction, and survival of earthworm *Lumbricus terrestris*, and the transport of microplastics, chlorpyrifos and its metabolites by earthworm activity in 60-day mesocosm experiment. Results showed that Bio-MP strongly inhibited earthworm growth and survival rate while the reproduction of earthworms was not affected by none of the microplastics. The combined effects of microplastic and chlorpyrifos on earthworm depended on the type of microplastic and their exposure concentration. CPF facilitated the transport of LDPE-MP while inhibited the transport of Bio-MP into the soil by earthworms. LDPE-MP facilitated the assimilation of CPF by earthworms while Bio-MP decreased it at 1250 g. a.i./ha CPF application rate. LDPE-MP did not influence the transport of CPF by earthworms into the soil while Bio-MP enhanced the CPF transportation. 3,5,6-Trichloropyridinol (TCP) was the main metabolite found in this study and the effects of microplastics on the TCP concentration in the earthworm bodies followed that of microplastics on CPF concentration in the earthworm bodies. Both LDPE-MP and Bio-MP decreased the TCP concentration in soil indicating that microplastic could extend the degradation half-life of CPF in soil. Therefore, we suggested that the type and exposure concentration of microplastic are important factors influencing the combined effects between microplastics and other pollutants, and their interaction effects should be considered when studying their fate in soil ecosystem.

4.10.P-Tu227 Uncertainty Analysis of the NOEC Estimation for Count Data Sets Based on Field Data and Virtual Experiments

Thomas Gräff¹, Pia Kotschik², Klaus Swarowsky³ and Silvia Pieper³, (1)German Environment Agency (UBA), Dessau-Roßlau, Germany, (2)German Federal Environment Agency UBA, Dessau, Germany, (3)German Federal Environment Agency (UBA), Germany

In terrestrial field experiments and aquatic mesocosm studies, the no observed effect concentration (NOEC) is in most cases an important endpoint. Therefore, identifying the most appropriate hypotheses test with the highest statistical power is an advantage. This is especially true when multiple testing approaches are used and the so-called alpha inflation has to be managed. The most common methods are the correction of the respective values from the t-tables or a correction of the alpha values itself (e.g. as in Holm- or Bonferroni-correction). In general, the preferred parametric tests have a higher power compared to non-parametric tests, but assume that data are (approximately) normally distributed and the variances are homogenous. In case of abundance or reproduction data sets, which consist of count data, a Poisson distribution is the correct underlying distribution. Additionally, especially for field tests, the sample size is low and variance structure heteroscedastic. Currently, the well-known t-tests of Dunnett and Williams are used to derive NOEC estimations for field tests or mesocosm studies. However, such multiple t-tests do not work well for count data due to the missing normal distribution and variance heterogeneity. In case of the Dunnett test, this can be compensated by combination with e.g. Generalized Linear Models and Generalized Linear Mixed Effects Models. By contrast, non-parametric tests as the U- test or the Jonkheer Terpstra tests display low power compared to the tests of the t- test family. Lehmann et al. (2015, 2018) developed the closure principle computational approach test (CPCAT) to address Poisson distributed data. As a major advantage, CPCAT does not require normal distribution or variance homogeneity and alpha inflation is avoided by the closure principle. Instead, the true Poisson distribution of the data is used as a basis for testing. We examined the practicability of CPCAT regarding derived NOEC-values when compared to those obtained using Dunnett (in combination with different models), Williams t-tests and non-parametric tests in a virtual experiment based on field data. The main goal was to investigate whether endpoints derived with CPCAT would be at least as protective as NOECs derived with other tests and how different scenarios would affect the outcome of the analysis regarding data variance. Numerical scenarios will be presented, covering different variance structures and effect levels in the treatments.

4.10.P-Tu228 New Tools for Predicting Environmental Concentrations in Soil in Regulatory Context - Potential Implications for the Soil Organism Risk Assessment of Plant Protection Products

Agnes Schimera¹, Sebastian Multsch², Melanie Bottoms³, Olga Irene Guevara Montemayor⁴, Klaus Hamme⁵, Stefan Kimmel⁶, Stefania Loutseti⁷, Michael Marx⁵, Amanda Sharples⁸, Frank Staab⁹, Krisztian Szegedi⁹, Frank Voss⁴ and Gregor Ernst⁶, (1)ADAMA Deutschland GmbH, Germany, (2)knoell Germany GmbH, Germany, (3)Syngenta, United Kingdom, (4)KNOELL CONSULT GmbH, Germany, (5)Bayer Crop Science, Germany, (6)Corteva Agriscience, Germany, (7)Syngenta Hellas Single Member S.A.C.I., Greece, (8)FMC, United Kingdom, (9)BASF SE, Germany

The EU risk assessment (RA) for soil organisms exposed to plant protection products is conducted as a two-tiered approach. At Tier 1, laboratory derived ecotoxicity endpoints are compared to predicted environmental concentrations in soil (PECsoil). If a potential risk is indicated, higher tier field studies as the only option can investigate whether effects on soil organism communities occur at relevant field application rates under natural conditions. We present results of an impact assessment investigating how the new EFSA guidance for PECsoil calculation published in 2017 may impact the soil RA in the future. More than fifty active substances and metabolites have been assessed. For the ecotoxicological RA, the PECsoil was divided by the regulatory acceptable concentration (RAC) for soil organisms based on EU agreed endpoints to calculate the failure rate (compounds with PEC/RAC ratio > 1). We focused on impacts of the new exposure framework on soil RA and discuss its applicability within the current EU RA scheme. Detailed modelling results are discussed in the poster of Multsch et al. We observed a considerable increase of PECsoil values for active substances (compared to current modelling) which differs between regulatory zones in the EU: Across all zones, elevated PECsoil-values (based on total concentrations) increased RA failure rates by up to 67%. Compared to the current failure rate of 14%, up to 5 times more field studies will be triggered if new modelling is implemented at Member State level. Yet, it is unclear how to translate exposure values from the new modelling tiers to ecotoxicological endpoints from either lab or field. Selection procedures of geographic locations for exposure assessment results in incompatible soil properties (e.g., organic carbon content, bulk density) between e-fate and ecotoxicological data. This inconsistency hinders scientifically reasonable comparison and interpretation. At present, the new modelling framework should not be used before the availability of

an updated soil organism RA guidance which specifies how these exposure values should be implemented in a tiered RA approach. Ecotoxicological ‘intermediate-tier’ effect studies or modelling approaches may be a potential option to overcome such discrepancies in the future but are currently not available/accepted. A sufficiently long transition period will be required to ensure alignment between the new modelling framework and the tiered assessment for soil organisms.

4.10.P-Tu229 Do We Know Enough About Pesticide Impacts on Soil LIFE in Southern Africa, Given Declining Soil Quality and Food Security?

Herman Eijsackers¹ and Mark Maboeta², (1)WUR/NWU, South Africa, (2)North-West University - Potchefstroom Campus, South Africa

Southern Africa is characterized by ‘old soils’, of limited quality. In the framework of climate change maintaining good quality, soils become more important. Soil organisms play an indispensable role in maintaining and improving soil quality. Therefore, we must know to what extent pesticides, used in large and small scale agricultural systems in southern Africa could affect the abundances and activities of soil organisms. To this end, we did a bibliometric inventory of CAB and Scopus databases for relevant research papers. The resulting numbers of research papers are limited and cover only a few soil species (mainly earthworm species) and limited numbers of pesticides (*viz.* Cu-oxychloride, chlorpyrifos, azinphos-methyl, carbofuran, mancozeb). The results show that these pesticides applied under field conditions can damage soil life. Data about the impacts of the most used pesticides in southern Africa are for the greater part lacking, however. Moreover, the knowledge about soil fauna species typical for SSA soils is almost absent, in particular, the soils of poor quality under dry environmental conditions. Therefore, there is a need to fill these data gaps with research on other soil species and pesticides. It is a question then, whether it is possible to rely on research carried out in other parts of the world and use bridging factors? Or is additional research in southern Africa needed?

4.10.P-Tu230 Inventory Analysis of the Contamination of Agricultural Land With Biocides, Pharmaceuticals and Plant Protection Products in Germany

Pia Kotschik¹, Marie Reppe², Daniela Gildemeister³, Daniel Sättler², Philip Klaas², Stephan Marahrens², Karlheinz Weinfurter⁴ and Silvia Pieper², (1)Umweltbundesamt / Federal Agency of Environment, Dessau, Germany, (2)German Federal Environment Agency (UBA), Germany, (3)Pharmaceuticals, Umweltbundesamt / German Environment Agency, Dessau-Roßlau, Germany, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Germany

Agricultural soils in Germany are exposed to a variety of substances. However, the overall residue contamination situation is unknown. Several substances are applied directly or indirectly to soils and can accumulate there - depending on the respective soil and substance properties. Published studies on agricultural soil pollution in Germany are limited and often restricted to single (often well known) substances or substance groups. Organisms living in such soils are exposed to numerous chemicals from different uses over a long period of time. However, the risk assessment for active substances of plant protection products (ppp), biocides and pharmaceuticals as well as industrial chemicals under the different European regulations does not consider multiple exposure of different substances. This has already been identified as one of the major deficits of the single substance assessment in the approval procedures of ppp (Topping et al., 2020; Frische et al., 2018), but is also common practice in the approval procedures of biocides and pharmaceuticals. So far, it is unclear to what extent multiple exposure is relevant in the field situation and whether neglecting the realistic exposure leads to an underestimation of resulting risks in the individual approval procedures of chemicals. In 2021, a project funded by the Federal Ministry for Environment, Nature Conservation and Nuclear Safety was initiated, with the aim of obtaining a first screening of the pollution level of agricultural soils in Germany together with the investigation of their biological conditions. Knowledge of the current contamination situation of agricultural soils is necessary to check the plausibility of models for regulatory substance approval. Moreover, current assumptions underlying risk assessment schemes for soil organisms can be checked against the situation in the field. An overview of the actual contamination situation in connection with a status survey of the soil organism community can therefore provide a valuable contribution to the further development of risk assessment of pharmaceuticals, biocides, ppp and industrial chemicals and can significantly influence approval decisions in the future.

4.10.P-Tu231 Effects of Pesticides on Earthworms and the Soil Microbiome in Agricultural Soils Across Europe. a Peek on Results From the SPRINT Project

Dennis Knuth¹, Paula Harkes², Esperanza Huerta Lwanga², Vera Silva³, Jakub Hofman⁴, Shiva Sabzevari⁵, Coen Ritsema² and Violette Geissen⁶, (1)Wageningen University and Research, Nederland, (2)Wageningen University & Research, Netherlands, (3)Wageningen University, Netherlands, (4)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (5)Masaryk University, Czech Republic, (6)Alterra Wageningen University and Research Centre, Netherlands

Recent research has shown that contamination of European agricultural soils with residues of plant protection products (PPPs) is not the exception but is rather the rule. Studies have shown that over 80% of analysed samples contain residues of PPPs, 58% mixtures of up to 13 different substances. Even in soils under organic management up to 5 PPP residues have been detected. Additionally, an investigation has found higher concentrations of currently used pesticides (CUPs) in earthworms compared to soils. Much is still unknown about the impacts of these residues in the environment, especially when mixed – often described as a ‘cocktail effect’. The H2020 SPRINT (Sustainable plant protection transition) project intends to determine the influence of PPPs on human health and the environment. Therefore, 10 case study sites (CSS) across Europe and one in Argentina, covering the main cropping systems, are studied. Each CSS contains 10 fields under conventional and 10 fields under organic management. In this study we focus on the terrestrial environment including soil, earthworms and soil microbiome. Collection of the environmental samples (*e.g.* soil and earthworms) took place in all CSS during the growing season of 2021, after 50 - 80% of

pesticides have been applied. We studied the effects of pesticide use as well as multiple pesticide on earthworm populations and the soil microbiome. Furthermore, we correlate these effects to the cropping system and the management practice. Our results show the effects of multiple pesticide residues under different conditions on the soil ecosystem. As a result, we will present bioindicators that are sensible to multiple pesticide residues. These data can be used as a base for the development of new EFSA guidelines regarding tests for pesticide effects on the terrestrial environment.

4.10.P-Tu232 Towards a Better Protection of Soil - the PROSOIL Project & the Development of Soil Toxicity Criteria for the CLP Regulation

Thomas Gräff¹, Monika Hammers-Wirtz², Enken Hassold³, Pia Kotschik⁴, Ines Prutz⁵, Bjoern Scholz-Starke⁶, Felix Stibany, Dr.⁷, Andreas Toschki⁸, Peter Von der Ohe⁹ and Korinna Ziegler¹⁰, (1)German Environment Agency (UBA), Dessau-Roßlau, Germany, (2)Research Institute gaiac, Germany, (3)German Environment Agency (UBA), Germany, (4)Umweltbundesamt / Federal Agency of Environment, Dessau, Germany, (5)German Environment Agency UBA, Germany, (6)darwin statistics, Aachen, Germany, (7)RWTH Aachen University, Germany, (8)gaiac - Research Institute for Ecosystem Analysis and Assessment, Germany, (9)Federal Environment Agency (Umweltbundesamt), Germany, (10)German Environment Agency (Umweltbundesamt), Germany

During the environmental hazard assessment for the soil compartment, ecotoxicity data on various organisms is generated and used in the context of different European substance legislations (e.g. REACH, pesticides, biocides, or pharmaceuticals). In order to categorize and better communicate the hazards of substances, the European Classification, Labelling and Packaging regulation (CLP) together with the international Globally Harmonised System (GHS) are central and overarching instruments across legislations. Despite the availability of soil ecotoxicity data, classification and labelling within CLP/GHS is currently based on aquatic toxicity criteria, i.e. defined regulatory threshold concentrations, solely. In the CLP context, it is assumed that existing criteria for aquatic organisms are conservative enough to sufficiently protect and inform on hazards for terrestrial organisms. Around 15 years ago, historic initiatives and proposals aiming at establishing terrestrial toxicity criteria for classification and labelling failed at the EU and UN level. Meanwhile, more ecotoxicity data became available. Building upon these developments, the PROSOIL project aimed at deriving toxicity criteria for soil organisms on a comprehensive data basis. As a first step, a comprehensive harmonised database of available ecotoxicity data for various soil organisms was compiled from regulatory repositories. The project focused on terrestrial organism groups potentially exposed to toxic substances via soil, i.e., plants, invertebrates (e.g., oligochaetes, collembolans, mites), and micro-organisms. Above-ground organisms such as bees, birds, or mammals were not considered. Secondly, toxicity ranges for different soil organism groups were analysed and possible toxicity thresholds were identified that might be used as toxicity criteria in the CLP context. Moreover, lists of 'candidate chemicals' were compiled that would be classified according to the proposed soil toxicity criteria. We come up with a proposal for soil toxicity criteria, which certainly warrants further discussions at EU level in particular in comparison to historic proposals.

4.10.P-Tu233 Comparison of Existing Methodologies Worldwide to Derive Retrospective Ecological Soil Protection Values: A CASE Study With Plant Protection Products

Gilda Federica Dell'Ambrogio¹, Mireia Marti-Roura², Janine Wong¹, Sophie Campiche¹, Marion Junghans³, Jean Mathieu Renaud¹ and Benoit J.D. Ferrari¹, (1)Swiss Centre for Applied Ecotoxicology, Switzerland, (2)Swiss Centre for Applied Ecotoxicology, Switzerland, (3)Swiss Centre for Applied Ecotoxicology EAWAG - EPF, Switzerland

The Swiss Federal Action Plan on risk reduction and sustainable use of Plant Protection Products (PPP) from 2017 has set the goal of reducing the environmental risk of PPP by 50% by 2027. In this context, it was established that ecotoxicological risk-based reference values (i.e. soil protection values) must be defined for PPP residues in agricultural soils. Although some methodologies for the derivation of soil protection values (SPV) for chemicals have already been proposed under different national or international regulations, most of them have mainly been applied for metals and commonly known organic pollutants. Only few have been used to derive values specifically for PPP. Available methodologies can be very different depending on the country and the regulatory context. In order to assess different performances of the methodologies to derive SPV for PPP residues in agricultural systems, four well-established methodologies used in retrospective soil risk assessment were used in two case studies. The considered PPP were diuron (herbicide) and fluazinam (fungicide). The applied methodologies were from the EU (EC, 2003), Canada (CCME, 2006), Australia (NEPC, 2013) and the United States US EPA (US EPA, 2005). For the same initial dataset, differences along the derivation process led to notable deviations in the final SPV (up to 6 orders of magnitude). One of the major factors responsible were differences in the data selection and in the quality evaluation process of the ecotoxicological data. As a consequence, different data subsets were used depending on the methodology. Also, the SPV extrapolation method (e.g. distribution or assessment factor method) differed between the tested methodologies. Our case studies further highlighted that the effect level considered acceptable can strongly vary depending on the protection goal of the SPV. Most approaches were traditionally developed for contaminated sites and persistent pollutants. Even though some methodologies considered agricultural land use in the derivation process, these ones were rarely applied to PPP (or PPP residues) and when it was the case, specific consideration for this kind of substances in an agricultural context are lacking. Although none of the tested methodologies could fully address the specific goals defined in the AP-PPP, some of them presented the potential to be adapted to consider PPP residues in agricultural fields.

4.10.P-Tu234 Soil Guidance Values: Towards the Long-Term Protection of Soil Quality From Effects of Plant Protection Product Residues in Swiss Agricultural Fields

Mireia Marti-Roura¹, Gilda Federica Dell'Ambrogio², Janine Wong², Sophie Campiche², Marion Junghans³, Jean Mathieu Renaud² and Benoit J.D. Ferrari², (1)Swiss Centre for Applied Ecotoxicology, Switzerland, (2)Swiss Centre for Applied Ecotoxicology, Switzerland, (3)Swiss Centre for Applied Ecotoxicology EAWAG - EPF, Switzerland

Plant Protection Products (PPP) are widely applied in Swiss agriculture and their impact on environmental health is of growing concern. In order to minimize the risk of PPP in the environment and promote their sustainable use, in 2017 the Swiss Federal Council approved an Action Plan for PPP (AP-PPP). PPP can reach the soil either by direct or indirect application and remain in the soil matrix over decades. Therefore, the persistence of PPP residues in the soil and their interaction with non-target soil communities has gained interest over recent years. In order to quantify the extent to which PPP residues affect beneficial soil organisms in in-crop areas, Soil Guidance Values (SGV) should be derived. SGV are intended to be ecotoxicological risk-based reference values (i.e., soil protection values (SPV)) to be used in conjunction with a biomonitoring program. Based on an extensive review of state-of-the-art methodologies for the derivation of SPV, we identified crucial points concerning PPP residues and agricultural land use, which are not covered by the existing guidelines. In this context, and based on the goals of the AP-PPP, the derivation process for SPV needs to be re-evaluated and adapted. For the derivation of SGV under the AP-PPP, data selection should primarily focus on biotests with soil organisms involved in the maintenance of relevant soil functions. Conflicts of objective may arise when the protection of non-target organisms interferes with the effects on the target organisms (e.g. protection of non-target plant species versus pest plant species under herbicide application). Ecotoxicity tests, endpoints and toxicity parameters should be representative of long-term effects (i.e. selection of population relevant endpoints and selection of the effect level). Suitable extrapolation methods have to be identified, especially since the scarcity of soil effect data is a recognized long-standing problem and a general cause of uncertainty for SPV. To this end, considerations and challenges towards a suitable and applicable derivation methodology for SGV are presented, emphasizing the aspects concerning soil quality in agricultural systems and the effect of PPP residues on soil organisms.

4.11 Natural toxins and biopesticides (Poster)

4.11.P-We206 Plant Toxins As WATER Contaminants - Which Are the Controlling Factors?

Hans Christian B. Hansen¹ and Thomas Bucheli², (1)Plant and Environmental Sciences, University of Copenhagen, Frederiksberg C., Denmark, (2)Agroscope, Switzerland

Most plants produce secondary metabolites or plant's specialized compounds that are toxic to humans. There are more than 200,000 of such bioactive compounds covering a huge diversity of molecular designs, chemical-physical properties, toxicities and modes of action. Plants produce these "chemical weapons" in their competition with other species, as regulators, and to defend themselves against pathogens or other stressors. Most of the plant toxins (PT) are produced in large quantities in the order of grams per square meter annually. Also, they are relatively polar and hence shows high mobility in the environment. Rain washoff, exudation and plant debris deposition transfer PT from plants to soil, from where they leach to aqueous recipients. The question is if the PTs are sufficiently stable along the track from plant to sink to eventually result in elevated concentrations in water reservoirs - surface water and groundwater - used for drinking water abstraction. Over the past 4 years we have conducted a Marie Curie ITN project with focus on natural toxins (plant toxins and cyanotoxins) and water contamination. The project called NaToxAq (<https://natoxaq.ku.dk>) has resulted in about 50 science papers on the topic. In this contribution we will present learnings and some of the main conclusions for PTs. Many new PTs have been found in natural waters including alkaloids, coumarins, flavanoids and terpenoids at concentrations typically in the ng/L to ug/L scale, and typically with peak concentrations during precipitation events. The fraction of total plant produced PT that leach is often low indicating that PT degradation in plant and in soil is extensive. Alkaloids (nitrogen containing natural compounds) has been identified as a group of prime interest in future studies as these compounds are produced by numerous crop and non-crop plants, some are very toxic and they degrade slowly. A crop-soil-water model (DAISY) has been adapted to describe production, transfer, degradation and leaching of the bracken toxin ptaquiloside.

4.11.P-We207 Comparing the Effects of Tannic Acid and Citronellol on the Physiological Profile of Soil Microbiota

Natalia Ferrando Lázaro¹, Cristina Gan-Oria¹, Guillermo Abajo¹, Antonio Valenzuela¹, M Rosa Pino², Diego Ballester¹, Eva Terrado¹ and Elisa Langa¹, (1)Universidad San Jorge, Spain, (2)San Jorge University, Zaragoza, Spain

Citronellol is a terpene with a wide range of chemical properties that suggest its potential to replace commercial products, used as mosquito repellents and/or larvicides. Tannic acid, on the other hand, belonging to the polyphenol family, has a reported antimicrobial activity, effective against different bacteria and fungi, which justifies its use as a preservative in the food industry. Despite such products from natural origin are credited with health safety, their promising application as substitutes for commercial antibiotics calls also for a rigorous assessment of their impact on the environment. This study assesses the ecotoxicity of Citronellol and Tannic Acid on a crop field microbial communities collected from CITA's facilities in Zaragoza, Spain. Both were measured using Biolog EcoPlates®, which contain 31 of the most frequent carbon sources found in crop soils and forests. Their capacity to degrade carbon sources was estimated with the averaged well colour development (AWCD). Five different concentrations of tannic acid (0.2, 2, 20, and 200 and 2000 µg/mL) and of citronellol (0.5, 12.5, 25, 37.5 and 50% in volume) were evaluated and their AWCD values were compared. The results revealed that tannic acid reduced microbial growth even at the lowest concentration in soil environments progressively, being 2 µg/mL the less harmful concentration. By contrast, all assayed concentrations for Citronellol resulted toxic for soil microbiota, affecting microbial community in a similar dramatic way. Without ruling out the possibility of considering them as future pesticides, given their proven antibacterial efficacy, it is also critical to determine their medium-long term impact on ecosystems before making decisions about its commercialization. The authors thank the financial support of Gobierno de Aragón: Departamento de Ciencia, Universidad y Sociedad del Conocimiento (Group E39_20R).

4.11.P-We208 Effects of the Tannic Acid on the Physiological Profile of River Microbiota

Guillermo Abajo¹, Cristina Gan-Oria¹, Natalia Ferrando Lázaro¹, Antonio Valenzuela¹, Eva Terrado¹, Elisa Langa¹, Diego Ballesterio¹ and M Rosa Pino², (1)Universidad San Jorge, Spain, (2)San Jorge University, Zaragoza, Spain

Tannic acid is a polyphenol, found in many plants and their extracts, mainly from their barks and roots. Its emerging utility as an antimicrobial agent and synergist with commercial antibiotics raises the need for an assessment of its long-term toxicity to the environment. This study evaluated the ecotoxicity of tannic acid on freshwater microbial communities from the Gállego river in Zaragoza, Spain. Biolog EcoPlates[®], containing 31 of the most common carbon sources found in forest and crop soils, were used to calculate both the averaged well colour development (AWCD), as an indicator of the entire capacity for degrading carbon sources, and the assortment of carbon sources, as an indicator of the physiological diversity. Four different concentrations of tannic acid (0.2, 2, 20, and 200 µg/mL) were assayed. The results showed a slight increase in AWCD and metabolite consumption for lower concentrations (0.2 and 2 µg/mL), followed by a progressive decrease for higher concentrations (20 and 200 µg/mL). Namely, a decrease in the ability to metabolize, polymers, carbohydrates, and amines/amides was measured. Therefore, this assessment of the metabolic profiles showed that river bacteria communities were affected by tannic acid, suggesting long-term modifications in the structure of river communities. This work allows us to better understand the impact of tannic acid on the environment, a necessary starting point for its future application as an environmentally safe alternative or adjuvant to commercial antibiotics. *The authors thank the financial support of Gobierno de Aragón: Departamento de Ciencia, Universidad y Sociedad del Conocimiento (Group E39_20R).*

4.11.P-We209 Plant Alkaloids in the Soil and Water Environment

Bjarne W. Strobel, University of Copenhagen, Denmark

Alkaloids are common compounds produced in plants species of many plant families. Plants appear as single or scarcely distributed in some areas, and as dense populations with high numbers of plants in other areas. The function of the alkaloids are multiple and often associated with regulation or defense against environmental stressors and pests threatening the plant. Competition and evolution create diversity in the chemical structure of the alkaloids, and most plants species present complex mixtures of alkaloids with specialized branches and side groups. The variety of structures of alkaloids present complex mixtures in the plant tissue, and hence the loss and exudation of alkaloids to the soil and water environment is a complex mixture that varies with time. The composition and occurrence varies over time and as response to with environmental stressors. The uncertainty or variation in chemical composition demonstrates the challenges known from the “Unknown or Variable Composition, Complex Reaction products and Biological Materials” (UVCBs) behavior in the environment. Experimental results from plant alkaloid research in field sites studies and lab studies are presented to illustrate current knowledge about occurrence and dynamics for a range of plant alkaloids like pyrrolizidine alkaloids, quinolizidine alkaloids and indole alkaloids. The chemical diversity within these types of alkaloids present in plant tissue over seasons, and exudates to rhizosphere soil and leached to soil solution and nearby freshwater resources is presented. The retention in soil types and transport routes are illustrated with experimental results from the recent Marie Curie ITN project “NaToxAq” Natural Toxins and Drinking Water Quality - From Source to Tap (<https://natoxaq.ku.dk>) with focus on toxins and water contamination. Plant communities of common ragwort, comfrey and butterbur in natural and set-aside areas are studied in connection with streams and rivers. Agricultural crops are represented by sweet lupines as a future valuable protein crop gaining popularity as potential crop adopted to the changing climate, and soybean represent the well-known agricultural crops. Alkaloids impact soil and freshwater and this presentation draw the picture across types and complex mixtures alkaloids in common plant communities.

4.11.P-We210 Ecotoxicological Concerns Associated With Complex and Variable Nature of Botanical Active Substances

Robin James Blake, Compliance Services International, United Kingdom

Botanical active substances, or plant extracts/oils, have increased in popularity in recent decades for pest and disease management as alternatives to conventional, synthetic pesticides. According to the SANCO and OECD definition, “a ‘botanical active substance’ consists of one or more components found in plants and obtained by subjecting plants or parts of plants of the same species to a process such as pressing, milling, crushing, distillation and/or extractions. The process may include further concentration, purification and/or blending, provided that the chemical nature of the components is not intentionally modified/alterd by chemical and/or microbial processes.” Whilst this biological origin may lead to a more favourable ecotoxicology profile compared to synthetic chemical active substances, natural occurrence does not imply that the use of such botanical active substances is always without risk and their complex and variable nature can make registration equally challenging. In the EU, botanical active substances fall under the scope of the Plant Protection Products Regulation (EC) No 1107/2009. It is often not technically feasible to radiolabel complex botanical active substances and therefore the SANCO guidance allows one or more component(s) to be identified as analytical “lead component(s)” and traced in the technical grade material. Lead component(s) can be the most frequently occurring substance(s) as demonstrated by analytical techniques or be the most biologically active component(s). However, the identity of the botanical active substance is considered to be the sum of all the components, not just the lead component(s), and this must be considered in the risk assessments. Therefore, it is feasible that other components are present that show a greater ecotoxicological concern compared to the lead component(s). This poster discusses real-life examples and strategies including (Q)SAR, concentration additivity, literature and comparison of other exposures with pesticide exposure to help alleviate ecotoxicological concerns.

4.11.P-We211 Biocontrol of Xylella and Its Vector in Olive Trees for Integrated PEST Management (BIOVEXO)

Angeles Jos, Universidad de Sevilla, Spain

Olive cultivation in southern Europe is a long-standing tradition, one that has shaped the environment and the culture in many

European countries. However, there is a growing threat to this part of history. *Xylella fastidiosa* is a pathogen that is increasingly causing diseases on olive trees and various other crops in the Mediterranean region. It wiped out a number of olive groves in Italy and Spain in only a few years, while infections have also been detected in France and Portugal. Unfortunately, the climate of the southern European Union is ideal for *Xylella*, and if the disease continues to spread, it could reduce yields of olive harvests by as much as 70 %. Currently, there are no pesticides available on the market proven to be effective against *Xylella*, which is spread by xylem-feeding insects – notably the spittlebug – common in the Mediterranean climate. Farmers are often forced to destroy infected plants or use chemical insecticides, damaging incomes as well as organic production. BIOVEXO will demonstrate environmentally sustainable and economically viable plant protection solutions that can be deployed as a method of integrated pest management. BIOVEXO's approach involves developing biopesticides that target *Xylella* – X-biopesticides – and those that target the insects spreading the disease – V-biopesticides. The X-biopesticide candidates might be based on an onion extract (a food industry by-product) and antagonistic bacteria; the V-biopesticide candidates might be based on a plant extract (also a food industry by-product), a fungus and a microbial metabolite. Funding: This project has received funding from the Bio-Based Industries Joint Undertaking (BBI-JU) under grant agreement no. 887281. The JU receives support from the European Union's Horizon 2020 research and innovation programme.

4.11.P-We212 Effect of Biopesticide Application on Thiamethoxam Uptake on Maize and Respective Residues on Guttation

George Adamidis¹, Dimitrios Arabatzis¹, Paraskevas Parlakidis¹, Christos Alexoudis¹ and Zisis Vryzas², (1)Democritus University of Thrace, Greece, (2)Agricultural Development, Democritus University of Thrace, Orestiada, Greece

Pesticides are mainly used in agriculture as weed, insect, and fungi control agents and represent important tools in pest management. Low-risk pesticides are proposed as another alternative environmentally friendly, non-chemical approach, which could be included in an integrated pest management schedule. The results of numerous studies showed that the application of biopesticides and arbuscular mycorrhizal fungi (AMF) formulations to crops leads to their symbiosis with the root systems of plants. AMF colonization has many beneficial impacts on crops such as increased nutrient uptake, drought resistance to pathogens, improved root physiology and enhanced plant growth. However, various factors can prohibit AMF to colonize plant roots including high application rates of chemical pesticides and fertilizers, tillage hyphal networks and selective breeding of crop varieties. On the other hand, AMF has also been shown to have unwanted impacts on the plant physiology and composition of beneficial bacterial communities including changes to the chemical composition of root exudates and competition for inorganic nutrients, respectively. The aim of this study was to detect and compare the residue levels of the neonicotinoid insecticide thiamethoxam on guttation when the maize is grown by the use of arbuscular mycorrhizal fungi (AMF). A two-year experiment (2020 & 2021) was conducted under pot conditions. A maize inbred line was selected for both years. The neonicotinoid insecticide Actara® (Syngenta Hellas) was applied alone and in the combination with a commercial formulation containing a mixture of *Trichoderma harzianum* and arbuscular mycorrhizal fungus. In the first application, the insecticide was applied in its recommended dose, while during the second application a double dose was used. The pots were thrice replicated. Guttation was collected in 6 different samplings, in the first morning hours. A HPLC-DAD analysis was used for determining the residue levels of thiamethoxam on guttation. The results revealed that guttation of E treatment of 2020 had residue levels ranged from 0.24 $\mu\text{g/g}$ (1st sampling) to 0.78 $\mu\text{g/g}$ (6th sampling), while guttation of the same treatment of 2021 had residue levels ranging from 0.56 $\mu\text{g/g}$ (1st sampling) to 0.19 $\mu\text{g/g}$ (6th sampling). Results of the 2020 cultivated plants treated with *Trichoderma harzianum* and arbuscular mycorrhizal fungus showed residue levels ranging from 0.26 $\mu\text{g/g}$ (1st sampling) to 1.1 $\mu\text{g/g}$ (6th sampling), while in 2021 of the same treatment showed results ranging from 0.11 $\mu\text{g/g}$ (1st sampling) to 1.66 $\mu\text{g/g}$ (6th sampling). These results suggest that plants that were grown by the combined use of *Trichoderma harzianum* and AMF (treatment M), developed a more dense and extensive rhizosphere that was able to uptake higher quantities of thiamethoxam. The combined application of biopesticides and conventional pesticides may alter the fate and lower doses can be considered in order to prevent the bee colony collapse disorder.

4.12 New developments in the characterization, testing and assessment of complex substances (MCS,UVCBs & MOCS)

4.12.T-01 In Silico Structure Elucidation & FAIR Information Management for Improved UVCB Assessment

Adelene Lai¹, Nina Sachdev², Alex Clark³, Marc Fernandez⁴, Leah McEwen⁵, Alexander Okonski⁴, Katrina Sullivan⁴ and Emma Schymanski¹, (1)University of Luxembourg, Luxembourg, (2)Wellesley College, United States, (3)Collaborative Drug Discovery, United States, (4)Environment and Climate Change Canada, Canada, (5)Cornell University, United States

Substances of Unknown or Variable composition, Complex reaction products, or Biological materials (UVCBs) are multi-constituent mixtures that make up approximately a quarter of international chemical registries. Many are high production, import, and usage substances like petroleum, essential oils, surfactants, and solvents. However, despite this high environmental relevance, fundamental information gaps pertaining to substance identity and properties persist. These gaps pose challenges to assessing their hazards, exposure, fate, and potential risks to the environment and human health. In most cases, basic structural and compositional information is not available, which hinders the development of appropriate testing strategies, applying quantitative structure-activity relationship models, fate and exposure modelling, and regulatory decision making. Moreover, what little information that does exist is typically not easily findable, accessible, interoperable, or reusable (FAIR), and is organised using data formats ill-suited to representing these multi-constituent substances with multi-faceted information properties in a machine-readable way. Overall, information availability is inconsistent across both databases and substances within databases (dependent on respective registrants' submissions), and current standard reporting practices/formats of UVCBs' identities do not reflect this phenomenon in a way that supports incorporating uncertainty within UVCB risk assessment. This work to be discussed used cheminformatics

methods to address (i) the specific challenge of missing structure information and (ii) the wider issue of standardising UVCB substance information within databases. First, structure elucidation was achieved by manually searching databases and combining fragment structures while incorporating representative constituent concepts. Assigning structures to UVCB substance names in this way facilitated a real-world regulatory prioritisation exercise. Second, Mixture InChI was explored as a viable cheminformatics format to represent UVCB substances within databases. Various examples of these approaches have been proposed as strategies towards filling critical UVCB identity information gaps and FAIR information management of UVCBs. Together, these initiatives are intended to support risk assessment activities by increasing the availability and accessibility of UVCB substance information.

4.12.T-02 Characterization of Mixtures by Assessing Chemical Similarity

Alena Celsie¹, J. Mark Parnis¹, Trevor Brown², Alessandro Sangion³, James M Armitage⁴ and Jon Arnot⁵, (1)Trent University, Canada, (2)TNB Research, Canada, (3)ARC Arnot Research and Consulting Inc. and University of Toronto Scarborough, Canada, (4)AES Armitage Environmental Sciences, Inc, Canada, (5)ARC Arnot Research & Consulting Inc., Canada

Many commonly used consumer and industrial products are mixtures composed of multiple chemical constituents. Evaluation of human exposure requires knowledge of a substance's chemical properties; for example, inhalation exposure predictions require input of constituent partial pressures. Partial and total vapour pressures of mixtures may be calculated using Raoult's law, which assumes the various constituents do not interact with each other, *i.e.*, that the system behaves in an ideal manner and the activity coefficient for each component is 1. Depending on the specific mixture components present significant intermolecular interactions may occur; for instance, hydroxyl-containing chemicals may undergo significant hydrogen bonding. These interactions result in deviations from ideality, in which case Raoult's law does not accurately predict vapour pressures and more sophisticated solvation theory methods such as COSMOtherm or UNIFAC may be required. This study aims to assess vapour pressure deviations from ideality expected for different mixture types based on the similarity of mixture components. For a set of binary mixtures, chemical similarity scores were assigned to each solvent pair using 1) Abraham parameters and 2) sigma moments as descriptors. Vapour pressures predicted using Raoult's law and COSMOtherm were assessed using root-mean square error (RMSE) values. A graph of Raoult's law RMSE against similarity scores are shown to give a good correlation for both sets of descriptors, with $R^2 = 0.5579$ for Abraham parameters and $R^2 = 0.5761$ for sigma moments. Results indicate that chemical similarity scores may be a promising metric for assessing deviation from ideality for inhalation exposure.

4.12.T-03 CHANCES2: A Project to Identify Toxicity of a Highly Complex Mixture and to Simulate the Results In Silico

Paul Thomas¹, Pascal Bichere¹, Nicolas DELPIT², Lise Mata³, Mélanie Persillon³, Marine Canton⁴ and Sylvain Antoniotti⁴, (1)KREATiS, France, (2)Laboratoires des Pyrénées et des Landes, France, (3)Laboratoire des Pyrénées et des Landes, France, (4)Université Côte d'Azur, France

The Compartmentalised Hazard Assessment for Natural Complex Extracted Substances (type 2) or CHANCES2 project aims to provide greater certainty in the environmental toxicity assessment of Highly Complex Substances for which toxicity is difficult to characterise. The Type 2 Natural Complex Substances (NCS2) UVCB substances of which < 90% of the composition is known (and often << 50%). As well as having the same difficult properties as other NCS (*i.e.* variable composition and volatile and/or hydrophobic constituents), NCS2s contain a large fraction of resins, waxes, *etc.* which makes them particularly difficult to analyse in the laboratory. The aim of this investigation was to propose a new method of hazard assessment for an NCS2 resinoid with a fractionation approach as follows: - Block 1 (the simplest block): corresponds to the fraction of low to intermediate solubility, which is quite volatile. - Block 2: corresponds to the fraction of the more soluble and non- or less volatile constituents, and therefore potentially bioavailable. - Block 3 (the hardest block to characterise): comprising all the other compounds in the NCS2 (insolubles). This fraction is assumed to be inert (or virtually). Further to testing the NCS complete, and then the three fractions separately using acute and chronic testing, an attempt is made to "reconstitute the toxicity" using *in silico* prediction methods adapted for WAF testing as described in Bichere and Thomas (2021). The first step was to analytically separate and then define the fractions. In a second step the fractions (Blocks 1, 2 and 3) were tested using algae, daphnid acute/chronic studies. In parallel, as the analytically defined fractions became available, the WAF toxicities of the two fractions containing identifiable concentrations of constituents were calculated using the iSafeRat® calculator. Next, the results of the toxicity testing and the *in silico* predictions for the first two blocks were compared. Finally, the individual blocks from the test results and *in silico* predictions were collated and the results compared to the acute tests performed on the whole substance. One critical aspect was to ascertain that no chronic toxicity for algae or daphnids could be attained when testing the inert fraction, such that this block could then be subtracted from the hazard prediction of the WAF. The project is ongoing but initial studies have been highly encouraging. Final results are expected to become available in early 2022.

4.12.T-04 Using Weight of Evidence to Assess Degradation Potential of Hydrocarbon UVCB Solvents

Christopher Prosser¹, Craig Warren Davis² and Louise Camenzuli³, (1)ExxonMobil Biomedical Sciences, Inc., Annandale, NJ, (2)ExxonMobil Biomedical Sciences Inc., United States, (3)ExxonMobil, Belgium

When evaluating the environmental fate of a chemical, it is not uncommon to have a rich dataset from which a conclusion can be drawn. However, the larger the dataset, the more likely there may be conflicting data points. This is due to the inherent variability when working with biological systems, differences in experimental design, and human error. Furthermore, when evaluating degradation potential of a chemical, it must also be recognized that persistence is not an intrinsic property of the test substance itself but may be impacted by a number of factors such as (but not solely): test substance concentration, nutrient availability, source of inoculum and chemical bioavailability. For these reasons when many data points for a single substance exist, it is necessary to evaluate them collectively using a weight of evidence (WoE) approach. WoE is fundamentally a systematic approach

for assessing all data holistically, assigning value to each and making a decision using best professional judgment. Substances identified as Unknown or Variable composition, Complex reaction products or Biological materials (UVCB), in particular hydrocarbon solvents, often have multiple lines of environmental fate evidence that can be utilized when evaluating degradation potential. Hydrocarbon solvents comprise a large group of UVCB substances with carbon number ranges between C5 and C20, and may include normal alkane, isoalkane, cyclic and/or aromatic constituents. The majority are UVCB substances comprising 100's – 1000's of individual constituents. Because hydrocarbon solvents may have a robust dataset including whole substance data as well as data on individual constituents likely to be present in the solvent, a WoE is often necessary to conclude fate properties of a substance. Here we lay out an approach for using WoE to assess degradation potential of hydrocarbon solvents applying four lines of evidence: whole substance testing, data from individual constituents, abiotic data, QSAR models and biological plausibility. These lines of evidence are applied to a case study of a hydrocarbon solvent. Each line of evidence is discussed specific to the solvent, weighed and assessed based on the OCED guidance document for performing weight of evidence. While this approach addresses persistence evaluation, application of this approach can be used for other endpoints for various regulatory frameworks (e.g. REACH).

4.12.T-05 Regulating "More Than One Constituent Substances" Under the REACH Regulation

Romanas Cesnaitis¹, Vincent Bonnotet¹, Anu Kapanen², Michal Skowron¹, Marta Sobanska³ and Chrystele Tissier⁴, (1)European Chemicals Agency, Finland, (2)European Chemicals Agency - ECHA, Finland, (3)European Chemical Agency, Helsinki, Finland, (4)ECHA-European Chemicals Agency, Finland

1. Introduction Regulating substances with more than one component referred also as “*more than one constituent substances (MOCS)*” (i.e. UVCBs, mono-constituent substances with impurity(ies), and multi-constituent substances with or without impurities) is challenging, as can be associated with (1) the large number of constituents, (2) the composition may be (partially) unknown and/or (3) the composition of the substance may be variable (e.g., seasonal and temporal variation in sourcing of raw materials). Therefore, it is important to, where needed, further develop approaches and guiding principles for the assessment and regulation of these substances. 2. Results and discussion Initial analyses by ECHA revealed that only for ca. 40 % of the UVCB substances registered under REACH a detailed chemical composition could be derived. Recently ECHA has applied some further categorisation of these UVCBs looking at the presence of chemical functional groups within these UVCBs as well as using the available information at composition level. **1. 2. MOCS**, while being substances, are chemically similar to mixtures, so a similar classification approach as for mixtures may need to be considered for MOCS. For the PBT and risk assessments several methodologies are available: *known constituents approach, fraction profiling, whole substance approach or combination of approaches* (e.g. petroleum substances, natural complex substances and inorganic UVCB substances). Community wide regulatory risk management measure has to clearly identify substances falling under the scope of the measure to ensure that (i) industry is able to comply with their obligations, and (ii) authorities can enforce the regulatory measures. The development of further understanding on which regulatory risk management tools are most appropriate to address MOCS is ongoing among authorities. 3. *Table 1 could look like this* Conclusions No unique assessment methodology can be recommended as MOCS can be very diverse. ECHA and industry have developed various guidance documents and tools to facilitate the assessment of those substances. However, there is a need to further develop a common understanding between authorities and industry on the hazard data needed, on how they could be generated and on regulatory risk management actions that can be initiated for MOCS containing constituents of concern. Work is ongoing on those different points in ECHA with the aim to provide more guidance to both industry and authorities on how to handle those complex substances.

4.12 New developments in the characterization, testing and assessment of complex substances (MCS,UVCBs & MOCS) (Poster)

4.12.P-We213 Biodegradation Assessment of UVCBs: Two-Dimensional Gas Chromatography With Peak Tracking of Two Petroleum Substances for Mapping Biodegradation Half-Lives

Lisbet Sørensen¹, Mari Creese¹, J. Samuel Arey², Odd Gunnar Brakstad¹, Deni Ribicic¹, Jonas Gros³, Delina Lyon⁴, Aaron Redman⁵, Louise Camenzuli⁶, Neil Wang⁷, Alberto Martin-Aparicio⁴ and Andy Booth⁸, (1)SINTEF Ocean, Norway, (2)Oleolytics LLC, United States, (3)Independent Consultant, Germany, (4)CONCAWE, Belgium, (5)Exxon Mobil Biomedical Sciences, Inc., United States, (6)ExxonMobil, Belgium, (7)TOTALENERGIES, France, (8)Climate and Environment, SINTEF Ocean, Trondheim, Norway

Biodegradation is a major removal process for petroleum substances released to the environment, and is controlled by the type of microbial activity and chemical structures present. Most hydrocarbon constituents have the potential to degrade. However, Unknown or Variable composition, Complex reaction products or Biological materials (UVCBs), such as petroleum substances pose a challenge for assigning constituent biodegradation half-lives, since they usually contain thousands of constituents. Only a few hundred constituents are readily quantified in petroleum substances with conventional one-dimensional gas chromatography techniques (e.g. GC–MS), often representing a small fraction of the total substance mass. Two-dimensional GC coupled to a flame ionization detector (GC×GC–FID) can separate and quantify thousands of constituent peaks in petroleum substances. However, matching peaks corresponding to the same constituent(s) on different chromatograms is challenging. We used advanced data-handling algorithms to track the mass changes in constituent(s) peaks across chromatograms corresponding to 7 time points in a laboratory-based biodegradation experiment on two dispersed middle distillate Gas Oils. Several steps were applied: baseline correction; automated peak delineation and peak integration; correction of peak tables for evaporative losses incurred by sample concentration; peak table normalization; peak table alignment; peak tracking; and primary biodegradation half-life calculations. The method was applied to dispersions of the two different Gas Oils that were biodegraded in rotating carousels at 13°C, using

natural non-amended seawater and low oil concentrations (2-3 mg/L). Samples were sacrificed in triplicate over 0–64 d. Hundreds to thousands of peaks were tracked, an order of magnitude more than traditional approaches. We confirmed known biodegradation patterns of oil compounds and extended our understanding to peaks not investigated by traditional methods. Rapid primary biodegradation was observed among the saturated and aromatic hydrocarbons, whereas biomarkers were conserved or show long half-lives. Overall, ~95% of the mass of tracked peaks was degraded during the 64-d experiment. Microbial community analyses showed rapid initial emergence of alkane-degrading bacteria, followed by a community shift after 14 d towards aromatic hydrocarbon degraders and heterotrophic bacteria, the latter associated with utilization of byproducts of oil degradation.

4.12.P-We214 Improving Prediction of Hydrocarbon Biodegradation in Aquatic, Soil, & Sediment Systems Using System Parameterization & Machine Learning

Craig Warren Davis¹, Louise Camenzuli², David M Brown³, Christopher Hughes⁴, Delina Lyon⁵, Alberto Martin-Aparicio⁵ and Aaron Redman⁶, (1)ExxonMobil Biomedical Sciences Inc., United States, (2)ExxonMobil, Belgium, (3)Ricardo, United Kingdom, (4)Ricardo Energy & Environment, Chester, United Kingdom, (5)CONCAWE, Belgium, (6)Exxon Mobil Biomedical Sciences, Inc., United States

Evaluation of chemical degradation processes, particularly, biodegradation, is a key element of chemical regulatory management around the globe. Technical complexity and costs associated with environmental biodegradation testing, particularly for UVCB substances, necessitates the advancement of non-testing methods (e.g., quantitative structure-property relationships (QSPRs)). A critical limitation of current models is the inability to incorporate test system and environmental conditions into predictions, leading to uncertainties in model relevance and reliability. This work highlights a novel model (HC-BioSIM) for predicting primary degradation rates (DT50s) of hydrocarbons integrating chemical structure as well as system-dependent parameters, using an expanded database of high-quality petroleum hydrocarbon (HC) DT50 data in water, soil, and sediment systems (N = 728, 1033, & 838, respectively). The HC-BioSIM model (RMSE = 0.34, 0.48, 0.57; R² = 0.52, 0.56, 0.68) significantly outperformed BioHCWin (RMSE = 0.75, 1.2, 0.89; R² = 0.17, 0.13, 0.38) in water, sediment, & soil, respectively. Average errors in predicted DT50s were reduced by 2.5x, 3.9x, & 2.6x. No significant bias as a function of HC class, carbon number, or test system parameters were observed. Finally, k-fold cross validations demonstrated low variability in model performance (R², RMSE) as well as parameter usage/importance. This strongly supports a high degree of generalizability of the model for application to external data. Additionally, the HC-BioSIM models provide improved accuracy of persistence categorization, with correct classification rates of 97%, 90%, & 85% for water, sediment, & soil compartments, respectively. This represents a significant improvement over the existing BioHCWin model (using intermedia extrapolation factors). For the first time, system-specific and environmental effects on the biodegradation of petroleum HCs can be quantitatively evaluated in water, sediment, & soil systems. The model reduces uncertainty and provides a better basis for assessment of environmental degradation for hydrocarbon substances. The model can be applied broadly across regulatory frameworks for risk management. The curation of high quality sediment & soil databases improves understanding of the relative persistence properties of hydrocarbons between environmental media, including assessment of the intermedia extrapolation factors used in persistence assessments and exposure models.

4.12.P-We215 Developing Guidance to Support the Persistence Assessment of Complex Substances - Challenges, Solutions and Case Studies

Christopher Hughes¹, Megan Griffiths, MSc², Emma Pemberton², David M Brown³, Eleonore Delouvrier⁴, Stefan Hahn⁵, Dieter Hennecke⁶, Graham Whale⁷, Michael Klein⁸ and Judith Klein⁹, (1)Ricardo Energy & Environment, Chester, United Kingdom, (2)Ricardo Energy & Environment, United Kingdom, (3)Ricardo, United Kingdom, (4)Ricardo Energy and Environment, United Kingdom, (5)Fraunhofer ITEM, Hannover, Germany, (6)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (7)SHELL, United Kingdom, (8)Fraunhofer IME, Germany, (9)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany

Persistence assessment is a cornerstone of chemical hazard and risk assessment and chemical regulation. However, the established frameworks under which chemicals are assessed for persistence and prioritised for further regulatory action have ongoing challenges in their implementation. Complex substances, also known as substances of Unknown or Variable composition, Complex reaction products or Biological materials (UVCBs), are uniquely challenging for persistence assessment. Their compositional complexity and variability can present significant problems for testing and reaching regulatory conclusions. For example, when testing is carried out on whole test substances, concerns have been raised whether the observed biodegradation reflects all constituents of the UVCB, making it difficult to draw a persistence conclusion. Questions also arise as to how the ever-increasing requirements for evaluating mono-constituent substances under existing frameworks should be applied to substances which contain many individual relevant constituents. UVCBs are very broad classes of substances, with widely varying compositional characteristics and complexity. It is evident that there is a need for further guidance to support routine regulatory assessments for complex substances. In this presentation the work of the Cefic-LRI ECO52 project to address these challenges will be presented. Information to support the persistence assessment of UVCBs has been developed to build on that currently documented in regulatory guidance. This has been based on a comprehensive review and consolidation of available information from scientific literature, and the practical experience of the ECO52 project team. UVCBs as a class of substances have been defined in terms of their types and characteristics, with examples. The specific challenges around assessing UVCBs, from both a testing and persistence assessment perspective have been detailed. The presented guidance expands on the ECHA UVCB assessment approach, incorporating novel approaches and developments from the literature, illustrated with case studies. It is envisaged that this information will prove useful to carry out persistence assessments of UVCBs as part of future routine regulatory work. It is clear that persistence assessment of UVCBs remains extremely challenging. Ultimately, bespoke approaches are required that incorporate additional lines of evidence and balance the demands for data with what is practically achievable.

4.12.P-We216 PetroRisk Version 8: Improved Exposure and Risk Assessment for Hydrocarbon UVCBs Using KNIME
Yves Verhaegen¹, Neil Wang², Louise Camenzuli³, Carolina Di Paolo⁴, Craig Warren Davis⁵, Aaron Redman⁶, Alberto Martin-Aparicio¹ and Delina Lyon¹, (1)CONCAWE, Belgium, (2)TOTALENERGIES, France, (3)ExxonMobil, Belgium, (4)Shell International, Netherlands, (5)ExxonMobil Biomedical Sciences Inc., United States, (6)Exxon Mobil Biomedical Sciences, Inc., United States

Petroleum substances (PS) contain an indeterminably large and variable number of different constituents, thereby complicating the environmental exposure and risk assessment (ERA) under REACH. ConcaWE's PetroRisk tool facilitates the ERA for such complex substances in line with ECHA Guidance. PetroRisk applies the Hydrocarbon Block Method to extrapolate substance compositional information to concentrations of thousands of representative constituents. For each constituent, the physico-chemical, partitioning and degradation properties, as well as Predicted No Effect Concentrations (PNEC), are embedded in the model in an open database. Subsequently, release estimates, Predicted Environmental Concentrations (PEC), and risks are quantified for each constituent individually. PECs are estimated by multiplying the releases to air, wastewater and soil from each Identified Use (IU) with constituent specific Fate Factors (FF). A use-independent FF database, generated using batch versions of the SimpleTreat and SimpleBox models, is embedded in PetroRisk, thereby avoiding the implementation of these complex multimedia partitioning tools into the model. The resulting constituent PECs are divided by the respective constituent PNECs to obtain Risk Characterization Ratios (RCR). All constituent RCRs are summed up to represent the substance risks resulting from each IU. PetroRisk has now been transcribed into a KNIME workflow. Compared to the previous Microsoft Excel-VBA based PetroRisk versions, the KNIME environment provides a more visual, traceable, and extendable environment, allowing the model to run in batch mode and facilitating the analysis of intermediary data, the communication of results to stakeholders, and debugging. The improved FF concept now provides the user the possibility to refine the exposure assessment. PetroRisk further assists the user in refining the assessment, by ranking emissions according to their contributions to each RCR, and it can implement an optimized set of Risk Management Measure (RMM) removal efficiencies to adequately mitigate undesired risks. Overall, version 8 further simplifies the ERA of complex substances and provides much more support to the user to refine the risk assessments.

4.12.P-We217 Examples of Refined BCF Assessment for Five Surfactants: In Vitro, In Silico, and In Vivo Data
Steven Droge¹, James M Armitage², Jon Arnot³ and Michael McLachlan⁴, (1)Wageningen Environmental Research (Alterra), Netherlands, (2)AES Armitage Environmental Sciences, Inc, Canada, (3)ARC Arnot Research & Consulting Inc., Canada, (4)Department of Environmental Science, Stockholm University, Stockholm, Sweden

Surfactants often occur in complex technical mixtures and fall outside the applicability domain of test guidelines and models. A key factor hampering risk assessment efforts for surfactants, is that there are often no, or highly uncertain, octanol-water partition coefficients (Kow). Since many surfactants are produced in high tonnage ranges, information about the bioconcentration factor (BCF) it is required. Most surfactants contain long hydrophobic alkyl chains, and may therefore bioconcentrate above regulatory BCF thresholds. The CEFIC project ECO37 aimed to develop a scientifically sound fish BCF assessment strategy for surfactants that does not rely on Kow. The experimental part of ECO37 included both sorption studies and in vitro assays, as well as in vivo BCF studies, aiming to collect consistent data on systematic series of anionic and cationic surfactants. These data should support the development of mechanistically-based models of surfactant bioconcentration. The membrane-lipid/water distribution ratio (D_{MLW}) is proposed as an experimentally feasible alternative to Kow. For ionic surfactants, phospholipids are the target lipid phase in tissues. In vitro S9 clearance assays with liver extracts from rainbow trout (RT-S9) combined with in vitro-in vivo extrapolation can be used to derive the whole body elimination rate via biotransformation. A tiered BCF assessment scheme for surfactants is proposed, with a baseline partition screening step based on D_{MLW} ($BCF_{baseline}$), and further refinement options to be considered if the $BCF_{baseline}$ is above a regulatory threshold. The current presentation shows the experimental data (in vitro vs. in vivo) and model outcomes for 5 different surfactant examples: 1) a non-biotransformed surfactant (PFOS), for which the screening $BCF_{baseline}$ step is indicative of in vivo BCF; 2) a rapidly biotransformed neutral surfactant (AEO); 3) a rapidly biotransformed anionic surfactant (LAS); 4) pH dependent bioconcentration of an ionizable amine based cationic surfactant (alkyldimethylamine); 5) gill permeation limited BCF for a permanently charged cationic surfactant (alkyltrimethylammonium). These examples display some shortcomings and challenges of the proposed refinement options for BCF assessment and the need to reduce uncertainties in approaches to estimate biotransformation (in vitro/IVIVE, in silico QSAR) to support regulatory acceptance.

4.12.P-We218 A Baseline BCF Screening Approach and Refinement Options for Surfactants
Steven Droge¹, James M Armitage², Jon Arnot³ and Michael McLachlan⁴, (1)Wageningen Environmental Research (Alterra), Netherlands, (2)AES Armitage Environmental Sciences, Inc, Canada, (3)ARC Arnot Research & Consulting Inc., Canada, (4)Department of Environmental Science, Stockholm University, Stockholm, Sweden

Surfactants are experimentally challenging chemicals leading to uncertainty in chemical assessment. They often are UVCB mixtures and fall outside the applicability domain of test guidelines and models. A key factor hampering adequate modelling efforts is that there are often no, or highly uncertain, octanol-water partition coefficients (Kow) for surfactants. For some surfactant types, fish bioconcentration factors (BCF) have been measured. BCF values for a variety of nonionic AEO and anionic LAS surfactants are relatively low, due to demonstrated rapid biotransformation. However, BCF is also demonstrated to increase for homologs with more hydrophobic tails. For cationic and zwitterionic surfactants, BCF data are nearly absent. Since many surfactants are produced in high tonnage ranges, and often contain long hydrophobic alkyl chains, reliable model predictions are needed to assess whether the BCF of untested surfactants are potentially above B thresholds, requiring additional (experimental) data. The CEFIC project ECO37 focused on developing a scientifically sound fish BCF assessment strategy for surfactants. The

first aim was to establish a partitioning based BCF screening estimate (BCF_{baseline}) using an experimentally feasible sorbent, equivalent to the Kow approach. Consistent series of membrane-lipid/water distribution ratios (D_{MLW}) are now available for 26 types of surfactants, for a total of ~80 individual surfactant structures. For ionic surfactants sorption to storage lipid (fish-oil) was orders of magnitude lower than D_{MLW} , indicating that phospholipid is the target lipid phase. PFOS is not biotransformed, and hence chosen as a BCF_{baseline} benchmark: a D_{MLW} of 80 000 L/kg and 1.25% phospholipid results in BCF_{baseline} of 1000 L/kg, comparable to reported *in vivo* BCF values of 800-1300 L/kg. The second aim was to evaluate refinement options for the BCF_{baseline} and advanced modeling. Measured *in vivo* BCF for most linear chain surfactants tested on rainbow trout are 1-2 orders of magnitude lower than BCF_{baseline} , confirming a large influence of biotransformation as determined in *in vitro* assays. For permanently charged cationic surfactants (QACs), BCF_{baseline} is overestimated as tissue distribution experiments showed negligible gill permeation. Amine-based surfactants showed pH-dependent BCF, indicating a key role of the minor fraction of neutral species in gill passage, while the D_{MLW} of the ionic form drives internal partitioning.

4.12.P-We219 Environmental Hazard Assessment of Metal Salts of UVCBs

Rhiannon Smith¹, Oliver Tosic², Graham Whale³ and Becky Marks⁴, (1)wca, United Kingdom, (2)Rhenus Lub GmbH & Co KG, Germany, (3)SHELL, United Kingdom, (4)WCA Environment Ltd, United Kingdom

Environmental hazard assessment criteria are not directly applicable to UVCBs. Here we provide examples for zinc naphthenate, a metal salt containing more than 100 constituents. For biodegradation, QSARs predictions were modelled for representative structures, but metal salts are outside the model domain. Data were read across from naphthenic acids, but regulators identified concerns on reading across from organic components to metal salts due to potential differences in solubility, thus bioavailability, and toxicity. No data were identified for most representative structures and isolation of specific constituents is not feasible. Therefore, biodegradation testing was conducted on the substance itself. The method, adapted from OECD 301, was extended to 60 days and, due to its sticky nature, the test item was mixed with a solid inert carrier before adding to the vessel. It was not feasible to test at a concentration below the NOEC for zinc but results for 100 and 200 mg/L zinc naphthenate showed very little difference in degradation. Ready biodegradability tests are generally not applicable for UVCBs, as degradation may represent removal of only some constituents, therefore it is proposed that all data are combined into a weight of evidence approach, but it is unlikely to be feasible to assess directly against ready biodegradability criteria. Short-term aquatic toxicity tests on zinc naphthenate were conducted as water accommodated fractions and reported as nominal loading rates. Zinc and TOC were measured but specific analysis was not feasible due to the large number and low concentrations of constituents. The presence of zinc is likely to contribute to any toxicity so a T/D test was conducted which gave a 7-day zinc concentration of less than the zinc short-term ERV but a 28-day result above the long-term ERV. A number of approaches have been used to obtain information but it is not clear how this should be interpreted due to a lack of clarity in the current guidance. For metal salts, both the organic and inorganic components need to be considered but, for UVCBs, constituent-based approaches are often not feasible and fail to consider the combined effects and potential differences in bioavailability of constituents. There are limitations with whole substance data and samples should be representative of all potential compositions, which is difficult where compositions cannot be well defined, especially for substances such as zinc naphthenate, which are complex and difficult to characterise, test and analyse. Clear guidance on the assessment of similar substances is required.

4.12.P-We220 Using the RTGill-W1 Cell Line to Investigate Cytotoxic and Molecular Effects of Sediment Extracts From the Agbogbloshie Electronic-Waste Site

Kritika Mittal¹, Jingyun Zheng², Stéphane Bayen¹, Julius Fobil³ and Nil Basu¹, (1)McGill University, Canada, (2)McGill University Faculty of Agricultural and Environmental Sciences, Canada, (3)University of Ghana, Ghana

Electronic-waste (E-waste) sites are notoriously contaminated with complex chemical mixtures thus challenging environmental monitoring, management, and remediation activities. Additionally, there is increasing awareness that traditional whole animal based toxicity tests are resource-intensive, expensive, and unethical. Given that E-waste sites are typically situated in low- and middle-income countries that tend to be poorly resourced, there is a need to develop more efficient techniques for application in such settings. The objectives of the current study were to A) perform simultaneous targeted analysis and non-targeted screening of plastic related contaminants in extracts prepared from 35 soil samples collected at the Agbogbloshie E-waste site (Accra, Ghana; classified as upstream-6, downstream-2, community-3, trade site-8, dump site-13, and burn site-3) through liquid chromatography coupled to hybrid quadrupole time of flight mass spectrometry (HPLC-QTOF-MS) in full scan mode, and B) to characterize the cytotoxic and molecular effects of these extracts on the rainbow trout (RT) gill cell line RTgill-W1, following the OECD test guideline #249. High concentrations of bisphenol A were measured ranging from 96.80 ng/g (in upstream, downstream, and community) to 255.62 ng/g dry weight (in trade site, dump site, and burn site). Other plastic-related chemicals such as phthalates were also detected, and the concentration of dibutyl phthalate was up to 384.83 ng/g dry weight (in trade site, dump site, and burn site). Gill cells were exposed to concentrations equivalent to 9.38, 4.69, 2.34, 1.17, 0.59, and 0.29 mg dry weight of extract (eQsed)/ml. Many of the samples from the various site types caused a decrease in cell viability % at 9.38 eQsed/ml, for example, two upstream and two community samples (6.9 - 66%), five dump site samples (5.2 - 31.4%), the eight trade site samples (2.2 - 53%), and two burn site samples (59.6 - 77.4%). The trade site group was the most cytotoxic, and the most cytotoxic sample was trade site #8 with cell viability dropping from 74.2% to 2.2% at 0.29 to 9.38 eQsed/ml. Further chemical analysis, and exposures to examine molecular effects of the sediment extracts on the gill cells are underway. This work is expected to support ongoing efforts in establishing the use of efficient alternative testing strategies in ecotoxicology with a focus on developing methods for use in contaminated sites in under-resourced locations.

4.12.P-We221 A Practical Approach to Prioritize Hydrocarbon Solvent UVCB Constituents for PBT Assessment

Christopher Prosser¹, Craig Warren Davis² and Louise Camenzuli³, (1)ExxonMobil Biomedical Sciences, Inc., Annandale, NJ, (2)ExxonMobil Biomedical Sciences Inc., United States, (3)ExxonMobil, Belgium

Accurate assessment of Persistent, Bioaccumulative and Toxic (PBT) properties of chemical substances is critical for appropriate chemical management decisions. This is difficult for Unknown or Variable composition, Complex reaction products or Biological materials (UVCB) substances, such as hydrocarbon solvents, as existing test methods were designed for single, discrete chemical substances that are often water soluble. This presents challenges as to how best to account for and mitigate inherent uncertainty in evaluating petrochemical fate and hazard data. Hydrocarbon solvents comprise a large group of substances ranging in carbon number between C5 and C20 and containing normal alkane, isoalkane, cyclic and/or aromatic constituents. Here we present a multi-step approach to evaluate representative structures in order to prioritize “worst case” constituents for PBT testing. In this approach, persistence is evaluated first as this is a logical first step to assess PBT/vPvB properties and precludes the need for animal testing. In Step 1, representative structures are selected from the Petrorisk model library (~1500 individual structures) covering the carbon ranges and chemical classes relevant to hydrocarbon solvents. The structures are screened for available peer-reviewed biodegradation data. Structures that demonstrate ready biodegradation are removed from further analysis. In Step 2, remaining structures are assessed through three biodegradation QSAR models. Structures with P/vP results in two or more QSAR models are carried forward for additional analysis; structures identified in less than two QSARS are eliminated from further consideration. Step 3 includes consideration of available bioaccumulation data to eliminate structures with little or no bioaccumulation potential. The remaining structures are those that have been identified in two or more QSARs as P/vP and have either no bioaccumulation data, or bioaccumulation data indicating B/vB. These structures will be tested based on the integrated test strategy (ITS) for persistence, as laid out in the ECHA R11 guidance document. Any constituent where a P/vP conclusion can be drawn at the end of Step 3, will undergo further assessment for bioaccumulation and or toxicity in Step 4 until an ultimate conclusion on PBT/vPvB properties can be reached. We will present the layout, logic and challenges with this approach in identifying “worst case” constituents for PBT assessment.

4.12.P-We222 A Tiered Assessment Framework for Ecological Risk Assessment of Unknown or Variable Composition, Complex Reaction Products, or Biological Materials (UVCBs)

Sandrine Estelle Deglin¹, Marc Fernandez², Sarah Hughes³, Claire Phillips⁴, Gerald Thouand⁵, Antony Williams⁶ and Michelle Embry⁷, (1)ILSI Health and Environmental Sciences Institute (HESI), United States, (2)Environment and Climate Change Canada, Canada, (3)Shell Global Solutions (US), Inc., United States, (4)Cefas, United Kingdom, (5)University of Nantes, France, (6)U.S. Environmental Protection Agency, United States, (7)HESI, United States

Complex substances such as multi-constituent substances (MCS) and UVCBs usually result from the industrial processing or extraction of natural substances or from chemical reactions. Because of the nature of source materials, and the potential variability inherent to production processes, these substances can contain many, sometimes uncharacterized constituents, whose concentrations may vary. As a result, UVCB/MCS risk assessment presents unique challenges to product registrants and regulators alike. To address these challenges, the UVCB Committee of the Health and Environmental Sciences Institute is building an exposure-based tiered approach considering the minimum level of information required to perform a robust ecological risk assessment. The first step (Tier 0) considers basic and readily available substance characterization and exposure information. Characterization information includes substance specifications, quality assurance data, and basic chromatographic or elemental data, while exposure information includes use/importation volumes and end uses. Tier 0 information is evaluated to determine whether more characterization information might be needed for a preliminary assessment. This first tier is critical to allow the rapid screening of UVCBs which may or not need in-depth characterization. This framework was tested through the development of three case studies (Cedar Oil, Alkyl Dimethyl Benzyl Ammonium Chlorides, and Hydrogenated Resin Glycerol Ester), which revealed characterization of substance complexity and biodegradation as key steps. Substance complexity, which is likely to determine the needed depth of substance characterization, was defined as the combination of variability in constituent concentrations, diversity of constituent chemistries and chemical properties, and belonging to the applicability domain of existing test models. Also critical is the determination of when biodegradation should be evaluated, and whether it should be measured on the whole substance or representative structures. This approach, which is expected to ensure that efforts and resources deployed for UVCBs risk assessment match actual needs and help streamline the risk assessment process, will be presented and discussed, including the evaluation of substance complexity, biodegradability, and associated challenges. *This abstract does not necessarily represent the views or policies of the U.S. Environmental Protection Agency or CEFAS.*

4.12.P-We223 Use of Tritium Radiolabelled Chlorinated Paraffin Test Substances in Environmental Testing

Andrew Jaques¹, Peizhi Lian², Edward Schaefer², Thomas Federle³ and Richard Mariner⁴, (1)Chlorinated Paraffins Industry Association, United States, (2)Eurofins EAG Agrosience, LLC, United States, (3)Thomas W Federle LLC, United States, (4)Euro Chlor, Belgium

The evaluation of chlorinated paraffins (CPs) for environmental endpoints is a priority given recent reviews under the Stockholm Convention and various national chemical regulations. Environmental fate and toxicity testing of CPs is hampered by their very low water solubility, highly lipophilic nature, and compositional complexity, resulting in significant analytical challenges, even with sophisticated equipment and techniques. Tritium (³H) has been occasionally used in environmental fate testing, but not used previously for CPs. An advantage of ³H radiolabelling with CPs is that tritiation is random so radiolabelling occurs at multiple sites along carbon chains as well as in all constituents within the mixture. Also, it results in high specific activity facilitating testing at more realistic environmental concentrations. Moreover, any commercial CP product can be tritiated allowing for direct testing of products on the market. To date, two separate CP substances have been tritiated, n-tetradecane with 30% Cl (wt.) and a

C14-17 commercial substance (MCCP) with 52% CI (wt.). The first tritiated material was successfully used to confirm and monitor test substance concentrations in a sediment toxicity test (OECD 225). Liquid scintillation counting (LSC) was used to measure the disposition of the radiolabel in the test system and chromatographic techniques were used to determine levels of parent and any metabolites. This same analytical approach and the second material were used to determine the rate and extent of biodegradation of MCCP in activated sludge (OECD 314B). The results showed >90% loss of parent MCCP within 24 hrs and >96% mineralization to tritiated water after 28 days with early formation of transient polar metabolites. These techniques greatly simplified the chemical analysis and allowed for accurate readings and improved mass balances at much lower concentrations not previously attainable. Both of these studies are being used in ongoing evaluations of MCCP in Europe, UK, USA and globally.

4.13 Pharmaceuticals in the environment – New insights, regulatory needs and knowledge gaps (Part I)

4.13.T-01 Feasibility Study of an Active Substance-Based Review System ('Monographs') and Other Potential Alternatives for the Environmental Risk Assessment of Veterinary Medicinal Products

Susanne Schwonbeck¹, Stefan Hahn¹, Franziska Breuer², Carolin Brinkmann³, Agnes Vosen³, Marija Radic³, Rodrigo Vidaurre⁴, Joseline Alt⁴, Kim Oelkers⁵, Adrian Mezler⁶ and Carolin Floeter⁶, (1)Fraunhofer ITEM, Hannover, Germany, (2)Fraunhofer ITEM, Germany, (3)Fraunhofer IMW, Germany, (4)Ecologic Institute, Germany, (5)TEPPE Rechtsanwälte, Germany, (6)Hamburg University of Applied Sciences (HAW Hamburg), Germany

In the EU, the environmental risk of a Veterinary Medicinal Product (VMP) is assessed for the marketing authorisation in a tiered approach. This product-based ERA system has a number of drawbacks for applicants, competent authorities and other actors. To name only a few, these include test duplication for the same API, the inconsistent evaluation of the environmental risks of similar VMPs containing the same API, the fact that legacy VMPs (authorised before 2005) are not addressed and thus do not have an ERA in line with the guidelines, and the absence of a regular review of the existing risk assessments in view of scientific progress. Both scientific and policy discussions about the shortcomings of the current ERA framework for the authorisation of VMPs and potential alternatives have been ongoing for several years. This has led to the inclusion of Art. 156 in the Regulation (EU) 2019/6 (VMPPR), where a “feasibility study of an active substance based review system (‘monographs’) and other potential alternatives for the environmental risk assessment of veterinary medicinal products” is demanded. An interdisciplinary consortium has been awarded with the study (SANTE/2020/E5/013) which was commissioned by the European Commission’s Directorate General for Health and Food Safety. The study collected information from a systematic literature search and from exploratory interviews with stakeholders to identify sources of relevant evidence and possible data gaps. The data has been used to structure and define the inherent processes of each of the different review systems proposed. This was complemented with information from structured interviews and an online survey with selected stakeholders. The qualitative and quantitative data was analysed to provide answers to the study questions of the call, to evaluate the different review systems for their feasibility and to address inherent uncertainties as well as the advantages and disadvantages to meet the general EU goals. The “monograph system” and two alternatives were examined with regard to their possible impacts as well as their efficiency and effectiveness in achieving the objectives of the VMPPR. The outcome of the feasibility study shall assist the Commission in preparing a report to the European Parliament and Council examining the appropriateness and practicability of moving to a substance-based review system (instead of the current product-oriented review system) and proposing options for further policy action.

4.13.T-02 Advances in Simulating the Fate of Animal Drugs in the US Using VETPEC Modelling Suite

Andrew Miglino, U.S. Food and Drug Administration, United States

The United States (US) Food and Drug Administration (FDA) Center for Veterinary Medicine conducts prospective environmental risk assessments to evaluate the potential for significant environmental impacts to occur from the approval of new animal drugs. To date, drug sponsors have relied on third-party tools methods for conducting environmental exposure assessments or calculating predicted environmental concentrations (PECs) of animal drugs. Therefore, US FDA, in collaboration with the US Environmental Protection Agency (US EPA), developed the Veterinary Environmental Transport and Fate Models for Predicting Environmental Concentrations (VETPEC). The VETPEC models calculate PEC values for animal drugs in manure, soil, and water. The modeling suite provides a singular framework that offers the potential to address the regulatory needs described in FDA Guidance for Industry 89 and 166 (Phase I and Phase II Environmental Assessments, respectively), and will provide drug sponsors with an easy-to-use and consistent method to estimate PEC values for use in exposure and risk assessments. In VETPEC v1.0, screening, refined, and mixed-use watershed models have been developed for intensively-reared and pasture-raised livestock. These models consider major environmental fate pathways for animal drug residues including (1) runoff and erosion from manure amended cropland, (2) direct runoff from feed yards and (3) direct runoff from pasture to surface water. The VETPEC models utilize current animal characteristics and US agricultural practices based on US FDA animal scientists’ expert knowledge and information reported in state and producer guidance. As animal drugs approved by US FDA are not restricted to specific locations in the US, the VETPEC models account for differences in soil, weather, and industry practices by leveraging crop scenarios originally developed by the US EPA for model farms throughout the US to predict daily and summarized PEC values for a 50-year simulation. The determination of whether impacts are significant will be based on comparison of these PEC values to predicted no effects concentrations and/or probability of occurrence (i.e., only 1 of the 100 default scenarios may have impacts). VETPEC incorporates tools to aid in the assessment of significant effects, allowing for both the industry investigator and regulatory reviewer to expeditiously evaluate whether effects may occur, how often they may occur, and the proximity of adverse events.

4.13.T-03 Managing Active Pharmaceutical Ingredient (API) Emissions From Manufacturing - an Industry Approach

Samuel K Maynard¹, Todd Davidson², Elizabeth Girardi-Schoen³, Neil Parke⁴, Alison Nimrod Perkins⁴, Joan G. Tell⁵ and Paul Barnett⁶, (1)AstraZeneca, United Kingdom, (2)Bristol Myers Squibb, United States, (3)Pfizer, United States, (4)Eli Lilly and Company, United States, (5)Merck & Co., Inc., United States, (6)GlaxoSmithKline, UK

Active Pharmaceutical Ingredients (APIs) can be present in the environment, primarily as a result of patient use. Manufacturing of APIs and medicinal products can also result in releases of APIs, however, these have historically been considered to be minor in terms of global load [1]. Whilst there is little empirical evidence to confirm the global contribution of manufacturing discharges in surface waters, at a local level manufacturing discharges could contribute more to the overall load of API and this may be particularly evident on a temporal basis [2]. Importantly, these discharges from manufacturing are within the control of the pharmaceutical industry and as such industry has been working for many years to understand and manage the discharge of APIs to protect the environment. The Pharmaceutical Supply Chain Initiative (PSCI) is a group of pharmaceutical and healthcare companies who share a vision of better social, health, safety and environmental outcomes in the supply chain. As a part of this aim PSCI member companies have prepared case studies demonstrating the management of API discharges. This presentation will share a summary of the approach utilised by industry to assess these discharges along with a small number of these case studies to highlight the work being done at manufacturing sites to improve and reduce the risk posed from API releases from manufacturing sites. Discussion will also summarise potential uncertainties in such assessments and ongoing industry activities to improve assessment and management approaches. References [1] BIO Intelligence Service (2013), Study on the environmental risks of medicinal products, Final Report prepared for Executive Agency for Health and Consumers [2] Anliker, S.; Patrick, M.; Fenner, K.; Singer, H. (2020) Quantification of active ingredient losses from formulating pharmaceutical industries and contribution to wastewater treatment plant emissions, *Environmental Science and Technology*, 54(23), 15046-15056

4.13.T-04 Minimising Experimental Testing on Fish for Legacy Pharmaceuticals

Anja Coors¹, Andrew Ross Brown², Samuel K Maynard³, Alison Nimrod Perkins⁴, Stewart Owen³ and Charles Tyler⁵, (1)ECT Oekotoxicologie GmbH, Germany, (2)Exeter University, UK, (3)AstraZeneca, United Kingdom, (4)Eli Lilly and Company, United States, (5)University of Exeter, United Kingdom

Various prioritization approaches have been proposed to address the considerable lack of ecotoxicological data needed to assess the environmental risks of legacy active pharmaceutical ingredients (APIs). Minimising, and ideally avoiding, the use of intact vertebrates is an ethical obligation that holds particularly in the absence of a regulatory requirement for ecotoxicological testing as is the case for legacy APIs. Within the research project PREMIER (*Prioritization and Risk Evaluation of Medicines in the Environment*, funded by the Innovative Medicines Initiative 2 Joint Undertaking), ecotoxicological data for approximately 25 case study APIs will be generated. We have developed a decision tree to ensure that *in vivo* testing with fish is avoided for those legacy APIs where other data allow for reliable substitution. A verification dataset of 96 APIs was taken through the decision tree in order to evaluate its robustness (i.e., the number of APIs erroneously excluded from *in vivo* fish testing) and sensitivity (i.e., what proportion of APIs would be considered for *in vivo* fish testing). The proposed decision tree and supporting evidence will be presented and discussed in detail.

4.13.T-05 Recent Developments and Applications of the Exposure to Pharmaceuticals in the Environment, ePiE, Model

Francesco Bregoli¹, Thomas Austin² and Ad Ragas³, (1)Environmental Science, Radboud University Nijmegen, Nijmegen, Netherlands, (2)Reckitt Benckiser, United Kingdom, (3)Environmental Science, Radboud University, Nijmegen, Netherlands

Thousands of active pharmaceutical ingredients (APIs) are detected in surface waters and pose risk to biota and human health. Although substantial monitoring effort is being done in the last decades, measuring all APIs everywhere is not feasible. Therefore, under the correct assumptions, modelling approaches are a solution to determine the APIs' environmental exposure potential everywhere. Oldenkamp et al. (2018) firstly developed the "Exposure to Pharmaceuticals in the Environment" model (ePiE), a numerical model able to predict APIs flow and fate from human consumption to surface waters at 1 km resolution. Within the European project PREMIER (www.imi-premier.eu), we have recently expanded ePiE to cover all the relevant river basins of the European Continent. Furthermore, the model is being enhanced in order to take into account advanced wastewater treatments, which are considered key processes to remove APIs. The new model domain was successfully tested with a hypothetical tracer compound. New applications have shown the model capability of producing enhanced predictions of APIs concentration within Europe. These upgrades together with recent model applications on specific medicines will be presented.

4.13 Pharmaceuticals in the environment – New insights, regulatory needs and knowledge gaps (Part II)

4.13.T-06 Use of Pharmaceutical Sales Data for Improved Prediction of Environmental Risk

Samuel Welch¹, Kristine Olsen², Jannicke Moe³, Mohammad Nouri Sharikabad², Knut Erik Tollefsen¹ and Merete Grung⁴, (1)NIVA - Norwegian Institute for Water Research, Norway, (2)Norwegian Institute of Public Health, Norway, (3)Norwegian Institute for Water Research (NIVA), Norway, (4)NIVA, Oslo, Norway

Pharmaceutical production, use and disposal offers a unique set of challenges to scientists and stakeholders, as environmental and health risk must be balanced despite oftentimes conflicting objectives. Despite this, data on the emissions, exposure and effects of pharmaceuticals can be limited or gated behind confidentiality requirements, even in nations at the forefront of environmental regulation. It is imperative that the contributions of pharmaceuticals to environmental risk landscapes in the past, present, and future are better understood, to improve risk characterisation and to ultimately facilitate efficient mitigation. In this presentation, we provide an update on our work applying pharmaceuticals sales data in Norway, 2016-2019, to estimate environmental exposure and thereby help inform on possible environmental risks. We have processed, quality-checked and standardised data on

sales and content of products from the Norwegian Institute for Public Health's Drug Wholesale Database. These data sources are then used to predict environmental concentrations (PECs) for roughly 500 Active Pharmaceutical Ingredients (APIs) per year. For combination drugs, our calculations include all APIs included in each product. Combining these PECs with publicly available Predicted No Effect Concentrations (PNECs), we were then able to calculate Risk Quotients (RQs) for these APIs. Initial notable results are the highlighting of sex hormones, such as levonorgestrel and ethinylestradiol, as key drivers of environmental risk, with RQ values between 100 and 10000. Other notably high-risk substances ($RQ > 1$) include the antiseptic chlorhexidine, the statin simvastatin, the painkillers naproxen, paracetamol, and ibuprofen, the antineoplastic abiraterone and the antibiotics ciprofloxacin and amoxicillin. The current environmental risk assessment procedures typically focus on single pharmaceutical products. Therefore, there is a possibility that combined effects of drugs with similar modes of action are underestimated. In our study, the total concentrations of APIs from different products will be included in the overall risk characterisation of each API, and will therefore also be accounted for in the risk prioritisation. To our knowledge, our approach provides an unprecedented level of detail and accuracy for predicting environmental concentration, in particular due to our careful inclusion of combination drugs and over-the-counter sales. We intend to next validate our predictions by comparison to measured environmental concentrations in Norway. We also intend to incorporate the calculated exposure and risk into a model for prediction of future environmental risks under changing climate and demographic scenarios.

4.13.T-07 Mixture Risk Assessment of Pharmaceuticals

Alejandra Bouzas Monroy¹, John Wilkinson² and Alistair Boxall³, (1)Environment Department, University of York, York, United Kingdom, (2)Environment and Geography, The University of York, York, United Kingdom, (3)University of York, United Kingdom

There is a growing concern that exposure to these environmental contaminants can result in negative effects on the health of ecosystems due to pharmaceuticals being ubiquitous pollutants, having been detected in surface waters in many regions of the world. Numerous studies have explored the toxicity of pharmaceuticals yet there remain knowledge gaps with only a small proportion of pharmaceuticals in use being tested and these tests primarily being performed on single compounds. The University of York performed a unique monitoring study exploring concentrations of pharmaceuticals in rivers across the globe, providing a foundation for assessing the risks of pharmaceuticals. Therefore, the aim of this study is to use the global monitoring data alongside published ecotoxicity data and predictive models to establish the level of risk posed by individual Active Pharmaceutical Ingredients (APIs) and mixtures of APIs to river systems across the globe. An extensive analysis of current research was conducted to obtain Median Effect Concentrations (EC50) and No Observed Effect Concentrations (NOEC) from chronic and acute apical effect studies and non/apical effect studies of the 53 detected compounds of three taxonomic groups (fish, *Daphnia* and algae). These data were then collated into a database and used to derive predicted no effect concentrations (PNECs) for each compound for surface waters. PNECs and measured concentrations were then used to calculate Risk Quotients (RQ) for pharmaceuticals using a single compound approach (apical and non-apical endpoints and mode of action effects) and a mixture approach at each of the sites monitored. Ten APIs presented an $RQ \geq 1$ in at least one of the 1052 sampling locations (sulfamethoxazole, nicotine, clarithromycin, caffeine, erythromycin, propranol, artemisinin, amitriptyline, and carbamazepine) using apical endpoints. Overall, 12.74% of the sampling locations contained concentrations of at least one pharmaceutical greater than the 'safe' concentrations for aquatic organisms based on apical effect endpoints. Meanwhile, 30.13% of all the sites in the global monitoring had an $RQ \geq 1$ when non-apical endpoints were used, 7.51% when Mode of Action effects were implemented and 24.24% when a mixture approach was applied. Currently, ecotoxicological risk assessments are mainly carried out through apical endpoints; however, this study shows that the use of a single compound approach based on only apical endpoints could underestimate the risk of APIs on non-target organisms in rivers around the globe. Therefore, this work's findings show the importance of utilizing a mixture approach in order to obtain a more comprehensive and 'realistic' perspective of pharmaceutical pollution worldwide.

4.13.T-08 Occurrence, Hazard, and Risk of Psychopharmaceuticals in European Surface Waters

Charlie Davey¹, Michiel Kraak¹, Antonia Praetorius², Thomas L ter Laak³ and Annemarie van Wezel⁴, (1)University of Amsterdam, Netherlands, (2)University of Amsterdam/IBED Institute, Netherlands, (3)KWR, Netherlands, (4)University of Amsterdam/IBED Institute, Amsterdam, Netherlands

Psychopharmaceuticals are primarily used to treat psychological disorders and illnesses, as well as other conditions relating to the nervous system and their use has been steadily increasing around the world. After human consumption and excretion, psychopharmaceuticals are emitted into the sewage system and eventually enter surface waters. Since psychopharmaceuticals are designed to interact with the nervous system and alter behaviour, these substances may affect non-target organisms at very low, environmentally relevant, concentrations. Yet, it remains virtually unknown if the presence of these psychopharmaceuticals in surface waters present an ecological risk for aquatic non-target organisms. The current study aimed to provide insights into the risk posed by psychopharmaceuticals and to identify the gaps in the current understanding of these drugs in European surface waters. First, the availability and quality of data on the concentrations of psychopharmaceuticals in surface waters (*exposure*) and on the toxicity to aquatic organisms (*hazard*) were reviewed. Public databases and literature were both used in obtaining these data. If both exposure and toxicity data were available, risk quotients (*RQs*, *risk*) were calculated. In cases where enough toxicity data were available, a species sensitivity distribution (*SSD*) was constructed, from which the hazardous concentration for 5% of the species (*HC₅*) was derived. In total, 703 drugs could be categorised as psychopharmaceuticals based on a combination of all anatomical therapeutic class (*ATC*) 'N' drugs and a list of illicit drugs according to the Dutch Opium Act. Of these, only for 87 compounds enough data were publicly available to calculate RQs. 23 compounds indicated some degree of, with at least one $RQ > 1$. Five of these, i.e. risperidone, escitalopram, carbamazepine, paracetamol, ibuprofen, and fluoxetine had at least 10% of average risk quotients above 1, and therefore carry the highest risk. Yet, only for aspirin, paracetamol, ibuprofen,

trichloroethylene, chloroform, phenol, fluoxetine, sertraline, and carbamazepine risk calculations were reliable in terms of availability and/or quality of data. The results from this study broaden the understanding of the risk of psychopharmaceuticals in the environment by highlighting which compounds are of concern, predicted to be of concern and which compounds lack the data for any calculation of risk.

4.13.T-09 The Emerging Threat of Human-Use Antifungals in the Agro-Environment

Laura Carter¹, Jonathan Brett Sallach², Emily Durant³, Tom Thirkell³ and Katie Field³, (1)University of Leeds, United Kingdom, (2)University of York, Heslington, United Kingdom, (3)The University of Sheffield, United Kingdom

Sustainable farming practices are increasingly necessary to meet the demands of a growing population under constraints imposed by climate change. However, these practices, in particular the reuse of wastewater and amending soil with wastewater derived biosolids, provide a pathway for man-made chemicals such as pharmaceuticals to enter the agricultural environment. A significant knowledge gap remains around the conserved biological potency of human-use antifungals in the environment and, in particular, their potential interaction with plant associated arbuscular mycorrhizal (AM) fungi. AM fungi associations with plant roots play a major role in plant nutrition through their engagement in bidirectional exchange of soil nutrients, in return for plant-fixed carbon compounds. We sought to better understand the impact of human-use antifungals, inadvertently introduced into the soil environment, on the community composition, structure and function of the microbes and fungi that play vital roles in soil nutrient cycling and plant nutrition. Wheat (*Triticum aestivum* L. cv. 'Skyfall') and spring onion (*Allium fistulosum* cv. '(Spring) White Lisbon') and mycorrhizal associates were exposed to environmentally relevant levels of the azole antifungals clotrimazole, miconazole nitrate and fluconazole. Plants were grown under greenhouse conditions as duplicate exposures: Exp. 1 included radiolabelled materials (³³P, ¹⁵N and ¹⁴C) for analysis of fungal colonisation and function and Exp. 2 without radiolabelled materials to track anti-fungal fate and impacts on the diversity of total fungi and the symbiotic AM fungi. We found transfer of essential plant nutrients from mycorrhizal fungi-to-plant was reduced in plants grown in azole-contaminated soils compared to those grown in non-contaminated soils. Interestingly, the observed effects on ³³P transfer from fungus-to-plant occurred without any significant impacts on the degree of mycorrhizal colonisation in response to azole exposure. This suggests that the anti-fungal pharmaceuticals are not at concentrations which are lethal to the fungi or are inhibitory on their ability to colonise plant roots, but they do hamper mycorrhizal facilitation of P transfer from soil to plants. Our work raises the major, yet underexplored, issue of exposure of soil biota to pharmaceuticals such as azole antifungals introduced via sustainable agricultural practices as a potentially globally important disruptive influence on soil nutrient cycles.

4.13.T-10 UTOPIC Database: The Uptake of Pharmaceuticals Into Crops. a Systematic Review and Assessment on the Uptake of Pharmaceuticals Into Crops

Harriet Sleight¹, Sylvia Toet² and Alistair Boxall², (1)Environment and Geography, Environment Department, University of York, York, United Kingdom, (2)University of York, United Kingdom

Pharmaceuticals may be released to agricultural environments following irrigation with wastewater effluent or through the application of biosolids or manure. The potential for these pharmaceuticals to be taken up into agricultural crops was first recognised in the late 20th century and pioneering studies on the uptake of pharmaceuticals into crops were conducted in the 2000s. Numerous studies have since investigated the extent of uptake of pharmaceuticals into crops following exposure, but these studies have not been systematically collated or compared. This study aimed to create a database to systematically review all of the existing empirical data on the uptake of pharmaceuticals into crops. This database facilitated a meta-analysis of the data providing an insight into the relationships between the chemical properties of different pharmaceuticals and the uptake pathways in different crops as well as how these vary under different environmental conditions.

Literature searches were conducted on both Scopus and Web of Science with the combined results yielding 1263 discrete articles. These articles were subjected to a robust screening process according to pre-defined screening criteria. The UTOPIC database was designed to systematically store details of the experimental design and results from the 150 studies which satisfied the primary and secondary screening criteria.

The UTOPIC database contains 8048 datapoints spanning 173 separate pharmaceuticals and 78 study crops. Clear trends in experimental design were identified with lettuce being the most studied crop and carbamazepine and sulfamethoxazole being the most studied pharmaceuticals. Significant relationships were identified in the extent of uptake between different crop types. The physicochemical properties of soils were also shown to influence uptake. However, the database highlighted a lack in the reporting of key soil properties limiting the significance of this result. No clear relationships were identified between pharmaceutical chemical properties such as the logKow of the pharmaceutical and the uptake into crops.

The UTOPIC database represents the first aggregation of work on pharmaceutical uptake into crops from scientists across the world. The database provides a wealth of experimental data which could be valuable in the parameterisation of future models. The database is currently being applied to a human health risk assessment and analysis of acceptable daily intake data.

4.13 Pharmaceuticals in the environment - New insights, regulatory needs and knowledge gaps (Virtual Only)

4.13.V-01 Assessing the Potential Impact of Experimental Conditions on Heterogeneous Effect Data for Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) in Aquatic Organisms

Odile Sellier¹, Marion Junghans², Alexandra Kroll³ and Mireia Marti-Roura⁴, (1)Université de Genève, Switzerland, (2)Swiss

Centre for Applied Ecotoxicology EAWAG - EPF, Switzerland, (3)Centre Ecotox, Switzerland, (4)Swiss Centre for Applied Ecotoxicology, Switzerland

Nonsteroidal anti-inflammatory drugs (NSAIDs) are widely used to reduce pain, fever, and inflammation. Due to a steady increase in consumption, aquatic organisms are increasingly exposed to NSAIDs despite generally good removal by WWTPs. Acute adverse effects of NSAIDs are expected to occur at comparatively high concentrations while chronic adverse effects have been reported in the low $\mu\text{g/L}$ range and below. Two prominent NSAIDs, diclofenac and ibuprofen have physicochemical properties that pose a challenge to aquatic toxicity testing. They are weak acids that dissociate at environmentally relevant pH, which changes their solubility, partitioning behaviour, and thus bioavailability. In addition, water solubility is very low. Assessment of aquatic toxicity studies for diclofenac revealed an unexpected heterogeneity of effect concentrations (in some cases covering 3-4 orders of magnitude) within a single species for identical or very similar durations and the same endpoint. In view of the dissociation behaviour and very low solubility, we hypothesize that differences in experimental conditions, e.g. pH, ionic strength, exposure volumes, handling, have resulted in differences in bioavailability of diclofenac. The occurrence of transformation products with dissimilar properties may likewise have affected the results. In order to assess the potential impact of experimental conditions on heterogeneous effect data for diclofenac in aquatic organisms, we are currently curating publically available data on physico-chemical properties of diclofenac to then test the correlation between different experimental parameters and experimental outcomes. A comparison with data already available for ibuprofen will be included.

4.13.V-02 Minimise Harmful Effects of Pharmaceuticals on the Environment: What Are the EU's Objectives?

Ines Rönnefahrt¹, Daniela Gildemeister² and Annika Buck³, (1)German Environment Agency - UBA, Germany, (2)Pharmaceuticals, Umweltbundesamt / German Environment Agency, Dessau-Roßlau, Germany, (3)German Environment Agency (UBA), Germany

The EU legislation on medicinal products is the primary means for ensuring quality, safety and efficacy of medicinal products and their safety for the environment. However, despite the well-established pharmaceutical legislation, risks to and from the environment persist. An analysis of the functioning of the EU pharmaceutical legislation reveals several shortcomings. Improvements are needed especially in the following areas: 1. Strengthening the environmental risk assessment in authorization procedures of medicinal products for human use 2. Closing knowledge gaps in particular for 'legacy' products that were authorised before the requirement of an ERA was established 3. Public access to the results of the environmental risk assessment 4. Improved surveillance in the use phase 5. Effective risk management measures along the entire life cycle of medicinal products 6. Appropriate linkage of pharmaceutical legislation with other regulatory areas

The above mentioned challenges of the EU legislation were also recognised in the EU Strategic Approach to Pharmaceuticals in the Environment, which was published in March 2019. The Pharmaceutical Strategy, published in Nov. 2020 states: "To respond fully to the objectives of a green economy, the regulatory framework needs to address the environmental implications of production, use and disposal of medicines. One of the major challenges is increasing antimicrobial resistance." These objectives are to be implemented in the ongoing revision of the EU pharmaceutical legislation. The Commission's proposal on the new pharmaceutical legislation for human medicinal products is expected in Q4 2022. In addition to the Pharmaceutical Strategy several other EU Green Deal strategies, such as the Zero Pollution Ambition for a toxic-free environment and the Chemical Strategy for Sustainability, which focus e.g. on the revision of the REACH and CLP Regulations and the pursuit of the 'one-substance – one assessment' approach, also contain objectives that will help minimise harmful effects of pharmaceuticals on the environment. A paradigm shift towards a substance-based ERA, the collection of ERA data in a harmonised EU database and a shared use of these data could be the key measures to ensure the environmental safety of medicinal products in use and to enable effective risk management measures along the entire life cycle. A much closer networking of the different regulatory areas is a prerequisite for this.

4.13 Pharmaceuticals in the environment – New insights, regulatory needs and knowledge gaps (Poster)

4.13.P-Tu235 An Integrated Modelling Approach to Assess Water Pollution by Veterinary Pharmaceuticals

Lara Wöhler¹, Pieter Brouwer², Denie Augustijn², Arjen Hoekstra², Rick Hogeboom², Brian Irvine³, Volker Lämmchen⁴, Gunnar Niebaum⁵, Markus Berger² and Maarten Krol², (1)University of Twente, Enschede, Netherlands, (2)University of Twente, Netherlands, (3)University of Leeds, UK, (4)Universität Osnabrück, Germany, (5)University of Osnabrück, Germany

Water pollution by veterinary pharmaceuticals resulting from livestock production is associated with severe environmental and human health risks. While upward trends in global animal product consumption signal that these risks might exacerbate toward the future, veterinary pharmaceutical related water pollution is currently insufficiently understood. To increase this understanding, the presented research assesses processes influencing veterinary pharmaceutical pollution from their administration to their discharge into freshwater bodies, using an integrated modelling approach. For the substances amoxicillin, doxycycline, oxytetracycline, sulfamethazine, and tetracycline we assess loads administered to livestock, excretion, degradation during manure storage, fate in soil and transport to surface water. Fate and transport are modelled using the VA transport model (VANTOM), which is fed with estimates from the Pan-European Soil Erosion Risk Assessment (PESERA). The grey water footprint (GWF) is used to indicate the severity of water pollution in volumetric terms by combining veterinary pharmaceutical loads and predicted no effect concentrations. The approach is applied to the German-Dutch Vecht river catchment, which is characterized by high livestock densities. Results show a veterinary pharmaceutical mass load decrease larger than 99% for all substances under investigation, from their administration to surface water emission. Due to metabolization in the body, degradation during manure storage and degradation in soil, pharmaceutical loads are reduced by 45%, 80% and 90% on average, respectively. While amoxicillin and sulfamethazine dissipate quickly after field application, significant fractions of doxycycline, oxytetracycline and tetracycline accumulate in the soil. The overall Vecht catchment's GWF is estimated at $250,000 \text{ m}^3 \text{ yr}^{-1}$, resulting from

doxycycline (81% and 19% contribution from the German and Dutch catchment part respectively). Uncertainty ranges of several orders of magnitude as well as several remaining limitations underscore the importance to further develop and refine the approach. In this context we specifically discuss the current lack of comprehensive pharmaceutical administration data for livestock. Here we include perspectives on what information at which aggregation level would have significant added value for environmental assessment of pharmaceuticals.

4.13.P-Tu236 Challenges Analysing Monitoring Data for an Insecticide Regulated Under Different Frameworks: A Case Study on Cypermethrin in the UK

Claire McMillan¹, Gregory Hughes¹ and Jonathan Newman², (1)Cambridge Environmental Assessments, United Kingdom, (2)Environment Agency, United Kingdom

Cypermethrin is a synthetic pyrethroid used as an insecticide in a wide range of products across various sectors, registered under the PPP (1107/2009), biocide (528/2012) and veterinary medicine (2001/82) regulatory frameworks. An important use in the UK is as an ectoparasiticide in veterinary medicines to treat sheep, cattle and horses. Its high toxicity and presence in surface water bodies has led to it being classified as an EC priority substance in 2013. Public water quality monitoring in the UK has identified exceedances of the EQS (annual average and maximum allowable concentration) and this work investigated potential sources of cypermethrin within catchments with a view to identifying sources, exposure pathways to surface water as well as assessing mitigation measures to promote the achievement of good chemicals status compliance. As part of this analysis, potential veterinary medicine sources were assessed using sales data and spatial analysis for a sheep dominated catchment (i.e. animal density and flock treatment specific to the catchment, analysis of managed grass adjacent to surface water, runoff percentage from grassland) alongside three main exposure scenarios (wash-off from treated animals following rainfall events, hardstanding runoff following spillages and drips during treatment and wash-off from animals fording rivers shortly after treatment). Other agricultural sources such as incorrect disposal of products, use of cypermethrin products for fly control in animal housing and losses from livestock sale yards were also considered. Results from the analysis were compared to water quality monitoring data for the sheep dominated catchment and results on the likely sources driving exceedances will be presented. Differences between regulatory environmental risk assessments and on farm practices that can lead to environmental exposure will be discussed as well as the challenges of interpreting water quality monitoring data for chemicals with multiple uses, regulated under different frameworks. The use of different approaches for assessing environmental hazard under veterinary (and other) regulations will also be discussed.

4.13.P-Tu237 Effects of Teflubenzuron on the Early Development of the Sea Urchin *Brissopsis lyrifera* and the Brittlestar *Amphiura filiformis*

Simon Rodriguez¹, Sam Dupont², Sanja Grzan³, Melina Schmelzer⁴, Julieta Vigliano Relva⁵, Tania Gomes¹, Adam Lillicrap⁶ and Ailbhe Macken⁷, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)University of Gothenburg, Sweden, (3)University of Dubrovnik, Croatia, (4)University of Goteborg, Sweden, (5)Ghent University, Belgium, (6)NIVA Norwegian Institute for Water Research, Norway, (7)Norwegian Institute for Water Research, NIVA, Norway

The salmonid aquaculture industry can be affected by biofouling and diseases. Different types of antifouling compounds and veterinary medicinal products (VMP), have been used to control biofouling and parasites such as sea lice. Teflubenzuron (TEF) is one VMP that has historically been used in Norway, but it is very persistent (half-life of 170 days in sediment) and has potentially toxic effects on non-target organisms. The main objective of this study was to assess the effects of TEF on two benthic organisms, representative of the Nordic environment. The sea urchin *Brissopsis lyrifera* was chosen because it can alter sediment grain distribution, while the brittlestar *Amphiura filiformis* is a burrowing organism that uses its arms for suspended feeding. Organisms were collected near the Kristineberg Marine Station (Sweden) in August 2021 using a Van Veen grab (30 m) and a trawl (60 m) for the brittlestar and sea urchin, respectively. Sea urchins were spawned using an intracelomic injection of 0.5 M KCl (ca.1 ml). Subsequently, eggs and sperm were collected for fertilization. Spawning in the brittlestars was induced by photoperiod and gametes were collected for fertilization. Prior to fertilization, sperm mobility, egg quality and gamete compatibility were evaluated for both species. After checking the fertilization success, fertilized eggs (1300 eggs/ml per bottle) were exposed for 5 days to 6 concentrations of TEF (0.001, 0.01, 0.1, 1, 10 and 100 µg/L), alongside a negative (just seawater) and a solvent control (0.01 % methanol). A 5 ml (replicate) sample was extracted daily from each bottle, 2-4 drops of Paraformaldehyde (4%) solution added and the number of eggs/larvae were counted for abnormalities and morphometric analysis using a microscope. On the first 3 days of exposure, length was measured, while on days 4 and 5, body length, body rod length and arm length were recorded. Effects on survival, growth, skeletal development and body symmetry of TEF were analyzed. Data analysis is ongoing but preliminary results point to effects on growth and body symmetry at 100 µg/L for both species. These results are part of the ANTIVENOM project which is assessing the effects of antifoulants and VMPs used in the salmon fishing industry in Norway.

4.13.P-Tu238 Environmental Risk Assessment of Veterinary Medicinal Products - Is a Change From the Current to an Alternative System Feasible and Reasonable From an Operational Perspective?

Susanne Schwonbeck¹, Stefan Hahn¹, Franziska Breuer² and Rodrigo Vidaurre³, (1)Fraunhofer ITEM, Hannover, Germany, (2)Fraunhofer ITEM, Germany, (3)Ecologic Institute, Germany

Pharmaceutical substances have been detected in surface waters in the European Union for more than 30 years. Since 2005, environmental risk assessments (ERAs) are part of the authorisation process for veterinary medicinal products. The ERA is prepared exclusively based on the product and not on the substance, and thus has a number of drawbacks, which led to discussions about alternative systems. An interdisciplinary consortium was awarded with a contract for a feasibility study of an active substance based review system ('monographs') and other potential alternatives for the environmental risk assessment of veterinary

medicinal products (SANTE/2020/E5/013) which was commissioned by the European Commission's Directorate General for Health and Food Safety. The different systems were examined with regard to their possible impacts as well as their efficiency and effectiveness in achieving the objectives of the VMPP: reduce the administrative burden, enhance the internal market, increase the availability of VMPPs, while guaranteeing the highest level of public and animal health and protection of the environment. In this study the following points and questions were addressed to gather important operational aspects to evaluate the feasibility: - For which authorised VMPPs are the ERA missing (at the European and national level) - Prioritisation of active pharmaceutical ingredients (API): hazard-based, based on current data gaps, risk-based? - Organisation and governance of a monograph system: responsibility for establishing and updating a monograph, arbitration, data collection, generation of environmental data, data storage, database etc.) - Check for appropriate types of cooperation for applicants – How are experiences from REACH and biocidal product regulation? - How would a possible monograph system fit in the risk assessment system for VMPPs? - Challenges while implementing a monograph system - Would alternative systems meet the goals of Regulation 2019/6? - Benefits and challenges for different stakeholder groups (e.g. companies, authorities, the public etc.) The above points were answered by collection of available scientific and grey literature, interviews with stakeholders and an online survey. The collected information for each identified alternative system were structured and analysed for advantages, disadvantages and if they would meet the goals of Regulation 2019/6.

4.13.P-Tu239 Influence of Manure Application Method on Veterinary Medicine Losses to Water

John Nightingale¹, Laura Carter², Chris Sinclair³, Phil Rooney⁴ and Paul Kay², (1)University of Leeds and Fera Science Ltd, United Kingdom, (2)University of Leeds, United Kingdom, (3)Fera Science Ltd, United Kingdom, (4)FERA, United Kingdom

Veterinary medicines are routinely used within modern animal husbandry, thereof presenting both environmental and societal risks such as antimicrobial resistance and toxicological effects to organisms. The environment is frequently exposed to veterinary medicines via the application of manures to land, however there is currently little understanding regarding the influence of commonly used application methods on veterinary medicine fate. To bridge this knowledge gap, a semi-field study was conducted to assess the influence of manure application methods on veterinary medicine surface runoff and leachate concentrations from both bare soils and pastures. The application methods that were assessed included broadcast, chisel sweep, and incorporation for bare soils whilst the pasture assessment only included broadcast and chisel sweep as incorporation is not representative of typical farming practices. A range of veterinary medicines were selected and applied as a mixture; these were enrofloxacin, florfenicol, lincomycin, meloxicam, oxytetracycline, sulfadiazine, trimethoprim and tylosin. All of the assessed veterinary medicines were detected within surface runoff and leachates, and the concentrations generally decreased throughout the irrigation period. Under the bare soil and pasture assessments concentrations ranged from 0.04 to 309.6 µg/L and 0.33 to 236.83 µg/L, respectively. The total percentage of veterinary medicines that were transported via surface runoff and leachate on bare soils ranged from 0.007 to 0.46%, 0.004 to 0.15% and 0.0003 to 0.11% for broadcast, chisel sweep and immediate incorporation respectively. More advanced manure application technologies (chisel sweep) were observed to reduce surface runoff and leachate concentrations by 13-56% and 49-88% over that of broadcast. Incorporating pig slurries substantially reduced the transport of veterinary medicines, surface runoff and leachate mass loads were reduced by 40-92% and 66-94% respectively. Manure application techniques did not influence surface runoff concentrations under the pasture assessment, although it was evident that chisel sweep can reduce leachate concentrations from 23-97% over that of broadcast. The presented study demonstrates that manure application techniques have a substantial influence on veterinary medicine fate within the environment, and these effects should be considered in the management of manures as a protective risk mitigative measure for aquatic compartments.

4.13.P-Tu240 The Effect of Anaerobic Pig Slurry Redox Potentials on the Degradation of Veterinary Medicines

John Nightingale¹, Laura Carter², Chris Sinclair³, Phil Rooney⁴ and Paul Kay², (1)University of Leeds and Fera Science Ltd, United Kingdom, (2)University of Leeds, United Kingdom, (3)Fera Science Ltd, United Kingdom, (4)FERA, United Kingdom

Veterinary medicines are frequently used within intensive livestock husbandry and there has been a growing interest regarding their environmental fate following manure application to land. However, research has seldom assessed the influence of pig slurry properties on the fate of veterinary medicines even though such an understanding is essential for a more robust environmental risk assessment. Changes within manure degradation rates have the potential to alter the concentration of antibiotics applied to land, and the outcome of the risk assessment. Research has seldom assessed the influence of anaerobic pig slurry redox potentials on veterinary medicine degradation, this is a precursor of the logistical difficulties that are faced in controlling redox potentials for long durations but here present a pragmatic cost-effect controlling system. The aim of this work was to investigate whether commonly reported redox potentials affect the degradation rates of acetyl-salicylic acid, ceftiofur, florfenicol, oxytetracycline, sulfamethoxazole, and tylosin. The employed redox potentials were -100 mV (reduced), -250 mV (anaerobic) and -400 mV (very anaerobic). A compound specific relationship was observed where the degradation of ceftiofur, florfenicol, oxytetracycline and sulfamethoxazole was inhibited under reduced conditions over that of very anaerobic; the respective DT₅₀ values were 0.7 - 1.84 h, 1.35 - 3.61 h, 22.2 - 49.8 h, 131 - 211 h and 35.4 - 94 h. In contrast, tylosin was found to degrade faster at reduced conditions over very anaerobic (DT₅₀ 6.88 to 19.4 h). The observed changes in degradation rates were found to alter the findings within a risk assessment (i.e., risk quotation to terrestrial and aquatic organisms). Therefore, the presented research demonstrates the importance of redox potential on degradation rates and suggests we need stringent harmonized redox control and numerous manure assessments to improve the environmental risk assessment of veterinary medicines.

4.13.P-Tu241 Monographs for Active Substances in Veterinary Medical Products - Data Gaps and Availability of Environmental Information

Arne Hein¹, Daniela Gildemeister², Ute Brandt¹, Silke Hickmann¹ and Ines Rönnefahrt³, (1)German Environment Agency (UBA),

Germany, (2)Pharmaceuticals, Umweltbundesamt / German Environment Agency, Dessau-Roßlau, Germany, (3)German Environment Agency - UBA, Germany

Since 2005 an environmental risk assessment (ERA) has been required for all new veterinary pharmaceuticals within the marketing authorisation procedure. Since then the availability of ERAs is continuously increasing, but there are still veterinary pharmaceutical substances on the market for which no ERA data exists. Art. 156 of the new veterinary regulation (EU) 2019/6 initiated a review of the rules for environmental risk assessment. The recently published “Feasibility study of an active-substance-based review system (‘monographs’) and other potential alternatives” by the European Commission (<https://doi.org/10.2875/94477>) recommends a monograph system. However, information is lacking for how many veterinary pharmaceutical substances complete ERA data are available to draft monographs and for which substances ERA data are still missing. At present, about 500 different veterinary active substances are marketed in Europe. Only a limited number of these are environmentally relevant and used in food producing animals. Following VICH GL 6 and the EMA supporting GL, based on their substance properties or their intended use and the subsequent exposure of the environment, less than 20% would be considered for an in-depth experimental environmental risk assessment according to the VICH GL 38 (Phase II ERA). This poster will list all active substances authorized in Germany for which a Phase II ERA is required. Considering all veterinary medical products marketed in Germany in 2020, we will provide information for which active substances information on their environmental safety is available or still missing. This substance lists will aid in predicting the workload during the implementation of a monograph system.

4.13.P-Tu242 Threats From Pets: Prioritisation of Companion Animal Parasiticides

*Isla Thorpe*¹, *Andrew Beckerman*², *Caroline Dessent*³, *Carmel Ramwell*⁴, *Susan Zappala*⁵ and *Alistair Boxall*³, (1)Environment and Geography, University of York, York, United Kingdom, (2)University of Sheffield, United Kingdom, (3)University of York, United Kingdom, (4)Fera Science Ltd, United Kingdom, (5)Joint Nature Conservation Committee, United Kingdom

Active ingredients within companion animal parasiticide products are of growing concern due to their widespread use and potential high potency to non-target organisms. Current risk assessments do not consider the complete ecotoxicological risk of these chemicals due to the assumed negligible exposure. Selected active ingredients used on companion animals have been detected in the environment. However, environmental occurrence data are available only for a handful of the many active ingredients in use. Therefore, the overall aim of this study was to prioritise active ingredients used in companion animals based on their potential to cause harm to the environment in order to inform future monitoring and risk assessment efforts. Product information on the parasiticides available on the market for treatment of cats and dogs along with ecotoxicological and fate data on the active ingredients used within these products were collated into a custom produced database. Product information collected included the active ingredients used, concentrations of active ingredients and frequency of use. Ecotoxicological and fate data collated included physicochemical properties, persistence, mobility, bioaccumulation and effects on algae, invertebrates and fish. Information has been collated on greater than 100 products; active ingredients from a range of chemical classes are included for example, macrocyclic lactones, neonicotinoids and phenylpyrazoles. These data are currently being used alongside models to identify those active ingredients most likely to cause environmental harm. The future focus of this research is to monitor the high priority active ingredients within the environment to determine baseline concentrations and subsequently to assess the potential risks of these substances to ecosystem health.

4.13.P-Tu243 A One-Health Approach to Control Residual Malaria Transmission - the Value of Ecotoxicology and Environmental Chemistry

*Andre Patrick Heinrich*¹, *Rolf-Alexander Düring*², *Hermann Sié Pooda*³, *Karine Mouline*⁴ and *Christophe Roberge*⁵, (1)Institute of Soil Science and Soil Conservation, Justus Liebig University Giessen, Giessen, Germany, (2)Justus-Liebig-Universität Gießen, Germany, (3)Centre International de Recherche-Développement sur l'Élevage en zone Subhumide (CIRDES), Burkina Faso, (4)Institut de Recherche pour le Développement (IRD), France, (5)MedinCell, France

In the fight against malaria, the success of current control tools like insecticide-treated nets and indoor spraying is often undermined by new behaviour of vectors to escape exposure. Vectors may also switch between human and animal hosts. In Burkina Faso, the ANIVERMATE project investigates treating peridomestic cattle with the endectocide ivermectin (IVM) as a complementary malaria vector control tool. Since excreted veterinary drugs can enter the environment and burden ecosystems, ecological consequences of IVM residues are considered upfront. IVM treatments were designed for 6 months and we monitored IVM residues in dung of Zebu cattle, treated with either an innovative injectable long-acting depot or monthly injections of a standard IVM formulation. In addition to IVM residues in fresh dung and blood plasma, we studied the environmental fate of IVM in stored dung and conducted sorption studies with soil samples from local villages. Phytotoxicity was assessed with 2 varieties of *Sorghum bicolor*. Mosquito mortality was evaluated in blood-feeding assays. With an observed 10 d-LC90 of 26 ng/mL in plasma, the depot may reduce residual malaria transmission to close vector loopholes. The long-acting depot resulted in significantly lower IVM peak concentrations in dung (1001 vs 3267 ng/g dw) and excreted IVM showed moderate fluctuations over the trial period. However, ecotoxicological effects of IVM on dung-dwelling Coleoptera and Diptera species are common. For adult dung beetles and flies, IVM in dung may be of lower toxicity but can show severe effects on larvae. Critically, knowledge on local dung and soil fauna is needed: In West Africa, termites and ants play a major role in dung management but risk assessment for these species is not included in guidelines and regulatory frameworks. Integrating ecotoxicological thinking, we show that it is worthwhile to include this mindset early on in human health interventions to reduce adverse impacts on natural resources and agricultural production. ANIVERMATE highlights the importance of including environmental risk assessment in a One-Health approach. The long-acting IVM depot for cattle provided significant mosquitocidal activity for up to 6 months and

may offer complementary and reliable mosquito control with manageable ecological side-effects. However, a One-Health solution can only be truly sustainable if the needs of human and veterinary health, ecology, and ecotoxicology are respected.

4.13.P-Tu244 Environmental Risk Assessment for Small Molecules Used in Targeted Cancer Therapy in Europe

Andreas Haener, Group SHE, F. Hoffmann-La Roche Ltd, Basel, Switzerland

Environmental Risk Assessments (ERA) according to the EMA ERA Guideline of 1 June 2006 (EMA/CHMP/SWP/447/00 corr 2) were performed for the seven Roche products ALECENSA (INN: Alectinib), COTELLIC (INN: Cobimetinib), ERIVEDGE (INN: Vismodegib), GAVRETO (INN: Pralsetinib), ROZLYTREK (INN: Entrectinib), TARCEVA (INN: Erlotinib) and ZELBORAF (INN: Vemurafenib). These targeted cancer therapy products came on the European market between 2005 and 2021. Due to their high patient safety and efficacy as compared with traditional chemotherapy medicines, these small molecules APIs are increasingly used in cancer treatments. Full ecotoxicity and fate data sets according to the EMA ERA Guideline are available. Wherever possible, the ERAs at the time of marketing authorisation application are supplemented with actual use data from IQVIA MIDAS per annum and country, incorporating population data from Eurostat for the years 2016–2020, in order to evaluate potential environmental risks arising from the effective use of these APIs. Potential environmental risks are not only assessed for surface water, groundwater and sewage treatment, but also for human health via drinking water. Whereas the groundwater assessment is concerned, calculations based on the existing EMA ERA Guideline and the new draft EMA ERA Guideline of 2018 are compared. A potential bioaccumulation is also addressed. Conclusions on potential risks for the aquatic environment of these seven small molecules used in targeted cancer therapy are given in the poster.

4.13.P-Tu245 Environmental Risk Assessment of Medicinal Products - an Investigation of the Generation and Availability of Environmental Data From the Medicinal Product Authorisation Procedure Under European Law

Kim Oelkers¹, Adrian Mezler², Susanne Schwonbeck³ and Carolin Floeter⁴, (1)TEPPE Rechtsanwälte, Germany, (2)Hamburg University of Applied Sciences (HAW Hamburg), Germany, (3)Fraunhofer ITEM, Hannover, Germany, (4)HAW Hamburg, Germany

The pollution of pharmaceuticals in European waters is of concern and risk mitigation measures should further be developed. Environmental risk assessments (ERA) have become part of the authorisation procedure of veterinary/human medicinal products since 2005/06, but they are generated exclusively on a product-by-product basis. This ERA system has several drawbacks, for example the data of the ERA are not sufficient available for authorities responsible for the quality of water in the EU neither for the public. Thus, the overall objective of this legal study was to determine whether and to what extent the generation and availability of data from the ERAs of medicinal products meet the requirements of environmental protection, in particular environmental information law - also in comparison to industrial chemicals, biocides and plant protection products. In the study the following hypotheses were investigated: 1. the medicinal product authorisation procedure is in conflict with the requirements of environmental information law 2. the ERAs of the medicinal products are information on emissions within the meaning of environmental information law and are thus to be published independently of conflicting commercially confidential information 3. the pharmaceutical legislation does not meet the requirements of water protection law 4. the information regimes of the REACH, Biocides and Plant Protection Products Regulation are comparatively effective with regard to the generation and availability of environmental data. In particular, detailed regulations have been implemented on: publication of environmental data, further use of the environmental data and cross-manufacturer use of environmental data. In order to resolve the conflict between pharmaceutical law on the one hand and the requirements of environmental information law and water protection law on the other, the regulations outlined in point 4 should be transferred in a comparable way to pharmaceutical law. In particular, regulations are needed according to which 1. the physicochemical endpoints, information on fate and behaviour in the environment, the results of the ecotoxicological studies as well as the PNEC values are not to be treated confidentially and are to be published, while 2. the study summaries are not to be treated as confidential and published unless the study owner has submitted a reasonable request for confidentiality which has been positively decided by the authority.

4.13.P-Tu246 Human Health Risk Assessment of Pharmaceuticals in the European Vecht River

Daniel Joao da Silva Tavares Duarte¹, Rik Oldenkamp² and Ad Ragas³, (1)Department of Environmental Science, Radboud University, Nijmegen, Netherlands, (2)Radboud University Nijmegen, Netherlands, (3)Environmental Science, Radboud University, Nijmegen, Netherlands

Active pharmaceutical ingredients (APIs) can reach surface waters used for drinking water extraction and recreational activities, such as swimming and fishing. The aim of the present study was to systematically assess the lifetime human health risks posed by 15 individual APIs and their mixtures occurring in the German-Dutch transboundary Vecht River. An exposure model was developed and used to assess the combined risks of oral and dermal exposure under a variety of exposure conditions. A total of 4500 API uptake values and 165 lifetime risk values were estimated for 15 and 11 APIs, respectively. Overall, the lifetime human health risks posed by the APIs and their mixtures were deemed acceptable under typical exposure conditions. Under very extreme exposure conditions, API mixture risks were of potential concern while the risks of individual APIs were negligible, with a few exceptions. The antibiotic doxycycline and analgesic phenazone showed the highest and lowest risks, respectively. Recommendations for water managers are provided to help improve the accuracy and utility of human health risk assessments of pharmaceuticals.

4.13.P-Tu247 Human Pharmaceutical Substances - Data Gaps and Possible Solutions

Daniela Gildemeister¹, Arne Hein², Annika Buck², Ute Brandt² and Ines Rönnefahrt³, (1)Pharmaceuticals, Umweltbundesamt / German Environment Agency, Dessau-Roßlau, Germany, (2)German Environment Agency (UBA), Germany, (3)German

Since 2006 the assessment of environmental risks for marketing authorisation applications in human pharmaceuticals is based on the guideline on the environmental risk assessment of medicinal products for human use (EMA/CHMP/SWP/4447/00 corr 2), which is currently under revision. For Germany, the German Environment Agency (UBA) is tasked with the evaluation of environmental risks of human pharmaceuticals. For several scientific questions during the revision process of the guideline UBA evaluated the ERA data submitted in the last years and this evaluation is updated now. The general EU human pharmaceutical legislation is also under revision. Strengthening environmental risk assessment is one of the aims of the revision. UBA supports the idea of establishing a catching up procedure for legacy pharmaceuticals connected to a database with publicly available environmental data in substance based monographs. Over the last decade, the regulatory work at UBA resulted in a non-public database containing effect data on approximately 300 active pharmaceutical ingredients (APIs). A considerable part of this data is currently not publicly available due to property rights held by the respective applicants or missing public assessment reports. For our API overview we start with all marketed APIs in Germany. Initially, we identify all APIs for which an ERA is required according to the guideline based on their chemical nature. After comparing them with the database of available ERAs, we focus on German consumption data, pharmaceutical groups with identified environmental risks and also monitoring data from the PHARMS-UBA database (www.uba.de/db-pharm) to identify most relevant APIs without environmental data. The provided API overview is one brick to build up a catching – up procedure for legacy human pharmaceuticals with unknown risks.

4.13.P-Tu248 Pharmaceutical PNECs for Manufacturing Effluents - Lilly's LAEG Program

Alison Nimrod Perkins, Michael Lee, Neil Parke and David Guntz, Eli Lilly and Company, United States

Eli Lilly and Company (Lilly) is a Research and Development-focused pharmaceutical manufacturing and sales company. Lilly has a mature manufacturing wastewater management program that ensures compliance with local regulations and protects downstream ecosystems. One part of this program requires adherence to containment limits on the amount of active pharmaceutical ingredients (APIs) that can be discharged to surface water and which are based on Lilly Aquatic Exposure Guidelines (LAEGs). LAEGs are similar to water quality standard (WQS) or predicted no-effect concentration (PNEC) values. These guidelines are set to protect aquatic organisms, humans eating fish and drinking water, and wildlife eating fish and drinking water downstream of Lilly facilities. LAEG values for Lilly APIs are presented along with an overview of methodology for derivation of the values. Lilly facilities are periodically assessed for compliance with containment limits and an overview of those results is presented. The program is being expanded to apply to vendors in the supply chain. An overview of results of compliance for those sites that have been assessed is presented.

4.13.P-Tu249 Prioritization of Active Pharmaceutical Ingredients Based on Predicted Environmental Risk

Cristiana Cannata¹, Thomas Backhaus², Anna Lombardo³, Stewart Owen⁴, Rhys Whomsley⁵ and Ad Ragas⁶, (1)Radboud University, Nijmegen, Netherlands, (2)University of Gothenburg, Sweden, (3)IRCCS - Istituto di Ricerche Farmacologiche Mario Negri, Italy, (4)AstraZeneca, United Kingdom, (5)European Medicines Agency, Netherlands, (6)Radboud University, Netherlands

The emission of active pharmaceutical ingredients (APIs) to the environment is of increasing concern. Given the enormous number of APIs being used (>1500 APIs in Europe), it is unclear which APIs cause the highest environmental risk and require mitigation. Although an environmental risk assessment (ERA) is mandatory for marketing authorization applications in the European Union, ERA data are not available for most medicines approved prior to 2006. Since it is unfeasible to collect extensive risk assessment data on all APIs, we need to prioritize APIs based on suspected environmental risk and further investigate the top ranking APIs to establish their true environmental risk. Within IMI PREMIER project (<https://imi-premier.eu>), a procedure developed to prioritize APIs based on suspected environmental risk was applied to 1402 APIs used in human medicinal products in Europe. The list of APIs was compiled by combining various inventories, such as EMA's Article 57 database, including medicines authorized in the European Economic Area, the FASS database, including medicines approved in Sweden, and the iPIE?sum database, providing access to various environmental fate and ecotoxicity data of APIs. APIs without a defined and retrievable structure, molecular weight or ATC code were excluded from the list; as were amino-acids, proteins, metal?containing APIs, hormones, antibiotics and molecules with a molecular weight lower than 100 g/mol or exceeding 1300 g/mol. A risk-based prioritization was performed combining an exposure estimate (measured or predicted environmental concentration; MEC or PEC, respectively) with a Predicted No-Effect Concentration (PNEC). We ran multiple prioritizations, using different data sources and proxies, making use of both empirical and predicted data. Starting from easily accessible data, the assessment was then refined using less conservative approaches, requiring more detailed and less accessible data. The number of APIs prioritized decreased as data need increased. We compared the resulting prioritizations to a reference ranking based on empirical data only, and determined the correlation between the relative positions of the common APIs. This correlation decreased as the use of predicted data increased. Ultimately, we identified the top ranking APIs of the prioritizations that better correlate with the reference ranking and we selected 15 APIs with relevant data gaps that will undergo further testing in the IMI PREMIER project.

4.13.P-Tu250 Behavior and Biochemical Effects of Trabectedin in the Zebrafish *Danio rerio*

Evila Pinheiro Damasceno¹, Cristiana Marques², Laura Rama², Amadeu Soares³, Leticia Lotufo⁴, Susana Loureiro³ and Maria D Pavlaki², (1)Department of Biology & CESAM - University of Aveiro, Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)Universidade de Aveiro, Portugal, (4)University of São Paulo, Brazil

Anticancer agents (AAs) pose a great environmental risk due to their increasing consumption and high toxicity to non-target cells. Once used, AAs go to wastewater treatment plants as part of domestic and hospital residues, where they are not efficiently removed. After released into the environment, AAs and their metabolites may promote toxicity (genotoxic, carcinogenic and teratogenic) to non-target organisms due to their modes of action. Among AAs, trabectedin, a cytotoxic AA, used in the treatment

of soft tissue sarcoma, shows no data regarding its environmental risk in the aquatic environment. To start filling in this gap, the aim of this study is to assess the effects of trabectedin at behavioral and biochemical level towards adults of the zebrafish *Danio rerio*. Six fish per replicate (quintuplicates) were exposed to 1.3 nM of trabectedin for 7 days. Fish's horizontal movements were recorded for 12 minutes, alternating 2-minute light and dark periods to provide the total distance travelled by fish and the fish's path angle. Afterwards, fish were returned to their respective aquariums to reduce their eventual stress levels due to handling for one hour, and then they were anesthetized on ice, dissected, and snap frozen for the subsequent enzymes' analysis. Cholinesterase (ChE) activity of the brain and lactate dehydrogenase (LDH) and glutathione-S-transferase (GST) of the muscle were measured through spectrophotometry and were expressed in weight of substrate hydrolyzed per minute per mg of protein. Trabectedin did not affect the total distance covered by adult zebrafish during alternating light and dark periods, as well the path angle rotation. However, statistical differences ($p < 0.05$) between the control and exposed groups were detected in GST and LDH activity, indicating a possible biochemical stress to the fish. The findings presented herein, indicate the increased potential of trabectedin to promote toxicity down to nanomolar range. Concluding, more studies are needed to better understand how trabectedin acts on the zebrafish's metabolic process to provide a suitable hazard prediction of this AA to the environment.

4.13.P-Tu251 Exposure to Environmentally Relevant Concentration of Selected Pharmaceuticals Alters the Life History in the Littoral Cladoceran *Simocephalus punctatus*

Jesús Rodríguez Estrada¹ and Felipe Fernando Martínez-Jerónimo², (1)Instituto Politécnico Nacional-ENCB, Mexico, (2)Escuela Nacional de Ciencias Biológicas, IPN, Mexico

Pharmaceuticals are emerging pollutants widely spread in aquatic ecosystems because its increasing use for human and animal health in the last decades. Despite the presence of these xenobiotics in waterbodies has increased, scarce information about the toxic effects that these pollutants can produce in aquatic biota is available. Medicines are used worldwide, and now concentrations from ng to $\mu\text{g L}^{-1}$ have been reported in many waterbodies, but concentrations as high as mg L^{-1} have also been documented in some rivers. Littoral cladocerans are organisms that can be exposed to water and sludges of wastewater treatment plants containing emergent pollutants that are not removed during treatment. In this study, we assessed the toxic effects of the antibiotic Amoxicillin, the antidepressant Venlafaxine, and the non-steroidal anti-inflammatory Diclofenac. Effects on the life history and growth of *Simocephalus punctatus* were assessed. Neonates of *S. punctatus* were exposed to environmentally relevant concentrations of each drug (0.1, 1, 10, and $100 \mu\text{g L}^{-1}$) for 21 days. Demographic effects were assessed through a Life Table approach determining R_0 , G , e , r , and V_x . The increase in size at 7, 14, and 21 days was also measured. Amoxicillin produced adverse effects on offspring, with 20.35% of the released progeny being dead. Diclofenac exposure increased life expectancy (e) and the net reproductive rate (R_0). Exposure to Venlafaxine decreased life expectancy, but population growth (r) increases in the cladoceran. Generation time (G) decreased in the high concentration of Amoxicillin, but G had no differences in cladocerans exposed to Venlafaxine and Diclofenac. The highest reproductive value (V_x) was observed in organisms exposed to the high concentration ($100 \mu\text{g L}^{-1}$) of each pharmaceutical. At 7-d, the body total length significantly decreased in organisms exposed to the high concentration of Venlafaxine and Diclofenac. At 21-d, organisms exposed to Venlafaxine had the largest body size (2.5 mm). The effects here observed on the reproduction and growth of *S. punctatus* warn about environmental risk caused by the presence of these pharmaceuticals in the aquatic ecosystems. Although not all the observed effects could be classified as unfavorable, other consequences at different study levels (biochemical or physiological) could be expected. Results here presented demonstrated the effects that environmentally relevant concentrations of drugs produced in the aquatic biota.

4.13.P-Tu252 Exposure to the Antibiotic Amoxicillin Produces Toxic Effects in the Cladoceran *Daphnia magna*

Miriam Hernández Zamora¹, Laura Martínez-Jerónimo² and Felipe Fernando Martínez-Jerónimo³, (1)Instituto Politécnico Nacional-Escuela Nacional de Ciencias Biológicas, Mexico, (2)Escuela Nacional de Ciencias Biológicas-IPN, Mexico, (3)Escuela Nacional de Ciencias Biológicas, IPN, Mexico

In the past few years, the presence of pharmaceuticals in aquatic ecosystems has received increasing attention due to the adverse effects that these pollutants can produce on the aquatic biota. Among the pharmaceuticals used in many countries worldwide, consumption of antibiotics is in the range of 60 to 70%; within this group, ampicillin, amoxicillin, and bacampicillin are commonly used to treat many diseases in both humans and veterinary medicine. Antibiotics have been recorded in different waterbodies at concentrations ranging from ng/L to $\mu\text{g/L}$. There is little information on the ecotoxicological effects of amoxicillin on aquatic biota, particularly in the zooplankton. For this reason, this study aimed to determine the chronic toxicity produced by amoxicillin in the cladoceran *Daphnia magna*. Acute toxicity was determined, and after this, subchronic toxicity studies were performed. *D. magna* individuals (starting from neonates) were exposed to the sub-lethal amoxicillin concentrations of 0.1, 1, 10 and 100mg L^{-1} , during 21 d at 25°C, 16:8 photoperiod, and feeding with $8 \times 10^5 \text{ cells mL}^{-1}$ of the microalgae *Pseudokirchneriella subcapitata*. Population growth, fecundity, and metabolic biomarkers were measured. Survival, accumulated progeny, and the number of neonates per clutch were quantified daily; the protein, carbohydrate, and lipid concentrations were determined at the end of the bioassay. Results showed that accumulated progeny was significantly higher in the concentrations of 10 and 100mg L^{-1} of amoxicillin than the control; however, age to first reproduction was significantly lower in 10 and 100mg L^{-1} of amoxicillin with respect to the control. The number of clutches was not significantly affected at any concentration of the antibiotic. The analysis of metabolic biomarkers in *D. magna* exposed to amoxicillin showed that the proteins, carbohydrates, and lipids increased significantly in the concentrations of 0.1, 1, and $1 \mu\text{g L}^{-1}$ of amoxicillin; nevertheless, biomarkers content decreased at the highest concentration of this antibiotic. Amoxicillin caused significant toxic effects in *D. magna*. Obtained results warn about adverse effects in zooplankton populations exposed to amoxicillin. It is essential to establish permissible limits for antibiotics before they are discharged in aquatic ecosystems, mainly via treated and untreated wastewaters, because of the documented negative effect on the aquatic biota.

4.13.P-Tu253 Feminine Contraception and Environment: A New Estetrol-Based Oral Contraceptive As an Environmentally-Friendly Alternative to Synthetic Estrogens

Sebastien Baekelandt¹, Laura Burattin¹, Céline Gérard², Céline Delierneux², Nathalie Leroux¹, Marie Goormans¹, Jerome Lambert¹, Valérie Cornet³ and Patrick Kestemont¹, (1)University of Namur, Belgium, (2)Mithra Pharmaceuticals, Belgium, (3)Université de Namur, Belgium

Estetrol (E4) is a natural estrogen produced by the fetal liver during human pregnancy. E4 has been recently approved in Europe in a combined oral contraceptive containing 15 mg E4 and 3 mg Drospirenone and is currently under development for its use in hormone replacement therapy. The synthetic estrogen ethinylestradiol (EE2), widely used in oral contraception, is described as a strong endocrine disruptor for aquatic organisms. In order to address the endocrine disruptive potential of E4, a Fish Short-Term Reproduction Assay was conducted according to OECD229 test guideline. Sexually mature zebrafish (*Danio rerio*) were exposed for 21 days to E4 or EE2 at environmentally relevant concentrations. Three concentrations of each hormone were tested: 1, 10 and 100 ng/L for EE2 (0.1 ng/L usually detected in surface waters) and 0.3, 3 and 30 µg/L for E4 (predicted environmental concentration calculated at 0.03 µg/L). Fecundity was quantitatively assessed daily throughout the experiment. At the end of the 21-day exposure period, vitellogenin (VTG) was quantified in body homogenates, and gonads were preserved for endocrine-related histopathology. EE2 considerably reduced egg production at 10 ng/L and significantly stimulated VTG production in both males and females at 10 and 100 ng/L respectively. Histopathology of fish gonads revealed interstitial cell hypertrophy/hyperplasia, interstitial proteinaceous fluid, oocyte atresia, granulomatous inflammation, decreased yolk formation and interstitial fibrosis. Regarding E4, no reduction in egg production was observed from 0.3 to 30 µg/L. However, VTG was significantly stimulated in males at 30 µg/L. Histological analyses of gonads from fish exposed to E4 revealed only a slight interstitial fibrosis in females and a slight interstitial cell hyperplasia and fibrosis in males at 30 µg/L. Estrogens are generally described as endocrine disruptors having strong effects on fish reproduction. However, the results of the present experiment lead to the conclusion that E4 has a much better environmental profile than EE2 and that the use of E4 in oral contraceptives will not affect fish reproduction.

4.13.P-Tu254 Immobile and Defenceless: Behavioural Effects of an Anticonvulsant on *Lymnea stagnalis*

Charlie Davey¹, Tom van der Meer² and Michiel Kraak¹, (1)University of Amsterdam, Netherlands, (2)University of Amsterdam IBED Institute, Netherlands

The majority of human pharmaceuticals are not completely metabolized by the human body, and are thus excreted and subsequently released into the aquatic environment, potentially affecting non-target species. A potentially concerning pharmaceutical is the anticonvulsant topiramate, which reduces neuron firing. Since non-target species could experience similar negative effects as humans, invertebrate behaviour and therewith their role in ecosystem functioning may be affected by the presence of topiramate in the aquatic environment. The aim of the present study was therefore to determine the effect of topiramate on the mobility and anti-predator response of the freshwater snail *L. stagnalis*. The snails were exposed to nominal topiramate test concentrations of 0, 0.01, 0.1, 1 and 10 mg/L, with 5 individually exposed replicate snails per concentration. After 24, 48, 72, 96 and 168 h of exposure, snail orientation was observed for 10 seconds per minute for 10 consecutive minutes and the anti-predator response (retraction and emergence) was scored during 3 minutes after gently probing the snails with a skewer. We observed that the orientation change of the snails exposed to the two highest topiramate test concentrations decreased significantly during the course of the experiment, resulting in a clear dose response relationship for the effect of topiramate on snail orientation, from which an 168 h EC₅₀ value of 0.89 mg/L was derived. The snails exposed to 10 mg/L topiramate also showed a decreased response to probing, with the non-responding snails not retracting into their shell after the stimulus. Hence, a clear dose response relationship was also obtained for the effect of topiramate on anti-predator response, resulting in an 168 h EC₅₀ value of 5.7 mg/L. The negative effects of topiramate on the mobility and anti-predator response of *L. stagnalis* coincide with side-effects in humans, such as psychomotor slowing, ataxia and confusion. Consequently, snails may become more predated and lose their ability to transfer organic material into energy, potentially disturbing the energy dynamics in aquatic ecosystems. Thus, the presence of the anticonvulsant topiramate in the aquatic environment could lead to immobility and defencelessness of invertebrates, potentially affecting ecosystem dynamics. It is therefore concluded that the increased flux of pharmaceuticals into the aquatic environment may alter ecosystem dynamics through changes in invertebrate behaviour.

4.13.P-Tu255 In Vitro Effects of Antibiotics on the Haemocytes of the Clam *Ruditapes philippinarum*

Jacopo Fabrello¹, Davide Asnicar², Greta Nicolussi¹, Maria Ciscato³, Valerio Matozzo⁴ and Maria Gabriella Marin³, (1)Università di Padova, Italy, (2)Department of Biology, Università degli Studi di Padova, Padova, Italy, (3)University of Padua, Italy, (4)University of Padova, Italy

Pharmaceuticals are biologically active compounds increasingly used in both human and veterinary medicine. Pharmaceuticals are continuously released into the aquatic environments by urban and farm waste waters. This could lead to detrimental effects on non-target species. In this study, we evaluated the *in vitro* effects of three antibiotics: Amoxicillin, Trimethoprim, Ciprofloxacin and – for the first time – a mixture of them on haemocytes of the clam *Ruditapes philippinarum*, a bivalve species widely used in ecotoxicological studies. Haemolymph was collected from the adductor muscle of clams and haemocytes were then exposed for 1 h in culture chambers to filtered sea water (FSW, as control) and to 1 µg/L of individual antibiotics or their mixture in FSW. After the exposure, several cellular responses were evaluated, such as haemocyte viability, lysosomal membrane stability, superoxide anion production, acid and alkaline phosphatase activity, and the frequency of both micronuclei and chromosomal aberrations. One hundred cells per slides (two slides per experimental conditions) were observed under a light or fluorescence microscope at 1000x. Statistical analysis revealed that the haemocytes viability was not affected, but all the tested antibiotics affected the lysosomal membrane stability. In addition, antibiotics and their mixture significantly increased the percentage of cells positive to

superoxide anion. The exposure to antibiotics strongly increased the number of haemocytes positive to acid phosphatase, but not to alkaline phosphatase. Lastly, the exposure did not influence the micronucleus frequency, whereas a significant increase in the frequency of cell aberration (multipolar cells) was observed. These results demonstrated that antibiotics could affect haemocyte parameters in *R. philippinarum*. Furthermore, amoxicillin and mixture showed the highest morpho-functional effects, but the mixture highlighted a non-additional interaction between antibiotics. Although the mechanisms of action of antibiotics on bivalve haemocytes need to be more fully investigated, oxidative stress-mediated toxicity is very likely.

4.13.P-Tu256 Inter-Laboratory and Inter-Exposure-Duration Endpoint Variability of Antibiotics in OECD TG 201 Studies Using the Same Test Organism

Ralf Arno Wess¹, Stefan Hoeger² and Matthias Loetscher³, (1)Innovative Environmental Services (IES) Ltd., Switzerland, (2)Innovative Environmental Services IES Ltd, Switzerland, (3)Université de Lorraine - UdL, France

Algal toxicity testing investigates effects on biomass (yield) and the growth rate to multiple generations of the test organisms. Therefore, acclimation and even adaptation may occur during the test period and can accordingly alter test results significantly. Consequently and despite the precise test protocol prescriptions of the OECD Test Guidance 201, which has been updated several times, there is variability in terms of test results from different experiments. This is a generally understood fact and considered in regulation in that the effects on the growth rate, if available, have to be preferred over biomass data. Additionally test ratings are proposed in the literature and used in regulatory practice in order to justify a reliability ranking of the available references. A collection of published data is presented and gives an idea of the order of magnitude of the intrinsic test result variability. The recent OECD TG 201 states a normal test duration of 72 hours. However, shorter or longer test durations may be used provided that all validity criteria can be met. The poster compares example results for antibiotics with test endpoints recorded in the same tests after 72 and 96 h. The influence of different exposure durations is shown and potential reasons are discussed. The order of magnitude of the Inter-Exposure-Duration result variability is compared with Inter-Laboratory variability.

4.13.P-Tu257 It Stays in the Family - Multigenerational Approach for Testing Long-Term Effects of Pharmaceuticals

Frederik Meyer¹, Thu Huyen Nguyen², Ute Kühnen³, Peter Von der Ohe⁴ and Mirco Bundschuh⁵, (1)University Koblenz-Landau, Landau, Germany, (2)University Landau, Germany, (3)Federal Environment Agency Germany, Germany, (4)Federal Environment Agency (Umweltbundesamt), Germany, (5)Institute for Environmental Sciences University of Koblenz-Landau, Germany

Organisms in surface waters are exposed to a variety of pharmaceuticals that were intended for human consumption or agricultural purposes. Because of the (pseudo-)persistence of many of these substances, it seems reasonable to consider an extension of the existing standardized ecotoxicological test methods covering longer exposure scenarios exceeding one generation. Therefore, this study proposes a method for a multigenerational test protocol considering the sensitivity of endpoints (i.e. response variables) and the technical feasibility for a worst case scenario. For this reason, complementary approaches relative to the OECD Guideline 211 were implemented to refine risk predictions and move towards a standardisation of multigenerational testing. For validation, a multigenerational test was performed, in which *Daphnia magna* were exposed to two pseudo-persistent model pharmaceuticals, namely the antibiotic ciprofloxacin and the glucocorticoid dexamethasone. High dexamethasone concentrations (4000 and 10000 µg/L) resulted in 100 % mortality after 7 days, while 640 and 1600 µg/L resulted in a significant decrease in reproduction in the parental generation (F0) after 21 days, which was enhanced in the subsequent generation (F1) under continued exposure. For the endpoint body size, the adverse effects intensified and were most prominent in the F1-generation exposure to 1600 µg dexamethasone/L. The results of ciprofloxacin showed a more complex pattern: body size, weight and reproduction were first significantly stimulated at low concentrations (i.e., 187.5 and 375 µg/L) in the F0-generation, while at high concentrations (i.e., 6000 to 12000 µg/L) opposite effects were found with significantly impaired reproduction, growth and increased mortality. These effects - positive and negative - intensified in the F1-generation. The development of a simplified Dynamic Energy Budget Models could thereby additionally support the scientific understanding on potential stimulatory effects at lower concentrations. Therefore, these additional variables can support the extrapolations to effects on the population level. Hence, the results indicate the potential relevance of a multigenerational test design for the accurate reflection of risks, particularly of persistent or pseudo persistent pharmaceuticals and could further help to refine risk assessment.

4.13.P-Tu258 Opioid Exposure Leads to Differential Behavioural Effects in Zebrafish Larvae

Joel Trummer¹, Jennifer Fitzgerald¹, Aida Kiani Fard¹ and Colette Michèle vom Berg², (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Eawag Swiss Federal Institute of Aquatic Science and Technology, Switzerland

Opioids find different uses in our society. Therapeutically, they are mainly used to treat acute and chronic pain or serve as a substitution in opioid dependence therapy. Due to their euphoric effect, they are also consumed in a recreational manner. Through human excretion of the parent compounds and metabolites, accidental spillage or disposal opioids are released into wastewater, and are only degraded to a limited extent. Consequently, various opioids can be detected in wastewater influents, effluents and surface water. Since opioid consumption (legal or illicit) is rising, their environmental occurrence is as well. However, their impact on aquatic species is currently only poorly understood. In this study, we used the zebrafish model to investigate the impact of fentanyl citrate and tramadol hydrochloride on the behaviour, physiology and morphology of zebrafish larvae. The light dark transition (LDT) test was used to assess the locomotor activity, which measures the larvae's reaction to alternating light and dark phases. Moreover, larvae were tracked from the side view to assess their vertical positions. Heart rates and swim bladders (SB) were measured from short video sequences recorded from larvae imaged under a binocular microscope. Exposure of zebrafish larvae to fentanyl citrate from 0 to 5 days post fertilization (dpf) lead to a reduced locomotor activity during LDT dark phases and a reduced heart rate at 10 µM. Moreover, the number of animals with uninflated SBs was increased at 10 µM compared to control

conditions, and that the sizes of the inflated SBs were smaller at this concentration. When larvae were exposed to fentanyl citrate and tramadol hydrochloride from 4 to 5 dpf, their SB sizes were expanded compared to control larvae. Moreover, larvae swam mainly close to the surface. SB expansion occurred around 3 hours of exposure to fentanyl citrate, whereas the surfacing behaviour was already induced after about 20 min of exposure. Our results show that different windows of exposure to the opioid fentanyl citrate during zebrafish development lead to differential behavioural, physiological and morphological effects. While developmental exposure leads to sedative effects and SB non-inflation, short exposures lead to uncontrolled surfacing behaviour and SB expansion. These effects can lead to impaired predator avoidance and feeding success and consequently to reduced survival chances of fish early life stages.

4.13.P-Tu259 The Interactions of Antipsychotics With the Cytochrome P450 System of Rainbow Trout and Its Impact on Hepatic Clearance of Pharmaceuticals In Vitro

*Tea Pihlaja*¹, *Elisa Ollikainen*² and *Tiina Sikanen*², (1)University of Helsinki, Helsinki, Finland, (2)University of Helsinki, Finland

The environmental residues of antipsychotic drugs are known to bioaccumulate and cause behavioral changes in fish. We have previously shown that the hepatic clearance of common antipsychotics (haloperidol, levomepromazine, risperidone) in rainbow trout in vitro is deficient or critically dependent on cytochrome P450 activity, which is known to be prone to inhibition by many xenobiotics including these antipsychotics themselves. In the present study, we screened a wider range of antipsychotics (citalopram, mirtazapine, sertraline, venlafaxine and its metabolite O-desmethylvenlafaxine) and anti-inflammatory agents (ibuprofen, ketoprofen, naproxen) for their half-maximal inhibitory concentration (IC₅₀) toward ethoxyresorufin O-deethylation (EROD, CYP1A) and benzyloxy-4-trifluoromethylcoumarin O-debenzylation (BFCOD, CYP3A) in rainbow trout liver S9 fractions (pH 7.8, 11°C). In addition, we determined the impact of P450 metabolism on their overall in vitro clearance based on OECD 319b, by selectively activating (with NADPH) and inactivating (without NADPH) the P450 system in RT-S9 incubations. The in vitro clearance (CL_{int, in vitro}) and IC₅₀ predictions were further corrected by fraction unbound (f_{u,S9}) determined for each compound in RT-S9 with rapid equilibrium dialysis assay. According to our results, all tested anti-inflammatory agents (diclofenac (control), ibuprofen, ketoprofen, naproxen), but only a few antipsychotics (levomepromazine, sertraline), are effectively cleared in RT-S9, and most of them show P450 dependent clearance rates in vitro. Among the test compounds, haloperidol (IC₅₀?10 µM), mirtazapine (IC₅₀?40 µM), levomepromazine (IC₅₀?2.5 µM), and sertraline (IC₅₀?0.3 µM) showed the strongest inhibition toward especially the EROD activity in RT-S9. The relevance of P450 inhibition for the hepatic clearance was further examined through mixture assays with diclofenac and naproxen. As a binary mixture (1 µM each), they did not decrease the hepatic clearances of one another. However, when incubated together with sub-inhibitory concentrations (10 nM each) of haloperidol, levomepromazine, mirtazapine, and sertraline, the clearance rates of diclofenac was decreased by ca. 40% (p < 0,0001, t-test) and naproxen by ca. 30% (p= 0,0002165, t-test). These data indicate the likelihood of and warrant for closer examination of synergistic P450 inhibition in rainbow trout in vitro.

4.13.P-Tu260 The Zebrafish Embryo - a Source of Tools for Risk Assessment of Pharmaceuticals in Marine Ecosystems

*Katharina Brotzmann*¹ and *Thomas Braunbeck*², (1)COS University of Heidelberg, Germany, (2)University of Heidelberg, Germany

Increasing amounts of therapeutic drugs represent one of the greatest benefits to modern society. However, by their consumption and improper disposal as well as industrial and hospital discharges and wastewater treatment plants, pharmaceuticals are now increasingly being documented in natural ecosystems. First investigated in freshwater systems, they can now also be measured in marine environments. Active pharmaceutical ingredients (APIs) are recognized as important contaminants of emerging concern, but environmental risk assessment can be very complex; in fact, good quality hazard and exposure data are scarce or publicly not available. Ongoing improvement of advanced analytical techniques increased the possibility to detect environmental APIs of different therapeutic classes such as antibiotics, non-steroidal anti-inflammatory drugs (NSAIDs), antidepressants and antiepileptics with concentrations ranging from a few ng/L to hundreds of µg/L, but knowledge on fate and biological effects is still fragmentary. Thus, for the development of reliable risk assessment procedures for APIs, basic information such as uptake, bioaccumulation, and excretion kinetics of APIs in aquatic organisms are required in addition to toxicity and teratogenicity analysis, API-specific modes-of-action in non-target organisms and effect evaluations of API mixtures. For that, the zebrafish (*Danio rerio*) represents a versatile tool by providing multiple endpoints for the ecotoxicological assessment of pharmaceuticals such as toxicity studies in early life-stages, the characterization of chronic and subtle effects under ecotoxicologically relevant exposure scenarios, and, thereby, identification of metabolic pathways that play a dominant role in cellular responses to stress. For investigating, e.g., neuroactive drugs, sensory organ toxicity (eyes, olfactory and lateral organs) can be investigated by simple staining procedures and conducting coiling and locomotor assays. Changes in behavior by API can be identified even in embryonic stages. Finally, combining several endpoints of this model system allows to define the most suitable biomarkers for early detection of APIs. Results may be used to adjust prescription and disposal practices of domestic medicines. Supported by BMBF under 724-40003-03F0906A within the PharmaSea consortium (AquaticPollutants Joint Transnational Call by Water JPI).

4.13.P-Tu261 Time and Dose-Dependent Effects of Neuroactive Antidepressants and Pesticides on *Caenorhabditis elegans* Behaviour

*Merel van der Most*¹ and *Nico van den Brink*², (1)Wageningen University & Research, Netherlands, (2)Toxicology, Wageningen University, Wageningen, Netherlands

With a rise of antidepressant prescriptions worldwide, there is an increasing concern for the impacts of these pharmaceuticals on nontarget organisms in the environment. Antidepressants are neuroactive compounds and can therefore affect an organism's

behaviour. Behaviour is a sensitive endpoint that can also translate to effects at a population level. Another interesting aspect of antidepressants is that they have shown non-monotonic dose-response (NMDR) curves, with effects at low concentrations that disappear at higher concentrations. Such NMDR relationships may have clear implications for risk assessment, however, the resolution of current studies is often too coarse to have sufficient insights into their relevance. Therefore, the current study was performed into the behavioural effects of the selective serotonin reuptake inhibitors fluoxetine and sertraline and the acetylcholinesterase inhibiting pesticide chlorpyrifos. A wide range of concentrations (ng/l to mg/l) was taken into account and three different types of behaviour were examined: activity, feeding and chemotaxis. In order to statistically examine the non-monotonicity, non-linear regression models (onephasic, biphasic and triphasic) were applied to the results. These models are multiplications of the commonly used Hill model. The results showed a triphasic dose-response curve for activity and chemotaxis after exposure to fluoxetine, but not to sertraline and chlorpyrifos. Effects of fluoxetine already occurred at low concentrations in the range of ng/l. The time dynamics of the effect on activity showed recovery or stabilization over time at higher concentrations. This pattern may be explained by feedback mechanisms, such as inhibition of further serotonin release, the presence of serotonin- absorbing neurons, and receptor desensitization. The effects at low concentrations and the non-monotonicity in the result confirm the relevance of examining such responses, which proves the importance of including a full range of concentrations in order not to miss these effects. Furthermore, this study raises the question of how to include non-monotonicity in mixture toxicity modeling. The nonlinear regression models give multiple EC₅₀s, which is not common in the current mixture toxicity concepts of concentrations addition and independent actions. To assess this, mixture toxicity studies with these compounds are currently being conducted and will be presented.

4.13.P-Tu262 Toxicity Assessment of Tetracycline and Sulfamethazine in Eisenia fetida Earthworms

Erik Urionabarrenetxea¹, Nerea Garcia-Velasco², Irantzu Vergara¹, Beñat Zaldibar¹, Ailette Prieto¹, Urtzi Izagirre¹ and Manuel Soto¹, (1)University of the Basque Country, Spain, (2)Centre for Experimental Marine Biology and Biotechnology (PIE-UPV/EHU), Univ. of Basque Country, Spain

An increasing global population carried with it the needs of using higher amounts of pesticides and fertilisers in order to satisfy human demands. Antibiotics are widely used to control microbial diseases; especially in livestock maintenance. However, these antibiotics are rapidly excreted and poorly absorbed by target organisms; being released into the environment and spread along with the horse manure. Moreover, slurry and manure are frequently applied in agricultural lands as fertilisers, potentially affecting soil organisms and unbalancing communities. Among the most affected soil organisms, *Eisenia fetida* earthworms must be highlighted due to their close contact with the soil matrix, their representative habitat (horse manure), and sensible response to pollutants. In this work, the toxicity of two different antibiotics: Tetracycline and Sulfamethazine (0, 5, 10, 50, 100, 500, 1000 mg/kg) is evaluated in *E.fetida* earthworms. With such a purpose OECD acute toxicity tests (OECD-204; Filter Paper Contact Toxicity Test and Artificial Soil Tests), OECD reproduction test (OECD-222) and riboflavin measurements in earthworm coeloma were carried out. Thus, digestive or dermal uptake routes are evaluated, allowing obtaining different endpoints at different times and biological complexity levels. After 2 days exposure to sulfamethazine and tetracycline 0, 5, 50, 500, 1000 mg/L concentrations through filter paper, nor mortality nor significant weight losses were noted; highlighting the absence of dermal toxic effects. After 14 days of exposure to sulfamethazine and tetracycline 0, 10, 100 and 1000mg/L concentrations in soil, neither mortality nor significant weight losses were observed among exposed earthworms; discarding acute damages including oral and dermal toxicity routes. However, an increase in Riboflavine content in coelome was recorded in organisms exposed to antibiotics. Earthworms exposed for 28 days to sulfamethazine and tetracycline 0 and 1000 mg/L concentrations in order to evaluate the potential reproductive damages exerted, did not show neither mortalities nor significant weight losses. Similarly, no significant reproductive damages in cocoon production or juvenile number were observed. At tested concentrations no significant effects were recorded at organisms level, however impairments in the immune system of earthworms could occur after exposure to antibiotics. The authors would like to thank: Kontrae project (KK2020-00007) and Basque Government (IT1302-19)

4.13.P-Tu263 Ecotoxicity of Three Widely Used Antibiotics on Non-Target Soil and Water Organisms

Cristina Gan-Oria¹, Antonio Valenzuela¹, Guillermo Abajo¹, Natalia Ferrando Lázaro¹, Eva Terrado¹, Elisa Langa¹, M Rosa Pino² and Diego Ballester¹, (1)Universidad San Jorge, Spain, (2)San Jorge University, Zaragoza, Spain

Antibiotics and their metabolites are mainly excreted through urine and faeces reaching aquatic and terrestrial ecosystems through the sewage system. Environment concentrations might produce adverse effects in wildlife and public health due to the emergence of bacterial resistance. The aim of this study was determining the ecotoxicological effects of this type of drugs, namely Chloramphenicol, Tetracycline, and Erythromycin, which are three of the most worldwide prescribed antibiotics. On literature, such compounds were found in environment at concentrations that can reach even 2 µg/L in rivers or 0.51 mg/kg in biosolids and may be subject to bioaccumulation. *Allium cepa* and *Daphnia Magna* were used as biological indicators of terrestrial and aquatic environments, respectively. *A.cepa* was exposed to the following concentrations of the three before mentioned antibiotics: 0.03, 0.3, 3, 30 and 300 mg/L. After a 72-hour incubation, the impact on the root inhibition was measured for the calculation of phytotoxicity on this vascular culture plant and revealed that EC₅₀ values were 102.34 (84.09 - 126.42) mg/L for Chloramphenicol, 106.58 (82.33 - 141.47) mg/L for Tetracycline and > 300 mg/L for Erythromycin. Acute toxicity in *D.magna* was studied using different concentrations for each drug: 200, 400, 600, 800 and 1000 mg/L of Chloramphenicol, 25, 50, 100, 200 and 400 mg/L of Tetracycline and 125, 250, 500, 1000 and 1500 mg/L of Erythromycin. Subsequently, the effects on *D.magna* mobility were measured. The dose-effect curve allowed calculation of the concentration for the test substance whereby a 50 percent of *D.magna* individuals were immobilized after 24- and 48-hours exposition concluding Chloramphenicol EC₅₀(24h) = 285.63 (235.12 - 333.92) mg/L and EC₅₀(48h) = 183.22 (117.31 - 229.32) mg/L; Tetracycline EC₅₀(24h) = >400 mg/L and EC₅₀(48h) = 165.83 (119.17 - 252.53) mg/L; Erythromycin EC₅₀(24h) = 498.72 (405.55 - 608.40) mg/L and EC₅₀(48h) = 197.53

(142.19 - 252.85) mg/L. These results show that antibiotics are not innocuous to non-target soil and water organisms and can produce both acute toxicity in *D.magna* and phytotoxicity in *A.cepa*. Even though EC₅₀ occurs at much higher concentrations than those reported in the environment, the continuous application of biosolids as fertilisers or repeated wastewater discharges do not discard a potential increase in accumulation to higher levels in the coming years. *The authors thank the financial support of Gobierno de Aragón: Departamento de Ciencia, Universidad y Sociedad del Conocimiento (Group E39_20R).*

4.13.P-Tu264 Linking Personality, Gut Microbiome and Response to a Pollutant in Zebrafish

Asma Al Shuraiqi¹, Raeid Abed¹, Aziz Al Habsi¹ and Michael J Barry², (1)Sultan Qaboos University, Oman, (2)Sultan Qaboos University, Muscat, Oman

All animals have unique behavioral patterns termed behavioral syndromes. From an ecotoxicological perspective we know little about how personality affects response to pollutants. Sertraline is one of the the most widely prescribed antidepressants and acts as selective serotonin reuptake inhibitor that increases the concentration of serotonin in the brain. It has frequently been reported as a contaminant in surface waters worldwide. The first aim of this study was to measure the effects of sertraline on the behavior of zebrafish and test the hypothesis that effects will vary depending on personality traits of the individual. The gut biome plays a critical role in regulating host physiology and enhances the development of the central nervous system (CNS) and brain responses. In addition, the gut microbiota interacts with host neuroendocrine system leading to behavior changes. Therefore, the gut microbiome acts as a key intermediary between the external and internal environments. The second aim of this study was to investigate the effects of sertraline on the gut microbiome and relate these changes to personality traits. Zebrafish were exposed to five concentrations of sertraline ranging from 5 ng/L to 5 µg/L for 29 days. All fish were individually tagged and their personality assessed for anxiety and boldness using standard behavioral tests before exposure and again after exposure. Additionally, shoaling behavior and response of the fish to a conspecific alarm substance were tested after exposure. At the end of the experiment, fish were euthanized and the gut microbiome determined using next-generation sequencing. We observed non-linear behavioral responses to sertraline, with fish exposed to 500 ng/L showing a stronger response to the conspecific alarm substance. We also observed treatment-related changes in the gut microbiome. We will discuss how these changes relate to personality responses in the zebrafish.

4.13.P-Tu265 Transcriptomic Profiling of Clobetasol Propionate Induced Immunosuppression in Challenged Zebrafish Embryos

Fabian Essfeld¹, Hannes Armin Reinwald², Gabriela Salinas³, Elke Eilebrecht⁴, Christoph Schaefers⁵ and Sebastian Eilebrecht⁵, (1)Attract Eco'n'OMICS, Fraunhofer IME, Schmallenberg, Germany, (2)Fraunhofer-Institut für Molekularbiologie und Angewandte Oekologie IME, Germany, (3)NGS - Integrative Genomics Core Unit, Germany, (4)Fraunhofer IME, Germany, (5)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany

In the ecotoxicological hazard assessment of chemicals, the detection of immunotoxicity is currently neglected, mainly due to the lack of suitable standardized procedures. However, there are different approaches tackling this issue. For example, immune challenge models using zebrafish embryos can detect significantly reduced mortality rates when the embryos were previously exposed to immunosuppressive substances. Other studies on fish infection models used transcriptomics to get a deeper insight into the underlying molecular mechanisms. In this study, we present a new approach combining the strengths of both methodologies; we performed global gene expression analysis during acute infection with and without potential immunosuppression by chemicals. For this, freshly fertilized zebrafish (*Danio rerio*) embryos were exposed to the immunosuppressive drug clobetasol propionate (CP). After 48 hours, the embryos' immune system was challenged by microinjection of different pathogen associated molecular patterns (PAMPs). Total RNA was extracted three hours post injection and the altered transcriptomic profiles were assessed by RNA-sequencing and bioinformatics analysis. We identified differentially expressed genes (DEGs) regulated by PAMP injection, CP exposure or a combination of both. In order to answer the question whether and how CP impairs an acute immune response, we categorized PAMP regulated DEGs into hyper-, hypo- and non-responsive genes to PAMP after prior exposure to CP. Hypo-responsive genes were of particular interest, because among them there were potential biomarkers for immunosuppression. Interestingly, we observed that the expression rates in the PAMP+CP condition were a result of additive effects from the individual conditions for almost every gene. Overrepresentation analysis was performed in order to get insight into involved biological processes (BP) and we found that the vast majority of enriched ontologies in the PAMP condition were relevant to the immune system. Hypo-responsive genes were predominantly involved in the complement system and in antigen processing, indicating those BP to be most significantly impacted by CP-induced immunosuppression. In this study, we have shown that our approach can be a powerful tool to detect immunotoxicity and identify biomarker candidates. Future validation of this method by testing further model substances could help to increasingly address immunotoxicity in environmental hazard assessment of chemicals.

4.13.P-Tu266 Carbamazepine and Aquatic Macroinvertebrates: Effects on Structure and Functioning and Behaviour

Elien Versteegen¹, Edwin Peeters², Ivo Roessink³ and Paul van den Brink³, (1)Wageningen Environmental Research - WUR, Netherlands, (2)Wageningen University & Research, Netherlands, (3)Wageningen Environmental Research, Netherlands

Current environmental risk assessment of psychotropic drugs fails to reflect on the subtle effects of low drug concentrations. Due to the biologically active nature of psychotropics, their interaction with the nervous system, and their resemblance to infochemicals, these drugs might affect behavior of organisms even at low environmental concentrations. At these low concentrations, effects on the individual survival might seem absent, but small changes in behavior may already result in changes at population and ecosystem level. To account for these subtle effects in the current environmental risk assessment, there is a need for new endpoints to assess effects across different levels of ecological organization (i.e. individual, population, community and

ecosystem). The setup of an outdoor mesocosm study that combines the evaluation of both traditional and behavioral endpoints is presented here. The effects of chronic exposure to 0.001 – 100 µg/L carbamazepine (an anti-epileptic drug) was studied in outdoor freshwater mesocosms for 14 weeks. The main aim of this study is to find correlations between sublethal behavioral effects and changes in the structure and functioning of an aquatic ecosystem as a response to exposure to low environmentally relevant concentrations of carbamazepine. To this end, a set of standard endpoints comprising: abiotic conditions, decomposition of organic matter, Phytoplankton Chlorophyll-a, and the species composition and abundance of zooplankton and macroinvertebrates was measured throughout time. In addition, non-standard behavioral assays investigated the effects on individual feeding behavior and activity of *Gammarus pulex* and *Lymnea stagnalis*. The project will report the effects observed on macroinvertebrate and zooplankton communities as well as on several endpoints describing the effects on individual primary producers and the functioning of the aquatic ecosystem. Determining whether these individual behavioral endpoints are relevant at higher levels of ecological organization could emphasize the relevance of using behavioral endpoints for regulatory purposes.

4.13.P-Tu267 Fate, Dissipation, and Degradation of Psychotropic Medications in Outdoor Mesocosms

Jose Luis Rodriguez Gil¹, Jonathan Challis², Braedon Humeniuk³, Heather Jovanovic³, Vince Palace¹ and Mark Hanson³, (1)IISD Experimental Lakes Area (IISD-ELA), Canada, (2)University of Saskatchewan, Canada, (3)University of Manitoba, Canada

Psychotropic medications, such as antidepressants or anti-anxiety drugs, are some of the most prescribed pharmaceuticals worldwide. They are also some of the most detected pharmaceuticals in freshwaters. With the unprecedented and lasting impacts of the COVID-19 pandemic on people's mental health, prescriptions for these medications are expected to increase globally. The widespread presence of pharmaceutical compounds in the environment has resulted in growing calls for improved risk assessment of this group, requiring high quality data on their fate, behaviour, and effects. Here we provide refined measurements of the fate and half-lives of nine psychotropic pharmaceuticals under semi-field conditions with or without organic sediment. In total, seven outdoor, aboveground, tanks were filled with ~2,300L of fresh water, with a ~15 cm layer of either organic sediment or gravel. Tanks were spiked with a mixture of amitriptyline, bupropion, carbamazepine, citalopram, clozapine, duloxetine, fluoxetine, lamotrigine, and venlafaxine at 50 µg/L (one sediment-containing tank remained un-spiked). Water and sediment samples were collected over 40 days and the concentration of the nine compounds was determined via high-resolution mass spectrometry, which allowed for the assessment of possible degradation products via non-target analysis. For most compounds, the water-column half-lives were less than 2 days, with the most rapid loss in tanks with organic sediment. Only three compounds showed water-column half-lives greater than 2 days, namely Venlafaxine (3d in sediment, 6d in gravel), Lamotrigine (45d sediment, 25d gravel) and Carbamazepine (42d sediment, 30d gravel). Bupropion and Clozapine displayed initial peaks in sediment concentration around 1 week after application followed by a decrease over the remainder of the study. All other compounds showed higher persistence in sediment with concentrations remaining relatively constant over the study duration. A preliminary mass-balance indicates Citalopram, Fluoxetine and, to a lesser extent Venlafaxine, are the most persistent with the total mass of compound (sum of compound in the water and sediment) remaining relatively constant over the 40d study. Common degradation products (e.g. desmethyl-venlafaxine) were also observed and showed similar dissipation patterns as the parent compounds. These data can help us improve existing fate models to better predict their exposure and improve their risk assessment.

4.13.P-Tu268 Psychotropic Drug Interactions in the Freshwater Bivalve *Dreissena polymorpha*: What Have We Learned?

Vincent Carré¹, Justine Flayac¹, Vincent Felten¹ and Laetitia Minguéz², (1)Université de Lorraine, France, (2)LIEC (CNRS UMR 7360, Université de Lorraine), France

The potential for pharmaceutical compounds to cause adverse effects on aquatic systems even at low concentrations has become an emerging concern. However, the risks associated with long-term exposures at these low concentrations are still poorly understood, and therefore remain to be demonstrated. Similarly, while drug interactions are well known for humans, studies on cocktail effects on bivalves, in particular, are still rare. World population growth and the increase in the number of people suffering from neuropsychiatric disorders raise questions about the effects of psychotropic drugs, which are frequently found in surface waters, on aquatic organisms. This poster will present some results obtained during the DiMetEP project supported by the French National program EC2CO (Ecosphère Continentale et Côtière), on the interactions between two psychotropic drugs (sertraline and carbamazepine) and a freshwater bivalve *Dreissena polymorpha* commonly used in environmental biomonitoring programs. Through a multi- and interdisciplinary design, taking into account the fate of drugs in bivalves (distribution and metabolism) and their long-term effects, this project provides new knowledge on drug interactions in a representative freshwater species of filter-feeders and empirical data for risk assessment and the development of predictive approaches.

4.13.P-Tu269 Caffeine in Coastal Waters of the Iberian Peninsula: Risks and Possible Use As a Marker of Anthropogenic Contamination

Yolanda Valcarcel Rivera¹, Sandra Mozas Blanco¹, Andreu Rico², Isabel López³, SALOME MARTINEZ¹, JUAN GRIMA⁴, UNAX LERTXUNDI⁵, GORKA ORIVE⁶, MIGUEL MOTAS⁷, OSVALDO SANTOS⁸ and JOSE LUIS RODRIGUEZ-GIL⁹, (1)Rey Juan Carlos University, Spain, (2)IMDEA Water Institute/University of Valencia, Spain, (3)IMDEA Water Institute, Spain, (4)GEOLOGICAL AND MINING INSTITUTE OF SPAIN, Spain, (5)Araba Psychiat Hosp, Araba Mental Hlth Network, Osakidetza Basque Hlth Serv, Bioaraba Hlth Res Inst, Pharm Serv, C Alava, Spain, (6)NanoBioCel Group, Laboratory of Pharmaceutics, School of Pharmacy, University of the Basque Country UPV/EHU, Spain, (7)University of Murcia, Spain, (8)University of Lisbon, Portugal, (9)University of Manitoba, Canada

Caffeine and its main metabolite, paraxanthine, have been widely detected in many environmental matrices, and organisms worldwide. Even though adverse effects at environmentally relevant concentrations have been reported by numerous studies, their

potential environmental risks, and particularly in coastal areas is yet to be determined. Given their widespread consumption, chemical stability, and relationship with other human pollutants, these compounds have been historically suggested as possible markers of anthropogenic contamination. This can be particularly relevant for coastal waters, where current regulations on bathing water quality focus on microbiological endpoints and ignore non-biological pollution. Our study determined the presence of caffeine and paraxanthine in coastal areas of Spain and Portugal, with the aim of testing the usefulness of these compounds as markers of anthropogenic pollution as well as assessing the risk posed by their current levels. Water samples were collected from beach and bathing areas, far from the discharge points of the treatment plants, in 16 sites along the Lisbon and Algarve (Portugal) coast, 18 along the coast of Cádiz (Spain)(spring / summer) and 12 in the Mar Menor coastal lagoon (Murcia). Composite samples were collected every 4 hours for 12 hours. Concentrations of both compounds were detected in all collected samples, despite the fact that all the samples had microbiological levels suitable for bathing. The highest concentrations of caffeine were detected on the beaches of Los Nietos in the Mar Menor coastal lagoon (Murcia), Galapinho/Sierra Arrabida (Portugal), and Chiclana in (Cádiz) (with 704, 315 and 286 ng/L, respectively). The highest values for paraxanthine were also detected in Los Nietos, the Algarve in Portugal and Algeciras in Cádiz (with 216, 205 and 126 ng/L, respectively). Laboratory effects data for chronic exposure was used, when available, for the derivation of Hazard Quotients (HQs). For caffeine, the highest HQ was obtained in Los Nietos (Mar Menor), Chiclana (Cádiz) and Algarve (Portugal) (14.1, 5.7 and 4.9 ng/L respectively). For paraxanthine, the HQ was high (HQ>10) in most sites, with the highest values obtained in Los Nietos, Algarve and Algeciras (54, 51.2, 31.5 ng/L respectively). Based on our results, caffeine and its metabolite can be useful markers of anthropogenic contamination in support of the assessment for water quality in bathing areas. This study has been funded by the Rey Juan Carlos University, through “bridge projects”. Acknowledgements: Ministry of Education and professional training through its program of stays “Senior, Salvador de Madariaga”.

4.13.P-Tu270 Concentrations of Chemicals of Emerging Concern Are Mediated by Seasonal Hydrodynamics in an Offshore Marine Environment

Anna Robuck¹, Michaela Cashman², Mark Cantwell², Michael Thompson³, Christine Gardiner⁴, Julia Sullivan⁵, David Wiley⁶, Pete DeCola³ and Rainer Lohmann⁷, (1)Icahn School of Medicine at Mount Sinai, United States, (2)U.S. Environmental Protection Agency, United States, (3)National Oceanic and Atmospheric Administration, United States, (4)University of Rhode Island, United States, (5)U.S. EPA, United States, (6)National Oceanic and Atmospheric Administration (NOAA), United States, (7)University of Rhode Island, Narragansett, RI

Many chemicals of emerging concern (CECs), including pharmaceuticals and personal care products, are distinct from legacy contaminants in their ability to travel readily in aqueous matrices, resulting in the common occurrence of CECs in aquatic systems receiving point and nonpoint source waste streams. However, little data currently describes CEC concentrations in marine ecosystems. Here we measured 17 pharmaceuticals, caffeine, sucralose, and 25 per- and polyfluoroalkyl substances (PFAS) surrounding a major wastewater discharge into Massachusetts Bay, USA. Water grabs were collected from surface and bottom water compartments, and field work was conducted during both stratified and unstratified water column conditions. Samples were analyzed for CECs using liquid chromatography coupled to tandem mass spectrometry. 10 of 17 pharmaceuticals, sucralose, caffeine, and 9 PFAS were detected in surface and bottom water at low (>40 ng/L) to very low concentrations (>2ng/L). Concentrations were proportional to proximity to the point source discharge, with the highest concentrations observed directly south of the outfall in accordance with regional circulation patterns. Stratified conditions mediated occurrence of CECs, with increased bottom water CEC concentrations during stratified conditions and increased surface water CEC concentrations during unstratified conditions. Concentrations of all analytes in both surface and bottom water were generally higher in winter, likely related to reduced biological degradation and uptake. This work highlights the potential for pharmaceuticals and other CECs to persist in marine environments, and underscores the need for further evaluation of potential impacts of these compounds in marine biota subject to chronic, low-level exposures.

4.13.P-Tu271 Environmental Fate of Estetrol (E4), a Native Estrogen Used in Oral Contraception

Erick Nfon¹, Patrick Kestemont², Glwadys Rausin³, Céline Gérard³ and Jean-Michel Fiodart³, (1)Smithers, United Kingdom, (2)University of Namur, Belgium, (3)Mithra Pharmaceuticals, Belgium

Estetrol (E4) is a unique native estrogen produced by the human fetus during pregnancy. E4 formulated as the monohydrate is a new active substance that received a positive opinion from the Committee for Medicinal Products for Human Use (CHMP) for use in a combined oral contraceptive. E4 is projected to enter the aquatic environment through effluents discharged by sewage treatment plants. The environmental fate of E4 was investigated using a battery of studies designed to describe its physical/chemical characteristics and potential for persistence and bioaccumulation in the environment. The mean measured octanol/water partition coefficient (log KOW) of E4 was determined to be 1.65. In a ready biodegradability study, the mean biodegradation was 3% after 28 days incubation. E4 is not significantly sorbed to soils and sewage treatment solids with Freundlich isotherm adsorption coefficients Kf between 88 and 147 in soils and 35 and 36 in sludges, respectively. In a 100-d aerobic-aquatic biodegradation study into two systems, E4 biodegradation rates in water were 0.182/d and 0.057/d (half-life 3.81 and 12.08 d, respectively) and in sediment were 0.103/d and 0.169/d (half-life 6.71 and 4.09 d, respectively). The results presented illustrate the transient nature of E4 in the aquatic environment and indicate that bioaccumulation of E4 would not be expected.

4.13.P-Tu272 Emissions of Imidacloprid From Sewage Treatment Plants From Use of Veterinary Medicinal Products in the UK

Jackie Atkinson¹, Beatrice Valles-Ebeling², Michael Starp², Nikola Bitsch, agr.³, Andreas Kampkoetter² and Jan Achtenhagen⁴, (1)Elanco Animal Health, UK, (2)Elanco Animal Health, Germany, (3)Elanco Animal Health GmbH, Germany, (4)knoell

Germany GmbH, Germany

Imidacloprid has been detected in some water samples taken from European rivers. Potential sources of imidacloprid include historical uses in outdoor and greenhouse plant protection products (ending end May 2022), in imported potted plants, fruits and vegetables, as well as in biocides and veterinary medicinal products (VMPs). In a previous work, we examined VMPs as a potential emission source of imidacloprid through modelling work considering the following 3 exposure pathways: 1. washing of dogs, 2. washing of pet bedding of cats and dogs and 3. walking dogs in the rain. The conclusion reached was that Imidacloprid containing VMPs make only a very small contribution to the levels of Imidacloprid detected in UK surface waters. The calculated environmental concentrations indicated an acceptable risk to aquatic organisms. Two additional exposure scenarios have been developed considering Imidacloprid containing spot-on and collar VMPs: 1. abrasion from treated animals to people's clothes and washing of these clothing followed by release to wastewater to the Sewage Treatment Plant (STP), and 2. release after stroking of cats and dogs followed by hand washing and release to surface water via STP. General parameters based on the Biocidal Product Regulation (BPR) or on product specific studies as used in the first three scenarios were taken into consideration for the new emission pathways with addition of scenario specific parameters. The aim of this further work was to model the additional pathways and to compare the Predicted Environmental Concentrations (PEC) of each scenario against the Predicted No-Effect Concentration (PNEC) of 4.8 ng/L (BPR). Additionally, the PEC values were compared against the draft 2021 Annual Average Quality Standard (AA-EQS) of 6.8 ng/L. This value was recently proposed by SCHEER in context of an update of the watchlist of the EU Water Framework Directive. Imidacloprid surface water concentrations calculated for the three original scenarios were also compared with the same chronic aquatic ecotoxicological endpoint. The calculated surface water concentrations for the five scenarios, which consider worst case situations, do not exceed the ecotoxicological thresholds indicating acceptable risks for aquatic invertebrate organisms. The models developed demonstrate a low exposure to the aquatic environment from the use of Imidacloprid containing VMPs.

4.13.P-Tu273 Pharmaceutical Bioavailability Regulation by pH and Dissolved Organic Carbon: A Common Mechanism?

Qiyun Zhang¹, Kristof Demeestere² and Karel De Schamphelaere³, (1)GhEnToxLab (Ghent University), Gent, Belgium, (2)Ghent University, Belgium, (3)Ghent University (UGent), Belgium

Since last century, adverse effects of anthropogenic chemicals on aquatic organisms have been identified and lead to progress in environment protection regulations. Yet, the basis of regulations is often risk assessment conducted in controlled laboratory conditions, but the toxicity of chemicals in natural environments are regulated by dynamic water chemistry factors like pH and dissolved organic carbon (DOC). At the SETAC Europe 31st annual meeting, we have presented a bioavailability model for the antibiotic ciprofloxacin (CIP) with the possibility to predict CIP toxicity under dynamic environmental conditions. Here, we will report on the impact of pH and DOC on the toxicity of ionizable pharmaceuticals with varying octanol water partition coefficient (K_{ow}) and acid dissociation constants (pK_a). Experiment results were applied to parameterize the key section of our model: an equilibrium module consisting of pH-dependent chemical speciation and DOC related binding processes, in order to examine how well the bioavailability model might be extrapolated to ionisable chemicals with properties distinct from CIP.

4.13.P-Tu274 Sustainable Treatment of Wastewaters Generated at a Chemotherapy Unit Through the Sequential Use of Microbial Fuel Cells and Constructed Wetlands

Carlos Lutterbeck¹, Ênio Machado¹ and lucia rodrigues², (1)University of Santa Cruz do Sul, Brazil, (2)Federal University of Rio Grande do Sul, Brazil

Due to a higher prevalence of cancer cases, there is currently a considerable increase in relation to the consumption of drugs used in chemotherapy treatments. These anticancer drugs (also called cytostatic) have been frequently detected in several aqueous matrices and because of their non-selective modes of action, that is, attacking both cancerous and healthy cells, they have a high toxic potential. Despite the low concentrations found in aquatic environments, when compared to other classes of drugs, several authors have repeatedly stated that, due to their cytotoxic, genotoxic, mutagenic and teratogenic potential, it is possible that these compounds may cause several damages to aquatic biota even at very low concentrations. In addition, such compounds may also have their toxicity magnified due to possible synergistic effects. Finally, it should be noted that cytostatic drugs have a refractory nature and thus are not removed/eliminated by conventional wastewater treatment systems. In this sense, the present study aims, through the sequential use of microbial fuel cells and constructed wetlands, to propose a sustainable alternative, both from an environmental and economic point of views, for the treatment of wastewaters generated at a hospital chemotherapy unit. The integrated system will be composed of a microbial fuel cell unit planted with *Chrysopogon zizanioides* and compartmented with glass wool barrier in order to control cytostatic residues and eventual degradation products, frequently detected in the effluents generated at the oncology center of the Ana Nery Hospital, and a constructed wetland unit vegetated with *Hymenachne grumosa*. The study will focus its actions on the degradation/elimination of these anticancer compounds, focusing mainly on toxicity tests since many of these cytostatic are not mineralized but only partially eliminated, generating by-products that can be as or even more toxic than the parent compounds and on the generation of bioelectricity. Thus, in addition to reducing the negative impacts resulting from the inadequate release of these effluents, the bioelectricity generated from the microbial cell may eventually be used in combinations of advanced oxidative processes that are integrated into the system, such as electrooxidation, UV radiation and ozonation.

4.13.P-Tu275 The Role of Seasonal Water Temperature Changes in Bioconcentration and Biotransformation of Psychoactive Compounds and Their Mixture in Wild Fish

Daniel Cerveny¹, Michael Bertram², Erin McCallum², Marcus Michelangeli², Adam Božik³, Petra Nováková³, Jerker Fick⁴ and Tomas Brodin⁵, (1)Swedish University of Agricultural Sciences (SLU), (2)Swedish University of Agricultural Sciences, Sweden,

(3)University of South Bohemia in Ceske Budejovice, Czech Republic, (4)Umea University, Sweden, (5)Swedish University of Agricultural Sciences (SLU), Sweden

Pharmaceutically active compounds (PhACs) have been shown to accumulate in aquatic and riparian food-webs. Yet, our understanding of how temperature, a key environmental factor in nature, affects uptake, biotransformation, and the subsequent accumulation of PhACs in aquatic organisms is limited. In this study, we tested to what extent bioconcentration of three psychoactive pharmaceuticals is affected by two temperature regimes (7 and 20°C) and how the temperature affects the biotransformation of parent compounds and subsequent accumulation of their main metabolites in experimental organisms. Selected pharmaceuticals represent a tricyclic antidepressant Amitriptyline, a selective serotonin reuptake inhibitor Sertraline and serotonin–norepinephrine reuptake inhibitor Venlafaxin. As an experimental organism, we used wild European perch (*Perca fluviatilis*) which represents both predator and prey species of high ecological relevance in food chains of boreal and temperate aquatic ecosystems. Fish were exposed to individual drugs as well as their mixture at concentration of 1 µg L⁻¹ and two temperature regimes resulting in eight different treatments. To describe the pharmacokinetics of target drugs, five individuals were sampled at 10 sampling points during the 14 days of exposure period within each treatment. Samples of blood plasma and brain were obtained from each sampled individual and are being analyzed using the liquid chromatography tandem mass spectrometry (LC-MS/MS) instrumentation. Parent compounds and their main metabolites will be quantified in each sample to describe the role of the temperature in pharmacokinetics of these antidepressants and possible differences in bioconcentration scenarios between warm and cold seasons of the year. Given that temperature is a fundamentally important environmental variable for ectothermic aquatic organisms, and is known to influence standard metabolic rate in fish, we expect that it would have significant effect on uptake and especially biotransformation of PhACs in fish. Such data are missing at the moment, but would be beneficiary for improving the models that start to be used for environmental risk assessment of pharmaceuticals (e.g. fish plasma model). As these models are extrapolating data from mammalian pharmacology, which are based on a stable body temperature, important variable might be missing to predict effects in aquatic ectotherms.

4.13.P-Tu276 Method Development for the Assessment of Bioaccumulation Potential of Pharmaceuticals in Fish

Klaudija Ivanković¹, Petra Kostanjevečki¹, Marijan Ahel¹ and Senka Terzić¹, (1)Ruđer Bošković Institute, Croatia

Active pharmaceutical ingredients (API) represent a group of the most prominent categories of emerging environmental contaminants. However, a vast majority of the currently published studies are focused on their occurrence and fate in abiotic environmental matrices like water and sediments while the data on API concentrations in aquatic organisms are still comparatively rare. Consequently, the existing knowledge on API bioaccumulation and metabolic transformations in the aquatic organisms is still inadequate. The key prerequisite to study bioaccumulation behavior of pharmaceuticals in the aquatic environment is the availability of analytical methods suitable for the reliable determination of trace concentrations of API and their metabolites in complex biological matrices. In this work, a novel multiresidue LC-MS/MS method for quantitative measurement of trace levels of selected APIs and their metabolites in freshwater fish was developed. In order to develop a robust analytical protocol suitable for reliable determination of 44 analytes, characterized by rather wide-range of physicochemical characteristics, in difficult fish matrices, the sample preparation protocol was optimized in a number of model experiments, by examining different combinations of extraction and clean-up techniques. The method development was performed using homogenized muscle tissue of *Squalius cephalus* (Chub) spiked with target analytes at low ng/g levels. In order to enhance the analytical reliability in complex fish matrices, the method included extensive usage of isotopically labelled surrogate standards. Two different extraction techniques, ultrasonic extraction and pressurized solvent extraction, were compared using different solvent combinations, taking into account two key parameters: absolute recovery (including extract suppression) and reproducibility. At the optimized conditions for LC/MS analysis, a Synergy Polar HPLC column was selected for chromatographic separation, using water and methanol, both containing 0.1% formic acid (v/v), as eluting solvents. The selectivity of the method was assured by highly specific MRM detection, using the two most abundant precursor/product ion transitions for each analyte and surrogate. The developed analytical method was used to assess API concentrations in feral freshwater fish from the Sava River (Croatia).

4.13.P-Tu277 Indoor Environments - Hospitals, Households of Oncology Patients and Others - As a Contamination Source of Hazardous Pharmaceuticals

Lucie Blahová¹, Ludek Blaha², Jan Kuta³, Lenka Dolezalová⁴ and Sarka Kozakova⁵, (1)RECETOX, Masaryk University, RECETOX, Brno, Czech Republic, (2)RECETOX, Masaryk University, Faculty of Science, Brno, Czech Republic, (3)Masaryk University, RECETOX, Czech Republic, (4)Masaryk Memorial Cancer Institute, Czech Republic, (5)Faculty hospital, Brno, Czech Republic

Antineoplastic drugs (ADs) used for treatment of cancer are substances with potentially hazardous properties. Assessment of indoor contamination by ADs allows to assess both human exposures and health risks and estimate release of ADs into the environment¹. The present study assessed levels and profiles of surface contamination in the hospital workplaces in the two Central-Eastern European countries, and provided the first research of surface contamination inside houses of oncology patients, hospices and retirement houses. Surface samples were collected in 32 different larger hospitals in the Czech Republic and Slovakia. In addition, repeated samplings of comparable sites were collected from households of oncology patients, as well as in 2 hospices and 3 retirement homes. The wipe samples were analyzed by LC-MS and ICP-MS for analysis of 11 ADs (cyclophosphamide – CP, 5-fluorouracil – FU, Paclitaxel – PX, Ifosfamid – IF, Irinotecan – IRI, Metotrexat – MET, Capecitabin – CAP, Doxorubicin – DOX, Docetaxel – DOC, Gemcitabine – GEM, Epirubicin – EPI, total platinum – Pt)². **1. 2. 3.** In hospitals, the most contaminated surfaces were floors of administered rooms and 50% of all samples contained both CP and Pt. Levels of ADs as well as frequency of exceedance of the recommended Threshold Guidance Values were comparable in both large hospitals

and smaller patient care units³. Other analyzed ADs were also commonly detected (namely GEM, IF, PX and IRI) but in lower concentrations compared to CP, FU and Pt. In households of oncology patients, contamination of carcinogenic CP was commonly found with maxima 500 pg/cm². Sweat of the patients is a important medium for the spread of the contamination. The studies in hospices and retirement homes indicated low exposures but pointed to potential long-lasting contamination by ADs. A monitoring of indoor environments documented wide-spread contamination by ADs. Maximum contamination in hospitals repeatedly exceeded 10 ng/cm², which calls for remedial actions and nurses administering chemotherapy were the main cohort in risk³. Carcinogenic CP was also found in households of oncology patients. The contamination levels in households were comparable to medians hospitals but potential exposures and risks to family members are only temporal⁴. Nevertheless, administration of chemotherapy, which is currently moving from (controlled) hospital healthcare to households³ may represent an issue, which should be further explored in detail. 4.14 Predicting the effects of global change on the emission, fate, effects and risks of chemicals in aquatic ecosystems: international collaboration and innovative approaches

4.14.T-01 The ECORISK2050 Project: Predicting the Effects of Global Change on the Emission, Fate, Effects and Risks of Chemicals in Aquatic Ecosystems

Paul van den Brink¹, Samuel Welch², Taylor Lane³, Alizée O.S. Desrousseaux³, Annika Mangold-Doring⁴, Francesco Polazzo⁵, Joanne van Dijk⁶, John Daniel Hader⁷, Markus Hermann⁸, Poornima Nagesh⁶, Rudrani Gajraj⁹, Sabrina K Roth¹⁰, Sophie Mentzel¹¹, Andrei Jarashneli¹², Anna Sobek⁷, Josef Eitzinger⁹, Jannicke Moe², Matthew MacLeod⁷, Merete Grung², Andreu Rico¹³, Annemarie van Wezel¹⁴, Benny Chefetz¹², Stefan Dekker¹⁵ and Alistair Boxall³, (1)Wageningen Environmental Research, Netherlands, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)University of York, United Kingdom, (4)Aquatic Ecology and Water Quality Management, Wageningen University & Research, Wageningen, Netherlands, (5)IMDEA Water Institute, Spain, (6)Environmental Sciences, Copernicus Institute of Sustainable Development - Utrecht University, Utrecht, Netherlands, (7)Stockholm University, Sweden, (8)Wageningen University and Research, Netherlands, (9)University of Natural Resources and Life Sciences (BOKU), Austria, (10)Environmental Science, Stockholm University, ACES, Stockholm, Sweden, (11)NIVA - Norwegian Institute for Water Research, Norway, (12)The Hebrew University of Jerusalem, Israel, (13)IMDEA Water Institute/University of Valencia, Spain, (14)University of Amsterdam/IBED Institute, Amsterdam, Netherlands, (15)Copernicus Institute of Sustainable Development - Utrecht University, Netherlands

By 2050, the world population will reach nine billion people and three quarters of the global population will live in cities. The development path to 2050 will be marked by shifts in land use and weather patterns, and by changes in the way water and food resources are obtained and managed all over the world. These global changes (GCs) will affect the emissions, environmental transport pathways and fate of chemicals, and thus affect the exposure of the natural environment to chemicals. Future changes may also alter the sensitivity of ecosystems to chemical exposure. To help address these issues, the ECORISK2050 project brings together a world leading and interdisciplinary consortium of universities, research institutes, industry and regulatory and governmental authorities to deliver a cohort of Early Stage Researchers (ESRs). The coupled training goals and research objectives of the project are: (1) to assess how the inputs of chemicals from agriculture and urban environments and their fate and transport are affected by different environmental conditions, including those of specific EU regions, and how this will change under GC scenarios in order to assess the likely increase in chemical risks to human and ecosystem health; (2) to identify potential adaptation and mitigation strategies that can be implemented in the short and medium term to abate unacceptable changes in risks, and use the GC scenarios to propose robust implementation pathways, and (3) to develop a set of tools for use by industry and policy makers that allow the impacts of a range of GC-related drivers of chemical risks to be assessed and managed. The project will deliver the next generation of scientists, consultants and industry and governmental decision-makers who have the knowledge and skill sets required to address the changing pressures that chemicals emitted by agricultural and urban activities pose to aquatic systems on the path to 2050 and beyond.

4.14.T-02 Forecasting Emissions of Metals to Urban Aquatic Environmental Using the Shared Socio-Economics Pathways (SSPs)

Alizée O.S. Desrousseaux¹, John Angus², Francesco Polazzo³, Andreu Rico⁴, Samuel Welch⁵, Anne Luise Ribeiro⁵, Jonathan Brett Sallach⁶ and Alistair Boxall¹, (1)University of York, United Kingdom, (2)Biorenewables Development Centre, United Kingdom, (3)IMDEA Water Institute, Spain, (4)IMDEA Water Institute/University of Valencia, Spain, (5)Norwegian Institute for Water Research (NIVA), Norway, (6)University of York, Heslington, United Kingdom

Urban environments are hotspots of metal pollution as they are areas comprising: high population density, heavy traffic, construction and demolition sites, industries activities and ineffective waste and wastewater management. Despite the fact that metals are causing harmful effects on the environment, the future outlook of metals emissions, which will be impacted by socio-economic change, climate change and technological development, is uncertain. This means that we have a limited understanding of how metals emissions in cities will change in the future. The shared-socio-economics pathways scenarios (SSPs), developed for scientists to study the future, provide a potential framework for predicting future chemical emissions. The aim of this project was therefore to study how will emissions of metals of current concern for aquatic systems could change in the future in urban environments in three cities: York (UK), Oslo (Norway) and Madrid (Spain). Research comprised four components: 1) review data on metal concentrations in urban environment worldwide, 2) identify metals that currently pose an unacceptable risk by

calculating risk quotients (RQ), 3) to monitor metals with an RQ >1 seasonally in Madrid, York and Oslo; and 4) develop a framework to extend SSPs to the chemical sector and to apply these to metals in the three cities. Data were found on metal concentrations in 9 urban rivers in 7 countries. Concentrations ranged from 0.03ug/L to 7 433 ug/L for iron in Manisa city in Turkey. Risk quotient was calculated for each continent. In Europe, 7 metals had a risk quotient above 1 (aluminum, copper, lead, mercury, nickel, silver, zinc) compared to 4 in Asia and 1 in North America. Aluminum, copper, nickel, silver and zinc were measured in Madrid, Oslo and York in spring and summer 2021. Expect for nickel and for copper in spring in Oslo, concentrations of aluminum, copper and zinc were systematically detected above predicted no-effect concentrations (aluminum: 4.4ug/L; copper: 0.44ug/L; zinc: 1ug/L) in the three cities. To be able to study how will metals emissions change in the future, a 4-steps framework was developed specifically to adapt SSPs storylines to chemicals. The framework allows the consideration of all socio-economics drivers of the society, allowing a broader understanding of metals in societies essential for decisions-making on metal pollution. The next steps of this research will be to develop priority chemicals emissions in the future for Madrid, Oslo and York using the framework.

4.14.T-03 Combined Effects of Heatwaves and the Herbicide Terbutylazine on Natural Zooplankton Communities: Implications for Global Climate Change

Sabrina K Roth¹, Francesco Polazzo², Ariadna García-Astillero Honrado², Laura Cherta², Anna Sobek³ and Andreu Rico², (1)Environmental Science, Stockholm University, ACES, Stockholm, Sweden, (2)IMDEA Water Institute, Spain, (3)Stockholm University, Sweden

Understanding the impacts of climate change and its extreme events, particularly heatwaves, on aquatic ecosystems requires exploring interactions with other anthropogenic stressors, such as pesticides. The herbicide terbutylazine serves as alternative pesticide to the in the EU banned atrazine, yet, it demonstrated lethal effects on phytoplankton communities, leading to indirect starvation of zooplankton. We exposed natural freshwater zooplanktonic communities to a simulated heatwave (one week duration) and the herbicide terbutylazine (15 µg/L) in different combinations of the two stressors. When applied individually, the heatwave increased the total abundance of zooplankton (3-fold higher). The herbicide application, however, did not affect the total abundance of the zooplankton. In contrast, the combination of the heatwave and terbutylazine had no impact on the community, suggesting antagonistic effects of the co-occurring stressors on zooplankton. Yet, the terbutylazine application affected the zooplankton indirectly and led to a community composition change. Future research should further investigate thermal and chemical stressor applications in sequence, as heatwaves are likely to increase in frequency in the future.

4.14.T-04 Sensitivity of Changing Macroinvertebrate Communities in a Warming World

Tom Sinclair¹, Peter Craig² and Lorraine Maltby³, (1)University of Sheffield, Sheffield, United Kingdom, (2)Durham university, United Kingdom, (3)The University of Sheffield, United Kingdom

Taxa have varying sensitivities to chemicals, and species non-exchangability means different assemblage compositions vary in sensitivity. In natural ecosystems, species composition of assemblages varies spatially in response to biogeographic factors, including temperature. Climate change will increase temperature and hence composition meaning sensitivity of assemblages to chemicals may shift. Here we explore the potential consequences of future climate change on the sensitivity of freshwater macroinvertebrate assemblages to chemical stressors using Great Britain as a case study. Macroinvertebrate assemblages under end of century (2080-2100) and baseline (1980-2000) climate conditions for were predicted for 753 sites. Differences in taxonomic composition were compared with Jaccard's index and changes to taxa identified. Freshwater macroinvertebrate toxicity data were collated for 40 chemicals grouped into insecticide, metal or narcotic. The hierarchical Species Sensitivity Distribution (hSSD) model was then used to predict the sensitivity of untested taxa using relatedness within a Bayesian approach. Species sensitivity distributions and HC₅ values were then calculated for each assemblage under baseline and future scenarios. All three climate scenarios resulted in a decrease in Jaccard's similarity compared baseline conditions (range of 0.76-0.80) and 55 taxa were lost from all sites under climate change conditions. The shift in taxonomic composition due to warming resulted in different effects depending on chemical identity and type. Under all three future climate scenarios, metals had a significant decrease in mean HC₅ value compared to baseline, indicating that macroinvertebrate assemblages became more sensitive to metal stress. Similar shifts in average sensitivity were not observed for insecticides and narcotics. Climate change shifted the composition of freshwater macroinvertebrate assemblages and their sensitivity to chemical stress. Climate-induced change in assemblage sensitivity meant on average assemblages were more sensitive to metal exposure under all future climate scenarios. Climate change also resulted in increased between-assemblage variation in the sensitivity of macroinvertebrates to all three chemical stressors, indicating that specific sites and their associated assemblages were exhibiting differential changes in chemical sensitivity. Therefore, site specific spatial variation in the effects of climate change should also be considered.

4.14 Predicting the effects of global change on the emission, fate, effects and risks of chemicals in aquatic ecosystems: international collaboration and innovative approaches (Poster)

4.14.P-We224 A Modelling Framework to Project the Future Sensitivity of Aquatic Invertebrates to Chemicals With Different Mode of Action

Francesco Polazzo¹, Sami Domisch², Martina Flörke³ and Andreu Rico⁴, (1)IMDEA Water Institute, Spain, (2)Institute of Freshwater Ecology and Inland Fisheries (IGB), Germany, (3)Ruhr-University Bochum, Germany, (4)IMDEA Water Institute/University of Valencia, Spain

Climate change has already modified several meteorological and hydrological parameters. However, the effects of the changing climate are expected to become more severe in the near future (2050). Changes in water discharge, increasing number of days

with low flow and increased water temperature will force many aquatic taxa to change their actual distribution to find suitable habitats. In the present framework, we use hydrological models able to project changes in several hydrological parameters combined with climate projections to predict changes in aquatic invertebrates' distribution at the European level. In order to simulate present-day natural flow regimes and future flow regimes under climate change, the global hydrology model WaterGAP3 is applied. All calculations for current and future conditions (2050s) are carried out on a 5' × 5' European grid. Calculations of future hydrological conditions are based on the Intergovernmental Panel on Climate Change (IPCC)'s Fifth Assessment scenarios, and predictions of future water availability are generated using the WaterGAP3 modelling framework. This modelling approach was subsequently exploited to derive projections on how the predicted changes in hydrological conditions are likely to shift present-day distribution of aquatic invertebrates, because of a modification of their habitat in terms of hydrology and climatology. Present and future freshwater macroinvertebrates distribution was modelled using Bioclimatic Envelope Models (BEMs) based on an ensemble forecasting framework built on six algorithms (generalized linear models, flexible discriminant analysis, classification tree analysis, random forest, multivariate adaptive regression splines, and maximum entropy modelling). Finally, we used the projected future species distribution to study how the sensitivity of aquatic invertebrates to chemicals with different modes of action is likely to change by 2050. To do that, we used species traits as common currency to calculate species sensitivity to chemicals with different mode of action. Overall, the framework we are presenting, is composed by several steps and combined numerous modelling approaches. It brings together experts from different disciplines, and it proposes, for the first time, a new tool able to give indications on how climate change is likely to shift the relative portion of sensitive aquatic invertebrates to chemicals with different modes of action.

4.14.P-We225 Incorporation of Direct and Indirect Climate Change Effects Into a Probabilistic Pesticides Risk Assessment: A Northern European CASE Study

Sophie Mentzel¹, Merete Grung², Marianne Stenrød³, Roger Holten⁴, Knut Erik Tollefsen¹ and Jannicke Moe⁵, (1)NIVA - Norwegian Institute for Water Research, Norway, (2)NIVA, Oslo, Norway, (3)Norwegian Institute of Bioeconomy Research NIBIO, Norway, (4)Norwegian Institute of Bioeconomy Research (NIBIO), Ås, Norway, (5)Norwegian Institute for Water Research (NIVA), Norway

Weather patterns in Northern Europe are projected to change with increased temperature and precipitation by 2050. These climatic changes can potentially affect the transport and degradation of pesticides in the environment. Moreover, agricultural practices are expected to change such as application patterns. The pesticide application rates are expected to be altered due to an increased frequency of potential plant disease and insect pests. In this study, we have used a Bayesian network to better integrate these potential direct and indirect climate change effects on the pesticide exposure in a probabilistic approach to risk assessment. The Bayesian network serves as a meta-model that incorporates predictions from a pesticide fate and transport model WISPE - World Integrated System for Pesticide Exposure. We ran the exposure prediction model for specific environmental factors linked to a representative Norwegian study area with specific soil and site parameters, as well as chemical properties under different scenarios of climate model projections (HADCM3-Q0 A1B SMHI RCA3 & ECHAM5-r3 A1B SMHI RCA3) and pesticide application pattern. The Bayesian network links the pesticide exposure predictions derived for the study area to effect distributions derived from toxicity tests to predict the risk quotient distribution. Thus, this approach considers both direct climate change impacts (on pesticides fate and transport) and indirect effects (on pesticide application). Compared to traditional (deterministic) risk assessment methods, this probabilistic approach can better account for uncertainty associated with climate projections.

4.14.P-We226 Enabling Forecasts of Environmental Exposure to Chemicals in European Agriculture Under Global Change

John Daniel Hader¹, Taylor Lane², Alistair Boxall², Matthew MacLeod¹ and Antonio Di Guardo³, (1)Stockholm University, Sweden, (2)University of York, United Kingdom, (3)University of Insubria, Italy

Agricultural practices emit a wide range of organic chemicals into the environment through the use of pesticides, veterinary treatments, chemicals in biosolids used as soil amendment, and chemicals in wastewater used in irrigation. Furthermore, the 21st century will be marked by a litany of global changes, including climate change, shifts in agricultural practices in response to climate change/shifting demand, and transitions toward a circular economy. These global change forcings portend changes in how and what types of chemicals will be emitted, their persistence and transformation, and the fate and transport mechanisms acting on them, all of which will drive changes in environmental exposure to these compounds. However, current methods do not consider these interlinked forcings in forward-looking exposure assessments. With a focus on European agriculture, we review existing literature to critically examine how global change drivers of agricultural chemical exposure may impact the 1.) emissions, 2.) persistence and transformation, and 3) fate and transport of chemicals in the coming decades. Key knowledge gaps include how the use of reclaimed wastewater for irrigation may change due to increased stress on water resources, how the use of veterinary medicines and pesticides may change under changing pest pressures, uncertainty surrounding changes in microbial degradation of chemicals, and a lack of modelling studies capturing projected changes in extreme weather events and the impact of this on chemical transport. To address these knowledge gaps, we advocate for a holistic approach towards agricultural chemical exposure assessment that considers the identified global change drivers. Similar to the IPCC's Shared Socio-Economic Pathway (SSP) approach that considers scenarios for future development and associated GHG emissions, we propose analysis of four Agricultural Chemical Exposure Scenarios (ACES) including one optimistic, one moderate, one severe, and one extreme scenario of the evolution of global change forcings in the context of chemical exposure. Such an analysis would bound possible agricultural chemical exposure futures and inform actions that could be used to mitigate exposures from exceeding threshold levels under future conditions. Enabling forecasts of environmental exposure to chemicals in agriculture is a vital step in ensuring the global-scale changes that affect agriculture over the 21st Century occur in a safe a sustainable manner.

4.14.P-We227 Testing the Influence of Temperature on Dissipation Rates of a Trace Mixture of Pharmaceutical Compounds in Freshwater Sediments

Taylor Lane¹, John Wilkinson², Brett Sallach¹ and Alistair Boxall¹, (1)University of York, United Kingdom, (2)Environment and Geography, The University of York, York, United Kingdom

The dissipation rates of pharmaceuticals are important considerations in chemical risk assessment, particularly under future environmental conditions where different European regions could experience elevated temperatures for longer periods, potentially affecting the kinetics of pharmaceutical dissipation. Freshwater sediments are also an understudied environmental compartment in this context with emissions of pharmaceuticals to freshwater bodies often occurring as a complex mixture of contaminants which can partition to sediments where they might persist and pose a risk. Therefore, the objective of this study was to investigate the dissipation kinetics of a pharmaceutical mixture in different freshwater sediments across a temperature gradient relevant to future environmental conditions to determine how temperature may drive changes in chemical dissipation rates and half-lives. A 96-day dissipation study was performed by collecting 6 freshwater sediments with contrasting physicochemical properties from across North Yorkshire, UK. The sediments were sieved to 2mm and allowed to equilibrate at either 12, 15, 20, 25 or 30°C for 10 days, before being spiked with a 6-compound pharmaceutical mixture (amitriptyline, atenolol, cimetidine, diltiazem, mefenamic acid and ranitidine) at a nominal concentration of 16.6 ng/g sediment (dry weight) for each study compound. Test replicates (n=18 per sediment and temperature) containing 3g spiked sediment and 4.5mL of field site water were then incubated in the dark at a respective test temperature for 96-days. Sub-samples (n=3) were collected on Day 0, 7, 12, 24, 48 and 96 to undergo a 3-cycle solvent extraction followed by UHPLC-MS/MS analysis to determine chemical concentrations of each study compound. Preliminary results showed nearly complete dissipation (e.g., DT95) of atenolol, mefenamic acid and ranitidine after 48 days at 12°C in all sediment types. At 30°C, complete dissipation after 48 days was observed for all compounds except amitriptyline, which notably showed similar persistence at 12°C and 30°C in three of the sediment types. Data for the remaining test temperatures and timepoints will help inform the dissipation kinetics and chemical half-lives of the pharmaceutical mixture. The influence of temperature and contrasting sediment composition on the dissipation kinetics of the pharmaceutical mixture will be discussed under the theme of supporting chemical risk assessment of pharmaceuticals.

4.14.P-We228 Atmospheric Transport of Compounds of Wastewater Origin Into Remote, Upland Lakes in Ireland: A Consequence of a Changing World?

Chris D. Metcalfe¹, Viviane Yargeau² and Julian Aherne³, (1)School of the Environment, Trent University, Peterborough, ON, Canada, (2)McGill University, Canada, (3)Trent University, Canada

Persistent organic pollutants of industrial origin are transported long distances in the atmosphere and deposited into aquatic and terrestrial ecosystems in remote regions. However, there has been little research to determine whether less persistent, polar compounds such as pharmaceuticals, drugs of abuse and constituents of foods and beverages are transported in the atmosphere. The objective of this research was to evaluate whether compounds of wastewater origin are present in four remote, upland lakes in Ireland that receive loadings from atmospheric deposition. In passive samplers deployed in the lakes for between 60 and 68 days, six compounds were consistently detected at levels that could be quantified, including the cannabinoid metabolite, tetrahydrocannabinol carboxylate (THC-COOH), caffeine, acetaminophen, and the artificial sweeteners, sucralose and saccharin. Cocaine, ketamine and tramadol were also detected in passive samplers deployed in some of the lakes, but at levels below the limits of quantitation. Except for caffeine, the estimated concentrations of the compounds in lake water were all below 150 ng/L. The highest concentrations of the target analytes were detected in two lakes located on the east coast of Ireland where weather patterns are dominated by westerly winds. These data are consistent with the transport of these compounds in aerosols originating from wastewater treatment plants in continental Europe and/or the U.K. and deposition in rainwater into the catchments of the remote lakes in Ireland. Continued monitoring is warranted to determine if an increase in the use of drugs of abuse and pharmaceuticals, plus changing weather patterns are contributing to contamination of remote lakes.

4.14.P-We229 Training As a Strategy to Mitigate the Impact of Climate Change

Camilla Puccinelli¹, Stefania Marcheggiani², Simona Gaudi³ and Laura Mancini³, (1)Istituto Superiore di Sanità, Rome, Italy, (2)Italian Institute of Health ISS, Italy, (3)Istituto Superiore di Sanità, Italy

“Connect science to politics and the population and provide health and climate change education for healthier cities” is one of the key Message of Rome International Charter on Health and Climate Change, addressed to policy makers and all the stakeholders involved in the management of climate changes. Cities must identify strategy and make intervention for adaptation and mitigation of climate change indeed actually they are heavily affected by climate change such as intense precipitation and heat waves; furthermore people must be educated about climate change, their effect on human health. The Italian Project, “Adaptation and mitigation to Climate Change: urban interventions for the promotion of Health – CLIM ACTIONS” funded by the Ministry of Health and coordinated by the Department of Epidemiology of Latium Region, aims to identify strategies and interventions to mitigate the urban heat island and air pollution, promoting health benefits for the population in the urban context of cities across Italy, Turin, Genoa, Bologna, Rome, Bari and Palermo. One of its activities is dedicated to share the knowledge about climate changes and their potential risks for human health to health professional sectors, stakeholders and citizens. The training is being realized through a on line course performed with the e-learning tools available on the platform of Istituto Superiore di Sanità (Eduiss). This course, based on scientific evidences covers following issues, climate changes and their impact on ecosystems and human health; urban heat islands, air pollution effects on citizens, and the role of green and blue spaces on human health, wellbeing and on mitigating climate change effects. This course will be based on Problem Based Learning PBL, a teaching method in which a simulating real problems used as the vehicle to promote student learning of concepts and principles as

opposed to direct presentation of facts and concepts. It will be dedicated to health professional sectors, stakeholders and everyone is interested to deepen the knowledge on climate change effects on human health.

4.14.P-We230 Human Health Through Environmental Protection: An Example of Management of Environmental Emergencies

Renata Pacifico¹, **Giampiero Baccaro**², **Elisa Nardi**³ and **Claudio Numa**³, (1)National Central for crises, environmental emergencies and damage, ISPRA-Institute for Environmental Protection and Research, Roma, Italy, (2)ISPRA - Institute for Environmental Protection and Research, Italy, (3)ISPRA Institute for Environmental Protection and Research, Italy

The environmental emergency affects both water, air and soil and requires the immediate activation of operational structures, which carry out environmental protection interventions. All European countries are committed to environmental protection and their policies are directed towards sustainable development. One of pillars of Green Deal is the protection of the health and well-being of citizens as well as the ecosystems in which they live. In order to face the challenge related to the protection of the health and safety of citizens and ecosystems, it is essential to act promptly and avoid that (not appropriately managed) events can cause the environmental degradation, determining direct deterioration of the quality of life and health conditions of citizens. It is essential to establish a close collaboration between citizens, institutionally responsible authorities, research bodies and the industry, in order to reach shared solutions. Environmental emergencies often have impact on human health both in terms of acute/chronic effects, including psychological effects, and of socioeconomic consequences that have implications on health. In case of emergencies occurring in Italy, the Italian Institute for Environmental Protection and Research (ISPRA) ensures scientific technical support to the responsible authorities. To ensure the effectiveness of the response, ISPRA has adopted a *Regulation for the activation in emergency*, which provides for integrated and synergistic management tools that are carried out through the activation of an Operational Network of Representatives of the Regional Agencies. This exchange network guarantees the circulation of information and experience, allowing the entire territory to properly address the occurrence of environmental criticalities, exploiting the best experiences and available skills. From ISPRA's activity, reports have emerged containing the description of the events and the operating procedures for activation with the Operational Network but also information on the most involved areas (43% surface water bodies) or on the type of predominant event (fire). By focusing on an actual case study, the goal of the research is to confirm that the scientific community addresses to all public and private components so that a process, currently unstructured, is promoted which pushes the private sector to invest in order to reduce the environmental and economic impacts of production, and the public authorities to propose solutions.

4.14.P-We231 Development of Chemical Emission Scenarios Using the Shared Socio-Economic Pathways

Poornima Nagesh¹, **Hugo de Boer**², **Annemarie van Wezel**³, **Stefan Dekker**² and **Detlef van Vuuren**², (1)Environmental Sciences, Copernicus Institute of Sustainable Development - Utrecht University, Utrecht, Netherlands, (2)Copernicus Institute of Sustainable Development - Utrecht University, Netherlands, (3)University of Amsterdam/IBED Institute, Amsterdam, Netherlands

The widespread use of chemicals has led to significant water quality concerns, and at the moment, the use of chemicals is still increasing. Henceforth, there is an urgent need to understand the possible future trends in chemical emissions to water systems. This paper proposes a general framework for developing emission scenarios for chemicals to water using the Shared Socio-economic Pathways (SSP), based on an emission factor approach. The proposed approach involves three steps: (i) identification of the main drivers of emissions, (ii) quantification of emission factors based on analysis of publicly available data, (iii) projection of emissions based on projected changes in the drivers, and emission factors. The approach is tested in Europe for five chemical groups and at a national scale for five chemicals representing pharmaceuticals, pesticides, and industrial chemicals. The resulting emission scenarios show widely diverging trends of increased emissions by 265% for ibuprofen in SSP3 to 75% decrease for diclofenac in SSP1 by 2050. While emissions typically decrease in SSP1 (sustainable development), they follow the historical trend in SSP2 (middle-of-the-road) and show an increase in the regional rivalry scenario SSP3 for most selected chemicals. Overall, the framework allows understanding future chemical emissions trends as a function of socio-economic trends. These scenarios can be used to model aqueous emissions to support risk assessment. While the framework can be easily extended to other pharmaceuticals and pesticides, it heavily leans on the availability and quality of historical emission data and a detailed understanding of emission sources for industrial chemicals.

4.15 Recent advances in Bioremediation and Phytoremediation of contaminated areas

4.15.T-01 Unveil Microbial Community Structure of Terrestrial Microbial Fuel Cells

Gian Luigi Garbini¹, **Paola Grenni**², **Ludovica Rolando**³, **Valeria Ancona**¹, **Domenico Borello**⁴, **Gabriele Gagliardi**⁴ and **Anna Barra Caracciolo**⁵, (1)Italian National Research Council, Italy, (2)National Research Council of Italy (CNR), Italy, (3)National Research Council of Italy, Italy, (4)La Sapienza University, Italy, (5)National Research Council - Water Research Institute, Italy

Soil contamination has great impact on soil fertility, plant growth, food quality and ultimately affect human health. The contamination of agricultural and industrial lands has direct and indirect effects on human health and ecosystem. Bioremediation is considered as an eco-friendly and economical approach and microbial fuel cells (MFCs) attracted much attention as an energy saving bioremediation tool. In particular, terrestrial MFCs (TMFCs) have many advantages like eco-friendly, cheap, safe, clean, easy operation and sustainability. TMFC is a promising system for the bioelectricity production as well as the soil remediation. In TMFCs, the anode is buried in water saturated soil connected via external circuit to cathode on top of soil. In the buried anode, a biofilm is generated and organic matter is degraded (oxidation) by exo-electrogen bacteria capable to donate electrons which are then simultaneously transferred to the cathode compartment via an external circuit. Protons produced by exo-electrogen bacteria in the anode, diffuse through soil to the cathode where oxygen is primarily used as the oxidant, due to its abundance and high

reduction potential. The flow of electrons generate electricity. Several studies reported that biofilm at anode is typically enriched by bacteria belonging to *Geobacter*, *Skermanella*, *Desulfucapsa*, *Desulfobulbus* and *Desulfuromonas* genera. In this work, we have analyzed the prokaryotic community structure of a TMFC amended with compost in three different points: anode, cathode and bulk soil at 2 months from the experimental set-up. Control TMFCs consisting of only soil were also performed. Electric measurements (power and voltage) were evaluated daily; moreover, abundance, viability, activity and structure (NGS analysis of the 16S rDNA) of the microbial community were evaluated at the start and end of the experiment. The results showed significant differences in the compost-TMFC microbial community among anode, cathode and bulk soil. At the anode, a higher cell abundance and activity than cathode and bulk soil were found. Moreover, an increase in the *Bacillus*, *Clostridia*, *Bacteroidia* and *Deltaproteobacteria* and a decrease in *Alphaproteobacteria* and *Actinobacteria* genera were observed at 2 months. *Gammaproteobacteria* were also reduced in presence of compost at the cathode and bulk soil. The genus *Geobacter*, an exoelectrogen bacteria, was found at anode and bulk soil in presence of compost. Interestingly, microbial soil activity was positively correlated to voltage and power generated by the MFCs.

4.15.T-02 Effects of Contrasting Biochars on Copper Speciation, Bioavailability and Toxicity in Trace Element-Contaminated Soil

Yinqi Tang¹, **Chen Wang²**, **Peter Holm²** and **Kristian Brandt²**, (1)Department of Plant and Environmental Sciences, University of Copenhagen, Copenhagen, Denmark, (2)University of Copenhagen, Denmark

Chromated copper arsenate (CCA) contaminated soils are commonly found at former wood impregnation sites and pose great risks to human and environmental health. Biochar has been proposed as an adsorbent for mitigating trace element toxicity in contaminated soil. We investigated the effects of fourteen biochars on the dynamics of copper speciation (Cu ion selective electrode), copper bioavailability (whole-cell bacterial bioreporter), and soil toxicity (seed germination and *Arthrobacter globiformis* solid-contact assays) in CCA contaminated soil during a controlled 56-day experiment. Specifically, our study focused on the dynamics of Cu speciation and bioavailability, as Cu was previously found to be the main toxicant in the studied soil (Tardif et al., submitted manuscript). Biochars were derived from bone meal (Bone), *Miscanthus* (M), *Miscanthus* straw (MSP), oil seed rape straw (OSR), rice husk (RH), sewage sludge (SS), softwood (SWP) and wheat straw (WSP) and were pyrolyzed at different temperatures (550, 700, 850 or 950 °C). OSR550 and OSR700 showed the best performance and increased soil pH while decreasing the free Cu²⁺ activity by 78%. All biochars except SWP550 significantly decreased bioavailable Cu ($p < 0.05$). Moreover, biochar treatments reduced soil toxicity as indicated by increasing plant shoot and root growth and increased bacterial dehydrogenase activity as determined by the *Arthrobacter globiformis* solid-contact assay. Soil toxicity was best predicted by the free Cu²⁺ activity. Hence, the free Cu²⁺ activity showed significant correlations (Spearman) with plant shoot length ($r = -0.86$, $p < 0.001$), root length ($r = -0.58$, $p < 0.05$) and soil toxicity determined by *Arthrobacter globiformis* assay ($r = 0.79$, $p < 0.001$). Bioavailable Cu could also well predict soil toxicity, whereas water-extractable Cu was a relatively poor soil toxicity predictor. In conclusion, our study showed a great potential of biochar derived from oil seed rape straw pyrolyzed at 550°C for remediation of chromated copper arsenate contaminated soils and soil toxicity mitigation was best explained by reduced free Cu²⁺ activity. Our study provides a basis for future development of effective custom biochars for Cu stabilization in trace element-contaminated soils and highlights the *Arthrobacter globiformis* solid-contact assay as a promising technique for evaluating soil toxicity dynamics during soil remediation processes.

4.15.T-03 Towards a Practical Guideline for Applying Carbon-Based Materials for Soil Remediation

Carlotta Carlini¹, **Sampriti Chaudhuri²**, **Nicolas Greggio¹**, **Diego Marazza¹**, **Oliver Mann³**, **Thorsten Huffer⁴**, **Thilo Hofmann⁵** and **Gabriel Sigmund⁵**, (1)Alma Mater Studiorum - University of Bologna, Italy, (2)Environmental Geosciences, Centre for Microbiology & Environmental Systems Science, University of Vienna, Vienna, Austria, (3)ESW Consulting Wruss, Austria, (4)University of Vienna, Vienna, Austria, (5)University of Vienna, Austria

Biochar application for immobilizing heavy metals and Polycyclic Aromatic Compounds (PACs) in contaminated soils has been a field of active research for the last decade. However, there is still a lack of guidance to put what has been demonstrated in the lab into practice. As not all materials are suitable for the same type of contaminant and/or application, a major difficulty for practitioners is the selection of suitable sorbents from the variety of carbon-based materials available (including biochar and activated carbon), which widely differ in their physical and chemical characteristics. A generic assessment of biochar quantities needed for a specific remediation application at full scale is not possible, due to these specific material properties, as well as differences in contamination scenario and soil properties. Here we aim to provide a guideline to evaluate the applicability of carbon-based materials for heavy metal and PAC contaminated soil remediation for scientists and practitioners alike. The guideline is built on literature-based as well as experimental work: we initially carried out a literature review collecting knowledge on the influence of feedstock, production temperature and possible modifications on a material's physical and chemical characteristics. We further conducted expert interviews with practitioners and regulators in Austria. Thereafter, laboratory experiments complemented the knowledge collected. For our experimental work, we used eleven carbon-based materials and a total of ten anonymized contaminated soil samples from existing remediation sites containing varying amounts of arsenic, antimony, cadmium, zinc, lead and PACs. The information gathered informed a table that provides contaminant-sorbent combinations suitable for immobilization, as well as an estimate of sorption affinity ($\log K_D$) that could be expected for a type of sorbent and a given contaminant. Overall, we present a workflow to determine site-specific suitability and tailored amendment rate of biochar for soil remediation. Our workflow will help decision makers assess whether biochar can be used at a given site.

4.15.T-04 Natural Bioremediation and Bioaugmentation of Soils Conditioned With Foaming Agents

Anna Barra Caracciolo¹, **Ludovica Rolando²**, **Paola Grenni³**, **Livia Mariani⁴**, **Jasmin Raueo⁵**, **Francesca Spataro⁵**, **Gian Luigi**

Garbini⁵, Andrea Visca⁵ and Luisa Patrolocco⁵, (1)National Research Council - Water Research Institute, Italy, (2)Water Research Institute - Italian National Research Council, Italy, (3)National Research Council of Italy (CNR), Italy, (4)CNR-IRSA, Italy, (5)Italian National Research Council, Italy

The mechanized excavation of tunnels produces large quantities of excavated soil that contains residual concentrations of foaming agents used to modify the mechanic and hydraulic behavior of soil. The classification as a by-product or as waste of excavated soils depends not only on the residual presence of known contaminants (e.g. metals, hydrocarbons, etc.), but also on the presence of other chemical substances such as anionic surfactants which are the main components of foaming agents (5-50%). For these substances there are no legislative limits, however their presence at certain concentrations can determine a potential toxicity of the excavated soil. Our research reports the main results on the biodegradation of the anionic surfactant sodium lauryl ether sulphate (SLES), with a focus on the recently selected microbial consortium capable of degrading anionic surfactants in a few hours and on its use in bioaugmentation applications. For this reason, three different experiment were set up: microcosm (to assess SLES biodegradability), isolation (to identify and characterize a bacterial consortium capable to degrade SLES) and bioaugmentation (to test if adding the bacterial consortium identified to spoil material enhanced the removal of the anionic surfactant residues) experiment. The main results of our research showed that the natural attenuation (with no human intervention) of SLES is expected due to natural microorganisms present in the excavated soil (28 days), but long degradation times cannot always meet the construction site requirements. This can be the case of tunneling for a metro in a city or through mountains along a sea coast, where a prolonged storage is not possible because of lack of space and the spoil material would be forced to be considered a waste. The identification of a natural bacterial consortium capable of promptly (9 hours) degrading SLES has significant potential for bioaugmentation purposes, permitting a shortening of the storage time for soil excavated with foaming agents at construction sites and a safe promotion of the subsequent reutilization of the soil for different purposes. In fact, the bioaugmentation experiments of the spoil material with the bacterial consortium previously identified, significantly improved (six times) the degradation time of SLES (DT₅₀ 1 day) compared with natural attenuation (DT₅₀ 6 days), ensuring a safe by-product and saving execution time and overall costs for the tunneling industry.

4.15.T-05 Assessment of Organic and Inorganic Contaminant Removal in Contaminated WATER by Mycofiltration, Through a Fixed Bed Column Approach

Sanele Mnkandla¹ and Patricks Voua Otomo², (1)National University of Science and Technology, South Africa, (2)University of the Free State, South Africa

Mycofiltration is an environment friendly technology which involves the treatment of contaminated water by passing it through a network of fungal mycelium. Fungal mycelia are said to employ mechanisms such as biosorption in the remediation of pollutants/xenobiotics. The current study seeks to conduct mycofiltration via a continuous fixed bed column approach. This allows assessment of the effect of various parameters such as inlet concentration, flow rate, pH, and column bed depth on the sorption capacity of the mycofilter in a continuous treatment process. The resulting breakthrough curves generated will thus give a representation of the pollutant-effluent concentration vs time profile, whilst kinetic models will evaluate column performance and predict scale up. A mycofilter of the *Pleurotus* fungal species is currently being cultured. Various substrates (hay, thatching straw, bamboo wood chips and aspen wood chips) have been prepared through cutting into small particles, soaking in 2 % (w/v) calcitic lime and pasteurisation, prior to mixing with *Pleurotus ostreatus* spawn 10 % (w/w) in 140 x 170 mm polyethylene bags. The bags were incubated in a dark, humid chamber to allow for substrate colonisation by mycelium, for a period of 14 days. Upon observations, degree of mycelium colonisation from highest to lowest: thatching straw > hay > aspen wood chips > bamboo wood chips. To create the mycofilters, the pre-myceliated substrate will be loaded into acrylic columns (1 x 10 cm), at various bed heights. Mycofilters will be further incubated for 7 days. A food colour solution will be passed through the columns at different flow rates, filtrate collected at time intervals and absorbances measured. Breakthrough curves will be plotted and amount of contaminant retained at both breakthrough time and saturation time, as well as biomass uptake capacity will be analysed. Study hypothesis: H₀: Mycofiltration via a continuous fixed bed column does not efficiently remove organic and inorganic contaminants in water. H₁: Mycofiltration via a continuous fixed bed column efficiently removes organic and inorganic contaminants in water. Mycofiltration, through a simple inexpensive continuous fixed bed column, will provide valuable information necessary for upscaling from laboratory pilot studies to industrial scale. Mycofilter fixed bed columns could thus possibly be applied in the management of point source pollutants e.g., effluent from wastewater treatment plants.

4.15 Recent advances in Bioremediation and Phytoremediation of contaminated areas (Virtual Only)

6.07.V-01 Assessment of Sunflower Capability in Restoring Soil Contaminated by PCBs and HMs in Microcosm Experiments

Valeria Ancona¹, Ida Rascio², Giorgia Aimola², Paola Grenni³, Gian Luigi Garbini², Daniela Napolitano⁴, Alessio Lacirignola⁴, Vito Locaputo², Angela Gatto², Marina Tumolo⁵, Daniela Losacco² and Anna Barra Caracciolo⁶, (1)Water Research Institute - Italian National Research Council, Italy, (2)Italian National Research Council, Italy, (3)National Research Council of Italy (CNR), Italy, (4)CISA SpA, Italy, (5)DISSPA, Italian National Research Council - Water Research Institute (CNR-IRSA), Bari, Italy, (6)National Research Council - Water Research Institute, Italy

Plant-assisted bioremediation (PABR) is a strategy based on interactions between plants and microorganisms in the rhizosphere, which promotes a reduction in soil contaminants. In fact, the plant root system can stimulate microbial activity in the rhizosphere favoring decontamination processes (biodegradation of organic xenobiotics and removal/transformation of the inorganic ones). In the last few years, several laboratory, greenhouse, and field studies were carried out to assess the effectiveness of PABR technology in recovering multi-contaminated soils. At laboratory scale, microcosm experiments allow studying natural soil

microbial populations under controlled environmental conditions (e.g., temperature, light, humidity, and so on). Recently, sunflower has been proposed for plant-assisted bioremediation purposes. This plant species was demonstrated to be able to absorb various heavy metals (e.g., Zn, Cu, Pb, etc) through its root system. Moreover, sunflower effectiveness in degradation of Persistent Organic Pollutants (e.g., DDT, endosulfan, different chlorinated compounds, and polychlorinated biphenyl-PCBs) was verified recently. In this work, a sunflower microcosm experiment was carried out for 3 months to assess sunflower capability in restoring soil historically contaminated by PCBs and heavy metals (HM). The soil was collected from a survey site located close to Taranto city (Southern Italy). Four different experimental conditions (presence/absence of compost and/or plant) have been set up. Chemical analyses of soil properties (e.g., pH, EC, OC, available phosphorous) and pollutants (PCBs and HMs) were performed at two sampling times (45, 90 days). Moreover, microbial abundance, dehydrogenase activity, and qPCR assays were performed for evaluating the autochthonous microbial community composition, structure, and functioning. Finally, a root exudates screening was carried out on planted pots in order to investigate the potential microbial-plant interactions occurring in sunflower-assisted bioremediation microcosm experiments.

4.15.V-01 Biodegradation Potential of Bacteria Species From Sub Soil of an Artisanal Oil Polluted Site

Nelson Nosa Obaretin¹, Chioma Blaise Chikere², Chidinma Peace Okafor, MRes³ and Blessing Samuel⁴, (1)Department of Microbiology, University of Port Harcourt, Port Harcourt, Nigeria, (2)University of Port Harcourt, Nigeria, (3)Africa Centre of Excellence in Oilfield Chemicals Research, University of Port Harcourt, Nigeria, (4)University of Port Harcourt Rivers State, Nigeria, Nigeria

The rising incidence of oil pollution caused by artisanal crude oil refining has resulted in the devastation of farmlands, aquacultures, and biodiversity loss. The purpose of this study was to assess the biodegradation capacity of bacteria species isolated from the subsoil of an artisanal oil contaminated site. Crude oil-polluted soil samples were collected in sterile containers from Tombia and Bodo Towns in Rivers State using a soil auger and brought to the laboratory for microbiological analysis. HUB isolation was accomplished by enrichment on Bushnell Haas broth. The average HUB and HUF counts after 72 hours' incubation were 4.6×10^5 CFU/g; 3.6×10^6 CFU/g for Tombia soils, 2.7×10^7 CFU/g and 2.5×10^7 for Bodo soils and 3.5×10^5 CFU/g; 2.2×10^5 CFU/g for Tombia soils, and 2.7×10^5 CFU/g; 3.0 CFU/g for Bodo soil respectively. Colorimetric method with the redox dye, dichlorophenol indole phenol (DCPIP) was employed for degradation screening. *Clostridium* spp, *Pseudomonas* spp, *Actinomyces* spp, *Fusobacterium* spp, and *Bifidobacterium* sp. were the HUB identified while *Candida glabrata*, *Microsphaeropsis arundinis*, *Neosartorya fischeri*, *Aspergillus niger*, *Aspergillus lentulus* were the HUF identified. The study's findings show that the contaminated site has microorganisms with significant biodegradation capacity, and it can be used as an eco-friendly and cost-effective strategy for bioremediation of severely polluted sites.

4.15.V-02 Long Alkane Degradation by Bacteria From Crude Oil Polluted Site

Israel Edamkue¹, Chioma Blaise Chikere¹, Nelson Nosa Obaretin², Chidinma Peace Okafor, MRes³ and Chidinma Ubazeuonu¹, (1)University of Port Harcourt, Nigeria, (2)Department of Microbiology, University of Port Harcourt, Port Harcourt, Nigeria, (3)Africa Centre of Excellence in Oilfield Chemicals Research, University of Port Harcourt, Nigeria

Petroleum hydrocarbons have been used extensively as a source of fuel. Due to this, exploration has gone on continuously with recurring oil spills within the Niger Delta region of Nigeria. In this study, soils from two different sites of crude oil pollution were subjected to tests to observe the degradation of long alkanes by bacteria found natively within these sites. Soil samples were collected and subjected to physicochemical tests using standard methods. Microbial counts were determined using enrichment and vapour-phase methods for enumeration of hydrocarbon utilizing bacteria. Bacteria were isolated and characterized using biochemical tests. The bacterial counts for the enrichment phase ranged from 5.23 to 185.0×10^4 cfu/g for the BSP soil, while it was from $4.1 - 747.0 \times 10^4$ cfu/g for the TSP soil and for the vapour phase method, 2.33×10^5 cfu/g for the paraffin oil setup for the BSP soil while it was 3.55×10^5 cfu/g for the paraffin oil setup for the TSP soil. In all soil, there was no growth of degraders for the paraffin wax setup. The isolated bacterial species found responsible for the degradation of paraffin (both oil and wax) were characterized and identified to belong to the following genera: *Acinetobacter*, *Arthrobacter*, *Pseudomonas*, *Rhodococcus* and *Bacillus*. It known that these bacteria may be employed in biodegradation set up to clean up the long alkane fractions in contaminated areas effectively as they utilized paraffin oil.

4.15 Recent advances in Bioremediation and Phytoremediation of contaminated areas (Poster)

4.15.P-Th140 Phytoremediation Potential of Contaminated Shooting Range Soil

Gintare Sujetoviene¹ and Jurate Cesynaite², (1)Vytautas Magnus University, Kaunas, Lithuania, (2)Vytautas Magnus University, Lithuania

Contamination of shooting ranges is an important environmental issue, and it is important to manage and control this pollution in the shooting ranges. The range contributes significantly to the contamination with heavy metals, especially lead. The aim of the study was test phytoremediation potential using a heavily contaminated shooting range soil in 80 days field study. In this field study two species (*Trifolium pratense* L. and *Medicago sativa* L.) were used for comparison of their phytoremediation efficiency. The concentration of lead in the soil in the most contaminated area of the shooting range was up to 54.5 g kg^{-1} . Significantly higher concentrations of heavy metals were found in the aboveground parts of both plant species when exposed to the most polluted shoot soil. The growth *M. sativa* was no so sensitive as *T.pratense* - significantly lower biomass of *T. pratense* was observed in plants grown in the soil of the shooting range compared to the control while *M.sativa* did not show significant growth changes under the exposure to contaminated soil., resulting in lower plant growth.

4.15.P-Th143 Heavy Metals Vermiremediation Potential Using *Eisenia fetida* at Different Sewage Sludge Treatments in Soil

*Inesa Kniuiptyte*¹, *Jurate Zaltauskaite*² and *Marius Praspaliauskas*¹, (1)Lithuanian Energy Institute, Lithuania, (2)Vytautas Magnus University, Lithuania

Sewage sludge production is constantly growing across the world, while sustainable sewage sludge (SS) disposal is a major environmental problem. In European Union the predominant valorization of sewage sludge is agricultural or forestry reuse for soil fertilization or land reclamation/restoration. Sewage sludge secondary use in agriculture is actively promoted for soil quality improvement due to its high amount of organic matter and nutrients. Along with many advantages of SS application to soil, it has drawbacks such as non biodegradable heavy metals, various organic contaminants, pathogenic organisms. Soil contamination with heavy metals not only endangers ecosystems, but also poses human health risk. Biological remediation of contaminated soil offers significant economic, energy, environmental and social advantages compared to traditional (physico-chemical) methods. Earthworms and their products (vermicompost) have emerged as a potential environmentally friendly option among biological remediation solutions. The purpose of this study was to assess the potential of the earthworm *Eisenia fetida* to remove heavy metals in SS supplemented soil. The vermiremediation process was performed at different SS soil treatments (0-200 kg/ha) using adult earthworms. As a result of vermiremediation, soil heavy metal concentrations were significantly reduced. Higher than 80 % vermiremediation efficiency was reached for a few heavy metals (Ni, Co, Mn), and the bioconcentration factors were as follows: Zn>Co>Cu>Ni>Mn>Cr. In addition, vermiremediation affected soil quality: soil pH was stabilized, organic matter mineralization quickened, K and Mg concentrations have slightly decreased, and the content of Ca and key nutrients (P, S) has increased. The greatest potential for vermiremediation was reached in SS soil treatments of 25-50 kg/ha. It is important to note that higher SS concentrations (> 100 kg/ha) in soil may limit this method's use due to possible lethal effects on earthworms and growth retardation. Altogether, the study suggests that vermiremediation using *Eisenia fetida* might be a sustainable, successful and environmentally friendly management strategy for stabilizing SS amended soil, reducing toxic effects and converting it suitable for safe use in agriculture.

4.15.P-Th144 Two-Way Reuse of Sewage Sludge Through Co-Composting With Sludge Derived Biochar

*Dmitri Drabkin*¹, *Rene Schatten*², *Konstantin Tertytze*³, *Yehoshua Maor*⁴, *Benny Chefetz*⁵, *Eyal Ben-Nevef*⁶ and *Nadav Ziv*⁷, (1)Freie University Berlin, Germany, (2)FU Berlin, Germany, (3)FU Berlin Berlin, Germany, (4)Phytor Lab, Jerusalem, Israel, (5)The Hebrew University of Jerusalem, Israel, (6)Compost Or, Israel, (7)Earth Biochar, Israel

This study is a part of the international project RESIDUE in the framework of the EU PRIMA programme with a special focus on Mediterranean area. The goal of this study is to investigate new ways of recycling of sewage sludge as a product of waste water treatment for agricultural use in Israel with a possibility of applying it to other Mediterranean regions with organic matter scarcity. For that purpose, we are testing the co-composting of sewage sludge with the biochar derived from local waste streams. Co-composting of biochar with organic matter is a promising way to turn waste materials into agricultural substrates. Our WG Geoecology achieved good results with co-composting of green waste with wooden biochar in previous projects (TerraBoGa, CarboTIP). At first, the input materials for the co-composting process were selected in Israel. The cooperation with Compost Or, which is the biggest sewage sludge recycling facility in Israel, allowed us to use representative sewage sludge input material, which is collected through over urban waste water treatment plants in Israel. Part of the recycled and composted sewage sludge is also used as an input material to produce biochar (carbonizate) at the Earth Biochar (subsidiary of Compost Or) facility, which is used for example as a soilless substrate for plants. We decided to take that sewage sludge derived biochar to enable the two-way reuse of sewage sludge through co-composting. For that purpose, an on-site composting trial was established at Compost Or facility with variants of 10, 20 and 30 vol.-% biochar in the composting mix. The pre-tests with biochar produced by WG Geoecology from composted sludge at different temperatures (500/600/700°C) showed positive results on biochar stability (H/C, O/C – ratio) and high nutrient contents. These biochars will be compared to biochar produced by Earth Biochar, especially regarding to increased heavy metal content due to input material properties observed in the biochars produced by WG Geoecology. The resulting composts will be characterized on basic physico-chemical parameters, heavy metals, PAH and plant-available nutrients. Leaching tests will be performed to investigate the mobility of nutrients and contaminants in the biochar-composts and in the biochar-compost applied to local soil. These composts will be applied later to Israeli soil in a greenhouse and lysimeter/field trial to assess soil quality improvement.

4.15.P-Th145 Enhanced Natural Attenuation Mediated by Autochthonous Bacteria for Recovering Cr(VI)-Polluted Groundwaters

*Marina Tumolo*¹, *Domenico De Paola*², *Vito Locaputo*², *Daniela Losacco*², *Pietro Cotugno*³, *Angela Volpe*², *Vito Felice Uricchio*² and *Valeria Ancona*⁴, (1)DISSPA, Italian National Research Council - Water Research Institute (CNR-IRSA), Bari, Italy, (2)Italian National Research Council, Italy, (3)University of the Studies of Bari Aldo Moro, Italy, (4)Water Research Institute - Italian National Research Council, Italy

The presence of Cr (VI) in groundwater, at concentrations significantly higher than legal limits, represents a widespread environmental problem. Environmental contamination is mainly related to the incorrect management of process water and by-products coming from numerous industrial processes involving chromium. Groundwater remediation can be conveniently achieved by reducing Cr (VI) to Cr (III), since the latter is less soluble and less mobile through environmental matrices, as well as a hundredfold less toxic for living organisms than Cr(VI). Biological reduction is potentially advantageous in terms of economic and environmental sustainability, especially in the case of large volumes of water. Ubiquitous organisms, characterized by high metabolic plasticity, such as bacteria, are able to detoxify the environment surrounding the cell by reducing Cr (VI). However, these microorganisms are generally heterotrophic and need an external source of nutrients to support their growth and

reproduction, especially in oligotrophic environments such as groundwater. Enhanced natural attenuation can be achieved by supplying suitable amendments that can both support bacterial biomass production and provide electrons for reductive processes. The NGS technologies applied to the 16S rDNA region can provide the structure of the native bacterial community, highlighting changes before and after treatment. This approach also allows investigating a possible amendment-driven enrichment of chromium-reducing bacteria. The capability of indigenous bacterial consortia to remediate Cr(VI)-polluted groundwater was investigated by a bioremediation test carried out at a microcosm scale. Microcosms setup was performed using deep saturated soil and groundwater collected from an industrial site in the territory of Barletta Municipality, where Cr(VI) was detected in groundwater at a concentration of about 140 $\mu\text{g L}^{-1}$. The effectiveness of two different amendments for Cr(VI) removal was tested. Results showed a clear dependence of Cr(VI) decay on the amendment used. Notably, yeast extract (200 mg L^{-1}) provided the highest Cr(VI) removal, in comparison with polyhydroxybutyrate (180 mg L^{-1}), whereas no removal was detected in the not amended control reactors. Bioinformatic analyses are ongoing in order to investigate changes in the bacterial community structure.

4.16 Tire wear and microrubber particles - from problems to solutions (Part I)

4.16.T-01 Modelling Tire and Road Wear Particle Fate & Transport in the Terrestrial and Freshwater Environment With a Global Perspective

Jos van Gils¹, Lora Buckman², Helene Boisgontier², Steffen Weyrauch³, Thorsten Reemtsma⁴ and Timothy Barber⁵, (1)Deltares, Delft, Netherlands, (2)DELTAWARES, Netherlands, (3)UFZ Leipzig, Leipzig, Germany, (4)Helmholtz Centre for Environmental Research, Germany, (5)ERM, United States

This presentation discusses the refinement and extension of the Tire and road wear particles (TRWP) Distribution Model developed by Unice et al. in 2019. This model provided the first integral catchment-scale TRWP mass balance for the Seine watershed (France/Belgium). The overall objective of the work presented was to provide scientifically convincing TRWP mass balances, by spatially and temporally explicit modelling of both mass balances and concentrations found in the environmental compartments water, soils and sediments, and to do so for three watersheds on different continents. To achieve consistent extensions to watersheds on different continents, spatial(-temporal) data available at a global scale had to be used. Such datasets were identified and accessed, to create a high-resolution (< 1km) hydrology and sediment delivery model using a process-based distributed open source modelling framework. Releases of TRWP were estimated at the country scale using statistical data from various sources, and were downscaled using global spatial datasets of population, settlement type and road networks. The model refinement included the implementation of improved terrestrial fate and transport algorithms to allow applicability under a wide range of climatic conditions. The aquatic fate and transport model was kept unchanged, describing transport and trapping of 4 size fractions of TRWP, 3 size fractions of natural suspended particles and 4x3 aggregates formed by hetero-aggregation. For model validation, new analysis results from surface water samples and samples from sediment traps from the Seine River were used. Successful model applications were developed for watersheds on three continents. Robust mass balances for the Seine are presented, grace to the high model resolution and the additional validation. By comparing the three watersheds, insights are generated in differences between the simulated basins caused by socio-economic, climate and storwater management practices gradients.

4.16.T-02 Estimation of Tyre and Road Wear Particle Emissions in Urban Aquatic Systems

Victoria Guadalupe Gutierrez Dominguez Ms¹, Alistair Boxall² and Colin McClean², (1)Environment Department, University of York, United Kingdom, (2)University of York, United Kingdom

Tyre and road wear particles (TRWP), which are generated from the contact made between the road surface and the tyre, have gained increasing attention due to the perception that they are making a significant contribution to microplastic contamination of freshwater systems. The considerable amount of particles released to the environment may have toxicological effects on aquatic organisms, due to the chemicals added during the manufacturing process and the adsorption of contaminants present in the environment. Annual TRWP emissions have been estimated for various countries, mainly in Europe. However, only a few studies have simulated the transport of TRWPs through surface runoff to freshwater systems. These have typically explored emissions at the regional level. In this study, we used a temporally and spatially resolved model to estimate tyre and road wear particle emissions in the City of York, UK. The exposure modelling used data on tyre particle generation rates, local weather patterns, land cover composition, wastewater treatment plant characteristics, and the drainage/sewerage to estimate emissions to different points in York's river system at a daily resolution. Average, maximum and minimum emission scenarios were modelled. The total TRWPs emitted into rivers in the City of York summed across vehicle types for the minimum scenario was 41 tonnes/year corresponding to a per capita emission of 0.19 kg/year. A total value of 86.30 tonnes/year and 128.75 tonnes/year, and a per capita value of 0.40 kg/year and 0.60 kg/year was calculated for the average and maximum scenario, respectively. Over the three scenarios, cars presented the highest emission values from the four vehicle types studied, whereas buses showed the lowest. Spatial variance of the TRWP emissions can be observed across the city's regions, where the highest emissions were found in the northeast and northwest of the city. Temporal variance is demonstrated between months, where the peak months in the 2017 simulation were February and October. The results can help identify high locations and times of high emissions (hot spots) enabling more accurate exposure and risk assessment and the targeting of future management approaches, such as improved road runoff treatment.

4.16.T-03 Distribution and Propagation of Tyre Wear in Germany and Fate in the Basin of the River Panke in Berlin

Ilka Gehrke¹, Jan Bloemer², Boris Dresen², Harald Sommer³, Franklin Lindow³ and Rainer Röckle⁴, (1)Fraunhofer UMSICHT,

Oberhausen, Belgium, (2)Fraunhofer UMSICHT, Germany, (3)Ingenieurgesellschaft Prof. Sieker mbH, Germany, (4)iMA Richter & Röckle GmbH & Co.KG, Germany

Tyre wear is considered the largest sources of microplastics in the environment in Germany, as for most industrialized countries. Several studies deal with the propagation of tyre wear via air, rainwater runoffs and water transport. However, only a limited knowledge about the spatial distribution of tyre wear as a starting point for propagation calculations exists. The present study integrates a traffic data and a probabilistic model in order to calculate the distribution of tyre wear along the roads as well as its fate in atmosphere and water bodies for the whole area of Germany. As example, this tyre wear model was applied for the river basin of the river Panke in Berlin. The traffic data model uses the average daily traffic volume (ADTV) in order to calculate the traffic volume for three road categories: rural roads, urban roads and motor ways. It defines specific road segments which are characterized by certain traffic situations such as brake zones at intersections, curve radius, and slope inclination. The probabilistic model assigns each street segment a relative wear intensity, which were adjusted by a constant factor in order to match a given total amount of tyre wear particles and is then submitted to the traffic data model for the calculation of the local distribution of tyre wear particles. The atmospheric transport model uses meteorological data to create maps with a resolution of 100m x 100m for Germany and 2m x 2m for the river basin Panke, respectively. It includes deposition, resuspension, sedimentation, transport and transformation of suspended tyre wear particles. The authors of the present study apply the material flow model STORM for the modeling of the source emissions: of the tyre wear particles in the river basin Panke. The maximum tyre wear load calculated for one discharge point accounts to 4,921 kg/a.

4.16.T-04 Physico-Chemical Property Estimations and Fate Predictions of Methoxymethylmelamines: Tire-Derived Transformation Products

Cassandra Johannessen¹ and J. Mark Parnis², (1)Chemistry, Trent University, Peterborough, ON, Canada, (2)Trent University, Canada

Hexamethoxymethylmelamine (HMMM) is a polymer crosslinking agent that is commonly used to manufacture tires on an industrial scale. Previous work has demonstrated that HMMM is a ubiquitous contaminant in urban surface waters due to its presence in tire-wear particles and its tendency to be transported into receiving waters during rain events through road runoff. It has recently been seen that this chemical readily transforms into numerous other compounds, several of which have also been detected in the aquatic environment. However, there is limited knowledge about the properties of HMMM, its precursor contaminants, and its transformation compounds. Furthermore, the environmental fate of these compounds is largely unknown, which limits the capacity for completing the required ecological risk assessments. To address these data gaps, this study utilized COSMO-RS solvation theory to estimate the physico-chemical properties of HMMM and its derivatives. The trends between the degradation of HMMM (often through demethoxylation) and the corresponding impact on the physico-chemical properties were established and discussed. Furthermore, the estimated values for these properties (e.g., solubility, vapour pressure, log Kow) were then used as inputs to the Equilibrium Criterion (EQC) fugacity-based multimedia model to predict the likely environmental fate of these tire-derived compounds. Three different emission scenarios were modelled in order to comprehensively assess the predicted chemical fate. These scenarios included: 1) input of the chemical equally into air, water, and soil, 2) input of the chemical into water only, and 3) input of the chemical into soil only. Overall, these compounds were predicted to readily partition into aqueous media, with distributions in water increasing with the loss of methoxymethyl groups. In addition, the persistence of the transformation products of HMMM was predicted to decline with the extent of these transformations. The EQC model predictions indicate that these compounds are subject to overland transport into surface waters. This study provides the first insight into the environmental behaviour and fate of HMMM and its transformation products and contributes to the growing literature on the hazards of organic chemicals present in tires and their environmental transformation products.

4.16.T-05 Evaluating Microbial Degradation of Tire Wear Particle Chemicals in Stormwater

Sumaiya Saifur and Courtney Gardner, Washington State University, United States

Growing concern over the ubiquity and potential environmental impacts of tire wear particles, particulate debris produced from the friction between tires and the road surface, has resulted in significant efforts to understanding their environmental fate and behavior over the past decade. Tire wear particle microplastics are chemically complex materials containing rubbers, reinforcing agents, resins, additives, process oils, net vulcanization agents, and other compounds that can leach into the surrounding terrestrial or aquatic environment, with poorly understood toxicokinetic and toxicodynamic properties. Hexa(methoxymethyl)melamine and 1,3-diphenylguanidine have been identified as chemicals that may be partially responsible for acute toxicity and mortality impacts observed in aquatic organisms like coho salmon. However, little information is available about the natural bioremediation potential of these contaminants. The goal of this research was to identify microbes in stormwater, which are frequently exposed to these contaminants, that may be capable of degrading hexa(methoxymethyl)melamine and 1,3-diphenylguanidine. Through selective culturing and subsequent Sanger sequencing, three putative biodegraders (*Bacillus cereus*, *Bacillus spp.*, *Lysinibacillus spp.*) have been identified that are capable of using hexa(methoxymethyl)melamine and 1,3-diphenylguanidine as their sole carbon source, a promising finding that can be used in future research to explore the potential for *in situ* bioremediation of tire wear particles.

4.16 Tire wear and microrubber particles - from problems to solutions (Part II)

4.16.T-06 Challenges and Ways Forward in Assessing the Ecotoxicity of Tire and Road Abrasion in Stormwater Runoff - Introduction to the RoadTox Project

Markus Thomas Schmitz¹, Selina Seibold², David Kleindienst³, Jessica Brockob⁴, Sabrina Schiwiy⁵, Regina Dolny⁴, Vanessa

Spelthahn⁴, Simone Lechthaler⁴, Volker Linnemann⁴ and Henner Hollert³, (1)Evolutionary Ecology and Environmental Toxicology (E3T, Goethe University Frankfurt am Main, Frankfurt am Main, Germany, (2)Goethe University Frankfurt, Germany, (3)Goethe University Frankfurt am Main, Germany, (4)RWTH Aachen University, Germany, (5)Goethe University Frankfurt am Main, Frankfurt, Germany

Recently, awareness and knowledge about tire and road wear particles (TRWP) in the context of environmental risk assessment have significantly increased. Yet, the fate and ecotoxicological effects of tire abrasion outside of communal wastewater treatment systems are insufficiently understood. Furthermore, there is a lack of data about how tire abrasion interacts with other pollutants from road runoff. Consequently, assessing the risk for aquatic environments emerging from TRWP polluted runoff faces the following challenges: (1) Due to structural and chemical variability of TRWP, no standardised sample preparation protocols for (bio-)chemical assessment are available; (2) The lack of environmentally relevant effect data complicates *a priori* decisions on endpoints of interest to investigate. Therefore, comprehensively investigating the ecotoxicity of TRWP demands for a scientific bottom-up approach generating a broad knowledge base covering both chemical and biological effect information for a variety of environmental model scenarios. The project "RoadTox" aims for a quantitative ecotoxicological risk assessment in stormwater runoff sampled from urban and extra-urban roads and federal highways. For this purpose, a comprehensive multi-endpoint bioassay battery paired with hydrological, physical, and chemical characterisation of the received runoff and its particulate matter will be performed. Addressed toxicological endpoints include dioxin-like activity, endocrine disruption, mutagenicity *in vitro*, and sublethal, transcriptional and behavioural effects in *Danio rerio* embryos. The received ecotoxicological information will be integratively analysed and combined with literature data to enable a meaningful risk assessment of the input of tire abrasion into the environment. RoadTox does not solely focus on the individual tire abrasion particles alone but the overall ecotoxicological impact of the road wastewater sample. Based on the quantitative results of the input pathways and the ecotoxicological risk assessment, interdisciplinary recommendations for actions aiming to minimise tire abrasion inputs will be developed. Here we will present the current state of the project, including past and present challenges and first data on physico-chemical profiling, EROD induction, anti-androgenic and estrogenic activity and effects on *D. rerio* embryos. The project is funded by the State Agency for Nature, Environment and Consumer Protection NRW (LANUV).

4.16.T-08 Tire Rubber Microplastics: A Hazardous or Harmless Material?

Victor Carrasco Navarro¹, Patricia Caballero Carretero², Ana-Belén Muñoz-González³, Suvi Seppänen¹, Aino Nuutinen¹, Jouni Sorvari¹, Jose-Luis Martínez-Guitarte³ and Jussi Kukkonen¹, (1)University of Eastern Finland, Finland, (2)National Distance Education University (UNED), Las Rozas, Madrid, Spain, (3)UNED, Spain

Tire rubber may be one of the most popular anthropogenic materials ever produced and consequently, tire rubber microparticles (also called microrubber) are released in very high quantities. In the water environment, tire rubber has been found in concentrations of 0.01 to 155 mg per g sediment dry weight. Furthermore, tire rubber contains many chemical additives that contribute to the material's final characteristics. Additives are potentially released to water and cause concerns related to their toxicity to natural ecosystems. They can be considered as a very complicated chemical mixture that may vary their composition depending on the environmental conditions. In our study, multiple approaches were used to detect the risks of microrubber to freshwater organisms. Factors such as size, sediment type, concentration of microrubber, toxicity of the leachates and three model organisms were used for this purpose. The monitored endpoints were mortality, emergence, sex ration, reproduction and growth (*C. riparius*), reproduction and growth (*Lumbriculus variegatus*) and growth (*Lemna minor*). In addition, gene expression was analyzed in *C. riparius* exposed to low levels of microrubber or their leachates. The results indicated that none of the factors tested related to microrubber particles (size or concentration in sediment) affected any of the endpoints examined in *C. riparius* or *L. variegatus*. In *C. riparius* exposed to leachates, analyses of the dose response curve yielded a LC₅₀ value of 47.3 ± 3.03%, what corresponded to 37.4 g L⁻¹ of tire rubber considering how the leachates were prepared. A similar pattern was found with *L. minor*, showing a reduced growth rate at a concentration of 30%. The gene expression analyses pointed at the generation of oxidative and cellular stress in *C. riparius*. More complete analyses of larvae exposed to particles and leachates separately during 24h and 10d will help us to determine the cellular pathways affected by microrubber and its additives. Our results indicated that organisms likely compensate the initial oxidative and cellular stress and overall are not affected in longer tests. Studies with the leachates indicated a more obvious toxicity that may not be environmentally relevant. However, chemicals present in the leachates may affect other important parameters such as growth at lower concentrations. The results prompted to further investigate the effects of both particles and chemicals present in tire rubber.

4.16.T-09 Evaluation of Tire Tread Particle Toxicity to Fish Using Rainbow Trout Cell Lines

William Dufefoi¹, Benoit J D Ferrari², Florian Breider³, Thibault Masset⁴, Etienne Vermeirssen⁵, Alan J Bergmann⁶ and Kristin Schirmer⁷, (1)Eawag - Swiss federal Institute of Aquatic Science and Technology, Switzerland, (2)Ecotox Centre Eawag-EPFL, Switzerland, (3)Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland, (4)EPFL, Switzerland, (5)Oekotoxzentrum Eawag-EPFL, Switzerland, (6)Ecotox Centre CH, Switzerland, (7)Eawag, Switzerland

Tire and road wear particles (TRWP) are generated by the abrasion of tires while driving, and questions were raised recently in regard to their potential contribution to microplastics released into the aquatic environment and their potential toxicological impacts. Our study aimed to determine the toxicity of TRWP and associated chemicals to fish using two Rainbow Trout (*Oncorhynchus mykiss*) cell lines representing the gill (RTgill-W1) and the intestinal (RTgutGC) epithelium. More specifically, we used cryogenically milled tire tread (CMTT) particles as a proxy for TRWP. These were applied to the cells directly, and in the case of RTgutGC cells, also after *in vitro* digestion to investigate if fish gastro-intestinal conditions could result in a different chemical profile and change the toxicity. In accordance with OECD TG249, cell viability was assessed after 24 hours acute exposure using a multiple-endpoint assay indicative of cell metabolic activity, membrane integrity and lysosome integrity.

Chemical composition of the exposure medium was analyzed to assess which chemicals could be responsible for the observed acute effects. We determined EC50 values after direct exposure to RTgill-W1 and RTgutGC cells at 2.01 g/L and 3.80 g/L, respectively, and a maximum no-observed-effect concentration of 10 mg/L. 2-Mercaptobenzothiazole was found at the highest concentration among organic chemicals leaching out from the particles. It could be a major contributor to the loss in cell metabolic activity based on its toxicity to Rainbow Trout *in vivo*, although additional particle or mixture effects cannot be ruled out at this point. Moreover, CMTT digestate EC50 was determined at 12.15 g of tire particle/L of digestive fluid. The observed toxicity could be due to high amounts of Zn, N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD), 1,3-Diphenylguanidine (DPG) or 2-Mercaptobenzothiazole leaching out during *in vitro* digestion. Although traces of 6PPD-quinone were measured in the exposure medium, further cytotoxicity assays using the RTgill-W1 cell line showed no significant toxicity of this compound up to 3 mg/L. Overall, our *in vitro* toxicity data agree with reports of acute fish (*in vivo*) toxicity and show that acutely toxic concentrations of CMTT are well above concentrations measured in river water (0.3 to 4 mg/L). Because higher concentrations have been detected in road runoff (>100 mg/L), more research into long-term effects of such high exposure is required.

4.16 Tire wear and microrubber particles - from problems to solutions (Virtual Only)

4.16.V-01 Addressing Tire-Related Pollution in Urban Runoff: Mitigation Options and Priority Data Needs

Kelly Moran¹, Alicia Gilbreath¹, Ezra Miller¹, Miguel Mendez², Diana Lin¹ and Rebecca Sutton¹, (1)San Francisco Estuary Institute, United States, (2)San Francisco Estuary Institute, Richmond, CA, United States

Recent investigations in the San Francisco Bay Area (California, USA) identified urban runoff as a major pathway for microplastics entering receiving waters, with black rubbery particles from tires estimated to be the single most common microplastic flowing into the Bay annually. Tire particles and associated contaminants pose toxicological risk to aquatic species. For example, one tire-related chemical, 6PPD-quinone (a degradate of a tire antioxidant) causes pre-spawn mortality in coho salmon. Based on conceptual models to synthesize and integrate our current understanding of tire particle sources and pathways to urban runoff, we developed a broad framework of control strategies for tire particles and the water pollutants they carry. The goal of the control strategy framework is to inform future research and management recommendations for managing tire-related water pollution. There are many available approaches to prevent and mitigate tire-related water pollution, from re-formulating tires to remove toxic ingredients, to reducing tire wear rates, to collecting wear debris at the point of emission from vehicles, to downstream collection and treatment of urban runoff to remove tire particles and chemicals. Among the many tire-wear-particle-related data gaps, several were identified as priorities because they have significant implications for future management decisions regarding tire wear debris. These include particle surface area measurements to determine the size fraction of tire wear particles that accounts for the majority of the surface area, which would inform design and location of on-vehicle and environmental systems to collect tire particles. Addressing tire wear particles and associated chemicals will require a holistic approach because it is not possible to separate the tire microplastics from the chemicals they contain, and because the topics that need attention are typically managed by different types of agencies and scientists (air, water, toxic chemicals). Turning research attention toward the priority data needs would inform development of mitigation measures that most cost-effectively address tire wear particle pollution.

4.16.V-02 Concentration of N-(1,3-dimethylbutyl)-n'-Phenyl-P-Phenylenediamine-Quinone (6PPD-Q) in Road Dust and Its Association With Environmental Factors

Kyoshiro Hiki¹ and Hiroshi Yamamoto², (1)National Institute for Environmental Studies (NIES), Japan, (2)National Institute for Environmental Studies, Japan

N-(1,3-Dimethylbutyl)-N'-phenyl-p-phenylenediamine-quinone, also referred to as 6PPD-quinone (6PPD-Q), is a by-product of a tire manufacturing additive and was recently identified as a toxic chemical causing acute lethality of coho salmon *Oncorhynchus kisutch* in urban watersheds. Despite its potential occurrence and ecotoxicity in receiving waters worldwide, available information on the occurrence and fate of 6PPD-Q is still limited. We collected dust samples deposited on road surfaces from May to October 2021, and quantified the concentrations of 6PPD and 6PPD-Q in the dust samples. Then we investigated the seasonal trends of the concentrations and association with road types and antecedent dry weather periods on 6PPD-Q concentrations. Our results showed that 6PPD-Q concentrations normalized by organic carbon content were the highest in May and decreased gradually, which may be due to higher atmospheric ozone concentrations in spring. Also, we found that the ratio of 6PPD-Q to 6PPD correlated with antecedent dry weather periods, which is consistent with the fact that the parent chemical, 6PPD, is more easily degraded compared with 6PPD-Q. These results can help to understand the environmental occurrence, fate, and behavior of 6PPD-Q.

4.16.V-03 Evaluation and Method Refinement of Pyrolyzer Technologies for Quantitative Py-Gc-MS of Tire Tread and TRWP in an Environmental Matrix

Julie Miller, Kathy Chan and Kenneth Unice, Cardno ChemRisk, United States

Microplastics (MP) are common and widespread particles in the environment that have been detected in a vast array of media, such as marine and drinking water, soil, sediment, food, air, marine mammals, and even humans. Recently, several working groups and regulatory agencies have proposed policies and frameworks for reduction and mitigation of MP pollution in the environment. MP can have a variety of particle morphologies, physico-chemical properties, sizes, colors, and shapes, making their identification and quantification an analytical challenge. Sources of MP include commercial products, textiles, plastics, fishing, and tire and road wear. The abrasion and wear of tires during use produce complex particles defined as tire and road wear particles (TRWP). Analytical methods capable of quantifying the amount of TRWP in the environment are critical to determining the

prevalence and environmental fate, however, the lack of comparisons between alternative mass-based methods represents a critical data need. In support of addressing this information gap, we evaluated three pyrolyzer technologies for pyrolysis-gas chromatography-mass spectrometry (Py-GC-MS), Curie point, microfurnace, and resistive, using three unique cryomilled tire tread (CMTT) samples in an artificial sediment matrix following ISO Technical Specification 21296:2017. The tire tread dimer markers used for quantification were 4-vinylcyclohexene (4-VCH), which is a marker for styrene-butadiene rubber (SBR) and butadiene rubber (BR), 4-phenylcyclohexene (4-PCH), which is a marker for SBR, and dipentene (DP), which is a marker for natural rubber (NR) or isoprene. Accuracy and precision for each pyrolyzer were compared for CMTT with and without artificial sediment matrix. Curie point and microfurnace performed well, producing acceptable precision (majority of samples with coefficient of variation < 20 %) and accuracy (majority of samples with CMTT recovery 50 – 200 %), suggesting these pyrolyzers are well-suited for quantitative Py-GC-MS of tire tread and TRWP in complex matrices. Our comparison data supported the subsequent exploration of potential method refinements, such as chromatography parameter modification, chemical pretreatment, and thermal desorption using microfurnace Py-GC-MS. Overall, these method refinements improved peak resolution and minimized interferences, supporting the utility and applicability of Py-GC-MS for quantification of TRWP and MP in complex environmental samples.

4.16.V-04 Unraveling the Toxicity of Tire-Wear Particle Contamination in Aquatic Organisms: From Chemical Mixture to Nanoparticle Toxicity

Eva Roubeau¹, Rachel Cheong¹, Laura Hernandez Rodriguez¹, Anca Baesu², Xiaoyu Gao¹, Paisley Thomson³, Diana C. Castaneda⁴, Stacey Robinson⁵, Stéphane Bayen¹, Subhasis Ghoshal¹, Valerie Langlois⁶ and Nathalie Tufenkji¹, (1)McGill University, Canada, (2)Government of Canada- Health Canada, Canada, (3)Institut National de la Recherche Scientifique (INRS), Quebec, Quebec, Canada, (4)Institut national de la recherche scientifique (INRS), Canada, (5)Environment and Climate Change Canada, Ottawa, Ontario, Canada, (6)Institut National de la Recherche Scientifique (INRS), Canada

From atmospheric urban pollution to urban runoffs, tire-wear particles are a concerning source of pollution and their ubiquity is raising global awareness. Indeed, the potential impacts of tire-wear particle pollution in aquatic ecosystems are of concern. Effects have been investigated in multiple species, from single-celled algae species to fish and amphibians, highlighting a potential harmful impact on several levels of the trophic chain. This raises questions regarding the effects on populations and ecosystems dynamics, and also regarding the mode of action of this complex mixture. Our work aimed to shed light on the toxicity of the different components of tire wear leachate, i.e. the chemicals vs nanoparticle fractions, on four freshwater model species of different trophic levels: *Chlorella vulgaris*, *Lemna minor*, *Daphnia magna*, and *Silurana tropicalis*. Through a series of filtrations, tire-wear particle leachate was divided into three different fractions: one fraction regrouping all components, i.e. dissolved organic chemicals and heavy metals, as well as particles below 0.2 µm, the second fraction containing only the dissolved species (i.e., heavy metals and organic chemicals), and a third fraction composed only of particles below 0.2 µm. The acute toxicity of each fraction was assessed in single-species assays using morphological endpoints, immobility and mortality, using modified standard OECD protocols. Our results showed that our separation method was effective in separating tire wear dissolved chemicals and particles, and that overall toxicity based on morphological endpoints and EC50s were different from one fraction to another, and among species. Some species showed high mortality at low concentrations, such as *D. magna*, whereas photosynthetic organisms required much higher concentrations to observe an effect on morphological endpoints and a decrease in growth. Overall, the whole fraction containing dissolved chemicals and particles was more toxic than the separated chemical and particulate fractions, suggesting a synergistic or additive effect between particles and chemicals. The overall sublethal effects observed during acute exposures are of concern in a context of potential chronic exposure, such as urban runoffs and atmospheric deposition, and raise questions regarding the potential impact of this pollution on trophic chains and population dynamics.

4.16 Tire wear and microrubber particles - from problems to solutions (Poster)

4.16.P-Mo230 Can We Trust Current Tire Wear Particle Emission Estimations?

David Mennekes¹ and Bernd Nowack², (1)Empa, St. Gallen, Switzerland, (2)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Tire wear particle (TWP) emissions gained recently more attention since they are considered to contribute a major share (estimates are up to 95%) to the overall microplastic emissions. Furthermore, TWP are suspected to be harmful to flora, fauna and humans. To estimate TWP emissions, recent studies calculated country-based emissions based on emission factors or material flow analysis. Here, we provide a closer look at the quality of 13 country based TWP emission studies (for Europe) published since 2000. We searched for all references and references of references which were used by these studies to derive TWP emissions by using internet search engines, libraries and e-mail contacts. We categorized all publications and arranged them in a network of publications showing who references whom and where the studies originally derived their data from. We found that the TWP emission studies base their TWP related information on a wide network of 66 publications. However, only in very few cases (15%) the studies directly referenced to a publication that actually measured TWP emissions. Mostly a study referenced to a review which either summarized different (review) studies or just referenced to another study. In total, we found only eight studies which experimentally measured TWP emissions but four of these studies originate from the 1970s, one analysed light vehicles and one only considered busses. This leaves us with only two about 20-years-old non-peer reviewed reports as basic source of release of TWP from tires during driving. Additionally, both of these studies are not referenced more than three times in the publication network. Considering how important TWP emissions are as a pollution in the environment, we were surprised how few studies with actual measurements we found and how many reviews are referenced overall. This clearly shows that the current TWP emission estimates are subject to high uncertainties which should be clearly communicated. We argue that new studies are

urgently needed, especially considering new developments in the car industry (e.g. heavier cars like SUV or e-mobility) or in the tire industry. We assume that policy makers would be highly interested in accurate TWP emission data to estimate potential risks with more confidence. Also, successfully implementing measures to reduce TWP emissions to the environment relies on such data.

4.16.P-Mo231 Effects of Tire Particles on the Reproduction of Earthworms (*Eisenia fetida*) and Bioaccumulation Potential of Tire-Related Chemicals

*Thibault Masset*¹, *Florian Breider*², *William Dufèoi*³, *Kristin Schirmer*³, *Alan J Bergmann*⁴, *Etienne Vermeirssen*⁴ and *Benoit J.D. Ferrari*⁵, (1)EPFL, Switzerland, (2)Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland, (3)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (4)Oekotoxzentrum Eawag-EPFL, Switzerland, (5)Swiss Centre for Applied Ecotoxicology, Switzerland

Tire and Road Wear Particles (TRWP) are produced during the wear of tire rubber on the road pavement and contain various chemicals originating from the road environment or from the rubber itself. Field measurements suggest that concentrations of TRWP could reach 0.1 - 100 g kg⁻¹ on the road side and the soil adjacent to the road. However, potential toxic effects of these particles on the soil organisms remain under investigated. Therefore, this study investigated the effects on survival, growth and reproductive output of environmentally relevant tire particle concentrations in soil on the earthworm species *Eisenia fetida*. The bioaccumulation potential of several commonly used tire-related chemicals was established and their bioaccumulation kinetics were determined. Cryogenically Milled Tire Tread (CMTT) particles were used as a surrogate for environmental TRWP. Four treatments were tested: Control soil (no CMTT), low contaminated soil (0.05% CMTT), high contaminated soil (5% CMTT) and a soil contaminated with CMTT leachate only (100 gCMTT/L). The tissue concentrations of 4 Polycyclic Aromatic Hydrocarbons and 5 other tire-related chemicals in the earthworms exposed to the treatment with CMTT leachate only, or to 0.05% CMTT, did not differ from the control. This was different for the worms exposed to 5% CMTT which exhibited much higher tissue chemical concentrations than the control. The Biota-Soil Accumulation Factor (BSAF) determined for the organisms exposed to the high contaminated soil were < 1, except for the apolar phenanthrene, fluoranthene and pyrene where the BSAF ranged from 1 to 2. This indicates that the tire-related chemicals exhibit a low bioaccumulation potential in *Eisenia Fetida*. A slight increase of the reproductive output with increasing CMTT concentration and a slight decrease of the weight of the juveniles exposed to CMTT was observed in the reproduction test. A possible explanation is that the higher energy cost for adult organisms to increase reproduction rate could lead to the lower individual weight of the juveniles observed. An alternative hypothesis is that the cocoons or juveniles were affected by the exposure to CMTT which prevented normal development or growth compared to the control treatment. More research is needed to confirm these results and reveal the underlying physiological mechanisms involved.

4.16.P-Mo232 Studies on Microrubber and Tire Accumulation Along Roadsides of Al Ain, Eastern Region of Abu Dhabi Emirates, UAE

*Rana Zeeshan Habib*¹, *Ruwaya Al Kendi*², *Furtuna Ghebremedhin*², *Mariam Elakashlan*², *Syed Haris Iftekhar*², *Vijo Poulouse*², *Abdel-Hamid Mourad*², *Tholkappian Ramachandran*², *Fathalla Hamed*² and *Thies Thiemann*², (1)Biology, United Arab Emirates University, Al Ain, United Arab Emirates, (2)United Arab Emirates University, United Arab Emirates

Materials made of rubber are a source of polymers released into the environment, where tire abrasions are a major contributor. In many hot, arid environs, whole tire losses are more common than in more moderate climates, and this can lead to the accumulation of additional tire material on the road sides, which over time can be the source of secondary microtires. Due to the lack of precipitation it is expected that modes of microtire relocation are more limited than in more moderate climates. This 2-year study examines the rubber/tire content from 23 sampling sites along roads within the city of Al Ain, Eastern Abu Dhabi Emirate, United Arab Emirates. The samples represent soils along roadsides and road dust, specifically from road curbs. Over 100 days, the fate of a number of sequestered rubber/tire particles was investigated, both in their natural locations on the road and along the roadside as well as embedded in soil under controlled outdoor laboratory conditions. Samples showed 2 – 148 microtires per g soil and 14-119 microtires per g road dust. It has been found that rubber/tire materials desiccate over time in the high temperatures found in the summer, become brittle and can break into much smaller pieces, resulting in micro-tire particles. Study of run-offs showed that tire particles are swept into storm drains during larger, very infrequently occurring rain events. However, the predominant mode of transport was found to be through air movement. Nevertheless, samples taken from an artificial lake and one Wadi (creek bed that seasonally carries water) within the confines of Al Ain, but off-road, have shown only few microtire particles so that the dispersion of microtires is not as pervasive as had been expected.

4.16.P-Mo233 Tyre Wear Particles and Small Microplastics (SMPs <100 Mm) From Highway Stormwater Runoff: Sampling, Pre-Treatment Procedures and First Results

*Beatrice Rosso*¹, *Elena Gregoris*², *Andrea Gambaro*¹ and *Fabiana Corami*², (1)Ca' Foscari University of Venice, Italy, (2)Institute of Polar Sciences, CNR-ISP, Italy

Highway stormwater runoff is a direct pathway for conveying microplastics (MPs) and other environmental pollutants from land-based sources to the aquatic and terrestrial environment. However, the concerns on stormwater for microplastic pollution and the other components of microlitter (additives and plasticizers) have grown exponentially and the knowledge on their pathways and impacts are now very limited. Important sources of microplastic in stormwater runoff are related to traffic vehicles, polymer-modified bitumen, road paint, atmospheric deposition and the wear of tyres. Hence, due to their small size, smaller MPs (SMPs, < 100 µm), additives and tyre wear particles (TWPs) can pose a risk for the environments as they can be ingested by different kinds of biota and can cause potential health problems for human beings. Only very limited studies have been paid attention to microplastics, especially SMPs, and TWPs from highway stormwater runoff with a consequent lack of knowledge regarding the

amounts, size, and composition of these pollutants emitted in the different environmental pathways. There are currently no standardized methods and harmonized techniques for the collection, pretreatments, contamination procedures, and analysis of SMPs and TWPs from stormwater runoff, making significant differences in the data of these pollutants studies difficult to compare. In this study, stormwater runoff samples were collected during different rainfall events from a trafficked highway near Venice, Italy. A pre-treatment procedure (e.g., oleo-extraction, purification, and filtration) was developed and optimized in a Clean Room (ISO 7) at Ca' Foscari University of Venice to prevent any possible plastic contamination. Quantification and simultaneous chemical identification were performed via MicroFTIR for SMPs, TWPs, additives, and plasticizers in stormwater runoff samples. Further, pyrolysis gas chromatography-mass spectrometry (Pyr-GC/MS) was developed to confirm the presence of specific SMPs and TWPs in the same samples analyzed. The cross-validation among MicroFTIR and Pyr-GC/MS techniques allows the standardization of pretreatment and analytical methods. Regarding TWPs, different tests were carried out and the first results of quantification and chemical identification of specific markers were obtained.

4.16.P-Mo234 Model Particles for Tire Wear Fate Studies

Steffen Weyrauch¹, Bettina Seiwert² and Thorsten Reemtsma³, (1)UFZ Leipzig, Leipzig, Germany, (2)Helmholtz Centre for Environmental Research – UFZ, Germany, (3)Helmholtz Centre for Environmental Research, Germany

An increasing number of studies investigate the organic constituents of tire and road wear particles (TRWPs), their transport into the environment and their potential effects on biota. Cryogenically milled tire tread (CMTT) is available as a relatively affordable and available testing material. However, the extent to which CMTT as test material compares with TRWPs has not been fully evaluated. This knowledge is important for a transfer of lab results with CMTT to the environment. Using a range of analytical techniques, this study compares the physical and chemical properties of CMTT with those of TRWPs that were generated using a tire test bench mimicking driving conditions to produce particles. Properties of this TRWP material are expected to be similar to those generated during normal driving. Physical and chemical properties of samples of CMTT and TRWP were investigated by a number of analysis techniques. Electron microscopy, particle size distribution, organic constituents (extractables) and the release of organics in water (leachables) are presented. This study shows marked differences of CMTT compared to TRWPs. CMTT particles have a different shape and a larger mean particle size compared to TRWPs. These differences in size and shape between CMTT and TRWPs may affect the release of organic constituents from the material. CMTT exhibited much higher contents of functional chemicals (factor 4 – 40), such as vulcanization accelerators and antioxidants. Reactive organics are transformed during the use of tires and the abrasion process due to heat and oxidation. The different reservoirs of organics in the specimen of CMTT and TRWPs led to higher concentrations in the leachate of CMTT. However, leaching appeared to be modulated by physical properties of the particles under study. Although CMTT is a more readily available test material, it may not always be a suitable surrogate for TRWPs. Its differences to TRWPs should be considered closely when interpreting lab results generated from CMTT.

4.16.P-Mo235 Flow Conditions and Retention of Road Related Microplastics in a Gully Pot: A Numerical Study

Elly Gaggini¹, Mia Bondelind², Yvonne Andersson-Sköld³ and Ekaterina Sokolova⁴, (1)Department of Architecture and Civil Engineering, Chalmers University of Technology, Gothenburg, Sweden, (2)Chalmers University of Technology, Sweden, (3)Swedish National Road and Transport Research Institute, Sweden, (4)Uppsala University, Sweden

Tyre and road wear particles (TRWP) are reported to be one of the largest sources of microplastics in the environment. TRWP are transported to surface waters and oceans by road runoff through stormwater systems. The presence of TRWP has been reported in sediment samples from gully pots. Gully pots are the first-line treatment step in the urban stormwater system, meaning that they can improve stormwater quality if TRWP can settle in the sand trap. However, there is also a risk that the gully pot can release TRWP during heavy rainfalls if larger flows can mobilize TRWP previously settled. Earlier studies on the efficiency of gully pots at retaining sand and other particles point to the synergetic importance of several factors: discharge flow rates, gully pot geometry, sand trap depth, amount of air bubbles entrained, and particle properties. These factors can be simultaneously evaluated using a modelling approach that can resolve details of the flow and take into consideration the geometry of the gully pot and the particle characteristics. In our study, computational fluid dynamics (CFD) was used to simulate the flow of water and air in a gully pot. A three-dimensional model of a gully pot, 0.35 m wide and with a sand trap depth of 0.39 m (full depth 1 m), was set up using commercial CFD software Star-CCM+ version 20.3. The volume of fluid method was used to describe the water and air phases. The main findings from the CFD model were validated against experimental data. The simulations indicated that air interaction largely affects the water flow, and that discharge volume causes different flow features in the gully pot. By gaining detailed knowledge of the hydraulics in the gully pot, specific flow features are visualized and the residence time of the water is determined in order to predict the effect on the settling of TRWP. Additionally, the CFD model will be coupled to Lagrangian particle tracking to simulate the behaviour and fate of individual particles in the gully pot. In this way, the retention of TRWP and the effects of size and density of TRWP on settling can be evaluated. This type of detailed simulations can be implemented in large scale models to describe transport processes affecting the fate of TRWP in the stormwater system. Modelling can hence be a useful tool to predict the occurrence of TRWP in stormwater systems and in the environment, to evaluate remediations techniques, and to support decision-making.

4.16.P-Mo236 Evaluation of Manufactured Treatment Devices in a Separated Stormsewer to Capture Low- and High-Density Tire Road Wear Particles

Kayli Paterson¹, Barbara Beckingham¹ and John Weinstein², (1)College of Charleston, United States, (2)The Citadel, Military College of South Carolina, United States

Tire road wear particles (TRWPs) emitted by vehicles due to the friction of tires on road surfaces are increasingly being recognized as a dominant fraction of microplastic/rubber in traffic-affected areas. TRWPs vary in density, size, shape, and

composition. Tire material has long been a subject of ecotoxicity assessment due to observations of toxic leachates. Due to potential toxicity, preventing environmental emissions of tire microrubber should be a priority. It is known that TRWPs are abundant in roadside soils and stormwater runoff and may accumulate in rain gardens and stormwater ponds, however, research is limited on fate of TRWPs in grey-stormwater infrastructure. Therefore, we investigated TRWP capture effectiveness of stormsewer inlet devices, also called manufactured treatment devices (MTDs). Sediment samples were taken under dry conditions from the chambers of 7 MTDs in Mount Pleasant, South Carolina USA. MTDs came in two varieties: a multi-chambered, flow-through baffle design and a single-chambered hydrodynamic vortex separator. Samples of road dust and sediment around the discharge site were also collected. Sediments were dried and sieved and analyzed for grain size, organic matter, and heavy metal content. Density separations were performed on the target sieve fraction (63-500 micron) using a NaCl solution (1.2 g/mL) and then a sodium polytungstate (1.9 g/mL) to distinguish high- and low-density fractions. TRWPs in these fractions were identified by morphology and resistance to heat, counted, and size measured using stereomicroscopy. A subset of suspected TRWPs were taken for pyrolysis-GCMS and scanning electron microscopy for quality assurance. In a preliminary analysis from 2 study sites, the concentration of low-density (< 1.2g/mL) and high density (1.2-1.9 g/mL) TRWPs across samples ranged 80-300 particles/g dry wt. and 150-400 particles/g dry wt., respectively. Although still under investigation, early results show that TRWP concentrations are ~2x higher in MTD sediments than in road dust. We will further evaluate if the size/shape and density of TRWP in the micro-size change across the stormwater pathway from road source through MTDs to environmental discharge points in tidal creeks. Analysis of the quantity and character of TRWPs as well as relationship to other sediment characteristics at our study sites will inform on the ability of advanced stormsewer infrastructure to mitigate roadway stormwater runoff sources of TRWP pollution.

4.16.P-Mo237 Ingestion of Crumb Rubber and Body Burden of Associated Contaminants in Marine Invertebrates and Fish

Fanny Hägg¹, Dorte Herzke², Vladimir Nikiforov³, Mari Creese⁴, Andy Booth⁵, Lisbet Sørensen⁴ and Claudia Halsband⁶, (1)UiT, Akvaplan-Niva, NILU, Norway, (2)Environmental Chemistry, NILU - Norwegian Institute for Air Research, Tromsø, Norway, (3)NILU - Norwegian Institute for Air Research, Norway, (4)SINTEF Ocean, Norway, (5)Climate and Environment, SINTEF Ocean, Trondheim, Norway, (6)Akvaplan-niva, Norway

Crumb rubber granulate (CRG) produced from end of life vehicle tires is widely used on artificial sports fields and to create urban artificial surfaces. It is known to contain a wide range of organic chemicals and metals, some of which are only just being identified and assessed. Weathering of such artificial surfaces releases both particles and the chemicals they contain into the environment, where they may be bioavailable and affect biota. *N*-(1,3-dimethylbutyl)-*N'*-phenyl-*p*-phenylenediamine (6PPD) has been identified as a chemical marker for CRG and tire wear particles. Both 6PPD and its transformation product, 6PPD-quinone, have been shown to be toxic to a number of different freshwater and marine organisms. The current study examines the ingestion of CRG (1 - 2.8; < - 1.2 mm) by a marine invertebrate and fish, the gut retention time of ingested CRG, and the body burden of tire-derived chemicals. Lumpfish (*Cyclopterus lumpus*) and Northern shrimp (*Pandalus borealis*) were exposed to CRG in laboratory experiments for 21 days; 7 days of exposure to CRG followed by 14 days of depuration. The stomach contents have been analyzed for ingested CRG and selected tissues (Lumpfish liver and blood; Northern shrimp hepatopancreas and muscle) have been characterized for tire-associated chemicals and metals. Analytical chemical techniques involved ICP-MS, pyrolysis GC-MS, GC-MS/MS and HRGC-HRMS (ThermoFisher, Orbitrap). CRG were found in 76% of exposed Lumpfish stomachs (n=90), where the number of CRG particles in the stomach increased during the exposure and peaked around day 8 followed by a decrease throughout the depuration. Ingested CRG was still found in some Lumpfish stomachs at the end of the experiment (day 21). Ingestion by Northern shrimp have been determined by pyrolysis-GC/MS. Analysis by HRGC/HRMS (ThermoFisher, Orbitrap) detected 6PPD (0.1 – 0.8 ng/μL) in 19% of Lumpfish blood samples analyzed (n=36), both at the end of the exposure and at the end of depuration. ICP-MS analysis of metals did not show increased concentrations of metals in any of the tissues for exposed individuals or over time for either Lumpfish or Northern shrimp. The current results suggest that ingested CRG can stay in the digestive system of Lumpfish longer than 14 days and that the particles may be leaching 6PPD during this period, suggesting bioavailability of CRG particles and associated chemicals to ecologically and commercially important marine organisms.

4.16.P-Mo238 Investigation on Toxic Effects of Diversely Polluted Road Effluents on Fish Embryos Using Danio rerio As a Model Species

Selina Seibold¹, Markus Thomas Schmitz², Regina Dolny³, Vanessa Spelthahn³, Simone Lechthaler³, Volker Linnemann³, Henner Hollert⁴ and Sabrina Schiwy⁵, (1)Goethe University Frankfurt, Germany, (2)Evolutionary Ecology and Environmental Toxicology (E3T), Goethe University Frankfurt am Main, Frankfurt am Main, Germany, (3)RWTH Aachen University, Germany, (4)Goethe University Frankfurt am Main, Germany, (5)Goethe University Frankfurt am Main, Frankfurt, Germany

While the number of vehicles registered worldwide is increasing, the fate of their remains continues to gain importance and presents a global environmental issue. Despite the large quantity of vehicle generated debris and the associated toxicological risk to the environment, the toxic effects of tire wear particles (microplastics), vehicle fluids, and other vehicle debris have been barely studied in environmental toxicology. The effects on the aquatic environment were addressed in the present study, which was created as part of the project 'Ecotoxicological assessment of tire abrasion in stormwater runoff of heavily trafficked roads – RoadTox' at the Department of Evolutionary Ecology and Environmental (E3T), Goethe University, Frankfurt am Main in cooperation with the Institute of environmental engineering (ISA), RWTH Aachen University. The road effluent samples have been taken from urban and extra-urban roads and federal highways in North Rhine-Westphalia (NRW), Germany. The overall toxicity of the samples on the aquatic environment was investigated, aiming for an ecotoxicological risk assessment. Road

effluents are chemically complex environmental samples composed of various vehicle debris rather than tire particle abrasion alone. Therefore, both filtered and unfiltered native road effluent samples were used instead of samples of individual substances or enriched extracts. This study used *Danio rerio* (zebrafish) as a well-established freshwater fish model species up to 120 hours post-fertilization. The fish embryo acute toxicity test (FET DIN EN ISO 15088) was performed for determining the acute (sub)lethal toxicity as well as the swimming behaviour, different *in vivo* biomarkers (e.g., acetylcholine esterase, EROD activity) and heartbeat tracking for cardiovascular abnormalities. These studies with *D. rerio* are part of the RoadTox project's comprehensive bioassay battery and consisted of several assays examining multiple sublethal endpoints (presented separately). The project is funded by the State Agency for Nature, Environment and Consumer Protection NRW (LANUV).

4.16.P-Mo239 Genotoxic and Estrogenic Effects of Cryo-Milled Tire Tread Particles Detected With High Performance Thin-Layer Chromatography (HPTLC) Based Bioassays

*Alan J Bergmann*¹, *Thibault Masser*², *Florian Breider*³, *William Dufey*⁴, *Kristin Schirmer*⁴, *Benoit J.D. Ferrar*⁵ and *Etienne Vermeirssen*¹, (1)Oekotoxzentrum Eawag-EPFL, Switzerland, (2)EPFL, Switzerland, (3)Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland, (4)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (5)Ecotox Centre CH, Switzerland

Vehicle tires abrade during use, generating particles that can be transported to aquatic environments. This work investigated (1) the worst case estrogenic and genotoxic potential of chemicals in tire particles, and (2) a more realistic exposure scenario of tire particle ingestion by fish. For (1), organic chemicals were comprehensively extracted from cryogenically milled tire tread (CMTT) with Soxhlet extraction. In (2), we approximated a fish digestion scenario with successive incubation of CMTT particles in simulated gastric and intestinal fluids. In these samples, we first identified and quantified eleven organic chemicals suspected of being associated with tire wear particles with LC-MS/MS. We evaluated estrogenicity and genotoxicity of the individual chemicals and CMTT samples with a yeast estrogen screen (YES) and umuC Chromotest (umuC) without metabolic activation, respectively, directly on HPTLC plates after chromatographic separation. Two individual chemicals were active in HPTLC-YES: N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD) and 2,2'-dithiobisbenzothiazole. Three chemicals were active in HPTLC-umuC: N-cyclohexyl-2-benzothiazolesulfenamide, cyclohexylamine, and 1,3-diphenylguanidine (DPG). Through chromatography, multiple estrogenic and genotoxic signals were detected in (1), total CMTT extracts, with up to 1 mg CMTT applied to HPTLC plates. Among the eleven chemicals measured in CMTT, DPG is one that was likely responsible for umuC genotoxicity of CMTT extracts. It was measured in CMTT at levels above the biological detection limit of umuC (2.5 µg in CMTT extract vs 0.65 µg lowest effect level, after applying to HPTLC plates), and the individual compound shared the chromatographic position of genotoxicity observed in CMTT extracts. In (2), simulated digestates of CMTT did not induce a response in either HPTLC-YES or HPTLC-umuC assay. Accordingly, DPG was also measured in CMTT digestates, although below the lowest effect level of DPG alone (0.27 µg in CMTT digestate vs. 0.65 µg lowest effect level). In summary, genotoxic and estrogenic hazards were (1) detected in comprehensively extracted tire particles, but were (2) below biological detection in simulated digestates, suggesting low concern in such a scenario. Future efforts will work to identify the remaining unknown toxicants to allow risk evaluation of these hazards and determine effects of environmentally representative tire and road wear particles.

4.16.P-Mo240 Plant Uptake of Tire Derived Chemicals

*Anya Sherman*¹, *Stephanie Castan*², *Thorsten Huffer*³ and *Thilo Hofmann*¹, (1)University of Vienna, Austria, (2)EDGE-Environmental Geoscience, University of Vienna, Vienna, Austria, (3)University of Vienna, Vienna, Austria

Tire wear particles, which have gained attention in recent years due to the toxicity of additives that leach from them, are ubiquitously present in urban stormwater. Many cities combine stormwater with municipal wastewater and treat it in conventional wastewater treatment plants, where, like thermo-microplastics, tire wear particles are expected to settle to sludge. Wastewater sludge, containing tire wear particles, is then often applied to agricultural fields as fertilizer. We expect that tire wear particles leach most of their additives once on the field, due to their relatively short residence times in WWTPs, and their comparatively slow additive release rates. This could pose a serious health risk to humans if edible plants take up and accumulate these additives from soil, a phenomenon which is well established for other classes of organic micropollutants. Therefore, in this study we evaluate lettuce uptake of 5 commonly detected tire additives: diphenylguanidine (DPG), hexa(methoxymethyl)melamine (HMMM), benzothiazole, N(1,3-dimethyl-butyl)-N'-phenyl-p-phenylenediamine (6PPD), and 6PPD-quinone. Under hydroponic conditions, we expose lettuce in one scenario directly to additives, and in another scenario, to tire particles themselves. We monitor the resulting concentrations of additives in lettuce roots and leaves, as well as in hydroponic nutrient solution, using a modified QuEChERS extraction method followed by measurement via liquid chromatography coupled with triple quadrupole mass spectrometry (LC-MS). After exposure, we remove lettuce plants to clean nutrient solution, and monitor degradation of the compounds in the plants over time. We also measure sorption of additives to root material, since high affinity to root material can impede translocation to leaves, which limits the amount of compounds reaching the edible part of the plant. Preliminary results indicate that all 5 additives are taken up by lettuce roots and are translocated to leaves. On the other hand, initial experiments indicate that stability in leaves is compound dependent. When looking at uptake results from a mass balance perspective, we find that less than 0.01% of compounds added to nutrient solution are taken up by plants, leading us to assume that except under very high concentrations, tire wear particles in agricultural sludge do not pose a serious health risk to humans.

4.16.P-Mo241 Reducing the Environmental Impact of Tire Wear Using a Supply Chain Approach

*Sya Hoekse*¹, *Ad Rags*², *Harold Krikke*³, *Jikke van Wijnen*³ and *Ansje Löhre*⁴, (1)Open University, Heerlen, Netherlands, (2)Environmental Science, Radboud University, Nijmegen, Netherlands, (3)Open Universiteit Nederland, Netherlands, (4)Open

University, Netherlands

Globally, tire wear is responsible for approximately 50% of the total amount of microplastics released to the environment. It is therefore not surprising that this topic has received an increasing amount of interest, both inside and outside the scientific world. In order to effectively reduce the environmental impact of microplastic particles, it is essential to understand the root causes and the pathways of microplastic particles in the environment. This study presents an approach that can support the identification and prioritization of mitigation measures for reducing microplastic pollution caused by tires. The approach links the quantification and spatial modelling of microplastic emissions to particular human activities using a supply chain approach. As a starting point, the tire supply chain, including resource extraction, production, use and end-of-life, is mapped to provide insight in the main leakage points and to provide a framework for close collaboration with stakeholders. Information for the supply chain mapping is derived from literature and stakeholders. As a mapping method SCOR is used, which is a process reference model for supply chain management. SCOR includes the mapping of processes, activities and performance, but puts limited emphasis on environmental impact. Subsequently, the main leakage points are described in terms of their contribution to microplastic emissions and environmental impacts. The emissions are quantified using an LCA-based approach, which results in an aligned functional unit to describe the quantified microplastic emissions from tire wear for the different supply chain links. The ultimate aim is to apply this approach in a specific geographical area and to explore the impact of different alternative interventions aimed at minimizing tire wear emissions.

4.17 Toxicokinetics and toxicodynamics in chemical risk assessment: data collection and model development

4.17.T-01 Accumulation-Depuration Data Collection in Support of Toxicokinetic Modelling

Aude Ratier¹ and Sandrine Charles², (1)UMR CNRS 5558 Laboratoire de Biométrie et Biologie Évolutive (LBBE), France, (2)University Lyon 1, France

Environmental Risk Assessment (ERA) for chemical substances often requires a bioaccumulation test which consists in both an accumulation and a depuration phases. The internal concentration over time within organisms is regularly measured during both phases. Output data are then analysed by a toxicokinetic (TK) model with uptake and elimination parameters to be estimated and used to provide bioaccumulation metrics as dimensionless ratios (e.g. BCF/BSAF/BMF). TK models are chosen according to input data; accounting for several exposure routes and different elimination processes, including metabolism. Regulatory speaking, bioaccumulation metrics are compared to decision thresholds to classify chemical substances as non-, low-, mid- or very bioaccumulative. MOSAIC_{bioacc} is a web application freely available from <https://mosaic.univ-lyon1.fr/bioacc>. It allows easy calculations of bioaccumulation metrics in an automated way. This avoids stakeholders investing in underlying technicalities, while benefiting from the most advanced modelling and inference methods, recently developed to improve effectiveness and robustness of bioaccumulation outcomes in full respect of regulatory needs. In particular, MOSAIC_{bioacc} systematically provides uncertainties on outcomes. It can deal with for any kind of species-compound combinations. Based on daily usage statistics, we know that MOSAIC_{bioacc} users are either from academia, industry or regulatory bodies, and from a lot of countries worldwide. The huge lack of raw TK data, together with an increasingly private collection of data sets got from the scientific literature, led us to the conclusion that a new publicly available accumulation-depuration (TK) database became essential, in full respect of the Findable, Accessible, Interoperable and Reproducible (FAIR) data principles. To date, our TK database gathers together more than 210 data sets, for more than 50 genus and more than 120 chemical substances. In this talk we will present a full meta-analysis of these data sets that are all available in a standardised format directly usable in MOSAIC_{bioacc}. Hence, we used the same modelling approach in calculating bioaccumulation metrics, a necessary condition to compare potential of chemically similar substances to bioaccumulate in a given species, for example. Our purpose will also be to illustrate the really added value of sharing data in the era we recently entered with Open Science.

4.17.T-02 A Generalised Physiologically Based Kinetic Model for Fish for Environmental Risk Assessment of Pharmaceuticals

Prof. Jan A.J. Hendriks¹, Jiaqi Wang, MSc², Tom Nolte³, Stewart Owen⁴, Rémy Beaudouin⁵ and Ad Ragas⁶, (1)Radboud University Nijmegen, Nijmegen, Netherlands, (2)Environmental Science, Radboud University Nijmegen, Nijmegen, Netherlands, (3)Radboud University Nijmegen, Netherlands, (4)AstraZeneca, United Kingdom, (5)INERIS, France, (6)Environmental Science, Radboud University, Nijmegen, Netherlands

With increasing medical and veterinary use, pharmaceuticals have been detected as emerging pollutants in global water bodies. Many of these pharmaceuticals reside in aquatic organisms such as fish, potentially imposing adverse effects on organism survival or fitness. Physiologically based kinetic (PBK) models have become essential risk assessment tools since they allow a mechanistic framework to understand toxicological effects in organisms. Fish is often selected as a model organism. However, fish PBK models often focus on specific species, which is impractical in a risk assessment context given the countless species. Moreover, many pharmaceuticals are ionisable and fish PBK models accounting for ionisation are rare. Therefore, the present study aimed to develop a generalised PBK model applicable to various fish and ionisable chemicals and to assess its performance. Fish organ weights, cardiac output and oxygen consumption were estimated through allometric scaling, and the Boltzmann-Arrhenius equation was applied to adjust for temperature differences. Exchange and partition coefficients were estimated through existing quantitative structure-activity relationship (QSAR) models, taking pH influence into account. Model performance was subsequently evaluated for five pharmaceuticals covering neutral and ionic structures. Consequently, only the fish body mass, the chemical properties and the exposure scenario were required as input. Two sets of results were computed. With biotransformation half-lives (HL) from EPI Suite, 73% and 41% of the estimations were within a ten-fold and a three-fold difference from measurements, respectively. With experimental biotransformation HLs, the performance improved to 87% and 59%, respectively.

For ionisable substances, only 24% of estimations were outside a ten-fold, more accurate than any of the existing species-specific PBK models. The present study is the first to develop a generalised fish PBK model that focuses on mechanism-based parameterisation and explicitly accounts for ionisation. The generalised model would facilitate its application across chemicals and species, improving efficiency and feasibility in a risk assessment context and supporting an animal-free toxicity testing paradigm. Given the evidence of accuracy and a lack of generalised PBK models to date, we regard our work as an essential step forward in chemical risk assessment.

4.17.T-03 Evaluating Predictive Toxicokinetic Models in *Daphnia magna* to Support Environmental Safety Decisions

Jacob-Joe Collins¹, Bruno Campos², Claudia Rivetti³, Thomas Moxon⁴ and Mark Viant⁵, (1)School of Biosciences, University of Birmingham, Birmingham, United Kingdom, (2)Unilever, United Kingdom, (3)Unilever, Sharnbrook, United Kingdom, (4)Unilever, UK, (5)University of Birmingham, United Kingdom

The large number of chemicals in use today represents a major challenge for regulators worldwide in determining environmental safety thresholds for chemicals whilst minimising the generation of new toxicity data. One proposed strategy for advancing the pace of chemical risk assessment is leveraging the use of *in vitro* data by creating robust quantitative models that predict the exposure levels of chemicals in environmentally relevant species. Toxicokinetic modelling is a new approach methodology (NAM) that provides reliable predictive capabilities which could lead to reduced animal use and increase efficiency, in terms of time and cost. While toxicokinetic models have been developed in some environmentally relevant species such as fish, these are still limited in invertebrates. Current available toxicokinetic models for *Daphnia magna* are chemical specific, derived by fitting individual chemical data, with limited application to other chemicals. This study aims to evaluate a range of one-compartment toxicokinetic models to predict the uptake and elimination of a suite of chemicals in *D. magna* by evaluating the models in terms of their accuracies of maximum internal concentration - C_{max} and the chemical uptake and elimination dynamics. Additionally, we plan on using *in silico* predictions of log K_{ow} and log D_{ow} to see whether these toxicokinetic models retain their performance when using predicted values to replace experimental values. To do so, a code infrastructure that encompasses multiple predictive uptake and partitioning models was developed in Python. All model combinations were found to predict C_{max} consistently when comparing predicted and experimental C_{max}, with the best and worst model combinations resulting in 90.4% and 67.3% of the predicted C_{max} values lying within 10-fold of the experimental C_{max}, respectively. However, preliminary results on the use of these models to simulate the uptake and elimination dynamics show significant deviation between predictions and experimental data, suggesting further work on model adjustment is needed. Additionally, our work has shown the potential to use predicted values to replace experimental log K_{ow} values without significant impacts on model performance, which furthers its applicability. This work could significantly improve regulatory and safety decision applications specifically in chemical risk assessment by providing robust predictions for C_{max} thus allowing for the use of *in vitro* data.

4.17.T-04 An Amended In Vitro-In Vivo Extrapolation Model to Consider First Pass Clearance Effects on Chemical Accumulation in Fish

Leslie J Saunders¹, John Nichols², Jon Arnot³, James M Armitage⁴ and Frank Wania⁵, (1)University of Ottawa, Canada, (2)U.S. Environmental Protection Agency, United States, (3)ARC Arnot Research & Consulting Inc., Canada, (4)AES Armitage Environmental Sciences, Inc, Canada, (5)University of Toronto Scarborough, Toronto, ON, Canada

In vitro-in vivo extrapolation (IVIVE) approaches have proven useful for evaluating the impact of biotransformation on chemical bioaccumulation in fish. Most IVIVE efforts to date have focused on predicting chemical bioconcentration in fish (aqueous only exposure), with less attention paid to the effect of biotransformation on chemical accumulation via the diet. Following dietary exposure, biotransformation of a chemical in the gastrointestinal tract (GIT) lumen, GIT epithelia, and liver can greatly reduce its accumulation. However current IVIVE models do not consider first pass clearance effects on dietary uptake and generally only predict biotransformation impacts on whole body elimination. Failure to model these processes correctly could result in underestimation of the true impact of biotransformation on chemical accumulation. Here we present an amended IVIVE (a-IVIVE) model that accounts for the effect of first pass clearance on chemical bioaccumulation in fish. The a-IVIVE model was parameterized using hypothetical data from typical *in vitro* biotransformation assays. We then simulated how biotransformation in the liver and GIT epithelia (alone or combined) may impact chemical accumulation occurring following dietary exposures. First pass clearance can greatly reduce the dietary uptake of contaminants; however, these effects are only apparent at rapid rates of biotransformation (i.e., for intermediate to high extraction efficiency chemicals). These first pass clearance effects were more pronounced when biotransformation in the GIT epithelia was considered, due to the combined impact of biotransformation in both tissues. Empirical *in vitro* biotransformation data and *in vivo* dietary uptake data for two PAHs (pyrene and benzo[a]pyrene) and two sunscreen agents (EHMC and octocrylene) were used to evaluate the relative contribution of the liver and GIT in mitigating dietary uptake and accumulation. For most chemicals, biotransformation in the liver and GIT epithelia could not explain reduced dietary uptake efficiencies reported *in vivo*. One possible explanation for this discrepancy is degradation occurring in the GIT lumen. These findings are consistent with previous work which suggest that luminal biotransformation can greatly reduce the dietary uptake of some organic contaminants. Focused studies investigating luminal biotransformation in fish should be conducted to corroborate these modelled results.

4.17.T-05 Organotropism, Bioaccumulation and Fate of Cadmium (Cd) and Zinc (Zn) in *Gammarus fossarum*, After Exposure to Environmentally Relevant Concentrations

Ophelia Gestin¹, Christelle Lopes², Nicolas Delorme³, Laura Garnero³, Olivier Geffard³ and Thomas Lacoue-Labarthe⁴, (1)CNRS umr 5558, France, (2)Lyon University, UMR CNRS 5558, Villeurbanne, France, (3)INRAE Lyon, France, (4)LIENSs CNRS & Université de la Rochelle UMR 7266, France

To improve the toxicity assessment on aquatic organisms, studying their organotropism through a dynamic approach can help to identify the tissues/organs playing a key role in metal regulation (e.g. storage or excretion) and therefore those of interest in ecotoxicology and biomonitoring. This study aims to compare for the gammarid *G. fossarum*: i) the organotropism between a non-essential, Cd, and an essential metal, Zn, at environmentally relevant concentrations; ii) the relative contribution of each organ in the total body burden; and iii) the contrasting internal regulation of both metals. Gammarids were exposed for 7 days (uptake phase) in ^{109}Cd and ^{65}Zn radiolabelled water at $52 \text{ ng}\cdot\text{L}^{-1}$ and $416 \text{ ng}\cdot\text{L}^{-1}$, respectively, and then placed in clean water during 21 days (depuration phase). At several sampling times, the target organs (i.e. caeca, cephalon, intestine, gills, and remaining tissues) were recovered and the Cd and Zn contents quantified by gamma-spectrometry. A one-compartment TK model was fitted, by Bayesian inference, on each organ/metal data set, leading to an estimation of TK parameters. The results show: i) a contrasting distribution pattern of concentrations at the end of the accumulation phase (7th day): gills > caeca > intestines > cephalons > remaining tissues for ^{109}Cd and intestines > caeca > gills > cephalons > remaining tissues for ^{65}Zn ; ii) Cd is slowly lost by all organs, especially by the gills where no loss was measured after a 21-day depuration phase; whereas Zn decreases sharply in all organs after 24 hours in the depuration phase; iii) the uptake and elimination rates were significantly lower for Cd than for Zn, except for the accumulation rate of gills; and iv) surprisingly, under conditions of dissolved contamination, the intestine plays a central role in the accumulation and removal of Cd and Zn, and to a greater extent than for the gills in the case of Zn. One of the major outputs of this work is the preponderant role of intestines in the uptake of metals under conditions of dissolved contamination, whereas the literature tends to show that the gills are the main pathway in freshwater crustaceans.

4.17 Toxicokinetics and toxicodynamics in chemical risk assessment: data collection and model development (Poster)

4.17.P-Tu278 Pharmacometrics Versus Toxicometrics: (Dys)Similarities?

Antonin PRAET¹, Ophelia Gestin², Christelle Lopes³ and Sandrine Charles¹, (1)University Lyon 1, France, (2)CNRS umr 5558, France, (3)Lyon University, UMR CNRS 5558, Villeurbanne, France

Whether one develops work in the field of pharmacology or in the field of toxicology, one can identify many points of both convergence and discrepancies. This is what this presentation proposes to highlight by identifying in these two major research areas what can be considered as similar or not in terms of questioning, hypotheses, mechanisms, experimental considerations, as well as modelling approaches. We will especially focus on quantitative approaches in both fields leading to either pharmacometrics or toxicometrics, that is methods in support of decision making either by health care personnel in the field of pharmacology, or by regulatory agencies in risk assessment in the field of environmental toxicology. Our comparison of quantitative approaches in pharmacology and toxicology will be based on two concrete examples. The first one comes from pharmacology and more specifically from the use of pharmacometrics on anti-infective agents employed in treatment of cystic fibrosis to better determine the right dose of antibiotics to use accounting for the between-individual variability. The second one comes from ecotoxicology where toxicometrics are used to assess environmental risks on freshwater invertebrates when they are exposed to heavy metals accounting for internal contamination routes. For both examples, kinetics modelling frameworks as recently developed will be presented and compared in their (dys)similarities.

4.17.P-Tu279 Models Used to Predict Chemical Bioaccumulation in Fish From In Vitro Biotransformation Rates Require Accurate Estimates of Blood-Water Partitioning, and by Extension Chemical Volume of Distribution

Leslie J Saunders¹ and John Nichols², (1)University of Ottawa, Canada, (2)U.S. Environmental Protection Agency, United States

In vitro-in vivo extrapolation (IVIVE) approaches have proven useful for evaluating the impact of biotransformation on chemical bioaccumulation in fish. For the extrapolation of biotransformation data, the sorptive capacity of the *in vitro* test system (e.g., liver S9), blood plasma, and the whole organism need to be considered. Liver S9-water (P_{S9W}) and blood-water (P_{BW}) partition coefficients are used to estimate a hepatic clearance binding term (f_U) that accounts for differences in bioavailability in either system. Several authors have reported that modelled bioconcentration factors (BCF) are sensitive to the selected f_U value, which may contribute to discrepancies in IVIVE modelling efforts. However, more recent research indicates that f_U remains relatively constant for substances with a $\log K_{OW} > 4$. Empirically derived or composition-based equations for prediction of P_{S9W} and P_{BW} produce f_U values within a factor of 1.5 to 2-fold, which suggests that the refinement of other model parameters may help to explain model discrepancies. The P_{BW} is also required to calculate an apparent volume of distribution (V_D), which adjusts for differences in sorptive capacity between the fish and blood. Although P_{BW} is used to estimate both f_U and V_D , the sensitivity of IVIVE model outputs to changes in V_D has not been investigated. In this study, we evaluated commonly used equations (empirically derived and composition-based) for prediction of P_{BW} and how differences in P_{BW} influence estimates of V_D . The V_D estimated using a composition-based approach remained relatively constant at $\log K_{OW} > 4$ whereas an empirical approach yielded estimates that progressively increase with $\log K_{OW}$. V_D values generated using these two approaches deviated by approximately 2- to 50-fold at $\log K_{OW}$ between 5 and 10. These differences in V_D directly translated to differences in extrapolated whole-body biotransformation rate constants and modelled BCFs, suggesting that errors in specification of V_D , rather than f_U , may contribute to IVIVE model deviations. This work highlights the uncertainty in V_D and the need for studies to investigate this IVIVE model parameter. Potential methods for experimental determination of V_D for hydrophobic chemicals are discussed.

4.17.P-Tu280 A Generic Toxicokinetic Model for Mammals: Case Study Applications for Rodents

James M Armitage¹, Alessandro Sangion², Liisa Toose, M.Sc.³ and Jon Arnot³, (1)AES Armitage Environmental Sciences, Inc, Canada, (2)ARC Arnot Research and Consulting Inc. and University of Toronto Scarborough, Canada, (3)ARC Arnot Research & Consulting Inc., Canada

Chemical regulations seek to protect the environment and human health. There is a recognized need to implement New Approach

Methods (NAMs) in chemical assessments and to reduce animal (vertebrate) testing. Understanding toxicokinetics (TK) in biological systems is critical for interpreting experimental testing data and for developing models to address data gaps. In this study we describe a one-compartment physiologically-based toxicokinetic (PBTK) model that can be readily parameterized to various mammalian species requiring only a few key biological parameters, e.g., body size, lipid content. There is also a minimal number of chemical input parameters required to simulate the TK of neutral and ionizable organic chemicals (IOCs), e.g., partition ratios, biotransformation rates and pKa for IOCs. The biotransformation rates can be obtained from *in vitro* bioassays or *in silico* methods (e.g., QSARs). The model includes a novel *In Vitro* – *In Vivo* Extrapolation (IVIVE) model for incorporating *in vitro* biotransformation rate data. The model performance is evaluated in a case study with independent *in vivo* data representing a diverse range of chemical partitioning and reaction properties.

4.17.P-Tu281 Investigating Machine Learning Approaches to Predict Toxicokinetics and Toxicodynamics in Aquatic Organisms

Jasmin Uhlhorn¹, Luigi Margiotta-Casaluci², Samuel K Maynard³ and Thomas Miller⁴, (1)Brunel University, United Kingdom, (2)Kings College London, United Kingdom, (3)AstraZeneca, United Kingdom, (4)Brunel University London, United Kingdom

Chemical contaminants are continually released into the aquatic environment which subsequently leads to the exposure of organisms. This exposure of these organisms can lead to toxicity through uptake processes that are related to the kinetics of the chemical compounds. Depending on different physiological and chemical factors, e.g. species, life stage, chemical and exposure concentration, organisms can be adversely affected through TKTD processes at different levels of severity, ranging from more subtle effects like behavioural changes to mortality. In the case of pharmaceuticals, this is specifically concerning as they are designed to affect specific molecular pathways and, thus, have a high probability of unintentionally affecting wildlife. To understand potential effects, uptake, biotransformation, and elimination of chemical compounds are critical to investigate. Currently, analytical testing methods to establish the safety profiles of compounds involves the use of live animals resulting in a high cost and animal usage. Furthermore, frameworks, like the 3Rs (Replacement, Reduction and Refinement), aim to reduce animal testing in research. Thus, alternative and supporting methodologies are needed. *In silico* methods based on artificial intelligence offer one possible approach to assess chemical risk. Hence, in this work we used liquid chromatography-tandem mass spectrometry to generate toxicokinetic data from aquatic organisms (e.g. fish and invertebrates) exposed to multiple classes of chemicals including pharmaceuticals and pesticides. The data was modelled via the development and validation of machine learning algorithms such as tree-based learners and artificial neural networks to predict uptake and elimination kinetics. Models developed were also applied to previously published effect-based data to enable prediction of toxicodynamic effects. Algorithms were compared for their predictive ability to generalise to new datasets. Validated models were further investigated to understand relevant parameters that influence TKTD processes. The approach offers a novel solution to assess chemical risk and increase our understanding of TKTD mechanisms for chemicals that are present in the aquatic environment.

4.17.P-Tu282 Mechanistic Insights on Structurally Similar cVMS Using Physicochemical Properties, Bioavailability, Metabolism and Toxicity Profiles

Kathleen Plotzke¹, Kent Woodburn², Jaeshin Kim², Ellen Mihaich³, Shihe Xu¹, Gary Kozerski¹, Sami Belkhiria⁴ and Debra McNett², (1)Dow Chemical Company, United States, (2)The Dow Chemical Company, United States, (3)ER2 and Duke University, United States, (4)Dow Silicones Belgium srl, Belgium

Regulatory and authoritative evaluations have grouped octamethylcyclotetrasiloxane (D4), decamethylcyclopentasiloxane (D5) and dodecamethylcyclohexasiloxane (D6), which are cyclic, volatile methyl siloxane (cVMS) substances with four, five and six dimethyl siloxane groups respectively, into one category (cyclosiloxanes) due to structural similarity with comparable physicochemical properties. For example, in 2018 the European Commission published a restriction on the use of D4 and D5 in wash-off personal care products (PCPs) in the European Union. The addition of D6 and extension to leave-on PCPs and “other consumer/professional products” for all three substances is also currently under evaluation by the European Commission. The Annex XV dossier justifies this grouping based on these substances’ “similar” chemical structures and hazard profiles (all are identified as vPvB substances, whilst D4 is also identified as a PBT substance). However, closer examination of these three substances demonstrates key differences in their behaviour from an environmental fate perspective and toxicity profiles that should be considered in regulatory assessments. A substance-by-substance approach demonstrates that although these three cVMS substances appear to have similar structures and physicochemical properties, key differences in physicochemical properties lead to differences in bioavailability, metabolism, toxicokinetic profiles and ultimately different toxicity profiles that question this grouping. This presentation provides a review of the chemical structures, physicochemical properties, bioavailability, metabolism, toxicokinetic and toxicity profiles that suggest that understanding potential for exposure and the modes/mechanisms of biological interactions are equally important for assessing the ability for read-across for this class of compounds.

4.17.P-Tu283 Investigation of the pH -Effect on the Toxicity, Uptake & Biotransformation of Metoprolol in Zebrafish (Danio rerio) Embryos, Utilizing LC - ESI - QTOFMS

Eleni Panagopoulou¹, Vasiliki Tzepkinli¹, Dimitrios E. Damalas¹, Reza Aalizadeh¹, Mona Schweizer², Heinz Köhler³, Peter Von der Ohe⁴, Rita Triebkorn² and Nikolaos Thomaidis¹, (1)National and Kapodistrian University of Athens, Greece, (2)University of Tuebingen, Germany, (3)University of Tubingen, Germany, (4)Federal Environment Agency (Umweltbundesamt), Germany

The release of emerging contaminants (such as pharmaceuticals) into the aquatic ecosystems has become an issue of concern among scientists. Most of them are frequently detected in the aquatic environment and may bioaccumulate in aquatic organisms causing adverse effects. Metoprolol (MET) is a cardioselective β -blocker, and it has been frequently reported in aquatic

environments between ng L^{-1} and ?g L^{-1} . Furthermore, MET is an ionizable organic compound (IOC). IOCs are substances whose chemical speciation (ionic or neutral form) is defined by the surrounding pH value. The uptake of the IOCs, and as a result their toxicity, is strongly affected by their speciation. However, the influence of the different pH values on the toxicity of IOCs has not been extensively evaluated in risk assessment studies. Zebrafish (*Danio rerio*) (ZFE) has emerged as a powerful alternative model organism, which is widely used in ecotoxicological research studies for evaluating the potential effects of xenobiotics on aquatic organisms. The aim of this study was to assess the influence of the different pH values of the test medium on the uptake, potential bioaccumulation, biotransformation, as well as the toxicity of the β -blocker MET in ZFE. Another goal was to determine the potential biotransformation products (bio-TPs) of MET and to assess whether the bio-TPs could contribute to the toxicity of the parent compound. For this purpose, the fish embryo toxicity test (FET) with ZFE was conducted at different pH values. The LC₅₀ values of MET at 3 different pH values were determined (6, 8, and 9) and were used for the exposure experiments of MET. For the extraction of MET in ZFE samples, organic solvents were added, and a bead-beating homogenization process was followed. Exposure water samples and ZFE extracts were analyzed by RPLC and HILIC in both positive and negative electrospray ionization mode, using LC-ESI-QTOF-MS. A target screening approach was followed for the identification of the parent compound MET whereas the detection and identification of tentative bio-TPs were performed through in-house developed suspect and non-target screening workflows. The internal concentrations (C_{int}) of MET in ZFE extracts were determined. The bioaccumulation of MET was evaluated and the bioconcentration factors (BCF) of MET were calculated. Also, the biotransformation of MET in ZFE was studied and many bio-TPs were detected. Finally, a potential biotransformation pathway was proposed.

4.17.P-Tu284 Physiologically Based Pharmacokinetic Model (PBPK) for Three Flame Retardants -TDCIPP, TCIPP, Tcep- in Animals and Extrapolation to Humans for Risk Assessment

Deepika Deepika¹, Vikas Kumar¹, Jose Domingo¹ and Marta Schuhmacher², (1)Universitat Rovira i Virgili, Spain, (2)Rovira i Virgili University, Spain

Flame retardants (FRs) are widely distributed in environmental samples (i.e., air, water and soil), animals and food. Dietary intake, as well as inhalation and dermal absorption are the major routes of exposure for humans. There are increasing concerns about health effects of these FRs by affecting the endocrine, immune, reproductive, and nervous systems. Among FRs, Tris(1,3-dichloro-2-propyl) phosphate (TDCIPP), Tris (1-chloro-2-propyl) phosphate (TCIPP) and tris (2-chloroethyl) phosphate (TCEP) are 3 widely used chlorinated organophosphate, which are frequently detected in humans. Because of their physicochemical properties, they are considered to have potential neurotoxicity in humans. In order to interpret the biomonitoring data in the context of chemical risk assessment, it is necessary to have a mechanistic framework that explains the distribution of FRs in the human body. Physiologically based pharmacokinetic models (PBPK) are widely used for toxicokinetic and dosimetry assessment. In the present study, PBPK models for three FRs (TDCIPP, TCIPP and TCEP) were developed in animals (adult male rat/mice) and further extrapolated to humans through allometric scaling. A 6-compartment PBPK was developed incorporating detail metabolic kinetic. Further optimization of several parameters was done for the toxicokinetic using Bayesian framework (Markov Chain Monte Carlo). Developed models were validated using experimental data with acute oral exposure and measured concentration in both feces and urine as major elimination routes. Finally, validated animal models were extrapolated to humans and were simulated for different exposure scenarios. The 3 FRs showed a similar metabolic profile (faster metabolism), and a short half-life. Most metabolites were present in plasma and brain of the mice for longer times, as predicted by the model. Even with single oral dosing, chemical stayed in the brain for a longer time, which may be one of the reasons behind observed neurotoxicity in human beings. In urine and feces, only the major metabolites BDCIPP, BCIPP and BCEP (only in urine) were detected. In further studies, we will use this model to predict the intake and exposure of these 3 FRs in humans using biomonitoring data based on urine data with reverse dosimetry technique. The current study may provide a translations tool for estimating the human health impact of FRs.

4.17.P-Tu285 Assimilation Efficiency of Cadmium (Cd) and Influence of the Exposure Pathways on Its Distribution, Toxicokinetic and Fate in the Organs of Gammarus fossarum

Ophelia Gestin¹, Christelle Lopes², Nicolas Delorme³, Laura Garnero³, Olivier Geffard³ and Thomas Lacoue-Labarthe⁴, (1)CNRS umr 5558, France, (2)Lyon University, UMR CNRS 5558, Villeurbanne, France, (3)INRAE Lyon, France, (4)LIENSs CNRS & Université de la Rochelle UMR 7266, France

Most of the studies conducted on metal bioaccumulation in freshwater crustaceans are focused on waterborne contamination and did not take into account the metal uptake through consumption of contaminated food sources. Thus, the quantification of both uptake pathways allows having a global picture of metal exposure for these aquatic organisms. To the best of our knowledge, no studies focused on the dietary bioaccumulation of Cd by assessing its toxicokinetic and organs distribution in the bioindicator species *Gammarus fossarum*. In a first step, the Cd assimilation efficiencies were assessed for two types of food usually consumed by gammarids. Thus, chironomids larvae and alder leaves were preliminarily radiolabelled with ¹⁰⁹Cd before a pulse chase feeding (2h) of gammarids. Once fed, the radioactivity content in individualized gammarid was followed along a 14-day depuration phase allowing to determine the Cd assimilation efficiencies and biological half-life of assimilated fraction. The first results show a Cd assimilation efficiencies of 60% and 52% for leaves and for larvae, respectively. In second step, gammarids were exposed for 6 days to alder leaves prior radiolabelled by ¹⁰⁹Cd, before being placed in depuration conditions with uncontaminated food for 11 days. The absence of dissolved ¹⁰⁹Cd released by radiolabelled food was monitored twice a day during exposure phase and daily during depuration phase. At several sampling time, the Cd contents were quantified in the gammarid organs, i.e. caeca, cephalon, intestine, gills and remaining tissues by gamma-spectrometry. The results show: i) a strong organotropism with difference of accumulation efficiencies among organs with caeca > intestines > cephalons > remaining tissues > gills at the end of phase of

exposure. In addition, ii) no Cd were measured in the gills confirming no recycling of ^{109}Cd in the dissolved phase and implying the absence of Cd exchanges between the contaminated organs and the gills in accordance with previous study carried on dissolved contamination. These results attest that the elimination of accumulated Cd by caeca, cephalons and remaining tissues did not request exchange processes that occur at the gills levels and imply a key role of the caeca and intestine in the fate of dietary Cd in gammarid.

4.17.P-Tu286 Toxicokinetic Modeling to Assess the Impact of Cadmium (Cd) Concentration Exposure on Metal Organotropism, Bioaccumulation and Fate in Gammarus fossarum

*Ophelia Gestin*¹, *Thomas Lacoue-Labarthe*², *Nicolas Delorme*³, *Laura Garnero*³, *Olivier Geffard*³ and *Christelle Lopes*⁴, (1)CNRS umr 5558, France, (2)LIENSs CNRS & Université de la Rochelle UMR 7266, France, (3)INRAE Lyon, France, (4)Lyon University, UMR CNRS 5558, Villeurbanne, France

The organotropism, toxicokinetic and fate of Cd in *G. fossarum* were previously assessed by following metal uptake and loss in caeca, cephalons, intestines and remaining tissues of gammarids exposed to $11 \mu\text{g.L}^{-1}$. Despite this study identified key organs for Cd bioaccumulation in acute conditions, such as caeca and intestine, the potential role of gills usually involved in metal uptake and elimination in crustaceans, was not considered. In this context, gammarids were exposed for 7 days to 3 environmentally relevant concentrations of Cd (i.e. 4, 52 and 350 ng.L^{-1}), by adding stable CdCl_2 to a fixed concentration of the radiotracer ^{109}Cd (i.e. 20 kBq.L^{-1}), allowing the quantification of very low Cd amount in small samples. Then, organisms were placed in depuration (clean water) for 21 days. At several sampling times, gammarids were dissected to recover the target organs: caeca, cephalons, intestines, gills and remaining tissues. The amounts of Cd in organs were measured by gamma-spectrometry, to obtain a Cd concentration per organ. First, the Cd distribution among the organs at the end of the uptake phase revealed that gills and caeca were the most concentrated regardless of exposure concentration. Second, the effect of water concentration on the Cd accumulation in each organ was tested by simultaneously fitting nested one-compartment TK models by Bayesian inference, applied synchronously to the 3 concentrations data sets available for each organ. The results showed that uptake rates differed as a function of exposure concentration for all organs except the intestines, in contrast to the organ-specific values for depuration rates. Finally, a multi-compartments TK model, associated to an iterative inference process, was fitted, for each concentration, to all organ datasets simultaneously to describe the fate of Cd among organs over time and find the “best” scheme of Cd management based on exposure concentration. The results showed the same pattern of inter-organs exchanges for the 3 concentrations, refining the hypotheses concerning the *in vivo* management of Cd. In addition to the absence of impact of the exposure concentration of dissolved Cd on its organotropism, toxicokinetics and fate in gammarids, this study allowed us to: i) work at environmentally relevant concentration; ii) observe that gills are the most concentrated organs in Cd; and iii) assume intestines are a pathway of uptake and loss, whereas gills are only a pathway of uptake and storage.

4.17.P-Tu287 Review of PBK Models for Fish Species of Non-Ionogenic Compounds for Use in Environmental Risk Assessment

*Alessia Giorgis*¹, *Thomas Moxon*², ***Bruno Campos***³ and *George Fitton*⁴, (1)Unilever R&D Colworth, United Kingdom, (2)Unilever, UK, (3)Unilever, United Kingdom, (4)Unilever Research Colworth, United Kingdom

The global regulatory landscape is currently experiencing a shift towards the introduction of New Approach Methodologies (NAMs) encompassing *in chemico*, *in silico* and *in vitro* approaches, driven by the need to eliminate or greatly reduce animal testing to support chemical safety assessment. One of the challenges to the use of NAMs in Environmental Risk Assessment (ERA) is to derive Points of Departure (PODs) and establish these as an alternative to the traditional Predicted No Effect Concentrations (PNECs). In order to implement the use of PODs in ERA, it is essential to quantify the chemical exposure under investigation as a concentration at the target site and reverse it to the external concentration required to achieve that POD internally. In this respect, the availability of robust *In vitro* *In vivo* extrapolations and physiological based kinetic (qIVIVE/PBK) models becomes fundamental. One key approach to achieve this is the use of PBK models to estimate internal concentrations of chemicals in aquatic species based on external concentrations and vice versa, from internal concentrations in *in vitro* systems to external (*in vivo* relevant), process also known as quantitative qIVIVE. Here we present a novel evaluation of available fish PBK models to estimate the internal concentration of non-ionogenic chemicals following exposure and discuss its relevance and future applications and developments. The three one-compartment models are the most representative and well known in the field which are currently available. They differ in some input parameters such as the lipid or the water content and they consider the influence of exposure time and fish trait parameters such as the fish weight and lipid fraction amongst others. Comparisons between experimental and predicted internal concentrations values were analyzed to evaluate the performance of the models. Overall, we demonstrate that the three PBK models achieve satisfactory results in the prediction of internal concentrations for organic neutral chemicals and the error remains within a 10-fold for all models. Lastly, we consider whether the performance of these models could be improved through further developments e.g., by adding multi-compartment and metabolism considerations among others.

4.18 When “multiple” matter to deal with mixtures and other stressor effects across levels of biological organisation

4.18.T-01 Assessment of the Joined Effects of Carbaryl, Dietary Restriction (DR) and Dietary Deprivation (Dd) on the Oligochaete Species Eisenia fetida

Sipho Sithole Sithole, *Patricks Voua Otomo*, *Ngitheni Nyoka* and *Michel Kamdem*, University of the Free State, South Africa
Toxicity studies are extensively used to evaluate the effects of toxicants upon organismal health. However, studies assessing the combined effects of chemicals and dietary restrictions are rare. For dietary studies, the focus has been on biological and ecological

parameters and seldom on the added influence of chemical toxicity. Dietary restriction (DR) and dietary deprivation (DD) have been shown to be significantly beneficial, in terms of lifespan gains and stress alleviation in nematodes. However, such beneficial effects still need to be evaluated in worm's species such as oligochaetes, especially in combination with other stressors. Our study evaluated the toxicity of carbaryl at various concentrations under both DD and To do this, we used the following dietary conditions: 100% (normal diet – 5 g oatmeal per 10 worms), 50% (or DR – 2.5 g oatmeal per 10 worms) and 0% (or DD – 0 g oatmeal per 10 worms). The following concentrations of carbaryl were used 0, 7, 14 and 28 mg/kg and effects on survival, reproduction, and biomass were assessed after 14 days of exposure. Preliminary results using the normal diet showed that carbaryl is toxic to earthworms, causing a total inhibition of reproduction in all the treatments (7-28 mg/kg). Survival data showed that the 14-day LC₅₀ was higher than 28 mg/kg, but a 14-day LC₂₀ = 11.238 (4.599-27.463) mg/kg was computed. Carbaryl also caused significant weight loss ($p < 0,05$) in the 7 mg/kg treatment. The results of ongoing experiments using the DR and DD diets will be processed and compared to those of the normal diet in due course. The findings will be discussed in light of the latest and most relevant literature.

4.18.T-02 Temporally Coupled Stress Provokes Antagonistic Response at Low Concentrations

Florian Schunck¹ and Matthias Liess², (1)System-Ecotoxicology, Helmholtz Center for Environmental Research (UFZ) Leipzig, Leipzig, Germany, (2)UFZ, Germany

Recent investigations revealed that consideration of pesticide pulses, which are subject to large temporal fluctuations, is elemental in environmental risk assessment. However, effects of sequential exposure in mixtures of environmental and chemical stress are rarely investigated, although such scenarios probably constitute the most dominant scenario in nature. Additionally, gaps of knowledge regarding the outcome of interactions between stressors exist. Research suggest that time and order of exposure can modify the response of pesticides in mixture with other pesticides or environmental stress. Their role concerning the interaction of stressors, however, is so far unclear. Therefore, we conducted a full factorial, four dimensional, multiple stress exposure experiment to probe the effect of exposure time and exposure order on interactions between stressors. We tested broad combination ranges of an environmental stressor (UV-B radiation, 6 exposure times) and a chemical stressor (Esfenvalerate, 10 concentrations) on the acute effect on *Daphnia M.* under 4 different exposure scenarios. We observe that the temporal distance between two stressors has a significant effect on their interaction. Applications of low stress doses, independent of the stress type, significantly increase the EC₅₀ response of the other stressor by a scaled difference of 39% of the control ($p = 0.0069$), if the stressors were applied one day apart. This effect disappears when the stressors are administered within a longer time interval of 3 days (-16% of control, $p = 0.13$). This finding is also reflected by average MDR values (1 day time lag: MDR = 0.54, 3 day time lag: MDR = 0.93), corresponding to antagonistic and additive behaviour respectively. We conclude that low – hormetic – doses of one stressor may provoke a decrease in response of the second stressor, if both are coupled in time, thus leading to observations of antagonism at low doses. With these findings we hope to add to the discourse of why mixtures often times behave antagonistically. Moreover, the results underline how the consideration of hormesis theory and related non-monotonic dose response relationships can help understand and predict effects of multiple stress in the field.

4.18.T-03 Accounting for Individual Environmental Conditions in Assessing Pollution Exposure of a Long-Lived Top Predator Population

Peter Vermeiren¹, Andreas Focks², Cynthia Munoz³ and Sandrine Charles⁴, (1)Faculty of Science, Radboud University, Nijmegen, Netherlands, (2)University of Osnabruck, Germany, (3)Radboud University, Netherlands, (4)University Lyon 1, France

Environmental stressors originating from both natural (e.g. food availability) and anthropogenic (e.g. synthetic pollutants) sources may have strong influence over extended periods on long-lived species. Consequently, environmental management needs to account for the cumulative long-term effects of multiple stressors on such species. Additionally, when population sizes are reduced with individuals exposed to multiple stressors, the behavior of individuals becomes relatively more important in determining population-level outcomes, these later being more relevant in terms of conservation actions for such species. We developed an individual based toxicokinetic (IBM-TK) model for American alligators as a case study of a long-lived top predator exposed to organochlorine pesticides. The model simulates internal chemical accumulation over the lifetime of individuals, accounting for dietary uptake, growth dilution and maternal transfer processes. The model furthermore considers the between-individual variability in pollution exposure, growth and reproduction directly stemming from food availability in these highly territorial species. Environmental conditions in lakes occupied by alligator populations (such as air and water temperature as well as food web composition) are also considered. Meanwhile, lifecycle development of alligators was modelled using a dynamic energy budget, calibrated against sparse data on growth during early life stages, nest productivity, and age at reproduction. At last, prior knowledge regarding parameter values were phylogenetically derived from related crocodile species in order to feed the Bayesian inference process leading to the parameter estimates of the whole model. Long-lived top predator populations play an important role in the structure and functioning of ecosystems. With this research we aim to contribute towards quantitative mechanistic understanding of the interactions of such species with environmental pollutants present in their natural environments.

4.18.T-04 Single Cell Analysis of Microalgae Cells After Exposure to Mixtures of Transition Metals and Organics

Wen Qin¹, Andrea Gaertner², Hans-Joachim Stärk¹, Yue Meng³, Beate Escher⁴ and Thorsten Reemtsma⁵, (1)Helmholtz Centre for Environmental Research – UFZ, Germany, (2)Helmholtz Center for Environmental Research (UFZ) Leipzig, Leipzig, Germany, (3)Helmholtz Center for Environmental Research - UFZ, Germany, (4)Helmholtz Centre for Environmental Research GmbH - UFZ, Germany, (5)Helmholtz Centre for Environmental Research, Germany

For a long time, the main focus has been placed on the exposure of organisms and risk assessment of individual classes of chemicals. Since the environmental pollutant landscape is more complex than one class of chemicals, the attention is starting to

shift towards the broader chemical spectrum of mixtures, including transition metals and organics and the resulting mixture effects. Complexation to a metal can alter the chemical behavior of the organic component as well as the metal. The aim of this study was to evaluate the response of the green alga *Raphidocelis subcapitata* upon exposure to mixtures of transition metals and organics. Different endpoints, including PSII inhibition and intracellular transition metal concentration changes, were measured. This paper proposes a precise and robust approach: Single cell analysis using inductively coupled plasma mass spectrometry (SC-ICP-TOF-MS) was combined with more conventional effect analysis, including measurements of growth rate and photosynthesis (PSII) inhibition, enabling a more in-depth study of the toxicology of mixtures to algae. *R. subcapitata* were exposed to varying copper or zinc concentrations and intracellular contents of Cu, Zn, Mn, P, and Mg were measured over a time period of 24 hours. Intracellular copper concentrations increased almost 60-fold within the first 30 minutes. Upon copper exposure, no significant changes in intracellular zinc concentrations were observed. Zn exposure resulted in a slower Zn uptake with a maximum at 24 h. Furthermore, intracellular copper concentrations increased upon zinc exposure. Mixtures of pyriithione and zinc have no effect on the PSII after 2h, compared to pyriithione by itself. Copper addition showed synergistic effects already after 2 hours. Toxic effects of mixtures can follow different theoretical models, concentration addition and independent action, identifying synergism, when the toxicity of two or more components is higher than predicted with the concept of concentration addition, or antagonism, when the mixture effect is lower than the mixture prediction for independent action. CuSO₄, ZnSO₄ and pyriithione (PT) were added to algae, the sum of toxic units (TU, $TU = TU_{\text{metal}} + TU_{\text{PT}} = C_{\text{metal}}/IC_{50,\text{metal}} + C_{\text{PT}}/IC_{50,\text{PT}}$, C = concentration, IC_{50} = inhibitory concentration triggering 50% of maximum effect) of metal and PT were < 1 indicating a strong synergistic effect of the mixture on the PSII inhibition.

4.18 When "multiple" matter to deal with mixtures and other stressor effects across levels of biological organisation (Virtual Only)

4.18.V-01 Cytotoxic Effects of PAHs Mixtures in Immortalized Hepatocyte Cells of Zebrafish (*Danio rerio*)

*Beatriz Matos*¹, *Isabella Bramatti*², *Mário Diniz*³, *Vasco Branco*⁴ and *Marta Martins*⁵, (1)Environment, NOVA School of Science and Technology, Caparica, Portugal, (2)MARE - Marine and Environmental Sciences Centre, Portugal, (3)UCIBIO, REQUIMTE, Portugal, (4)Research Institute for Medicines (iMed.Ulisboa), Faculty of Pharmacy, Universidade de Lisboa, Lisboa, Portugal, Portugal, (5)MARE Marine and Environmental Sciences Centre, Portugal

Polycyclic aromatic hydrocarbons (PAHs) are persistent contaminants ubiquitously present in the environment. The main source is combustion of fossil fuels from anthropogenic activities. Given their high molecular weight, low solubility and high lipophilicity, PAHs are hardly degraded, persisting and accumulating in the environment. PAHs always appear as complex mixtures of compounds in the environment but, nonetheless, research has focused mainly on the effects of single compounds, not counting with interactions effects between compounds that may result in an unpredictable outcome comparing to exposures to single PAHs. The aim of the present work is to assess the interaction cytotoxicity effects of different of PAHs, considering different proportions of each PAH in a mixture. For this purpose, *Danio rerio* hepatocytes cell lines (ATCC® CRL2643™) were used as in vitro model. ZFL cells are a robust model system for toxicity studies due to the easiness to culture and manipulate and due to their capacity to retain several of the organs' metabolic functions. To assess the cytotoxicity of these compounds, ZFL cells were exposed to different PAHs usually present in the environment, at concentration within nM to μM range to produce valid concentration-response curves. The exposures were performed using individual PAHs (Phenanthrene, Benzo(A)pyrene, Fluoranthene and Benzo(B)fluoranthene) and their complex mixtures considering different proportions of each PAH, namely: i) at mixture ratios proportional to the EC50 of each component; ii) mixing all substances at ratios proportional to the individual EC10/20; and iii) at environmentally-relevant proportions based on data in scientific literature from sediments and estuarine water samples. Cytotoxicity was carried out through Neutral red, MTT and Trypan blue assays. The Combination Index (CI) was applied to data to reveal the nature of the PAH interactions (synergistic, antagonistic and additive). ULisboa's Strategic Project (UIDB/04138/2020; UIDP/04138/2020) all financed by national funds from Fundação para a Ciência e Tecnologia.

4.18.V-02 Identification of Frequently Used Mixture Combinations of Endocrine Disrupting Chemicals in Household Chemical Products Using Association Rule Mining

Inhye Lee and *Kyunghee Ji*, *Yongin University, Korea, Republic of (South)*

Consumers use a variety of products and are exposed to many chemicals contained in them. However, previous studies evaluating the risks associated with exposure to chemicals in consumer products have focused on individual chemicals. In the present study, mixture combination of endocrine disrupting chemicals (EDCs) in household chemical products (HCPs) was identified using association rule mining and toxicological big data. After collecting information on the product names and ingredients of HCPs from the website "Living Environment Safety Information System", we unified chemical names labeled with different names and matched with chemical identifiers. Chemicals potentially exhibited (anti)estrogenicity, (anti)androgenicity, thyroid hormone disruption, and steroidogenesis inhibition were identified using ToxCast database. The frequently used mixture combinations were identified by utilizing the association rules of the R program. Among the 11,064 products, a total of 7,603 products were finally analyzed excluding products for which no ingredient was provided or duplicate products. Among the 1,241 chemical substances, 293 substances were identified to have endocrine disruption, and these EDCs were prevalent in cleaners, synthetic detergents, fabric softeners, air fresheners, and deodorants. The most prevalent combination was ethanol, hexyl cinnamaldehyde, geraniol,

citronellol, and benzisothiazolinones. The results of this study will be useful for the management of EDCs in HCPs and future studies on mixture toxicity. Acknowledgement: This study was supported by Korea Environment Industry & Technology Institute (KEITI) through the Technology Development Project for Safety Management of Household Chemical Products, funded by Korea Ministry of Environment (MOE) (Grant no. 288 2020002960006; 1485017189).

4.18.V-03 The Hierarchy of Multiple Stressors' Effects on Benthic Invertebrates: A CASE Study From Two German Rivers

Nele Markert¹, Barbara Guhl² and Christian Feld³, (1)North Rhine-Westphalia Office of Nature, Environment and Consumer Protection (LANUV), Germany, (2)North Rhine-Westphalian State Agency for Nature, Environment and Consumer Protection (LANUV NRW), Recklinghausen, Germany, (3)University Duisburg-Essen, Germany

The ecological status of surface water bodies is influenced by a variety of anthropogenic stressors, such as elevated nutrient concentrations or hydrological and morphological alterations. Furthermore, a multitude of different micropollutants, e.g. pesticides and pharmaceuticals, is released into the environment every day where they are present in complex mixtures. Both the combined effects of multiple stressors as well as the effects of mixtures of micropollutants have been addressed in previous research studies. However, often micropollutants have been analyzed separately from other stressors or have not been directly included in multiple-stressor studies. This study analyses the effects of 19 different stressors belonging to physico-chemical, hydrological and morphological stressors as well as variables representing the mixture toxicity for 42 selected micropollutants. The stressors are put into a hierarchical context according to their relative impact on the invertebrate communities. The stressor hierarchy is derived from a multiple-stressor dataset and benthic invertebrate taxalists from two catchments, the River Erft and the River Niers, in Germany. Redundancy analysis and subsequent variance partitioning were applied to quantify individual and combined stressors' effects. Significant stressors were elevated concentrations of sulphate and chloride and structural alterations as well as hydrological alterations characterized by the frequency of high flow conditions and the flow variation. Variance partitioning indicated a predominant effect of physico-chemical stress, with subordinate effects of morphological and hydrological alterations, whereas only a minor share of the explained variance could be attributed to mixture toxicity in this case study. This study highlights the importance of considering all relevant stressors in the planning of management programs to improve the ecological quality of rivers. However, this study also revealed a major challenge for multiple-stressor studies, i.e. the compilation of multiple-stressor-datasets. Hydrological data, for example, were only available for a small fraction of biological and chemical sampling sites, leading to the limited number of sampling sites analyzed in this study. Furthermore, sampling of chemical pollutants may be limited by the sampling methodology; grab sampling, as applied in this study, may be less suitable to capture the full range of relevant pollutants.

4.18 When "multiple" matter to deal with mixtures and other stressor effects across levels of biological organisation (Poster)

4.18.P-Th146 Mechanisms of Combined Stress Effects

Matthias Liess Liess, UFZ, Germany

In polluted ecosystems, a large number of toxicants and environmental stressors may occur simultaneously generating additive, antagonistic and synergistic effects. Some stressor combinations show combined synergistic effects that go far beyond what is expected when using current effect models. This high degree of uncertainty makes it difficult to predict the biological effects of combined stressors. For many decades two concepts have been applied to predict the combined effects of toxicants: (i) Combined effects of similar acting toxicants are usually assessed with the concentration addition approach (CA). (ii) Combined effects of dissimilar acting toxicants are generally assessed using the effect addition approach (EA). However, predicting the combined effect of toxicant mixtures with different modes of action provides contradictory results. Instead, effects of dissimilar acting stressors have successfully predicted with the "Stress Addition Model" (SAM). However, additionally factors as intraspecific- and interspecific competition determined the magnitude of effects. Therefore, the aim of this presentation is to identify those mechanisms that determine combined stress effects. The various existing approaches to modelling combined stressor effects have been applied to a large number of controlled experiments and field studies. This combined evaluation reveals that the magnitude and nature of interaction can be predicted with knowledge on the environmental conditions, the state of adaptation and the toxicant mode of actions.

4.18.P-Th147 Mixture Toxicity and Interactive Effect in a Binary Ciprofloxacin-Copper Mixture to *Microcystis aeruginosa*: Focusing on Low Effect Levels of Copper

Qiyun Zhang¹, Kristof Demeestere² and Karel De Schamphelaere³, (1)GhEnToxLab (Ghent University), Ghent, Belgium, (2)Ghent University, Belgium, (3)Ghent University (UGent), Belgium

Currently, a knowledge gap remains in the field of mixture toxicity, especially those consisting of chemicals belonging to different categories (e.g., metal-pharmaceutical mixture). Here, we employed cyanobacteria toxicity experiments to study the toxicity of a mixture made of two chemicals with very different modes of action (MoA), the heavy metal copper (Cu) and the antibiotic ciprofloxacin (CIP), using a modified ray-design. The type of interaction between different concentration levels of copper and ciprofloxacin were analyzed using the concentration addition (CA) model and the independent action (IA) model, with a focus on the impact of low-effect levels of Cu on CIP toxicity to *Microcystis aeruginosa*. IA was found to describe Cu-CIP mixture toxicity better than CA, but including the global interactive effect significantly improved the performance of CA. Antagonistic effects in Cu-CIP mixture were found in with CA. A further investigation at two pH levels (8.0 and 9.0) found that

low-effect levels of copper (EC10) did not significantly affect CIP toxicity. The implications of our findings for risk assessment and EU environmental quality standards (EQS) for single compounds within a mixture context will be discussed.

4.18.P-Th148 Use of an Aquatic Mixture Toxicity Excel-Tool in the Risk Assessment of Plant Protection Products

Marcus Hillebrand¹, Sabine Duquesne², Tobias Frische³, Alf Aagaard⁴, Signe Pedersen⁵, Wolfgang Krämer⁶, Manuela Trobej⁷, Christoph Gassner-Schneckenleithner⁶, Mathilde Hauge Skarsjø⁸ and Mathilde Zorn⁹, (1)German Federal Environment Agency (UBA), Germany, (2)UBA, Federal Environment agency, Germany, (3)Federal Environment Agency (UBA), Germany, (4)Pesticides and Biocide Division, Italy, (5)Danish Environmental Protection Agency, Denmark, (6)Austrian Agency for Health and Food Safety, Austria, (7)AGES - Austrian Agency for Health and Food Safety, Vienna, Austria, (8)Norwegian Food Safety Authority, Norway, (9)Ctgb, Board for the authorisation of plant protection products and biocides, Netherlands

In the EU the aquatic risk assessment of plant protection products with more than one active substance requires a calculation of the risk of the mixture toxicity (MixTox). This assessment, which is described in the Guidance on tiered risk assessment for edge-of-field surface waters by EFSA, is quite complex and time consuming. Risk assessors from different member states have developed a calculation tool for the mixture toxicity risk assessment. This MixTox tool is intended to 1) ease the calculation, 2) harmonise the assessment, 3) minimise the risk of mistakes, and 4) facilitate the delivery of appropriate and consistent risk calculations for applicants and regulatory authorities. The tool (“AGD_AquaMix_v1.15”) is an Excel document composed of different worksheets including 1) an introduction, 2) input of toxicity and exposure data, 3) risk assessment that follow the steps described in the scheme of the AGD and finally 4) the conclusion for the acute risk assessment. In addition to the user guidance information presented in each worksheet, a living FAQ document “FAQ_MixedTox_v1” has been developed to complement the tool and includes recommendations beyond those provided in the AGD. The MixTox tool with the FAQs have been distributed to all European pesticide risk assessment stakeholders including EU member states in the beginning of 2021 (<https://zenodo.org/record/4593676#.YZOMgucxmUk>). This poster includes examples to illustrate how to use this tool and the lessons learned from the development of the tool (e.g. how to make the mixture risk assessment simpler and more “user-friendly” when applied in practise and how to better include long-term toxicity).

4.18.P-Th150 What Are the Toxicokinetic and Toxicodynamic Mechanisms Underlying the Synergistic Interactions Between Chemicals in Mixture Exposures?

Kevin Noort¹, David Spurgeon² and Henriette Selck³, (1)UK Centre for Ecology & Hydrology (UKCEH), Wallingford, United Kingdom, (2)Centre for Ecology & Hydrology, United Kingdom, (3)Roskilde University, Roskilde, Denmark

In realistic environmental conditions, a large amount of toxic chemical substances occur together, generating interactive effects that can be synergistic, additive, or antagonistic. Due to the large number of combinations of chemicals that can occur together, assessment of chemical mixtures relies on the use of predictive models. These models, however, do not sufficiently consider the effects of mixtures, and cannot predict their interactive effects. Among these effects, synergistic interactions are seen as of greater importance for risk assessment practices, as these can increase toxic effects of a mixture to far beyond what is predicted. Synergistic interactions are the outcome of some sort of interaction between chemicals, whereby either one affects how the other is taken up to the target site (toxicokinetic) or what it does at the target site (toxicodynamic). Processes that can be affected by chemicals to lead to synergism are bioavailability, uptake, internal transport, metabolism, binding at target site and excretion. One example of synergism in invertebrates can be observed between azole fungicides and pyrethroid insecticides. Azoles (triazoles and imidazoles) have fungicidal activity in the membranes of fungi by targeting the C14-demethylase in sterol biosynthesis. In the body of an invertebrate, however, azole fungicides have been suggested as likely candidates to inhibit a wide range of cytochrome P450 monooxygenases (CYPs) or bind glutathione-containing compounds such as glutathione-S-transferases (GSTs). Both groups of enzymes have a role in the binding, sequestration and/or detoxification of pesticides. However, recent studies showed multiple cases where the synergistic effects of these azole compounds cannot be fully explained by these processes alone and thus, we do not know the full mechanistic attribution of synergism for azole exposure. My objective is to gain a better understanding of the synergistic interactive effects of azoles, and I aim to identify and model the toxicokinetic and toxicodynamic traits underlying the observed synergistic effects. My approach will include the assessment of synergistic mixture effects using multiple apical endpoints (i.e., survival, growth, development), it will include the application of a novel methodology for *ex vivo* testing of enzymatic activity in terrestrial invertebrates, and will utilize modelling of the full range of observed responses by using Dynamic Energy Budget theory.

4.18.P-Th151 Endocrine Disruptive Effects of Water-Soluble Agrochemicals Extracted From Maize and Pecan Soil

Itzé Horak¹, Suranie Horn² and Rialet Pieters³, (1)North-West University, South Africa, (2)North-West University, Cape Town, South Africa, (3)North West University, Potchefstroom, South Africa

Although beneficial in reducing crop losses, applied agrochemicals end up in non-target environments after irrigation and rainfall. When fractions of these chemical mixtures are accessible to living organisms for uptake across cellular membranes (bioavailable), they pose a threat to human and aquatic health. One of the toxicological effects associated with pesticide exposure is endocrine disruption—whereby the chemicals act as agonists and/or antagonists of endogenous nuclear receptors, including the mammalian aryl hydrocarbon receptor (AhR), androgen receptor (AR), and oestrogen receptor (ER). This study aimed to investigate the endocrine disrupting (ED) effects associated with the bioavailable fraction of agrochemical mixtures associated with maize soil in South Africa. Composite soil samples were collected in two maize growing regions—the Mpumalanga province and Vaalharts Valley—known for their extensive herbicide application. Water-soluble compounds were extracted from the soil using deionised water to mimic environmental conditions and obtain the bioavailable fraction. An *in vitro* H4IIE-*luc* reporter gene assay was performed to establish whether the soil extracts contain AhR ligands. This was followed by assessing (anti?)androgenic and

glucocorticoid activity using the human breast carcinoma cell line MDA-kb2. Lastly, the T47D-kbluc cell line was used to screen the water-soluble agrochemical residues for antagonistic oestrogenic activity by evaluating binding to the ER. The MTT [(3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) viability assay was run in parallel to the reporter gene bioassays to ensure that (i) the concentrations under investigation were not cytotoxic towards the respective cell lines and (ii) as quality control to prevent false negative reporter gene assay results. Results from the *in vitro* bioassays indicated that compounds present in the water-soluble extracts of the soil did not activate the AhR or AR. However, at the concentrations evaluated in this study the soil-extracts from some sampling locations caused AR and ER inhibition, indicating ED effects. The identity of the chemicals that likely caused the effects should be further investigated by applying chemical screening to the soil-extracts.

4.18.P-Th152 Characterisation of Cumulative Risk of Contaminants to Organisms Exposed to Stormwater in Oslo, Norway

Anders Ruus¹, Raoul Wolf², Karina Petersen³ and Knut Erik Tollefsen³, (1)NIVA, Norway, (2)Norwegian Geotechnical Institute (NGI), Oslo, Norway, (3)NIVA - Norwegian Institute for Water Research, Norway

Oslo, the capital of Norway, is situated by the Inner Oslofjord. The fjord is affected by municipal discharges, industry and boats/ships. Furthermore, various environmental contaminants enter the fjord by rivers and streams, and through stormwater. The conditions of the Inner Oslofjord have been monitored by several different monitoring programs, and data for concentrations of a wide range of contaminants have been reported in biota, water and sediment samples. The objective of the present study was to use data gathered through the “Urban fjord” monitoring programme (administered by the Norwegian Environment Agency and carried out by NIVA) to perform a retrospective cumulative environmental risk assessment (CRA), identify species groups of highest risk for toxicological effects and identify the main contributing stressors to the predicted environmental risk. “Urban fjord”-data from 2016 [2] was imported into the NIVA Risk Assessment database (NIVA RAdb, www.niva.no/radb). Concentrations in stormwater were used to perform a retrospective CRA for different species groups (taxa) including molluscs, algae, invertebrates, worms, crustaceans, and fish. Effect data for the pollutants were compiled by, and processed in, NIVA RAdb. NIVA RAdb was used to calculate cumulative risk quotients (CRQ) for the different species groups for acute and chronic effects. Metals were in most cases the main contributors to the CRQ in fish, crustaceans and molluscs, and molluscs was the taxon with the highest CRQ for chronic effects. The study shows that there is a predicted risk for biological effects in organisms exposed to stormwater entering the Inner Oslofjord. *Acknowledgement:* Financing-RCN268294 “Cumulative hazard and risk assessment of complex mixtures and multiple stressors (MixRisk)” and NCTP: NIVA’s Computational Toxicology Program, NCTP (www.niva.no/nctp).

4.18.P-Th153 Target Screening and Mixture Assessment of Chemical of Emerging Concern in the River Aconcagua (Chile)

Pedro Inostroza¹, Sebastian Elgueta², Martin Krauss³, Werner Brack⁴ and Thomas Backhaus⁵, (1)Biological and Environmental Sciences, University of Gothenburg, Gothenburg (Sweden), Sweden, (2)Universidad de las Américas, Chile, (3)Helmholtz centre for environmental research - UFZ, Germany, (4)Helmholtz Centre for Environmental Research – UFZ, Germany, (5)University of Gothenburg, Sweden

Aquatic environments have been widely characterised by mixtures of micropollutants worldwide and scientific evidence has demonstrated a myriad of adverse effects on aquatic life (e.g., disruption of hormonal pathways and inhibition of neuronal synapsis in non-target organisms). Nevertheless, there are knowledge gaps about the chemical and ecological status of freshwater in developing countries. The River Aconcagua basin (Chile) is a basin under high water competition by mining, agriculture, and urban areas. Several settlements and relevant national economical activities (mining, agriculture, and petrochemical industries) stretch along the river. Consequently, a diverse and complex pollution fingerprint occurs, driven by the various land uses. In this study, we used an on-site large volume solid-phase extraction sampler (LVSP) to collect 50 L of water at nine different sites (3 “reference” sites, 3 tributaries, and 3 sites along the river). Organic micropollutants were extracted and their concentrations were quantified using LC- and GC-High-Resolution Mass Spectrometry. The target-screening list comprised 824 chemicals from different chemicals groups (e.g., pesticides, pharmaceuticals and personal care products, industrial chemicals, and some transformation products). The mixture assessment was conducted applying both the toxic unit approach and the species-sensitivity distribution modelling in order to predict effects at different trophic and community levels, respectively. We quantified 153 chemicals and overall, 5 biocides, 35 industrial chemicals, 51 pharmaceuticals and personal care products, and 62 pesticides were found at one or more sampling sites. Site-specific chemical fingerprints were used for mixture assessment and our results predicted that exposed aquatic organisms (e.g., decomposers, primary and secondary consumers) in tributaries and lower part of the main river were at risk. The risk drivers were pesticides followed by pharmaceuticals. We predicted the next trophic sensitivity secondary consumers > primary consumers > decomposers > primary producers in the River Aconcagua Basin.

4.18.P-Th154 Multiple Stress Effects: From Sub-Organismic to Population Level

Naeem Shahid¹, Ayesha Siddique², Ulrike Rolle-Kampczyk³, Martin von Bergen⁴, Saskia Knillmann⁵ and Matthias Liess Liess⁶, (1)System-Ecotoxicology, Helmholtz Center for Environmental Research - UFZ, Leipzig, Germany, (2)Ecotox, Helmholtz center for Environmental Research-UFZ, Leipzig, Leipzig, Germany, (3)Helmholtz Center for Environmental Research - UFZ, Germany, (4)Helmholtz-Centre for Environmental Research UFZ, Germany, (5)Helmholtz-Centre for Environmental Research (UFZ), Germany, (6)UFZ, Germany

In natural ecosystems, long-term detrimental effects of pesticides may occur at very low concentrations, below those considered safe by the governmental risk assessment. Mechanisms potentially responsible for this unexpected sensitivity include environmental stress-factors such as food deficiency. Here, we used *Daphnia magna* as a test organism and investigated how food

limitation – a common ecological stressor – affects the mixture toxicity of a pyrethroid insecticide and an azole fungicide. Further, we investigated how food stress interacts with insecticide-induced biochemical fingerprints. We revealed that under low food conditions, the strength of synergism between esfenvalerate and prochloraz increased with an increasing concentration of prochloraz independent of the null model. Under high food conditions and at concentrations of prochloraz $\geq 32 \mu\text{g/L}$, we observed a marginal synergistic effect with an MDR = 2.1 at $32 \mu\text{g/L}$ prochloraz and 2.2 at $100 \mu\text{g/L}$ prochloraz when using CA as a null model. In contrast, the combination of both pesticides and food stress caused synergistic effects shown by an MDR = 10.9 even at $1 \mu\text{g/L}$ of prochloraz that is frequently detected in the environment. To investigate the sub-organismic response to multi-stress, we measured metabolomic perturbations in *Daphnia magna* following a 24h exposure to esfenvalerate under high and low food conditions. In total, 160 metabolites covering the groups of amino acids, fatty acids, lipids and sugars were analyzed. At $0.001 \mu\text{g/L}$ esfenvalerate – a factor of >200 below the acute median lethal concentration (LC_{50}) – the endogenous metabolome was significantly affected. Further, the effect under low food conditions was considerably stronger compared to high food conditions. Individual metabolites showed up to 7-fold stronger effects under low food conditions. In general, the metabolomic changes were largely dose-specific and increased over seven days after contamination. We conclude that common environmental stressors can strongly increase the synergistic effects of toxicants. Further, the metabolomic changes might be a possible key to explain population-level changes at ultra-low pesticide concentrations in the field.

Track 5: Life Cycle Assessment and foot-printing

5.01 Advancement in Life Cycle Inventory Modelling: better data, more accurate assessments (Part I)

5.01.T-01 Increasing the Resolution of Parametrised LCA Models Using Machine Learning

Valentin Starlinger and Jonas Eliassen, 2.-0 LCA Consultants, Aalborg, Denmark

Due to an accelerating globalization and constant economic growth it is important to keep track of the effects human activities have on the environment. This also ensures that decision makers have the possibility to base their actions on quantitative results. One method that is used to quantify the environmental impacts of a product or service is life cycle assessment (LCA). Using machine learning to aid and improve this process is a topic that has received little attention so far, especially when compared to other research areas that try to tackle environmental crises. Given the impacts machine learning has had in many different applications over the last years, it is important to investigate if and how machine learning can be used as a tool to enhance LCA research. Two areas that were identified by the authors, where machine learning algorithms can add value compared to traditional approaches are: (1) prediction speed once the model is fully trained and (2) the possibility to train networks on a reduced parameter set using feature selection. The increased prediction speed allows the model to be used to predict data over a very large set of input parameters. This could be used to increase the resolution at which LCI data is available. It could also be used to aid LCA researchers in sensitivity analyses. This work presents a method of how data can be generated from a parametrised LCA model to create a machine learning data set on which models can be trained. It showcases this using an example LCA model for cars as a case study. The random forest and neural network models used, both show promising prediction accuracy with R^2 values of 0.994 and 0.996 respectively. While the case study shown in this paper uses a LCA model of cars, the approach can be used on any parametrised LCA model. This could allow to generate LCI data with much higher resolution in the parameter space. The downside of using machine learning is the blackbox nature of the resulting models and therefore a loss in transparency. This work aims to highlight areas where machine learning can be applied beside this disadvantage. Using this approach to generate LCI data with high spatial resolution is an area that looks particularly promising and should be investigated in future research.

5.01.T-02 Modelling Fish Products in the Big Climate Database

Michele De Rosa¹, Jannick Schmidt¹, Stefano Merciai², Ivan Muñoz³, Miguel Astudillo³ and Jonas Eliassen¹, (1)2.-0 LCA Consultants, Aalborg, Denmark, (2)2.-0 LCA consultants, Nederland, (3)2.-0 LCA consultants, Spain

Global food production accounts for around a quarter of greenhouse gas emissions. Access to information about a food's CO_2 footprint is crucial if we are to steer the production and consumption of food in a more sustainable direction. We developed a free, open access database, the Big Climate Database, of 500 of the most common foods in Denmark and calculated their carbon footprint. The database was developed for CONCITO, the Danish green think-tank. The initiative has a broad societal perspective and can be used by citizens, public authorities, and businesses alike. For this reason, the database was awarded the 2021's Nordic Council Environment Prize. Key principles of the database are consistency of modelling principles and emissions models for all crops, animals, and food processing industries in all countries in the world; completeness of life cycle inventories, avoiding cut-off of flows achieved by using EXIOBASE as background database, a multi-regional hybrid input-output database; modularity, ensured by the calculation modules contributing to the database, which can be revised, replaced and expanded. Here we present in detail the model of the fish products in the Big Climate Database. In total, there are 51 seafood products in the database. The fish module accounts only for the aquaculture production, based on the evidence that wild-caught fish is a constrained resource, i.e., it is currently not possible to increase the yield of capture-fisheries (wild fish), because the carrying capacity of the ecosystems is fully exploited (or beyond) in virtually all parts of the world. The amount of capture-fisheries has been stable for the last thirty years, while inland and marine water aquaculture have supplied the entire additional demand of fish in this period. Currently, about half of the world's fish production originates from aquaculture, in particular the aquaculture of some species, such as Salmon, Tilapia, Trout, Bream, Pike and some mollusks, such as mussels, prawn, and shrimp. These are indicated as "flexible species" The identification of the flexible (unconstrained) species is based on the regression slope for 2008-2018 in FishStat and it differentiates between freshwater fish, marine fish and mollusk. The 51 seafood products correspond to

common supermarket fish products, including filleted fishes, canned or in brine products. Packaging and other materials are therefore also taken into account.

5.01.T-03 Environmental Footprint of French Food Products

Justine Catel¹, Gustave Coste¹ and Arnaud Helias², (1)INRAE, France, (2)INRAE - ITAP, Montpellier, France

Product environmental footprint is an eternal compromise: The assessment has to be specific, to best represent production and processing choices in the value chain. Unfortunately, this need for specific data quickly becomes an obstacle and makes the work too big to do on a large scale. In contrast, generic data offer a less expensive result, but these default values only allow for inter-category comparisons, so differentiating products within a category is impossible. This balance between specificity and simplicity needs to be overcome. For food, the proportions of ingredients in products are a determining factor for the environmental footprint and reveal intra-category discrepancies. We have developed the PEFAP calculator (Product Environmental Footprint According to Packaging data) which automatically estimates environmental impacts based on the information available on the packaging. Based on the partial list of ingredients (an ordered list, but with often unknown proportions) and nutritional data available on packaging, the algorithm finds the most likely footprint by the convergence of the result over Monte Carlo runs. From a barcode, the user obtains in a few seconds a specific footprint of the product (data table and summary web page of the evaluation). Footprints have already been calculated for the 150'000 reasonably reliable products from the Open Food Facts database. This includes a subset of 30,000 products with data that are considered fully reliable. These data are used in combination with the average quantity consumed in France for the major food categories. Unsurprisingly, the consumption of animal products has the largest impact and the impact decreases as the water content increases (with beverages appearing as the least impactful categories). But within these broad trends, significant intra-category variability is observed, sometimes exceeding an order of magnitude. This underlines the importance of going beyond a generic value for an environmental footprint and integrating the specificity of the products. The creation of this algorithm allows describing the effects of (1) diet changes (i.e. inter-category consumption changes), (2) product changes (i.e. intra-category consumption changes) and (3) their respective importance (inter- versus intra-category) to identify the most important drivers for a less impactful diet.

5.01.T-04 Data Collection in the LIFE Cycle Inventory (LCI) Analysis Phase - a Methodological Guidance Using LIFE Cycle Inventory (LCI) Blocks

Karen Saavedra Rubio¹, Nils Thonemann², Eleonora Crenna³, Bruno Lemoine⁴ and Alexis Laurent⁵, (1)Department of Environmental and Resource Engineering, QSA section, DTU (Technical University of Denmark), Kgs. Lyngby, Denmark, (2)Danish Technical University, Lyngby, Denmark, (3)EMPA, Switzerland, (4)Bernier Fachhochschule (BFH), Switzerland, (5)Technical University of Denmark, Denmark

The data collection process, performed during the life cycle inventory (LCI) analysis phase, is the most resource-demanding and time-consuming step when conducting a life cycle assessment (LCA). Despite being an essential step, the methodological framework for the LCI analysis phase as described in ISO14040/44 is not detailed enough, and a clear and systematic stepwise approach guiding LCA practitioners through the data collection process when conducting an LCA is still missing. As a result, variations in the implementation of the LCI data gathering process occur, leading to different levels of detail when reporting LCI data and ultimately hampering transparency and reproducibility in LCA studies. A critical review of guidance documents and LCA studies was conducted to obtain a state-of-the-art on LCA data collection practices and based on the observed gaps, a systematic, comprehensive, and detailed stepwise framework is proposed, along with recommended methods and a flexible and customizable LCI data collection template to assist LCA practitioners with the data collection process in the LCI phase. The framework consists of three steps: planning of data collection (Step 1), data gathering process (Step 2), and LCI block finalization (Step 3). The applicability of the framework and the LCI data collection template were tested using an illustrative case of NMC811 lithium-ion batteries. The framework assisted the LCA practitioner in customizing the accompanying reusable LCI data collection template, helped structure the workflow within the LCI data collection step, and facilitated the communication between the LCA practitioner and LCI data providers. Both tools allowed a full-fledged data collection in the LCI stage and are applicable for all LCA case studies. Furthermore, they could help overcome transparency and reproducibility issues of LCI data. We call for applying these two tools when conducting LCA case studies to enhance the reliability of LCAs in the scientific community, policy, and society.

5.01 Advancement in Life Cycle Inventory Modelling: better data, more accurate assessments (Part II)

5.01.T-06 Lost in Translation? Insights From the GLAD Elementary Flow Mapping Project

Carl Vadenbo¹, Antonio Valente², Simone Fazio³, Koichi Shobatake⁴, Ashley Edelen⁵ and Thomas Sonderegger⁶, (1)ecoinvent Association, Zürich, Switzerland, (2)European Commission - Joint Research Centre, Italy, (3)EC-JRC, Italy, (4)TCO2 Ltd., Japan, (5)Eastern Research Group, United States, (6)ecoinvent Association, Switzerland

The *Global LCA Data Access (GLAD)* network is a platform hosted by UNEP for finding and accessing life cycle assessment (LCA) datasets from different data providers. But the various data exchange formats and nomenclature systems currently used in LCA pose a major hurdle for data interoperability. The main goal of this work was to consistently map the elementary flows (EFs) found in the nomenclature lists of four major LCA databases (ecoinvent v3.7; Environmental Footprint v3.0 by the European Commission; IDEA v2.2 and v2.3 of Japan; and the U.S. Federal LCA Commons, FEDEFLL v1.0.3). Six steps were carried out iteratively to establish bidirectional mapping between the four flowlists: (i) define EF lists and mapping file format; (ii) provision of source and target flowlists to be mapped; (iii) defining/refining the match criteria for mappings; (iv) generate EF mapping; (v) cross-review; (vi) finalization. The procedure involved the iteration from step (iii) to (v) until the mappings reached the desired

quality, and could be finalized (vi). EF lists were separated into two main components, referred to as ‘contexts’ (sub-/compartments) and ‘flowables’ (e.g., chemical substances). The items of the two components were mapped, and subsequently reviewed, separately. Steps (iv) and (v) were conducted with the help of two IT tools specifically developed within the project. The main result are 12 unidirectional mapping files between the four nomenclature systems, including matching criteria used by the mapper tool (e.g., by name, by CAS, by synonym, etc.). The results are discussed in terms of the level of coverage, i.e., the percentage of EFs of the source list covered by the flows available in the target list. The coverage range from around 20% to 99%. Higher levels of coverage are achieved by the larger flowlists, namely ILCD-EF v3.0 (coverage within 89-99%) and FEDEFL v1.0.3 (62-95%), on the target side. The results show that the mapping approach defined within GLAD is generally applicable, and as such potentially extendible to other lists, and it achieved significant mapping coverage. The activities performed represent a starting point towards better harmonization, and eventually the definition of a common reference EF list, for consistent mapping of inventory data and LCIA methods. In this regard, extensive involvement of stakeholders (e.g., software providers, method developers, and data providers) is essential to advance data interoperability in LCA.

5.01.T-07 Towards More Realistic Global Sensitivity Analysis for Life Cycle Assessment Studies

Aleksandra Kim¹, Chris Mutel², Andreas Froemel³ and Stefanie Hellweg⁴, (1)Paul Scherrer Institute, Villigen, Switzerland, (2)Paul Scherrer Institute (PSI), Switzerland, (3)Swiss Federal Institute of Aquatic Science and Technology (EAWAG), Switzerland, (4)ETH Zurich, Switzerland

Life cycle assessment (LCA) is a well-established methodology for environmental impact assessments of goods and services throughout their entire value chain. The complex global supply chains and their non-trivial effects on the environment, contain numerous sources of uncertainty and variability, which can lead to uncertain LCA results that are hard to interpret. Various LCA studies used Global Sensitivity Analysis (GSA) to gain better understanding of uncertainty drivers in impact assessments. However, only few were conducted for complete LCA models that reflect real-world conditions. In this work, we propose an efficient and reliable GSA protocol that is applicable to large nonlinear background systems, while taking dependencies between related technological and natural processes into account. The implemented correlated sampling uses real data measurements of electricity mixes in Europe, parameterization of life cycle inventories, carbon and land balancing, and adds uncertainties to markets while preserving their production volumes. Reliability of our GSA approach comes from validation of sensitivity results at all steps of the protocol. Results for the case study of Swiss household consumption indicate that only tens of LCA model inputs out of hundreds of thousands drive uncertainty in LCA scores. As a consequence, in order to reduce uncertainty and increase robustness of LCA results, only few processes need data improvement. Hence, the proposed GSA protocol allows to locate wide uncertainties in life cycle inventories that require better data quality or modeling, as well as identify processes that cause strong model response even when their uncertainty is narrow. The latter need particular attention, because they are capable of making substantial differences in interpretation of LCA results. All implementations developed in the scope of this work are freely available as Python packages.

5.01.T-08 Consequential Life Cycle Assessment of Wild-Caught Fish Products

Jonas Eliassen¹, Michele De Rosa¹ and Jannick Schmidt², (1)2.-0 LCA Consultants, Aalborg, Denmark, (2)Aalborg University, Denmark

The food industry accounts for a sizeable amount of global greenhouse gas emissions exacerbated by a growing population and increasing consumption per capita. Life cycle assessment (LCA) is a popular method used to quantify environmental impacts in a life cycle perspective. This presentation showcases a consequential LCA of 3 seafood products which aims to assess the environmental impacts from the consequences of an increase in demand for the products. Supply of wild-caught fish have stagnated in recent decades due to the oceans reaching their ecological carrying capacity, whilst supply of fish from aquaculture has seen rapid growth. This indicates that wild-caught fish are constrained and aquaculture is the marginal source of fish which will increase its production to meet higher demand. Thus, a consequential LCA of fish products typically excludes the constrained supply of wild fish and focuses on the marginal increase in aquaculture production. This study presents a more complete consequential LCA of three products from the company Kangamiut Seafood: Fileted cod, peeled prawns and shell-on prawns. The functional unit used is 1 kg of each product. This model accounts for the consequences of increasing demand for Kangamiut Seafood products, namely that other fishing companies are displaced. Thus, we include this displacement of the average industry activity as part of the model. Additionally, aquaculture is included due to increasing the market demand for fish products which cannot be met by wild-caught fish. Consequently, the environmental footprint of the products is calculated using inputs of aquaculture, Kangamiut Seafood’s landing and processing operations as well as the displacement of the industry average operations. This enables a consequential LCA which includes the cause-effect relations on the market for fish products and can account for improvements within the constrained wild-fish supplier and thereby enabling the differentiation of different fishing methods with varying environmental impacts. In this view, the fishing company can quantify any improvements in their operations in relation to the total impact from their product in a consequential perspective. Improvement scenarios are included to assess the benefits of improving Kangamiut Seafood’s landing operations.

5.01.T-09 Quantifying Uncertainty Elements in LCI Modelling of Chemical Mixtures Used for Footwear Production

Giovanni Codotto¹, Laurent Vandepaer² and Massimo Pizzol¹, (1)Aalborg University, Denmark, (2)On AG, Switzerland

The fashion industry is a fast-growing sector that requires the application of high amounts of chemical substances along the different production processes involved. Consequently, a large degree of pollution is generated, both in terms of ecosystem and human health. Lately, many fashion brands have realized the magnitude of environmental burdens created by their products and have thus committed to transition into more sustainable alternatives. This objective is often supported in the industry by Life

Cycle Assessment studies. However, in the long and complex supply chain of fashion products, accurate data is often lacking and difficult to retrieve. For this reason, the chemical substances can be improperly assessed leading to an inaccurate compilation of the Life Cycle Inventory. The purpose of this work is to analyse a specific case study for the production of footwear and quantify quantitative and qualitative sources of uncertainty related to the modelling of chemical substances. These uncertainties are identified in different elements of both foreground and background data systems and are quantified stochastically by randomly sampling a significant number of inventory values within their range of uncertainty. The set of values obtained are used to model the inventory for the production of one functional unit. An impact assessment for global warming potential is performed to evaluate the contribution of the single elements to the total output of the model. Results show that uncertainties in both data systems are substantial, and a wide range of different results can be obtained from the LCA of the same product. The outcome is expected to determine what is the level of confidence in the LCI of industrial products, such as footwear, requiring use of chemical substances.

5.01 Advancement in Life Cycle Inventory Modelling: better data, more accurate assessments (Virtual Only)

5.01.V-01 Ecodesign of Urban Project Using City Information Modelling

Alexandre Mielniczek¹, Charlotte Roux² and Florence Jacquino¹, (1)Gustave Eiffel University, France, (2)Navier - ENPC, France

Environmental impacts are to be taken into account as early as possible in the design stages of urban projects so as to be able to select the most sustainable design. Nowadays, more and more district digital models, modelled according to BIM (building information modelling) standards and guidelines, are produced during the conception and construction of new or renewed districts. Those so-called City Information Models (CIM) can store data about buildings, underground utilities, roads, city furniture and vegetation (positioning, dimensions, materials and sometimes technical properties). Data about buildings are already used for LCA at the building scale (Marrero et al. 2020) and have been exploited at the district scale to evaluate impact of materials used for construction (Delval et al. 2018). A consequential approach (ie. evaluating environmental consequences of a change in the existing system, here the building stock or the city) could be considered as the most relevant for ecodesign objectives but is too rarely performed (Frischknecht et al. 2016; Roux 2020). Complementary data from CIM could be used to enhance consequential LCA at the district scale and simulate various scenarios (local climate conditions, shadow analysis from building morphology, impact of public spaces, roads and underground utilities, etc.). This induces a greater complexity as far as data modelling and processing are concerned. Research on urban analysis from CIM data has shed light on numerous issues to be tackled in order to be able to perform analysis at the district or city scale thanks to a CIM, including georeferencing, level of detail management, definition of specific entities and property sets and need for generalized entities (Deprêtre et Jacquino 2021). Through this work, we aimed at identifying more precisely CIM data potential for consequential LCA at the district scale in order to propose new methods and processes and test them on case studies. A literature review is performed on eco-design and city information modelling aside with a review on existing city models. Main research potential to improve LCA of urban project are identified and classified according to the goal and scope of the study. A first field case study is exposed and major drags and opportunities to district LCA are discussed in this specific case where an existing model has been developed without considering an eco-design objective.

5.01.V-02 Energy Analysis of Air Conditioners Using Big Data and Artificial Intelligence

Genta Sugiyama¹, Tomonori Honda² and Norihiro Itsubo¹, (1)Tokyo City University, Japan, (2)National Institute of Advanced Industrial Science and Technology, Japan

In October 2020, the Japanese government announced its “2050 Carbon Neutral” vision, and as a mid-term goal, it set a target in its Global Warming Prevention Plan to reduce Greenhouse Gas (GHG) emissions in 2030 by 45% from the 2013 level. In particular, the household sector is need to achieve the largest reduction of all sectors, with a 66% reduction from the 2013 level over the remaining nine years. Among home appliances, the power consumption of air conditioners (ACs) is particularly sensitive to outside temperature and consumer’s lifestyles, and the amount of power consumption fluctuates greatly depending on the time of year. Therefore, to reduce GHG emissions from electricity, which account for about half of all GHG emissions from households, it is essential to make efforts to reduce electricity consumption by reviewing consumer’s lifestyles. The concept of Life Cycle Assessment (LCA) is used when aiming to reduce GHG emissions. LCA is a method to quantitatively evaluate the environmental impact of each life stage of a product or service, from procurement of raw materials, manufacturing, transportation, use, disposal and recycling. Through this assessment, hot spots can be identified and utilized to formulate strategies for reducing GHG emissions. In the LCA case study of ACs, it was shown that the usage stage of ACs accounts for about 90% of the environmental impact, and that the calculation results vary greatly depending on the local climate and operating conditions. In addition, the Japan Industrial Standard, which is used as a guide for the usage time in the conventional calculation, assumes 18 hours of usage time per day, which is not a realistic figure for calculation. Therefore, it is stated that it was difficult to collect the data necessary for the calculation of GHG in the existing survey. As described above, energy analysis and environmental impact assessment using existing industry data on air conditioners are based on scenario settings and do not reflect the actual status of air conditioner use, which has been an issue. In this research, we will use hourly data of 70,000 ACs and artificial intelligence to clarify the actual use of each region and climate. Then, future estimates based on future temperature scenarios will be conducted based on the clarified usage conditions, and changes in heating and cooling demand due to climate change, lifestyles and equipment performance toward the realization of a carbon-neutral society will be examined.

5.01.V-03 Global Spatialized Pesticide Application Data for Use in LCA

Yuyue Zhang¹, Anja Gladbach², Marissa B Kosnik³, Peter Fantke⁴, Luke Settles⁵ and Daniel Glas², (1)DTU (Technical University of Denmark), Denmark, (2)Bayer Crop Science, Germany, (3)Technical University of Denmark (DTU), Denmark, (4)Technical University of Denmark, Denmark, (5)Bayer Crop Science, United States

Pesticides (active chemical ingredients in plant protection formulations) are widely used for agricultural pest, weed and disease control, with estimated three million tonnes applied in 2018. Hence, reliable life cycle inventory (LCI) data for emissions of pesticides are crucial for assessing as well as optimizing crop protection actions and minimizing environmental impacts across various agricultural practices, for identifying related hotspots, and for evaluating agrifood products and systems in life cycle assessment. Since pesticide emissions are usually unknown, they must be estimated from reported mass applied and treated area. However, such a global application dataset including ideally all relevant agricultural crops, regions, and crop protection practices is currently missing to generate LCI data for the wide range of marketed pesticides. The aim of this study is to address this gap by generating a global, comprehensive, and spatially resolved application dataset for currently marketed pesticides as a starting point for quantifying LCI emission data and to be coupled with respective toxicity and ecotoxicity characterization results for pesticides. The starting point is the AgroWin dataset, purchased via Bayer CropScience from a commercial data provider covering 673 crop types with 368 crop growth stages were included, with more than 1100 pesticides applied to these crops across 94 nations or regions for 2018. The dataset was first curated and harmonized to align the information. Then different statistical imputation methods were applied to fill in gaps in the reported dataset for crop growth stage, application method, and applied pesticide amount. Finally, resulting pesticide application data were combined with geospatial crop distribution maps to generate a set of global gridded maps of 5 arc-min resolution. Our global pesticide application dataset constitutes a viable starting point for generating emission and impact score information for use in life cycle assessment and environmental footprinting of agrifood systems and beyond. Furthermore, spatialized pesticide application maps inform how to improve current agronomic crop protection practices, in line with national and regional regulations.

5.01.V-04 Regionalizing Ecoinvent With EXIOBASE for More Precise Inventory and Regionalized Impact Assessment in LCA

Sidi Peng and Stephan Pfister, ETH Zurich, Switzerland

Different hybrid LCA approaches have been developed in the past, mainly for extending process-based LCA with input-output data. One main research area and data gap in LCA is the limited spatial detail of background data. State-of-the-art Life Cycle Inventory (LCI) databases like ecoinvent have a global coverage, but low regional resolution, with the main exception of energy mixes. In this study the industry-by-industry input-output-table of the Exiobase database is used to increase the regional resolution of the ecoinvent LCI database. For this purpose, new LCI unit process datasets are created for all regions in Exiobase, based on corresponding dataset in the ecoinvent database. The economic relation between the industry sectors and regions from Exiobase is then employed to re-link the newly created unit process datasets. It means that all processes in ecoinvent are allocated to respective regions in Exiobase and in case without a direct match, the processes from aggregated ecoinvent regions are copied for all Exiobase regions within these (e.g. RoW and RER). Because every process in the resulting “technosphere” matrix with more than 335’099 rows and columns has a clearly defined location, the supply chain includes origins of input processes as reflected by multiregional exchanges in Exiobase. Our study regionalizes the full ecoinvent database with Exiobase and thus combines to state-of-the-art databases and the different strengths. While ecoinvent provides more precise technological representation, Exiobase provides more regionalization. The result is an automatic way to derive markets for processes in ecoinvent and thereby allows utilizing regional process available in ecoinvent, such as electricity mixes, in the supply chain of all ecoinvent processes. It has to be noted that sector resolution is limited as in all MRIO studies, and important market mixes should still be improved by more specific data in the future. We analysed several cases in detail to showcase the advantages of the new database. For example, water consumption impacts of beef production, including regionalized impact assessment. While the LCI results of the regionalized inventory only changed by around 5-10% (since the process specific exchanges such as irrigation water have not been adjusted), the LCIA scores using AWARE fluctuated by up to 90% for the 44 countries covered in Exiobase.

5.01.V-05 Validation of a Conceptual Framework for Better Understanding of Environmental Performance of Product Cascades: A Case Study of Reuse of Shell Jackets

Hampus André¹ and Anna Björklund², (1)Sustainable development, Environmental Science and Engineering, KTH Royal Institute of Technology, Stockholm, Sweden, (2)KTH Royal Institute of Technology, Sweden

Life cycle assessment (LCA) research on the environmental performance of circular economy (CE) measures enabling product cascades e.g. such as reuse and repair and has been criticized for not taking sufficient account of functional (in)equivalency of circular and new products, displacement rates, rebound effects, product use and user behavior. Because of this, our understanding of the environmental performance of CE is limited and, probably, overoptimistic. A conceptual framework has been developed to make it easier for practitioners to collect and structure data used for better modelling related to the mentioned limitations. Ultimately, the aim of the framework is to contribute to better understanding of the environmental performance of CE measures. The purpose of this paper is to validate the usefulness of that conceptual framework. The usefulness of the framework is validated through a case study on reuse of shell jackets enabled by “premium second-hand” stores. The framework prompts data collection on product-user characteristics such as functionality (both strict product-related properties and broader properties related to user values), use cycle duration, product lifetimes, frequency of use, price and displacement. It also offers a structure for mapping such data into a coherent and comprehensive comparison. Data is collected through user questionnaires, interviews with store managers, sales statistics and lab tests (on functionality deterioration over the life cycle e.g. water repellency). The collected data, inter alia, allows for testing the sensitivity of functional units, e.g. ownership-oriented, in-use-oriented and functionality-oriented.

Results are indicated to be sensitive to the functional unit definition which calls for sensitivity analysis in CE LCAs where several functional unit definitions could be sensible. This case study demonstrates the significance of aspects included in the framework which are largely overlooked in state of the art CE LCAs of product cascades. In doing so, it demonstrates the usefulness of collecting and organizing data which underlie these aspects through the use of the framework. Thereby, the framework seems to be an accessible and time-saving tool which allows for capturing a higher level of complexity in CE LCAs. Future research could develop it further by application in other sectors. As yet, it is a useful contribution towards better understanding of the environmental performance of CE.

5.01 Advancement in Life Cycle Inventory Modelling: better data, more accurate assessments (Poster)

5.01.P-Mo242 Comparison of Municipal Solid Waste Management Systems Using the Economic Input-Output LIFE Cycle Assessment Method

Rasit Firat Deniz¹, Xiaoju Chen² and Nur Orak³, (1)Environmental Engineering, Marmara University, Istanbul, Turkey, (2)Carnegie Mellon University, United States, (3)marmara university, Turkey

Solid waste management is not only an environmental problem but also causes universal economic loss. Within the scope of this study, existing field data for packaging waste management systems in Avcilar Municipality of Istanbul, Turkey, is used to compare the environmental impacts of the current collection method with the alternative collection scenarios. The Economic Input-Output Life Cycle Assessment (EIO-LCA) method is used for the analysis. The field data obtained by the licensed packaging waste collection company of Avcilar Municipality through field observations. For this stage, a recording system was developed in the sorting facility and the expenditures of 18 different items such as waste amounts, fuel costs, and worker expenses. NAICS codes and expenditure items in the packaging waste sectors were matched. In this study, Scenario 1 (S1), Scenario 2 (S2), and Scenario 3 (S3) were defined as 0% separation rate (mix waste), current separation rate (1.6%), and 50% separation rate. Results show that CH₄ is the main contributor to the total GHG emission for S2, while CO₂ becomes an equally important emission for S3. The main reason of high CH₄ emission in S2 can be the increased amount of mixed waste with organic waste content. The increase of CO₂ in S2 compared to S1 can be related to several factors such as more vehicle use and related fuel consumption in S2. There is no significant change for N₂O and other emissions between different collection scenarios. Among the three scenarios, S3 has the lowest GHG emission value: 950 t CO₂-eq less than S2 and 454 t CO₂-eq less than S1. The results show that alternative package waste management systems and better practices have a high potential to reduce GHG emissions in Istanbul and other cities of Turkey.

5.01.P-Mo243 A Parameterized Model for the Evaluation of Marine Operations' Impacts During the Installation Stage of Offshore Wind Farms

Manel Sansa¹, Romain Besseau², Paula Perez_Lopez³, Rhoda Fofack-Garcia⁴ and Melanie Douziech⁵, (1)France Energies Marines, Brest, France, (2)Mines Paris, PSL Research University, France, (3)MINES ParisTECH - OIE Research Center, Sophia Antipolis Cedex, France, (4)France Energies Marines, France, (5)Agroscope, France

Offshore wind farms have known a growing success since 1991 in Europe due to higher and more stable electricity generation compared to onshore wind farms resulting from more constant winds and almost no land use apart from the onshore substation to connect the turbines to the grid. During the installation stage, offshore wind farms require marine operations to transfer and install their different components. These operations have potential environmental impacts. In the scientific literature, the environmental impacts associated with the life cycle of wind farms are typically estimated using the Life Cycle Assessment (LCA) methodology. However, these LCAs often lack a detailed modelling of the installation stage. In fact, the assembly stage modeled in most of these studies only accounts for the fuel consumption linked to the used installation vessels. Also, most studies tend to report the climate change impacts of offshore turbines only, despite the larger range of potential environmental impacts associated with this type of electricity production. Finally, most published LCAs are static and specific for one offshore wind farm installation and thus difficult to adapt for other geographical or temporal contexts. The aim of this study was to include an extensive modelling of the on-site installation and assembly considering the required vessels into a flexible parameterized LCA model. This model builds uponecoinvent inventories and an already existing parameterized LCA model of offshore wind farms. This model extension adds site and vessel-specific parameters associated to the on-site erection and assembly stage to the model, using the Python *lca_algebraic* library. Moreover, we go beyond climate change impacts and explore additional potential impacts categories associated with the electricity production from offshore turbines following the recommendations of the ILCD handbook. Results from this study will enable a better modelling of the installation stage of offshore wind farms and a more accurate estimation of the overall environmental impacts of these farms.

5.01.P-Mo244 Closing the Gaps in LCA of Lithium-Ion Batteries: Case Study of a Lab-Scale Battery Cell

Merve Erakca¹, Sebastian Pinto Bautista², Samineh Moghaddas³, Manuel Baumann³, Werner Bauer³, Lea de Biasi³ and Marcel Weil², (1)Karlsruher Institut für Technologie (KIT) - Institut für Technikfolgenabschätzung und Systemanalyse, Germany, (2)Helmholtz-Institute for Electrochemical Energy Storage HIU and Karlsruhe Institute of Technology KIT, Germany, (3)Karlsruhe Institute of Technology KIT, Germany

Battery storage systems have become a major pillar in the transformation of the energy and transportation sectors seen during the last decade. Lithium based batteries are the dominating technology in this process, making them constant subjects of sustainability analyses. Several Life Cycle Assessments (LCAs) for Lithium-ion Batteries (LIBs) have been performed over the last years to assess their environmental footprint, but the amount of primary data available concerning their manufacture remains low. This work presents a screening of the most recent environmental assessments for LIBs with the goal of identifying deviations of

results, remaining gaps and challenges, while also providing a detailed LCA of a lab-scale battery cell production. It is observed that many studies repeatedly refer to only a few disclosed datasets for their own analysis, while some others do not provide their data acquisition process in a clear manner. This creates a need for new transparent datasets in order to perform more reliable and robust assessments. The analysis hereby presented offers primary data of battery manufacturing, which contributes to reduce the data gaps in this field. Transparent description of data, sources, assumptions and results eases the understanding of the different dynamics within the life cycle of the batteries, which lastly determine its environmental profile. The hotspots identified in the baseline analysis are related to process inefficiencies, characteristic of lab-scale production. A sensitivity analysis provides insights into the potential effects of upscaling. When the manufacturing conditions reflect industrial-scale production levels, the footprint of the cells is drastically reduced, dropping to values comparable to those presented in the literature. Significant improvements in most categories have already been observed when only the throughput of cells in the dry-room is increased. Additionally, ensuring low material loss-rates will grant the largest improvements related to resource criticality. Lastly, if the upscaling goes in hand with a transition to clean energy sources, the combined benefits could bring the footprint down to a small fraction of the initial estimations.

5.01.P-Mo245 Combining Electrochemical Cell Models With Primary Data for Advancing the Assessment of Emerging Stationary Battery Systems

Jens Peters¹, Friedrich Jasper², Jana Späthe³, Manuel Baumann², Marcel Weil⁴ and Sebastian Pinto Bautista⁴, (1)Universidad Alcalá de Henares, Spain, (2)Karlsruhe Institute of Technology KIT, Germany, (3)Karlsruhe Institute of Technology (KIT), Germany, (4)Helmholtz-Institute for Electrochemical Energy Storage HIU and Karlsruhe Institute of Technology KIT, Germany

While detailed life cycle assessment (LCA) models for electric vehicle (EV) batteries are available, this is not the case for stationary battery systems (SBS). The latter are mainly modelled based on inventory data from EV batteries, although their layout differs substantially. In addition, the cell chemistries typically used in SBS differ from those of EV batteries due to the lower relevance of energy density for stationary applications. Especially iron phosphate-based lithium-ion batteries, but also emerging cell chemistries like different sodium ion chemistries are promoted for SBS. However, little information about the corresponding materials and system components used in SBS is available, and the uncertainty in the life cycle inventory (LCI) models is correspondingly high. To overcome this situation, we present a complete LCI for five emerging sodium-based cell chemistries, derived from a detailed cell modelling starting from basic electrochemical parameters, relying on a modification of the BatPac dimensioning tool. The openly available tool also incorporates a new cell-specific recycling model and readily generates inventory data for manufacturing and recycling of the different cell chemistries, taking into account their individual material composition. These inventory data on battery cell level are then combined with primary data for a stationary home storage system, obtained from a piece-by-piece disassembly of an existing system. In combination, this significantly advances the state of the art in LCA of SBS and reduces modelling uncertainties. In fact, the differences to previous assessments are significant, both in terms of the battery system components (with electronic components contributing more to the total environmental impacts of the SBS than frequently assumed), but also regarding the battery cells, where high differences between different cell chemistries are obtained. Interestingly, some of the assessed sodium ion battery cells show a very promising performance and might therefore be a promising alternative to current lithium ion batteries for SBS.

5.01.P-Mo246 Towards Better Modelling of Inventory Uncertainty

Chris Mutel, ETH Zurich, Switzerland

In most LCA practice, uncertainty analysis is locked in a cupboard under the stairs - part of the family, but not given the same love as the other children. Current practice lacks tools that allow us to better express the knowledge we have about the performance of systems we are trying to model. The best available option for expressing non-linear relationships is writing formulas as text strings, an approach that is not portable across software systems, does not allow for software best practices such as testing and continuous integration, and does not scale beyond a few datasets. In this poster, we introduce a set of innovations available as free and open source Python software, with a reference implementation in the Brightway framework. The first step is to recognize that not all inventory calculations can or should be done by the LCA software. Instead, we introduce defined interfaces, which allow for dataset-specific values to be generated by outside software or web services on-demand during the static or stochastic LCA calculation. In a case study, these interfaces allowed for two-way communication between LCA software and an Aspen simulation. We also extend the concepts of "pre-sampled data" to make such arrays the core of iterative LCA calculations. By supporting the use of arrays of data, instead of a single static vector of "best-guess" values, one can incorporate both measured population data and multiple possible scenarios in a single, intuitive structure. These arrays can express correlation across datasets or even databases, and have no inherent limitations in their flexibility. In many cases, they will have substantially higher quality than fitted probability distribution functions. Finally, we define an open data format, based on the Datapackage standard, which allows for static and stochastic inventory data and metadata, including population and scenario data, to be exchanged across computers and even LCA software systems. This datapackage also separates the computation of LCA results from inventory data entry, allowing for cloud-based calculations. Although the innovations described here have so far only been implemented in the Brightway ecosystem, we encourage other developers to borrow our code and ideas to allow the community to substantially improve the quality of our inventory models, especially under uncertainty. Rigorous uncertainty assessment is a critical component of comparative LCA.

5.01.P-Mo247 Quality and Temporal Relevance of Lithium Supply Data for Life Cycle Assessment

Mudit Chordia¹, Sanna Wickerts², Anders Nordelöf³ and Rickard Arvidsson⁴, (1)Chalmers University of Technology, Gothenburg, Sweden, (2)Environmental systems analysis, Chalmers University of Technology, Gothenburg, Sweden, (3)Environmental Systems

Analysis, Technology Management & Economics, Chalmers University of Technology, Göteborg, Sweden, (4)Environmental Systems Analysis, Chalmers University of Technology, Gothenburg, Sweden

Lithium-based batteries are increasingly being implemented for storing energy, both in transportation and stationary applications. As battery manufacturing matures and becomes more efficient, the environmental burdens of these batteries shift upstream, for example to the lithium supply. The majority of the current global lithium supply comes from two sources – spodumene mined in Australia and brines extracted in Chile. In this study, we review existing life cycle assessment literature on lithium production regarding data completeness and quality, as well as temporal and geographical relevance. Preliminary results indicate that the currently most used datasets in life cycle assessment studies of lithium-based batteries lack quality and representativeness of current operations. To address these gaps, this study compiles several new datasets for lithium production representing different geographies, technical processes, and lithium grades. First, we compare the inventory data of other existing lithium supply datasets, both older and newly compiled, regarding their quality and representativeness. Second, we look at future scenarios for lithium supply based on global proven reserves and analyze the influence of changing grades on future environmental impacts. Third, we examine the potential for reducing environmental impacts from the lithium-supply chain by linking all electricity inputs to renewable sources. Finally, we use the various lithium datasets compiled in this study to update the results of a giga-scale lithium-ion battery manufacturing in a recently published study. We focus on climate change and mineral resource use impacts. Additionally, to inform a growing debate in scientific literature around the water use impacts related to brine and freshwater extraction in water-stressed regions of the world, such as the salars in South America, we use regionalized water use assessment indicators to further assess the burdens of battery production from water use perspective.

5.01.P-Mo248 FAIR Data in LCA - Principles to Practice

Agneta Ghose, Planning, Aalborg University, Denmark

The key to increase the reliability of a LCA is to increase reproducibility, interoperability and accessibility of its data. Implementation of data management in addition to integration of data services can facilitate the development of FAIR LCA inventory data. We present and discuss the type and appropriateness of different data structures and technologies to manage the diversity, size, and complexity of current and future data sets that are relevant in LCA context. We show how implementing a data management plan for LCA studies supports the FAIR data principles. For example, ensuring data description (metadata format and documentation), legality (licensing, confidentiality, ethics) and storage (repositories, publications). With respect to interoperability, we introduce the benefit of linking LCA databases to the semantic web. Semantic web supports the ability of computer systems to exchange data with shared meaning. Integration of LCI data to the semantic web provides opportunities to work with data outside the domain, thus improving quantity and type of data availability. This work contributes to the definition of best practice measures to support the development of database infrastructure for LCA.

5.01.P-Mo249 Site-Specific Life Cycle Inventory Modelling of Lithium Carbonate Production From Brines

Vanessa Schenker¹, Stephan Pfister², Christopher Oberschelp³ and Stefanie Hellweg², (1)Institute of Environmental Engineering, Institute of Environmental Engineering, ETH Zurich, Zurich, Switzerland, (2)ETH Zurich, Switzerland, (3)ETH Zurich, Zurich, Switzerland

The transition towards low-carbon technologies requires metals. One of them is lithium required for energy storage, in particular for the electrification of the mobility sector. However, lithium extraction is associated with environmental impacts. The energy-intensive production of lithium carbonate contributes to climate change, while the lithium extraction from brines affects water scarcity in arid areas and hence, fragile wetland and lake ecosystems. A specific focus in science has been lithium extraction at the Salar de Atacama in Chile where life cycle inventories (LCI) exist. However, due to the increasing demand for lithium, brine operations in Argentina, the U.S., and China have started to produce lithium carbonate. Processing is adapted to the brine chemistry since impurities, such as magnesium or boron, highly impair the lithium recovery rate during processing. Hence, the question rises if the existing LCI still reflect environmental impacts of lithium carbonate from brines. This study aims to quantify the environmental impacts of 1 kg lithium carbonate (battery grade). We modelled LCIs for five brine operations in Argentina, Chile, and China. Scientific literature, patents, and company reports were used to develop processing sequences. A detailed analysis of relevant processes yielded the quantification of resource consumption as well as waste production. The ReCiPe endpoint method (2016) applying the hierarchic perspective was used to assess environmental impacts. Since transportation heavily contributes to health impacts from climate change and fine particulate matter formation, these impacts are crucial when assessing impacts of lithium carbonate production from brines. The variability of both impact categories is substantial. The Chinese salt lake has highest impacts due to heat and electricity demand. Lithium carbonate produced from the four brine operations in Argentina and Chile have lower impacts. Their impacts are dominated by the chemicals demand. Hence, highly resolved LCIs as resulting from our research are required to (1) identify environmental hotspots, and to (2) find mitigation potentials within the lithium supply chain. These modelled LCIs are furthermore crucial to (3) assess the contribution of lithium carbonate production to the total environmental impacts related to Li-ion batteries and to (4) create a solid data base for the future evaluation of secondary lithium carbonate production.

5.01.P-Mo250 LCA on Different Production Routes of Calcium Zincate Synthesis

Sergi Arfelis¹, Pere Fullana¹, Irene Malpartida², Vincent Caldeira³ and Alba Bala¹, (1)UNESCO Chair in Life Cycle and Climate Change (ESCI-UPF), Spain, (2)Deasyl, S.A., Switzerland, (3)Easyl, France

Calcium zincate may be used in zinc anode of an alkaline electrochemical generator, heterogeneous catalyst for the production of biodiesel or antifungal products. The conventional reactions which have been studied in the synthesis of calcium zincate are: 1) Hydro-chemical route, 2) Hydro-thermal route and 3) Hydro-mechanical route. These processes present several drawbacks, such

as requiring long reaction time or having numerous energy intensive steps. The Hydro-thermal route seems to be the most competitive conventional reaction for calcium zincate production at laboratory. The presentation will show the life cycle environmental impacts of a new and unusual synthesis which is part of the field of mechanochemistry: Hydro-micro-mechanical route. It will be compared towards the hydro-thermal route at a lab-scale. This new process, patented by EASYL (2016), may be operated continuously and at industrial scale. In addition, its environmental impacts will be assessed for the production of Calcium Zincate crystals for 7 different scenarios. The results will be forecasted for 2030 and 2050 taking into consideration the European electricity mix modifications according to SDGs Roadmap. Finally, this comparison will be complemented with an economic analysis and an optimisation of the transportation strategy.

5.01.P-Mo251 LCA Data Collection for Decision-Making in Process Selection of Conversion of Woody Biomass Into Sugars

Polina Yaseneva¹ and Niamh Ryan², (1)Cambridge Institute for Sustainability Leadership, University of Cambridge, Cambridge, United Kingdom, (2)University of Cambridge, United Kingdom

Woody biomass could potentially become a viable raw material for the future sustainable chemical industry. For this, a suitable regulatory framework must exist, that would create favourable economic conditions for wood biorefineries. Such policies must be developed on the basis of scientific evidence, in this case - data supporting the environmental advantages of the bio-based feedstocks to the chemical industry. The most suitable methodology for comprehensive evaluation of environmental performance of technologies is life cycle assessment (LCA). European Commission's report on environmental Impact assessment of bio-based products proposes use of modular approach when collecting life cycle inventory data according to life cycle stages of a bio-chemical. In this review, we collected process data on existing semi-industrial processes of wood fractionation and attempted to match them with LCA datasets available in open sources in order to compare environmental performance of different methods. It has been revealed that the majority of the openly available studies do not contain transparent inventory data and, therefore, cannot be verified or re-used. Lack of inventory data also prevents comparison between studies of the same processes performed with different evaluation methods or using different system boundaries. While it is frequently argued that revealing full inventories is impossible due to issues of commercial sensitivity, since a full inventory may be reconstructed to reveal technological details that may form the basis of a competitive advantage, the lack of inventories is hampering transition to sustainable technologies, as decisions on policies to take technologies forward rely on science-based evidence. It is, however, possible even today to represent processes as input-output black-box models, such that any commercially sensitive details are not made public while the important environmental data over the whole supply chain is available. This issue is discussed within the context of full digitalisation of the chemistry value chain, which is likely to be reflected in forthcoming national and regional policies.

5.01.P-Mo252 Unravelling Modelling Strategies of Algae Systems: Towards Improved Transparency and Interoperability in Life Cycle Inventories

Lea Braud¹, Kevin McDonnell² and Fionnuala Murphy², (1)University College Dublin, Dublin, Ireland, (2)University College Dublin, Ireland

Life Cycle Assessment (LCA) has been used for more than 20 years to assess the environmental impacts of algae systems. The diversity of algae species, cultivation techniques, and processing pathways has led to unique algae system designs. In addition, the methodological choices made by practitioners in the goal and scope and Life Cycle Inventory (LCI) increase the variability of LCA results. This study introduces a framework to enhance the transparency and interoperability of data inventories and therefore improve the comparability of LCA results. An extensive literature review was conducted to identify the modelling approaches used to mitigate the environmental impacts of algae systems over the past 20 years. The outcomes of the review served as basis for the development of the LCI framework. The results of the literature review showed that the main strategies used to mitigate the environmental impacts of algae systems include the consideration of multiple products, the use of the bioremediation potential of algae, and the design of closed-loop systems. Although seasonality influences the algal biomass content and productivity, temporal variations were rarely considered in data inventories. Finally, the analysis of the methodological choices highlighted the strong link between the functional unit, modelling perspective (attributional versus consequential), and method to solve multifunctionality. The modular LCI framework builds on Brightway2 and uses additional Python packages to include seasonal variations into LCI, facilitate co-products management, and simplify the linking of foreground and background systems. A dynamic algae growth model generates seasonal data for an open raceway pond cultivation system. Foreground and background scenario development allows the assessment of various algal biorefinery designs with different biogenic carbon flow dynamics. The algorithm was tested using data collected in a pilot scale *Spirulina* cultivation facility in the frame of the European SpiralG project (BBI-H2020). The algae dynamic growth model can be adapted to any micro- or macro-algae system and the flexibility of the LCI framework allows to conduct prospective LCA studies. Therefore, this tool could be used to support the development of any algae-based products from laboratory to commercial scale.

5.01.P-Mo253 Using a Regionalized Plastics LCA Database to Assess Environmental Impacts of Elastomers in Lightweight Applications

Laura Stellner, Arne Kätelhön and Raoul Meys, Carbon Minds GmbH, Germany

In the context of a global commitment to mitigate climate change, the automotive industry is forced to drastically reduce the carbon footprint and energy consumption of its fleets. For this purpose, elastomers can be used, as they reduce the weight and thereby energy consumption of each vehicle. To evaluate the application of novel elastomer materials, Life Cycle Assessment (LCA) is a powerful tool to determine the environmental impacts of products and services, providing a holistic view across environmental impact categories and life cycle stages. However, to provide a reliable decision basis for LCA practitioners, LCA

studies for the chemical and plastics industry require a large amount of data on chemical products and processes across global production and utilization chains. Gathering this data is especially challenging for industries with highly complex and globalized production chains, like chemicals and plastics. To support decision making, we developed a novel LCA database compliant with the ISO standards 14040 and 14044. Our chemical and plastics database contains approx. 1000 chemicals and plastics in up to 190 regions. The database is derived from a regionalized bottom-up model of the global chemical and plastics industry and is based on technical data as well as market and trade data. Thereby, the bottom-up model enables chemicals to be tracked throughout the global economy. Our bottom-up approach starts at the chemical plant level, linking information about the production site, production volume and production technology to detailed technical models for each production technology. Subsequently, these individual plants are allocated to integrated production sites and national, technology-specific or supplier-specific production mixes. Moreover, national consumption mixes are calculated by combining national production mix information with trade data. In this presentation, we use the novel LCA database to conduct an LCA study for the application of novel elastomer materials based on renewable resources, such as CO₂ and biomass. The work is part of the public project ReLEA, funded by the German Federal Ministry for Economic Affairs and Energy.

5.01.P-Mo254 Virtualization of Production Processes: An Innovative Approach for the Life Cycle Inventory and Dynamic Life Cycle Assessment

Mirco Piron¹, Alessandro Marson², Junzhang Wu Sr³ and Alessandro Manzardo⁴, (1)Università degli Studi di Padova, Padova, Italy, (2)University of Padova, Padova, Italy, (3)Department of Industrial Engineering, University of Padova, PADOVA, Italy, (4)University of Padova, Italy

Life Cycle Assessment (LCA) is used as a tool to assess the environmental impacts of a product, process or activity throughout its life cycle providing support for product eco-design. The Life Cycle Inventory (LCI) is the second of the four phases of the LCA methodology regulated by the ISO 14040 and ISO 14044 series of international technical standards and represents the most energy and time-consuming phase of LCA. The complexity of the LCI is one of the factors that makes LCA studies difficult to carry out within the business because it requires specialists capable of conducting the analysis, a strong collaborative attitude of management and a factory staff able to conduct the collection of primary data in an effective manner. In this context technologies involved in Industry 4.0 give a comprehensive view on how companies are organized and let acquire precise data on production activity. The analysis of these data, together with the development of new digital paradigms, represents an exploitable new focus to make the production more efficient, profitable and sustainable. The potentiality of this comprehensive data collection drives the present research project to define a method that integrates the Life Cycle Assessment with the availability of data provided by Industry 4.0. Specifically, is focused on the Digital Twin (DT) concept defining a procedure to develop a physical-to-virtual connection system that will lead to a dynamic Life Cycle Inventory construction as well as a dynamic evaluation of environmental impacts related to the production processes. Research results illustrate a framework for the construction of the digital twin system to make the Life Cycle Assessment dynamic and comprehend the improving transparency, completeness and interconnection between product, company and Life Cycle Inventory.

5.01.P-Mo255 A Triple Bottom-Line Evaluation of the Production of Animal Feed From Food Waste: A Life Cycle Assessment Approach

Alaa Eyad AlSaleh and Esra Eisa Aleisa, Kuwait University, Kuwait

We perform a triple bottom line (TBL) assessment of the environmental, economic, and social impacts of the production of animal feed from food waste (FW). Animal feed production scenarios (SRs) are compared to the current options of sanitary landfilling and incineration with energy recovery. Within TBL assessment, the environmental bottom line (BL) applies a gate-to-grave life cycle assessment (LCA) approach considering a functional unit of 1 ton of FW. The system boundaries are expanded to account for animal feed production savings and recovered energy. The economic BL is calculated through a cost-benefit analysis of the total costs and profits associated with the given technologies. The social BL relies on SWOT (strengths, weaknesses, opportunities, and threats) analysis to identify the key strengths, weaknesses, opportunities, threats, and strategies of the SRs associated with waste management systems. The analytic hierarchy process (AHP) is adopted to integrate and prioritize the alternatives based on the pairwise comparison techniques inherent in this method. The AHP ranked the animal feed production scenario as the optimal scenario, with a 45.01% preference over the other alternatives. Environmentally, the animal feed production scenario scored the worst in the climate change human health impact category due to the heating energy consumed during feed production and the low nutrient recovery rate (13.5%). However, further sensitivity analysis of this rate justified the above conclusion. Financially, the incineration scenario was the most economical scenario, followed by the animal feed production and landfilling scenarios. Socially, the animal feed production scenario scored the best in most indicators, while the incineration scenario scored the worst. All the assessments provide a basis for policy-makers to evaluate new technological FW management advances to improve current FW management systems.

5.01.P-Mo256 Prospects of Integrating Ecosystem Services Into Life Cycle Assessment: Application to a Mediterranean vineyard

Amandine Pastor¹, Esron Heineman², Eleonore Loiseau³, Arnaud Helias⁴, Philippe Roux⁵, Rossano Ciampalini⁶, Joao Pedro Nunes² and Damien Raclot⁷, (1)INRAE, UMR ITAP, lab ITAP-Elsa, groupe Elsa, France, (2)Wageningen University and Research Centre, Netherlands, (3)UMR ITAP, France, (4)INRAE - ITAP, Montpellier, France, (5)INRAE - Elsa-Pact Chair, France, (6)INRAE, UMR AGROECOLOGIE, France, (7)IRD, UMR LISAH, France

Life cycle assessment is a powerful tool to compare the environmental impacts of different systems along the stages of agriculture production. However, when it comes to representing the multifunctional aspects of agriculture, LCA has shown some limitations

[1]. Indeed, if a conventional farming system provides, in general, higher yields than agriculture with organic/soil conservation practices, then the environmental impacts of conventional farming are then more diluted into an agricultural product than with an organic farming system. Some of this misrepresentation is due to the coarse resolution of spatial data used in LCA (from archetypes to regional and/or national scales), some of it is due to methodological shortcomings such as the integration of nature's benefit into farming systems in LCA. Recent studies have proposed several frameworks for including ecosystem services in LCA [2]–[6]. However, there is yet a consensus on a common method despite the recent research advances. Today, there is a need to understand the state of the art of the proposed methods and whether implementation difficulties stem from data availability and/or accessibility, process modelling, and/or both. In this study, we present the state of the art from previous frameworks proposing the integration of ES into LCA methodology and tested recent developments on a specific case study: a Mediterranean vineyard Roujan. In this research, we evaluated several ecosystem services (water yield, erosion and carbon sequestration) with various spatially-explicit modelling techniques (from biophysical modelling with the LandSoil model [7] to more empirical models like InVEST). The objective of using spatially-explicit modelling is to improve the representation of biophysical fluxes in the LCA modelling chains. To test the different existing methodologies, we have chosen Roujan, a Mediterranean vineyard in the south of France that has been monitored for several years. This site is also representative of the Languedoc region where vineyards are the main agricultural activity. We then compared several input datasets, ES methods, and their respective impacts in LCA assessments. At this stage, the ES that were assessed are: < u1:p> - Carbon sequestration due to land-use change and land management with the InVEST model< u1:p> - Erosion due to different land use and land management with the LandSOIL and InVEST models< u1:p> - Water yield with the InVEST model< u1:p> The results presented offer a new perspective on how and why ecosystem services should be integrated into LCA assessments, especially for achieving a carbon-neutral society by 2050 in the context of achieving several SDGs.

5.02 LCA estimating trade-offs of emerging bio-based products and their uses

5.02.T-01 Effect of Environmental Prioritization in the Design of Biobased Supply Chains

Carlos García-Velásquez, Christof Defryn and Yvonne van der Meer, Maastricht University, Netherlands

Polyethylene terephthalate (PET) is one of the most used polymers worldwide, but its production relies on fossil-based feedstock. PET is made through the polycondensation of terephthalic acid (PTA) with ethylene glycol (EG). Both monomers are produced from the naphtha cracking; however, technological advances have made possible their production out of biobased resources. EG is produced from ethylene that can be synthesized from bioethanol using different biomass (food crops and lignocellulosic biomass). The technology for biobased EG is already commercially available, mainly using sugarcane. On the other hand, para-xylene (PX) is the main building block for PTA production, but its production still relies on naphtha cracking. Different pathways for PX production are available, from commercial scale (GEVO process) to lab-/pilot-scale (Alders-Diels reaction). All these technological pathways use biomass (corn and sugar beet) to produce PX. From the economic perspective, these biobased alternatives seem feasible, especially in the current lack of support to fossil-fuel companies and high oil prices. However, the environmental benefits of these alternatives compared to the fossil-counterpart are still unclear due to the lack of knowledge on the environmental impact of biomass feedstocks (greenhouse gas emissions – GHG and other impacts), and the complexity in the design of the supply chains (SC). This study aims to understand the link between the environmental impacts of biobased materials (using the 100% biobased PET as study case) and the design of biobased SC that includes economic and environmental criteria. The analysis focuses on the European context. Life cycle assessment (LCA) is used as method to quantify the environmental impact of the biobased PET production using sugar beet for EG and *Miscanthus* for PTA. The feedstock selection for both monomers was based on the technological maturity (e.g., production of bioethanol from sugar beet) and the future relevance (e.g., *Miscanthus* is a non-food crop with high biomass yields and benefits for soil). The life cycle optimization (LCO) methodology is used to establish the link between the economic and environmental performance of the biobased PET SC. The accounting of environmental impacts in optimization models for designing SC helped identify the impact categories (global warming, fossil depletion, eutrophication) with the highest contribution to the abatement of emissions in the whole supply chain.

5.02.T-02 Life Cycle Assessment of Brown-Seaweed-Based Plastic Production and End-Of-Life

Maddalen Ayala¹, Marianne Thomsen² and Massimo Pizzol¹, (1)Aalborg University, Denmark, (2)Aarhus Universitet, Denmark

The production and end-of-life of fossil-based plastics threaten the environment. While some bio-based plastics are presented as a potential solution to avoid fossil-based plastics, these usually have a high impact on land-use change. Seaweed is compound of biopolymers potentially used to produce plastic. Moreover, seaweed cultivation has environmental benefits and does not need land resources to grow. This study uses alginate, a polymer in brown seaweed, to create a bio-based plastic. This analysis aims to assess the production and end-of-life of this bio-based plastic using a consequential life cycle assessment (LCA). Different scenarios will be analysed: Incineration, recycling and biodegrading the bio-based plastic. The preliminary results show the impacts of producing this bio-based plastic, without considering the CO₂ uptake of seaweed cultivation and the end of life of the bio-based plastic. These preliminary results show that electricity is one of the highest impacts. The final results will include the CO₂ uptake of seaweed cultivation in the sea and different end-of-life scenarios, maintaining the carbon balance.

5.02.T-03 Py-Lca-Bio Open-Access Python-Based Integrated Platform Toward Fully Automated Life Cycle Assessment and Sensitivity Analysis, a Biorefinery CASE Study

Hanie Zarafshani¹ and Karel Van Acker², (1)KU Leuven, Leuven, Belgium, (2)KU Leuven, Belgium

Lack of transparency in life cycle assessment (LCA) analysis forecasts a wide range of LCA results, for example, the global warming potential (GWP) in the production of chemicals from the biorefinery may vary between a 50-80% reduction when

compared to conventional fossil-based chemical productions. One explanation for the difference in LCA results is the disparity in the utilized established assumptions to generate the LCA models and interpretation of the LCA results. Aside from that, the inventory computations are non-transparent, single-use, case-specific calculations that are not performed based on an open standard platform. Furthermore, manually uploading data to LCA software results in a time-consuming and error-prone LCA. Further methodological research may be necessary to improve the LCA results' transparency, reproducibility, and interoperability. The study aims to bridge this gap and develop an open-source python-based platform for extensively automating LCA study, including computing inventory and performing local and global sensitivity analysis of LCA results. This platform will thus allow for quick, free, and transparent biorefinery LCA study and local and global sensitivity analysis and uncertainty quantification of LCA results for several indicators concomitantly. The developed platform, named as PY-LCA-Bio, has four primary objectives: Setting up a framework for transparent and reproducible LCA studies of a biorefinery. Having an extensive facilitative function: Since the developed platform is considered an open-source platform, other researchers are encouraged to contribute to the project by modifying and expanding the platform's capabilities to meet their needs. Developing interoperability function: PY-LCA-Bio can swap formats and interface with other software. Increasing the contribution to sustainability analysis and improvements: PY-LCA-Bio, like all other open-source software, is entirely free to use and has no hidden costs. By performing the LCA with PY-LCA-Bio, it is possible to build life cycle inventory, perform LCA and perform the Global and Local sensitivity analysis along with the uncertainty analysis with just one click. Importantly, the produced inventory in PY-LCA-Bios is not limited to usage in PY LCA Bio. It can be used for the LCA of biorefinery on any platform.

5.02.T-04 Challenges Aligning LCA Results Across Bio-Based Industries

Søren Løkke¹, Massimo Pizzol¹ and Agneta Ghose², (1)Aalborg University, Denmark, (2)Planning, Aalborg University, Denmark

This paper reviews the challenges faced in applications of life cycle assessments of biobased production, and suggests how to deal with this challenge. The vision of the European bioeconomy is 1) to strengthen, scale-up and diversify the biobased sectors, 2) to deploy local bioeconomies across the whole of Europe, and finally 3) to understand the ecological boundaries of the bioeconomy [1]. The complexity of the biomass resource supply and demand makes it difficult to estimate what is the sustainable use of bioresources, and biobased sectors are predicted to grow, and thus increasing the demand for bioresources. This increases the demands for decision support safeguarding that the bioeconomy is operating within safe ecological limits. The paper investigates implementation of LCA's in research and innovation studies funded by the European Union, as well as current initiatives towards harmonising LCA practises. Central questions are *key challenges and needs with respect to the development of an LCA practises?* that can guide a sustainable development of the European Bioeconomy, and *how to achieve a balancing of two major strategies of standardisation vs a science-based approach to LCA.* The paper identify 7 core areas with challenges and needs, and conclude that LCA of biobased production faces challenges underlining the need to develop an overall framework for assessment of biobased products. This framework need to depart from the current standardisation trend in regulatory LCA and turn towards a science-based approach: 1) using integrated assessment models for scenario modelling, 2) building on consequential modelling of competition for biomass and land, 3) developing harmonised models for dynamic and time dependent carbon accounting, 4) derive sets of biodiversity and socioeconomic indicators, and 5) establish a harmonised guide to uncertainty analysis.

5.02 LCA estimating trade-offs of emerging bio-based products and their uses (Poster)

5.02.P-Mo257 Assessment of Corn Cob Particleboards - Thermal and Environmental Performance

Ana Isabel Ramos¹, Ana Briga-Sá², Sandra Pereira², Mariana Correia², Jorge Pinto², Isabel Bentes² and Carlos A. Teixeira², (1)INEGI, Porto, Portugal, (2)UTAD, University of Trás-os-Montes e Alto Douro, Portugal

Corn cob is considered an agricultural bio-waste with potential to be incorporated in the building sector, as a thermal insulation material. Nonetheless, more research is needed to establish a detailed analysis regarding building materials' thermal performance, when this waste is reused as raw material to assess their sustainability profile. This study aimed at evaluating the thermal behavior and the environmental impact of two distinct corn cob particleboards using different glue binders: Polyvinyl Acetate (PVA) and Fabricol AG222 (FAG222). An experimental study was performed to analyse the particleboards' thermal performance, allowing the estimation of the thermal transmission coefficient. A sustainability analysis was then carried out using a lifecycle assessment (LCA) tool according to ISO 14040 and ISO 14044. The functional unit "mass of material required to provide a thermal resistance (R) of 1 m²C/W" was considered for the calculation of the environmental impacts. The production and disposal phases were considered, incineration and landfill being the end-of-life options considered. Both particleboards have shown potential to be used as a sustainable building material for the thermal insulation of walls, FAG222 showing similarities with the current commercial insulation materials. Both options display environmentally friendly profiles, albeit the particleboard with PVA offers enhanced results for the landfill scenario. The estimation of land use change is the next step to be performed, in order to understand if a process scale-up would enable a viable path, consistent with circular economy principles. This research work is thus a contribution to the scientific knowledge regarding the valorization of agriculture wastes and by-products as potential eco-friendly building materials.

5.02.P-Mo258 Analysis of Key Issues and Methodological Guidance for Life Cycle Assessment in the Field of Circular Bioeconomy

Vanessa Zeller¹, Almut Güldemund² and Liselotte Schebek³, (1)Institute IWAR, Technische Universität Darmstadt, Darmstadt, Germany, (2)Technische Universität Darmstadt, Germany, (3)Technische Universität Darmstadt, Germany

The use of biowaste, biobased residues and CO₂ as feedstock for bioeconomy is promoted as an alternative to cultivated biomass that increases the pressure on land resources. Using alternative substrates for products with a higher added value compared to

waste treatment technologies, is part of the circular bioeconomy (CBE) concept. It is often expected that high-value use of alternative feedstock is environmentally beneficial, but further research on the performance of CBE-inspired products is needed. When conducting life cycle assessment (LCA) in the field of bioeconomy, the practitioner is confronted with specific methodological and data-related challenges regarding the assessment of CO₂, waste and by-products as feedstock and the modelling of circularity types that cannot be grasped with existing models (e.g. closed, open loop recycling; product cascading). Based on a literature review this study analyses these key issues, assessing CBE case studies and general methods used in circular economy. For the literature review, search queries and selection criteria were developed for two key issues and for the application areas. The analysis of selected studies was guided by the question whether the methods are suitable for decision support and whether they are applicable to biobased circular systems. The key word search resulted in a significant amount of articles (46% case studies, 54% general methods), most of them addressing circularity evaluation. The analysis of the selected literature identifies whether a clear differentiation between feedstock types is made and which methods are applied to evaluate their impacts. First results indicate that CBE case studies use the approach of “alternative fate” when biowaste are used, but apply other approaches for by-products. The next analysis step will link approaches with the decision context stated in the study and identify methods that support decision making. Evaluation of the selected general methods for the handling of feedstocks indicates that specific methods are available for different feedstock types. Also, rules for a consistent handling of the feedstock input side and the product output side are available, recently translated into generalized equations. However, their applicability for biobased feedstock is demonstrated for few examples only and the general suitability is not sufficiently discussed. From the results conclusions will be drawn about the necessity of improvements of the current modelling practice. We will further conclude about the suitability of methods for decision support and transferability of general methods to CBE applications. With this study we contribute to a more consistent modelling of alternative feedstocks and circularity in the emerging field of CBE.

5.02.P-Mo259 Environmental Evaluation of Phosphorus Recovery Processes From Wastewater Sludge Using LIFE Cycle Assessment

Gaspard Chantrain¹, Sylvie Gros Lambert² and Angelique Leonard¹, (1)University of Liege, Belgium, (2)University of Liège - Chemical Engineering, Belgium

In addition to the sanitary aspect of wastewater treatment, another function of wastewater treatment plants is to recover phosphorus from wastewater in order to limit the eutrophication phenomena that can severely damage ecosystems. This extracted phosphorus is mainly concentrated in the wastewater sludge. Nowadays with the ban on land spreading of this sludge, treatment options such as incineration are becoming more and more common. One of the problems with this method of sludge valorisation is that it breaks the cycle of phosphorus, which ends up in the residual ashes, often sent to landfill. In this context, the Interreg Phos4You (P4Y) project addresses the phosphorus (P) challenge. P is an essential nutrient for all living organisms. Though it is a finite resource on earth, P is largely wasted today. The EU acknowledged this by adding Phosphate rock to its list of critical raw materials in 2014. P4Y aims to develop technologies for phosphorus recovery from sludge. Various processes are developed and promoted during this project, ranging from thermo-chemical treatments to bio-acidification followed by precipitation directly integrated into the water treatment plant. A life cycle assessment (LCA) was carried out on four of these phosphorus recovery processes to quantify the environmental impacts of the processes and to identify the most polluting steps within each process, in an eco-design approach. The particularity of this LCA is to include the wastewater treatment plant in the system boundaries and then not to opt for the zero-burden assumption for the sludge. Sewage sludge is therefore not considered as waste and has an environmental cost. In order to avoid allocation problems between the water treatment function and the sludge production function of the treatment plant, two options have been studied. The first methodological approach is the extension of the system boundaries to take into account the wastewater treatment plant in addition to the treatment of the sludge produced. The system studied with this option in the framework of the Phos4You project therefore has two functions, wastewater treatment and phosphorus fertiliser production. The second methodological approach used is the avoided burden. This approach studies a system with only the wastewater treatment function and considers the fertilisers produced by recovering phosphorus from the sludge as avoided mineral fertiliser production. The environmental study showed that two of the four recovery technologies had an environmental advantage compared to the baseline scenario of sludge incineration. Acknowledgements - The authors would like to thank the Phos4You project (INTERREG VB NWE, n° NWE292), partly financed by the European Regional Development Funds, and the Walloon Region.

5.02.P-Mo260 Towards Including Non-Gaseous Climate Agents in Impact Assessment Methods for LCA of Wood Products in Canada

Charles Alexandre¹ and Annie Levasseur², (1)École de technologie supérieure, Canada, (2)Construction Engineering, École de technologie supérieure, Canada

Climate research made some progress in terms of quantifying non-gaseous climate drivers such as albedo modification from land use change and/or transformation and adding their influence into climate metrics, as these impacts have been shown important, particularly in boreal forests. Current life cycle assessment (LCA) methodologies exclusively include gaseous forcing agents, using equivalencies (potentials and timeframes). A few papers proposed a methodology to incorporate albedo modification into established metrics, but they do so by emulating a gaseous behaviour i.e., using characterisation factors (CFs) converting an instantaneous biogeophysical forcing agent (albedo) into a greenhouse gas equivalent. Some have noted the disparities between current climate metrics and the prompt nature of albedo. We think that albedo must be included differently into LCA in order to better represent the dynamics of forest management (steady-state, increased or decreased harvest rates, etc.). Our goal is, by using albedo change in Quebec forest management as a case study, to demonstrate the validity of empirical inclusion of non-gaseous climate drivers in LCA. We simulated the regrowth of a typical forest stand using age-albedo data for each cover types surveyed

by Quebec's forest ministry. This way, after using a dynamic tool such as DYNCO2, developed to implement the dynamic LCA method, we can approximate the cumulative forcing as the added influence of albedo modification during the life cycle of a hectare of forest during its regrowth. This newly quantified cumulative RF arising from ρ_{albedo} , in watts per m^2 and per hectare of a certain forest type, can be combined to regionalised production values for each cover type (in kg/ha) and added to the existing environmental databases (i.e., ecoinvent). From then on out, every attributional analysis using wood products will include the impact of ρ_{albedo} . We hypothesise that the results will be representative of each cover type and will add a predictable influence on the LCA of wood products in Quebec. If validated, the resulting method could be extended to Canada's entire boreal forest. Furthermore, a more comprehensive analysis of the climate impact from non-gaseous radiative agents will lessen the likelihood of selecting sub-optimal solutions. We hypothesise that the results will be sufficiently representative of each cover type to add a predictable influence on the LCA of wood products in Quebec.

5.02.P-Mo261 Environmental Assessment of Lignin-First Integrated Biorefinery Flowsheets: A Comparative Study for Bio-Based Platform Chemical Production

Ponnapat Watjanatepin¹, Jordy Verboven², Annelies De Meyer², Wouter Arts³, Sander Van den Bosch³, Miet Van Dael², Bert Sels³ and Karel Van Acker³, (1)KU Leuven, Leuven, Belgium, (2)VITO Flemish Institute for Technological Research, Belgium, (3)KU Leuven, Belgium

As the technological improvements in today's world advance, along with the rising demands in consumer products to accommodate the increasing world's population, the demand for platform chemicals has also increased gradually over the past years. For instance, the production of platform chemicals such as phenols have surpassed 10 million metric tons per year in 2015 and is expected to increase to at least 13 million metric tons in 2026. Consequently, climate change phenomena became more and more intensified as greenhouse gas emissions and other polluting substances are increasingly released due to the rise in linear consumption and production patterns. To this end, there are continued efforts to address the multifaceted climate change problem by various strategies, including reducing the fossil fuel dependency for platform chemicals, among others. This study has the ambition to address the significance of this shift towards bio-based platform chemicals rather than the current conventional chemical products derived from fossil fuels. Integrated biorefineries are one of the potential routes for bio-based chemical production, which has significantly lower environmental impacts when compared to conventional fossil-based production. This study investigated the environmental performance of the conceptual novel integrated biorefinery within the scope of the NIBCON project in Flanders, Belgium, based on various process flow diagrams. The integrated biorefinery converted wood chips feedstock into refined lignin oils along with the pulp and the aqueous sugar solution. The refined lignin oil can be subsequently upgraded into platform chemicals like phenols. To this end, a life cycle assessment was performed with the ReCiPe 2016 methodology in order to assess the environmental performance of the conceptual integrated biorefinery, excluding the energy demand of the bioreactor. The obtained results were then compared with the Hock's process, which is the conventional fossil-based production. The results demonstrated that the integrated biorefinery performed better than the conventional process in all cases for all impact categories except for land use and freshwater consumption. The global warming potentials for all biorefinery cases, excluding biogenic carbon, ranged from 0,59 to 2,06 $\text{kg. CO}_2 \text{ eq.}$ for all cases of the integrated biorefinery as opposed to 4,37 $\text{kg. CO}_2 \text{ eq.}$ for the fossil-based production when assessing the environmental performance of 1 kg. of refined lignin oil production. Critical process parameters, such as the energy consumption, water use and solvent recycling percentage, were also identified and investigated by means of the sensitivity analysis to determine further improvements on the integrated biorefinery technology. The research highlighted the importance of limiting or decreasing petroleum-based chemicals dependency, leading to significant reductions in global warming potential. Therefore, the study demonstrated that the novel integrated biorefinery could be an environmentally viable technological concept for producing bio-based platform chemicals.

5.02.P-Mo262 Systemic Assessment of Environmental Impacts of Regional Bioeconomies Using Biogenic By-Products and Wastes - a Stepwise Approach and Selected Results From a CASE Study on a German Metropolitan Area

Almut Güldemund¹, Vanessa Zeller² and Liselotte Schebek³, (1)Technical University Darmstadt, Germany, (2)Institute IWAR, Technische Universität Darmstadt, Darmstadt, Germany, (3)Technische Universität Darmstadt, Germany

By substituting fossil by bio-based resources bioeconomy (BE) concepts aim at being more sustainable while ensuring food and resource security. However, the growing demand for cultivated biomass may increase competition for land and lead to an intensification of agriculture and forestry, contributing to e.g. biodiversity loss. Changing the resource base towards biogenic by-products and wastes and processing them into high value products is part of the circular BE (CBE) concept and discussed as a potential solution to reduce such problems. The transition towards the BE is a global trend, with worldwide more than forty countries implementing political BE strategies. However, the successful implementation of a BE depends on regional conditions. This is especially given in the case of CBEs using biogenic by-products and wastes. Their availability varies regionally due to differences in conditions such as the density and kind of local industry, agriculture, forestry and population. Therefore, it is necessary to evaluate the environmental impacts of CBE at the regional level. In our poster we introduce a stepwise approach to develop BE technology scenarios that reflect regional conditions and to evaluate the environmental consequences of their implementation using LCA. The methodological proposal includes the following steps: (1) regional quantification of biogenic waste and by-products at the NUTS-3 level based on statistical data. (2) Identification of further region-specific conditions (e.g. industry focus, technological know-how) that should be considered in (3) region specific technology scenarios. They comprise a set of biogenic waste and by-product valorising technologies that match the regional conditions. In step (4) the environmental impacts of the selected BE technologies are evaluated using consequential LCA following the need to consider changes in feedstock demand or product supply. Finally, in step (5) the LCA results that are determined at the technological level must be extrapolated to the regional level. Based on the availability of biogenic waste and by-products the mix of technologies that can be

implemented in the region is determined. From the case study on the German metropolitan region Frankfurt Rhine-Main we show exemplary results, including the quantification of biogenic waste and by-products and the environmental impacts from the LCA of an innovative BE technology.

5.02.P-Mo285 Assessing Contribution of Food Label to Biodiversity Through a Predictive Indicator

Bastien DALLAPORTA¹, Anne Asselin², Natacha SAUTEREAU³ and Christian Bockstaller⁴, (1)ITAB, France, (2)Sayari, Saint Germain en Laye, France, (3)ITAB, French Research Institute of Organic Food and Farming, France, (4)Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France

The development of an environmental impact label on food products based on Life Cycle Assessment (LCA) is ongoing in France and Europe to meet environmental concerns, especially those linked to biodiversity drastic erosion. LCA shortcomings regarding impacts assessment on biodiversity concern coverage of some biodiversity components, inclusion of some farming or landscape management practices. We present a predictive indicator assessing the contribution of different food labels to biodiversity. This indicator is operational, transparent and adapted to all agricultural productions. Starting from the method of Lindner et al. (2019), we integrated more precise knowledge on the cause-effect relations between practices and impacts on biodiversity into the algorithms, using an original aggregation method based on fuzzy decision tree (Bockstaller et al. 2017). We aimed at describing associated biodiversity and applied the method on food quality and farming management labels (e.g. organic farming). Relevant management variables impacting biodiversity and principles guiding their structuration into a hierarchical decision tree were identified through a literature review. Current state of knowledge guided the CONTRA method parametrization regarding fuzzy class limits, membership functions and decision rules. Data to calculate indicators were retrieved from label guidelines. Missing data due to management items not covered by guidelines were assessed by available observations, or else, by average value from databases or experts. The new indicator distinguishes impacts on, on the one side, mobile species, and on the other side, species considered as “non-mobile” (plot-dependent). Organic farming label yielded good results for the systems we studied (annual crops) while results are variable for other labels and guidelines. In terms of outlook, i) the indicator will be compared to LCA methods and fields observations, for validation ii) calculations may be refined by integration of data on landscape context, and iii) calculation of indicator will be extended to a larger sample of labels.

5.03 Life Cycle Assessment (LCA) in frameworks for policy-making: different scales of assessment, data sources, and policy uses (Part I)

5.03.T-01 Impacts on Fuel Producers and Customers of Conflicting Rules for LCA

Tomas Ekvall¹, Sofia Puolikidou², Miguel Brandão³ and Tomas Rydberg², (1)Chalmers University of Technology, Sweden, (2)IVL Swedish Environmental Research Institute, Sweden, (3)KTH - Royal Institute of Technology, Sweden

Fuel producers and other commodity suppliers are increasingly affected by conflicting rules for life cycle assessment (LCA). They may get multiple requests for LCAs to be used in various contexts. This may require the application of different methodological approaches that may vary in scope, system boundaries, data demands and more. This results in increased cost and competence requirements for producers as well as confusion among other actors including their customers. Differences in methodologies might also lead to various outcome, conclusions and conflicting guidance regarding what fuel to prioritize or develop. We have studied the actual differences when applying different frameworks. The EU Renewable Energy Directive (RED), the EU framework for Product Environmental Footprints (PEF), and the frameworks of Environmental Product Declarations (EPD) all have different assessment and modelling requirements. The work has contained both an analysis of the methods from a conceptual point of view and by carrying out case studies on selected fuel production pathways (ethanol from corn, fatty acid methyl ester, biogas from food waste, HVO from used cooking oil, advanced ethanol from food waste and sawmill residues and pyrolysis oil from used tires). Results obtained for a specific fuel could differ substantially depending on the framework applied and the assumptions and interpretations made when applying this framework. Especially modelling of waste management can be very important for the results when the biofuel is produced from waste. Our results indicate a much higher climate impact for, for example, HVO and biogas when assessed with the PEF framework compared to the other frameworks. This is because PEF assigns at least part of the production of primary materials and energy to the use of recycled material and recovered energy. Developing Category Rules for biofuels for PEF and EPD could and should help clarifying remaining ambiguities.

5.03.T-02 A Critique of the EU's Revised Renewable Energy Directive and the Delegated Regulation Supplementing the Directive

Michele De Rosa, 2.-0 LCA Consultants, Aalborg, Denmark

The EU's revised renewable energy directive (RED II) and the EU's Delegated Regulation (DR), supplementing the Directive, establish criteria for the determination of high and low indirect Land-Use Change (iLUC) risk associated to the expansion of feedstock production into land with high carbon stock. In this work we argue that the criteria adopted by the RED II and by the DR exclude a-priori some feedstocks due to their country of origin, although they show lower environmental impacts per unit of product and penalizes specific product based on the global direct Land-Use Change (dLUC) associated to them instead of the iLUC. We perform an in-depth review of the RED II, the DR and of the “The Global Biosphere Management Model” (GLOBIOM), which was applied to quantify the LUC GHG emission in two studies commissioned by the EU to support the drafting of the RED II. Based on the review, we highlight the limitation of the RED II and DR especially on the quantification of the iLUC of different sources of biodiesel, in particular: palm oil, rapeseed oil and sunflower oil, and soybean oil. We performed a detailed LCA to compare the GHG emissions of those oil and compared the results with the results obtained with the GLOBIOM model. **1. 2.** The EU's RED II and the DR fail to distinguish between direct and indirect LUC. Instead, they set criteria for

determining iLUC based on the dLUC recorded during the period 2008-2015, although these are entirely different concepts. Thus, the criteria for determining low iLUC-risk feedstock are based on past status and/or past changes. They do not account for the actual iLUC effects triggered when demanding the production capacity of land at a global level. Moreover, the RED II and the DR fail to capture key differences in crop management practices as well as national and regional differences in palm oil production. They fail to distinguish between RSPO certified and non-certified palm oil, even though RSPO certified production explicitly addresses the main sources of GHG emissions occurring in oil palm cultivations: the drainage of peat soil and deforestation. Therefore, they risk compromising the efforts made by RSPO certified palm oil producers in Southeast Asia to reduce the GHG emissions of oil palm, which is the oil crop with the highest yield and thus lowest iLUC per unit of product. We conclude by providing recommendations to correct the criteria for determining high and low iLUC risk feedstock.

5.03.T-03 Considering Spatio-Temporal Dynamics in Assessing Long-Term Scenarios in Territorial LCAs: Application to Irrigated Areas

Nicolas Rogy¹, Amandine Pastor², Philippe Roux³, Thibault SALOU⁴, Agata Sferratore⁵, Nicolas Géhéniau⁶, Armand Crabit¹, Arnaud Helias⁷ and Eleonore Loiseau⁸, (1)INRAE, France, (2)INRAE, UMR ITAP, lab ITAP-Elsa, groupe Elsa, France, (3)INRAE - Elsa-Pact Chair, France, (4)Institut Agro Montpellier, MONTPELLIER, France, (5)Société du Canal de Provence et d'aménagement de la région provençale, France, (6)BRL Ingénierie, France, (7)INRAE - ITAP, Montpellier, France, (8)UMR ITAP, France

Territorial Life Cycle Assessment (T-LCA) is a meso-scale adaptation of the conventional LCA framework, allowing to assess the environmental performance of a territory and an associated land planning scenario while taking into account its multifunctionality (e.g. the economic, social or environmental functions of land use). This framework is used either to diagnose impact hotspots of territories or to compare the performance of territorial land-planning alternatives. In the latter case, eco-efficiencies ratios, i.e. services provided by the territory to its environmental impacts, can be used to identify trade-offs between the socio-economic and environment dimensions. To date, the approach has been static, assessing the impacts of a land use scenario in a given year. However, the environmental performance of a system can be affected by environmental disturbances such as climate change. This work aims at exploring the integration of a dynamic approach in the comparison of eco-efficiencies of territorial trajectories to consider potential environmental feedback in a prospective perspective. The proposed methodological developments will be used to compare the dynamic eco-efficiencies of agricultural planning scenario with or without irrigation considering effects of climate change. Following the T-LCA framework, the scenarios studied were first defined, then, inventory data were collected. In order to take into account the effects of climate change on system performance, the FAO's agronomic crop model AquaCrop is used. It allows considering several effects of climate change such as the increase of temperature and CO₂ concentration, or the change of precipitation regimes on both yields and water needs of crops present in the studied territories. The climate scenario used in this study is the RCP8.5 from the IPCC. The results of this study showed that an environmental feedback on human activity, climate change on agricultural areas, was successfully included in the T-LCA framework. It underlines the fact that it is crucial to consider the spatio-temporal dynamics when performing an environmental assessment to identify false good ideas. Other feedbacks could be considered such as local water depletion or soil erosion to perform a complete prospective T-LCA.

5.03.T-04 Should Human Toxicity of Pesticides Be Considered in Environmental Labelling of Food Products? A Proposal Using LCA for the French Context

Céline Gentil-Sergent¹, Anne Asselin², Aurore Wermeille³ and Natacha SAUTEREAU⁴, (1)ITAB, France, (2)Sayari, Saint Germain en Laye, France, (3)Sayari, France, (4)ITAB, French Research Institute of Organic Food and Farming, France

Introduction Environmental labelling of food product is nowadays a key subject for policies and consumers in Europe, and an experimentation is ongoing in France. Its scientific council proposed to base it on LCA and PEF reference framework to assume compatibility with European work. They also questioned the inclusion of residue impacts, pointing that the regulation already ensures the sanitary quality of food with maximum residue limits (MRLs). However, in agri-LCA, (eco-)toxicity is dominated by pesticides and in particular, by ingestion with residues which is the main route of exposure (Fantke and Jolliet 2016). The aim of our research is to highlight the possibility and urgent need to consider pesticide impacts from environmental exposure and residues within LCA for food environmental labelling purpose. **Methods** In Agribalyse, 8 crops representing the main crop families (e.g. cereals) were selected. According to OLCA-Pest recommendations on PestLCI, pesticide emission fractions to the environment and crop leaves were used. Then emissions were allocated to correspondings USEtox_{LC}-Impact and dynamiCROP compartments, respectively to assess environmental exposure and residues. An intermediate approach of LC-Impact with the dynamic version of USEtox 2.12 was developed to have characterisation factors of human non-cancer toxicity at mid-point with a 100 years time horizon. **Results and discussion** Our method allows us to account for the impacts of pesticides including residues on human health in LCA and to compare different types of farming practices. The results show that human non-cancer toxicity is in general 3 orders of magnitude higher than with EF method. Impacts from residues are mostly dominating total human impact of pesticides for conventional productions, except for tubers. Within our 22 scenarios, pesticide residues account for up to 99.5% of all pesticide-related impacts, despite amount of residues estimated to be below the MRLs; hence a potential health impact was assessed. **Conclusion** A methodology to assess human toxicity due to pesticides was proposed for food environmental labelling purposes. We are challenging that MRLs is already wholly addressing human health due to pesticides. Indeed, LCA shows that doses of ingested chemicals below MRLs can still have potential impacts on humans. Thus, environmental labelling of food product should consider impact of pesticides on human health, as recommended by the LCA scientific community.

5.03 Life Cycle Assessment (LCA) in frameworks for policy-making: different scales of assessment, data sources, and policy uses (Part II)

5.03.T-06 A Life Cycle Approach for Sustainable Aviation Biofuels Production: The Carbon Offsetting and Reduction Scheme for International Aviation (CORSA)

Neus Escobar¹, Gonca Seber², Robert Malina³ and Hugo Valin⁴, (1)Integrated Biosphere Futures (IBF) Research Group, Biodiversity and Natural Resources Program, International Institute for Applied Systems Analysis (IIASA), Laxenburg, Austria, (2)Hasselt University, Hasselt, Belgium, (3)Hasselt University, Belgium, (4)International Institute for Applied Systems Analysis (IIASA), Austria

The Carbon Offsetting and Reduction Scheme for International Aviation (CORSA) requires airlines to offset their greenhouse gas (GHG) emissions above 2019 levels either by buying carbon offsets or using Sustainable Aviation Fuels (SAFs). These are defined as drop-in jet fuels derived from biomass or waste. CORSA establishes that SAFs should not be produced at the cost of land classified as primary forests, wetlands or peatlands after 1 January 2008; and have at least 10% lower life cycle GHG emissions than conventional kerosene. GHG reductions shall be calculated by using life cycle assessment (LCA), including emissions from direct land use change (DLUC). This study estimates potential GHG savings of SAF production pathways, considering variability in DLUC emissions. Attributional LCA is applied to quantify gCO₂-eq/MJ from well to wake; combined with IPCC's Tier 1 approach. Several oilseeds, as well as lignocellulosic and starch-based crops, are examined as feedstocks to be respectively used in Hydroprocessed Esters and Fatty Acids (HEFA) and Alcohol-to-Jet (ATJ) pathways. Changes in GHG emissions relative to fossil kerosene vary widely depending not only on the feedstock but also on the underlying land use transitions and crop management practices. Lignocellulosic and starch-based crops deliver substantial GHG savings, except in scenarios with conversion of improved grassland (for maize and switchgrass only) or temperate forests. Camelina, pennycress, and salicornia offer GHG advantages over other oilseeds, due to assumptions on co-products' allocation. Jatropha and oil palm show a better GHG performance than annual oilseed crops, mainly due to soil organic carbon gains and carbon sequestration in crop biomass. Both perennial crops meet the CORSA threshold unless produced at the cost of carbon-rich land uses. Soybean, rapeseed, castor bean, and tobacco may only be eligible for HEFA production if grown on arable land or degraded grassland. Results highlight how variability in DLUC is critical in determining the GHG implications of SAFs. DLUC emissions can negate any potential GHG savings of both HEFA and ATJ pathways, especially when forests or natural shrublands are lost, which justifies the need for the CORSA sustainability criteria. The adequate consideration of DLUC effects becomes crucial for the future development and application of CORSA, to ensure the deployment of SAF technologies and effectively promote carbon-neutral growth.

5.03.T-07 Assessing a Project Environmental Footprint: A Methodological Framework

Clara Tromson and Olivier Rethore, ADEME, France

There is currently a need for comprehensive, holistic and multi-criteria assessment methods to evaluate the environmental impacts of a project and to support decision-making. "Project Footprint" (Empreinte Projet in French) is an operational framework, developed by the French Agency for Ecological Transition (ADEME) to assess any project environmental footprint. Its aim is to help project leaders and stakeholders to assess a project or an action. The Project Footprint methodology proposes an interpretation of consequential LCA for the projects whose implementation does not lead to large-scale changes in the economic system, by considering the direct and indirect consequences of a project. It includes the contributions of ADEME "QuantisGES" method and make it more robust with a multi-criteria approach and requirements inspired by international LCA standards. In this method, the project footprint is calculated as the difference between the impacts of a reference scenario with no action taken and the impacts of a scenario where the project occurs. The Project Footprint methodology offers five maturity levels, from the simple qualitative assessment to a structured quantitative assessment that can be communicated externally. As an operational approach, it guides the user all along its application of the methodology: It gives guidelines and a step-by-step method which starts with a characterisation of the targeted project, to structure a consequence tree and to calculate the quantified project's impacts. Furthermore, the methodology also offers some support to conclude on the project environmental relevance with a level of reliability. Additional recommendations are made regarding the results communication, according to the selected approach level. To facilitate the application of the methodology, real-life case studies are provided to the user. The Project Footprint methodology is a first step to assess a project's environmental impacts by providing a transparent and reliable framework. In order to help better decision making, the methodology can be adapted to the context and objectives of the assessment and gives the user relevant environmental information.

5.03.T-08 Towards a Simplified Life Cycle Assessment Tool for Urban Agriculture

Erica Dorr, Christine Aubry and Benoit Gabrielle, Université Paris-Saclay, AgroParisTech, INRAE, France

Urban agriculture (UA) is emerging as a tool for cities to tackle multiple social and environmental issues. As cities and regions support the development of UA through dedicated programs, food planning, and urban policies, questions remain about its environmental impacts. Life cycle assessment (LCA) is useful to quantify impacts, compare types of UA, and assess the actual benefits (or impacts) that are assumed to come with UA. Our goal was to create a simplified LCA tool adapted to UA to support policy makers and planners. This would help them decide which types of UA to implement, quantify the contributions of UA to urban sustainability goals, and could lead to product-level impacts for communicating with consumers. Through a systematic literature review and meta-analysis, and work with 9 UA case studies, we advanced and questioned several features of UA LCAs. A main takeaway was that very little is known about the environmental performance of UA, and relatively few LCAs have been done. Therefore, there were not enough resources or knowledge to simplify LCAs for UA. Main barriers were the variability of UA and uncertainty about UA practices. Indeed, from our work with diverse case studies, we witnessed great difficulties in data collection due to changing practices, the young age of farms, regular turnover of farmers and volunteers, and lacking focus/interest in data collection because of other main goals. In a first step to address this, we created an LCA framework and set

of guidelines to improve and harmonize UA LCAs, discussing system boundaries, data sources, and system modeling decisions. More data area needed about practices in UA, so we provided recommendations for how to collect this data, and summarized useful values for when collection is not possible. This framework is the first focused attempt at making UA LCAs more accessible, feasible, reliable, and consistent. Our findings can directly support the creation of a simplified UA LCA tool in a next step, and an improved body of literature on UA LCAs at the farm-level. Better farm-level LCAs will improve studies of scaled-up UA at the city-level (or beyond to the national-level) to evaluate, for example, how UA could help meet cities' climate change reduction goals. We concluded that although LCA of UA may not yet be mature enough for tools or streamlining, assessments of individual case studies can yield valuable insight for improved design and management of UA.

5.03.T-09 Technology Choice Model As an Option to Support Decision-Making in Policy-Making: A CASE Study on Allocations in the Petrochemical Industry

Jana Elisabeth-Anna Enking¹, Stefano Cucurachi¹ and Arnold Tukker², (1)CML Leiden University, Netherlands, (2)Leiden University, Nederland

Standard LCA studies with one on one comparisons can support policy-making, but often a greater context is relevant to guide policy-makers. This is especially true for interlinked industries such as the petro-chemical industry where most processes produce multiple products simultaneously (multifunctional processes). The Technology Choice Model (TCM) can be one option to support decision making. TCM allows decision making in a broader context while still being able to represent production alternatives at the technological level, and consider supply chains and their alternatives. We use a case study on the chemical industry with a focus on the influence of allocations on decisions. Allocation methods are common practice to split environmental impacts between products of a multifunctional process. Our case study covers 24 bulk chemicals and 293 production technologies based on naphtha and natural gas. Products include methanol, ethylene, propylene aromatic compounds and their derivatives. All technologies are described by mass and energy balances, which are used to build a technology matrix. Results demonstrate that decisions without massive use of allocations are possible and usage of allocated data lead to wrong decisions. Additional emissions due to the usage of allocated data vary between 20% and 160% in our case study depending on the allocation method and compared to a system expansion approach. A comparable system could also be used to assess policy measures and their effect on supply chains or the introduction of emerging technologies, such as bio-chemicals. Further applications could include recycling intense industry such as plastic or metal industries and assessment could be expanded for multi objective optimization.

5.03.T-10 Sketching Science-Based Environmental Transition Plans for Industries With EEIO: Illustration by Canada's Road SECTOR

Anne de Bortoli¹ and Maxime Agez², (1)Génie chimique, CIRAI - École Polytechnique de Montréal, Canada, (2)CIRAI - École Polytechnique de Montréal, Canada

Building effective environmental transition plans for industries and companies is challenging due to the lack of quantitative understanding of their ecological responsibility over their value chain. Companies mostly turn to Life Cycle Assessment (LCA) to perform specific environmental quantifications. Yet, Environmentally-Extended Input-Output (EEIO) is very efficient on a wider scale. We illustrate the usefulness of EEIO in the case of the Canadian road industry. An EEIO database has been developed for Canada: Open-IO Canada. The database uses different sources of inventories: economic supply and use tables as well as GHG emissions and water use reported by StatCAN, the governmental body responsible for Canada's statistics, and pollutants reported by Canadian facilities in the National Pollutant Release Inventory. Open-IO Canada then uses ImpactWORLD+ characterization factors to estimate the multicriteria environmental impacts of economic sectors or products and services. This database is used to understand key environmental drivers of Canada and its road sector with a consumption-based approach. Results show that the construction sector is the second most impacting sector in Canada (10-31% depending on the indicator) but that the road industry impacts are more limited (0.6-1.8%), with 1.3% of GHG emissions and damage to human health and ecosystems, mainly driven by bridge materials and energy consumption. Priorities could be to reduce the impact of concrete and crude oil purchases, and direct emissions through the investment in new machinery. The contribution of activities often neglected in roads LCA (capital goods, staff consumptions, services) is substantial. Direct emissions present very low contributions except for the GWP (29%): focussing environmental strategies on scope 1 has a limited impact if not done by the entire supply chain. Good correlations ($R^2 > 0.9$) of intermediate purchase contributions between GWP and the two damages point out GWP as a suitable proxy for holistic evaluation of this industry's green purchase plans. Finally, on the life cycle of Canadian roads, construction and maintenance account for 5% of GHG emissions, against 67% for its use stage and 27% for vehicle manufacturing and maintenance: focusing on the road industry is not a priority to decarbonize road transportation, contrary to building and maintaining roads to lower vehicle consumption and wear, or directly reducing vehicle manufacturing and tailpipe GHG emissions.

5.03 Life Cycle Assessment (LCA) in frameworks for policy-making: different scales of assessment, data sources, and policy uses (Virtual Only)

5.03.V-01 Advanced Wastewater Treatment Technologies: What Are the Techno-Economic and Environmental Challenges?

Sabrina de Boer¹, Jorge González-Rodríguez², Julio J. Conde² and Maria Teresa Moreira², (1)Universidad de Santiago de Compostela, Spain, (2)University of Santiago de Compostela, Spain

Surface water quality is threatened by the release of organic micropollutants (OMP) originating from human activities. Policy makers have different options to counteract this trend, one of them is the upgrade of existing wastewater treatment plants with advanced treatment stages, capable to remove or degrade OMP. Switzerland is the first country which has implemented a

nationwide legislation requiring wastewater treatment plants (WWTP) to reach an 80% removal from a set of indicator substances. On the EU level however, there is still a controversial discussion on how to evaluate advanced treatments, considering technoeconomic and environmental aspects. With this contribution, we want to fuel the discussion on the base of a comprehensive summary of the technological state of the art of advanced wastewater treatment options. Our systematic search shows that conclusive life cycle assessment studies are still underrepresented in the peer-reviewed literature compared to the available technological data, but highly needed for implementing sustainable solutions. We concluded that all implemented treatments have strengths and drawbacks. For example, while the removal efficiency of membrane processes is outstanding compared to adsorption or (advanced) oxidation processes, high energy demands make their application unattractive in regions with elevated energy prices, and sustainability will depend on the energy mix used. In Europe, there is a trend to implement activated carbon adsorption and ozonation. Despite the availability of full-scale data, the reviewed LCA studies came to contradictory conclusions on their environmental impact. This shows that the individual selection of system boundaries and regionalization of impact categories can improve the case-by-case evaluation but on the expense of a decreased transversal applicability of the studies. The lack of data regarding novel advanced treatment technologies, especially in the field of photocatalysis and electrochemical treatments forces researchers to base environmental analysis on lab-scale data, provoking a paradigm shift towards prospective LCA.

5.03.V-02 Comparing Data Sources for National Consumption Footprints: The CASE of Germany

Philip Nuss¹, Esther Sanye-Mengual² and Serenella Sala³, (1)German Environment Agency (UBA), Germany, (2)European Commission Joint Research Centre, Italy, (3)European Commission - Joint Research Centre, Italy

Policy efforts increasingly focus on the environmental impacts of production and consumption along the full supply chain of products. For this purpose, the European Commission – Joint Research Centre (JRC) developed the Consumption Footprint, a Life Cycle Assessment (LCA)-based framework that assesses the environmental impacts of EU consumption through a full bottom-up approach based on around 160 representative products in five areas of consumption (i.e., food, housing, mobility, household goods and appliances). This indicator could be implemented by EU countries such as Germany to complement existing monitoring frameworks. However, the Consumption Footprint targets the implementation in all EU member countries and, therefore, employs EU-wide national-level data sources (such as Eurostat), while there are additional national data sources that could be used for a more fine-grained analysis. The goal of this study is to compare the use of different national data sources for the assessment of the environmental impacts of German consumption using the approach of the JRC Consumption Footprint indicator. The exercise followed the three-step process of the Consumption Footprint with specific focus on the calculation of the consumption intensities, where the two different data sources were compared. The scope of the analysis covered the consumption of (average) German citizens for the time period 2010-2018. Several national data sources could be employed for the analysis, requiring a clear prioritization, and data gap filling. Comparing data sources and resulting impacts unveiled different levels of detail and of scope. On the one hand, for some areas of consumption and product groups, more detailed data sources are available at national level (e.g., from consumer spending surveys). This can support capturing emerging consumer product trends (e.g., increased use of e-bikes or tablet PCs) and highlight missing products. On the other hand, consumption intensities can vary due to different scopes (e.g., focusing on household vs. entire consumption; inclusion of indirect consumption in services). The study concludes by comparing results obtained with the Consumption Footprint approach with national footprint estimates and downscaled planetary boundaries for Germany. Finally, ideas on how the indicator might complement existing monitoring frameworks are highlighted.

5.03.V-03 Coupling Agent-Based Modelling With Territorial LCA to Support Agricultural Land-Use Planning

Tianran Ding and Wouter Achten, Université Libre de Bruxelles, Belgium

The development of the life cycle assessment (LCA) adapted at the larger scale - “territorial LCA” (TLCA) - shows advantages in assessing the environmental impacts of a multi-functional territory. However, the TLCA approach and its developments are limited to evaluating the impacts of the land-use scenarios on a static basis. In contrast, a territory is a complex and dynamic system in which individual decisions play a significant role. This work aims to develop a dynamic territorial LCA approach linking TLCA with agent-based modelling (ABM), a widely used tool to simulate individual agents’ decisions for supporting policy analysis and planning. A case study was implemented to examine the bioenergy crop development with demonstration farms installed at different locations in an agricultural territory (Wallonia). We consider farm size, revenue, and familiarity (distance to successful adopters) as influential factors. Geographical Information Systems (GIS) was employed for spatial data treatment. The results show that different initial locations for demonstration farms would lead to different dynamic results at the territorial level. The case study presents the capability of spatio-temporal simulation of the territory dynamics with the developed model, taking into account farmers’ adoption decisions and site-specific conditions. Such knowledge on the interactions between human behaviours and land-use scenarios could bring insights for policy-making, supporting reasonable land planning at the territorial level. Besides, by employing GIS to estimate spatially explicit inventory of unit processes, this work fills the research gap of the lack of application linking LCA, ABM, and GIS together. While the case study was conducted for bioenergy crop development, the coupled framework is by no means limited to it, and other areas such as forest management may benefit from the framework. Furthermore, this work will benefit from cutting-edge research such as life cycle sustainability assessment, behavioural economics, and social networks.

5.03.V-04 Critical Transmission Industries in the Global Supply Chain Networks to Reduce Embodied Emissions

Fumiya Nagashima¹, Shohei Tokito² and Tesshu Hanaka³, (1)Kindai University, Higashi-osaka, Japan, (2)Yamagata University, Japan, (3)Nagoya University, Japan

Productions and consumptions of goods and services have clearly contributed to the economic growth in the world, whereas those economic activities brought about environmental loads, especially greenhouse gases (GHG) emissions. Industries and firms seek to reduce their environmental loads of their products through their whole supply chains, that is, *environmental footprint* (e.g., carbon footprint) to contribute the climate change mitigation. Therefore, supply chain management from upstream to downstream industries i.e., the inter-industry (or inter-firm) collaboration are essential in order to reduce the supply chain emissions effectively. In the field of industrial ecology, the environmentally extended input-output analysis has been used to trace the embodied GHG emissions in whole supply chains. The set of industries and the inter-industrial transactions in the input-output table can be regarded as *network*. Here, we apply the concept of *betweenness* originated from network analysis to the input-output analysis, and develop the new approach to identify transmission industries environmentally critical for supply chain management. In the perspective of global economy, we especially focus on the territorial emissions embodied in international exports to utilize the demands for both final and intermediate goods in foreign countries. Critical transmission industries here represent the hub industries which participate in the global supply chains and induce domestic territorial emissions. These industries have potential to enhance the creation of domestic value-added from global supply chains and simultaneously contribute emission reduction targets such as Paris agreement. We use Eora, the global multi-region input-output table, and identify the environmentally critical transmission industries with a focus of the industries in Japan, United States and China as a case study. This new approach can help firms to find opportunities to mitigate GHG emissions in their supply chain networks.

5.03.V-05 Increased Ecotoxicological Impacts Due to Reduced Pesticide Application: An Anomaly in Designing Low-Input Paddy Rice Production and Necessity of Precise Characterization

Longlong Tang¹ and Kiyotada Hayashi², (1)National Agriculture and Food Research Organization, Tsukuba, Japan, (2)National Agriculture and Food Research Organization, Japan

Pest management strategies to improve agricultural sustainability aim to minimize human health and environmental risks associated with pesticide use. However, some management practices, such as a low-input agricultural system that reduces the pesticide use by adjusting the active ingredients (AIs), may induce the use of low-dose alternative AIs with a higher efficacy on target organisms but at the same time a stronger ecotoxicological impact on non-target organisms, consequently leading to an unintended increase in risk. Here we developed a precise evaluation method that can better distinguish the differences among AIs and designed an impact assessment of pesticide uses on eight paddy farms in Japan using the method to demonstrate the effectiveness of a transition from conventional to low-input managements. The proposed precise method contains a simulation model to calculate pesticides emitted from a paddy field, and a list of characterization factors (CF) originally calculated based on a nonlinear concentration-response function (CRF). This allows providing detailed emission results considering local water management in paddy field and precise CFs considering parameters both the hazardous concentration potentially affecting 50% of the species (HC50) derived from a species sensitivity distribution (SSD), and the slope of the SSD, and hence can lead to a better understanding of the effects derived from the change in AIs. The results of the case study showed that, in general, the reduction in the number of AIs applied contributes to an impact reduction, but the effects varied widely on individual farms, especially with some farms (three of the eight farms) resulting in an opposite increase in impact. The factors causing the increased impact are found to be not only the use of a highly toxic alternative substance, but also the change in emissions. The proposed precise method was confirmed can better capture the difference among active ingredients, and consequently, effectively contribute to the farm's impact reduction goals due to pesticide use.

5.03.V-06 The Impact From LCA on Policies for Plastic Waste Handling in the Fishing and Aquaculture SECTOR

Hans Jakob Walnum¹, Fredrik Moltu Johnsen² and Torunn Hønsi², (1)STIFTINGA VESTLANDSFORSKING, Norway, (2)Western Norway Research Institute, Norway

In this paper, we identify how LCA and life cycle perspectives could help to create a circular economic value chains in accordance with sustainability for plastic waste handling in the fishing and aquaculture sector. Our research questions are: (1) What existing (regional), national and European policies directly and indirectly affect handling of plastics in the fisheries and aquaculture sector? (2) How can new policies based on LCA and life cycle perspectives promote more sustainability and circularity for handling plastics in the sector? Thus, addressing how LCA in the future could be used to improve policy in a more environmental benign direction in the fisheries and aquaculture industry.

5.03 Life Cycle Assessment (LCA) in frameworks for policy-making: different scales of assessment, data sources, and policy uses (Poster)

5.03.P-Tu288 A Life Cycle Assessment Framework for Improving Household Refrigerators Sustainability of Food Systems: A Review

Junzhang Wu Sr¹, Alessandro Manzardo², Alessandro Marson³, Mirco Piron² and Antonio Scipioni², (1)Department of Industrial Engineering, University of Padova, PADOVA, Italy, (2)University of Padova, Italy, (3)University of Padova, Padova, Italy

Food waste (FW) leads to substantial economic, energetic, and environmental loss worldwide. According to Eurostat's Domestic Material Consumption (DMC), the food sector requires a total of 1.44 Gt material resource input per year, which accounts for 20% of the European Union's total DMC. It is estimated that 35% - 62% of avoidable FW occurred at the household level in developed countries, reflecting great potential opportunities for reducing environmental and social impacts. This review focuses on embodied environmental trade-offs between household refrigerators and the food system associated with FW at a consumer level. A well-integrated household refrigerator with a food system benefit for community's health, food security, and nutrition. This study mainly explores the inherent trade-off of reducing FW and its associated environmental impacts by deploying

household refrigerators, a refrigeration technology that would increase environmental burdens due to energy consumption and refrigerant leakage emissions. Therefore, it examines the trade-offs between the increased energy use due to food refrigeration and the GHG savings of reduced FW at a household level.

5.03.P-Tu289 Freshwater Ecotoxicity Assessment of Measures Promoting Agricultural Biomass Production Can Inform Policy Making on Biofuels

Raül López i Losada, Centre for Environmental and Climate Science - Lund University, Sweden

Sweden's ambitious climate-mitigation strategy for the transport sector is dependent on the possibility to increase its agricultural biomass production for biofuels. Policy stimulating agricultural biomass mobilization is needed to keep pace with a high biofuel implementation rate, but large-scale agricultural production changes pose a series of environmental risks. Assessing the environmental impacts of policy alternatives for promoting agricultural biofuels is therefore a much needed scientific input for policy-making. However, effectively quantifying the environmental impacts of policy measures is challenging due to the dynamic nature of agricultural systems, which involve complex interactions among human actors and the environment. This study combines an Agent-Based Model (ABM) with Life Cycle Assessment (LCA) methods, and aims to assist decision-making to quantify the potential ecotoxicity implications of relevant agricultural policy alternatives. First, we model spatially-explicit production shifts likely to occur in an intensive arable cropping region in Sweden if farmers are required to grow a minimum proportion of their farm area as grass ley. This is done by means of AgriPoliS, an ABM that is frequently used to predict farmers' responses to changes in agricultural policy. The novelty of our study is that we then couple the ABM results to LCA methods to expand the policy analysis to a relevant environmental impact category. This is done by assessing the potential freshwater ecotoxicity impact of predicted changes in pesticide application by means of the chemical characterisation model USEtox and pesticide fate model PestLCI, a site-specific pesticide inventory and local soil properties and climate. While literature suggests that lower returns from grasses can be compensated over time with higher productivity due to soil benefits of leys in crop rotations, our results show the extent to which mobilizing biomass with low farming inputs in intensive farming regions can reduce impacts from pesticide application. Our approach therefore establishes a quantitative relationship between policy promoting biomass and its implications in terms of regional freshwater ecotoxicity impacts. This contributes to expanding the environmental assessment of land-based biofuels at a time when their overall sustainability is highly debated.

5.03.P-Tu290 Environmental Assessment: ADEME Guidance to Select the Right Methods

Olivier Rethore, ADEME, France

Expectations in terms of environmental assessment (EA) have risen considerably during the last decades, while at the same time the methods have become more sophisticated and diversified to meet needs that have gained in maturity. There are thus many EA methods, which may be more or less related, addressing different contexts, scope of evaluation, periods or even assessment objectives. EA must also adapt to various users and prescribers. All this emphasizes the importance of having a common framework allowing for harmonized implementation of EA. The goal of the guide presented here is to serve as a basis for such a framework. We believe anyone interested in EA can find this guide useful to better understand the role and limits of the main existing methods, and which one to select depending on one's context and objectives. This guide aims to help understand the various EA methods and to choose one or more methods adapted to a given assessment context. It contains three main complementary components: 1. Twenty individual factsheets allowing, in a few pages, to become more familiar with a given method. 2. A mapping of these methods in order to better understand their respective positioning; 3. A decision-making flowchart to help users to select the method(s) adapted to their needs. The purpose of this guide is to help anyone select one or more methods suited to its needs in terms of Environmental Assessment. However, it is only a first step towards a better understanding of EA. It does not deal with the operational and detailed implementation of each of the methods investigated, and it could and should be supplemented by specific frameworks, training modules, guides of best practices and so on. ADEME is currently working on it and welcomes cooperations.

5.03.P-Tu291 Environmental and Social Impacts Assessment Caused by the Growing Demand for Electric Vehicles

Kakiuchi Sayaka¹ and Norihiro Itsubo², (1)Tokyo City University, Tokyo, Japan, (2)Tokyo City University, Japan

Of the global greenhouse gas emissions, transportation CO₂ from gasoline and diesel combustion from all forms of road traffic, including cars, trucks, and buses, accounts for about 16%, of which passenger travel accounts for 60% of the total [1]. In addition, the LCA (Life Cycle Assessment) of EVs shows that the environmental impact up to the manufacturing stage is significant [2]. It has been predicted that the stock of EVs will reach 230 million units by 2030 [4]. The stock of EVs is expected to reach 230 million units by 2030 [4], and restrictions on gasoline and diesel vehicles are scheduled to be imposed by 2030, mainly in Europe. The increasing demand for each component due to the shift to EVs is expected to have a significant impact on the raw material procurement stage. Rare metals are indispensable in the current EV manufacturing technology, but the use of rare metals poses a great risk. In particular, cobalt which is used in lithium-ion batteries is heavily sourced from the Democratic Republic of Congo (DRC), where social risks such as child labor and work hazards have been reported [5]. In addition, there are concerns that the shift to EVs may not only lead to more serious social risks but also the loss of natural capital associated with mining. Thus, the increased demand for rare metals used in batteries can contribute to the deterioration of natural, human, and social capital, but there is no method to properly assess these impacts. The purpose of this study is to examine the impact of the shift to EVs on climate change and the associated social risks using the LCA methodology. Conduct an inventory analysis in accordance with ISO 14040, the international standard for LCA. The social impact will also be calculated. For the meta-analysis of LCA studies, we will collect automotive LCA studies that have been conducted so far and extract process data on raw material production, assembly, use, and recovery/recycling for each vehicle model, or quote data from integrated reports. These data will be analyzed

using LCA software and the inventory results will be discussed. If any missing data is identified in the cited data, it will be supplemented with a substitute database or alternative values. As for social impacts, we will use the Social Hotspots Database and A Product Social Impact Life Cycle Assessment database to calculate and discuss the impacts on child labor, forced labor, and gender equality. Show the number of hours worked under each impact, compare by vehicle type, and explore where the supply chain hotspots for specific EVs exist. [1] Our World in Data, *Sector by sector; where do global greenhouse gas emissions come from?* Hannah Ritchie, September 2020 [2] Goldman Sachs, *New era in Co2 regulation: EVs to be tested across life cycle, not only on running performance*, December 2019 [3] EUROPEAN COMMISSION, *'Fit for 55': delivering the EU's 2030 Climate Target on the way to climate neutrality*, July 2021 [4] IEA *Global EV Outlook 2021*, April 2021 [5] Amnesty International, *"THIS IS WHAT WE DIE FOR"*, 2016

5.03.P-Tu292 Should We Use Plastic Shelters to Protect Seedlings for Afforestation?

Charnett Chau¹, Andrea Paulillo², Nancy Lu³, Mark Miodownik³ and Paola Lettieri³, (1)University Colleege London, United Kingdom, (2)Chemical Engineering, University College London, London, United Kingdom, (3)University College London, United Kingdom

Restoration of forested land represents an effective strategy to contribute to net-zero target emissions by enhancing the removal of greenhouse gases from the atmosphere. The most common afforestation strategy envisages planting seedlings, which are germinated and grown to the desired age at tree nurseries, with plastic shelters to increase growth and survival of trees. However, the use of plastic shelters is hotly debated, not least because shelters are often left on-site, contributing to plastic pollution in the environment. This work presents a comprehensive Life Cycle Assessment (LCA) study that compares the environmental impacts of current and prospective scenarios for plastic shelter-aided seedling planting compared with a base case where shelters are not employed. The underlying objective is to support policy- and decision-making. The work focuses on the UK but results and conclusions are valid for other temperate oceanic regions. The scenarios investigated are a combination of different shelters materials (including bio-based ones) and end-of-life strategies. The analysis demonstrates that (i) on average planting seedling without shelters is the most preferable option across most environmental impact categories (including Climate Change), and in terms of weighted results, (ii) polypropylene shelters are preferable to bio-based alternatives, including polylactic acid-starch blends and bio-polypropylene, (iii) recycling is the most environmentally advantageous end-of-life treatment. The LCA results also show that the carbon emissions of the scenarios investigated are negligible when compared to the amount of carbon sequestered by a tree in 25 years.

5.03.P-Tu293 Developing Policy Recommendations for Short Food Supply Chains in Europe

Jens Lansche¹, Laura Iten¹, Pauline Audoye², Laura Farrant² and Melanie Douziech³, (1)Agroscope, Switzerland, (2)CTCPA, France, (3)Agroscope, France

Food production in many areas is distant from consumers, both spatially and socially, and value creation is concentrated in a few actors with high market power. Moreover, food supply contributes significantly to climate change (GWP) and other negative environmental impacts such as eutrophication and acidification. Short food supply chains (SFSCs) can potentially contribute to reducing these problems and are therefore an element of the EU's rural development strategy in the context of the Common Agricultural Policy. This raises the question of what characteristics SFSCs need to have in order to promote better sustainability. The integrated sustainability assessment of selected case studies in the presented project therefore consisted of a sustainability assessment of SFSCs in comparison with conventional food chains. We present exemplary results for GWP for one type of SFSCs (cooperative shop) compared to the conventional supply chain in the rural (RSC) and the urban (USC) context. Transport distance, type of vehicle for consumer transport and quantity of products purchased by the consumer for a given purchase act could be identified as the key parameters for the overall GWP of a food chain. For the SFSC (electric vehicle charged with low emission electricity) to have a lower impact than the RSC, the food basket needs to be of at least 8kg. For the USC, the food basket needs to be of at least 16 kg. In order to derive recommendations for decision-makers, it was necessary to generalise the case studies to a higher level and to calculate scenarios derived from them. Due to the relatively high uncertainty, we did consider different sensitivities for most relevant aspects in order to obtain more robust results and recommendations. Through explicit consideration of the value chain, the recommendations can be derived for each actor (consumer, producer, policy-maker). For the policy-makers, we came to the following main points: Firstly, to foster the development and continuation of traditional farmers' markets and cooperative shops, where primary producer can sell their goods in an easily accessible public area – ideally with complementary shops nearby. Secondly, to provide platforms for primary producers to connect and build networks of complementary primary producers. Implementing these recommendations will enable consumers to minimize their individual transport per complete food basket, thus reduce the specific environmental impacts of shopping trips.

5.03.P-Tu294 Pathways to Planetary Health Diets: Are National and Regional Food Based-Dietary Guidelines in Line With the Environmental Targets of Eat-Lancet Recommendations?

Cristina CambesesFranco¹, Ricardo Rebolledo Leiva², Gumersindo Feijoo³, Maria Teresa Moreira³ and Sara González-García², (1)Universidad de Santiago de Compostela, Spain, (2)Universidade de Santiago de Compostela, Spain, (3)University of Santiago de Compostela, Spain

Dietary choices are shifting globally - driven by social and technological breakthroughs- in ways that are negatively affect both human health and the environment. A sustainable transformation of dietary patterns and the food systems that deliver them is an urgent need in order to meet the Sustainable Development Goals and the Paris Climate Agreement. The convergence of global dietary patterns around predominantly plant-based diets is a global challenge, mainly due to the substantial impact of the livestock sector on water quality and greenhouse gases emissions. Given the severity of the problem and their multinational nature, global

public health dietary recommendations should complement national and regional government food-related initiatives, such as national food-based dietary guidelines (FBDGs). With these needs and challenges in mind, the EAT-Lancet Commission developed a global planetary health diet, which consists largely of a diversity of plant-based foods and low amounts of animal source foods. Therefore, the purpose of this research was to compare the global EAT-Lancet recommendations with dietary guidelines from Northern and Southern Europe and America in terms of carbon footprint (CF) and water footprint (WF). This study employs a Life Cycle Assessment methodology to enable a complete evaluation of the CF and WF. The individual recommended daily dietary intake was chosen as the functional unit. The analysis was carried out from a cradle-to-consumer approach and the system was divided into three stages: i) Food production stage, ii) Distribution to wholesale and retail and iii) Distribution from retailers to households. According to the results, when compared EAT-Lancet to other recommended diets in Europe and America, none met all the environmental targets set by EAT-Lancet in all food categories. Overall, negative deviations around CF and WF using EAT-Lancet as a reference were higher for dairy. Therefore, moderate dairy reductions in national and regional FBDGs have a significant potential for transitioning to low carbon and low water footprint eating habits worldwide. To sum up, this work identifies that shifts towards universally sustainable diets could generate collateral benefits, such as minimizing diet-related GHG emissions and the protection of water resources to reduce the environmental footprint associated with food consumption, as well as promoting habits that improve the health of the population.

5.03.P-Tu295 Environmental Assessment of Introducing Lupin Crop in a Wheat-Base Rotation System Under an Ecological Regime

Ricardo Rebolledo Leiva¹, Cristina Cambeses Franco², Maria Teresa Moreira³ and Sara González-García¹, (1)Universidad de Santiago de Compostela, Spain, (2)Universidad de Santiago de Compostela, Spain, (3)University of Santiago de Compostela, Spain

The diversification of agricultural activities is a fundamental strategy to face soil degradation, food security, and climate change. In this sense, the incorporation of legumes in cereal-based rotation systems is presented as a sustainable strategy to improve soil nutrient levels and reduce environmental impacts. This work aims to evaluate, from an environmental perspective, the effect of lupin cultivation in a Galician winter wheat-based rotation system under an ecological regimen. The life cycle assessment (LCA) methodology was applied for a rotation system over a six-year period, which considers Galician winter wheat as the main product, and lupin and potato as the alternative products. Therefore, the rotation system evaluated (RS1) has the following cultivation sequence: lupin (LPN) + Galician wheat (Ge-WW) + potato (PT). The overview of this study was to collect primary data associated with the rotation crops to quantify their environmental impacts, identifying their advantages or disadvantages. Moreover, the system under study is compared with the rotation system without lupin cultivation (RS2), i.e., Ge-WW + PT. Comparing the environmental profiles of both rotation systems was based on a land management approach as the functional unit (i.e., in terms of ha). In addition, the impact categories evaluated are Global Warming (GW), Freshwater eutrophication (FE), Marine eutrophication (ME), Terrestrial ecotoxicity (TET), Freshwater ecotoxicity (FET), and Fossil resource scarcity (FRS), through the Recipe v1.04 midpoint method. Some of the results indicate that in the GW category is obtained 3.07 t CO₂e, meanwhile, 3.42 kg P eq in FE, 38.12 kg N eq in ME, and 633.03 kg oil eq. Moreover, comparing both rotation systems, in the GW category the introduction of lupin led to an impact reduction of 25%. In FE produce an increase of 29%, meanwhile in ME leads to a reduction of 80%. Regarding eco-toxicity-related categories, include lupin led to a slight increase in both with about 1% and 10% for TET and FET, respectively. Finally, FRS also presents a marginal increase of 2%. This study encourages stakeholders and decision-makers to understand the environmental impacts of diversification strategies in order to achieve sustainable agricultural systems.

5.04 Life Cycle Impact Assessment modeling and application (Part I)

5.04.T-01 Fate Factors for Microplastics Emitted in the Marine Environment

Carla Hajjar, CIRAI - École Polytechnique de Montréal, Canada

Microplastics (MPs) impacts in the marine environment have been linked to their physiology. Because of their small size (1 μm–5mm), they are available to the marine ecosystem through ingestion, egestion, and tissue transfer. Impacts have been linked to growth hindering, blockage of the digestion tract, internal and external wounds, and even mortality. Since MPs emissions are expected to keep on increasing, assessing their potential impacts in the marine environment is important. Current life cycle assessment (LCA) does not account for MPs. Life Cycle Impact Assessment (LCIA) does not provide characterization factors (CFs) to quantify potential impacts of MPs emissions to the marine environment, which is underestimating the potential impacts of the products studied. MariLCA (Marine impacts in LCA) is an international working group supported by the Life Cycle Initiative and FSLCI. It focuses on developing harmonized CFs for environmental impacts pathways of marine litter, especially plastics. This project falls within MariLCA's work, by developing FFs for MPs emitted to oceans. FFs are developed for different marine sub-compartments (beach, water surface, water column, and sediments) at two different scales (continental and global), identified in a recently developed framework, since the fate mechanisms and the exposure of the marine ecosystem to MPs differ within the ocean. This study prioritizes main parameters influencing the fate in the marine environment leading to the development of FFs for different MPs categorized based on their physical properties, such as shape (cylinder and spherical) and density (low, intermediate, and high). Moreover, this work identifies the need for regionalization based on the influence of environmental factors (water currents, biofilm density, etc.) on the fate. For each category, a rate k matrix is developed that accounts for rate transfers of MPs between different marine sub-compartments, and removal rates (including degradation, and deep burial). Transfer rates are obtained using a tracking model (TrackMPD) that records the trajectory of virtual MPs emitted at different locations in the oceans. FFs are then obtained from these k matrices. They are expressed in kg per $k_{emitted}/d$. CFs can then

be obtained by combining FFs with exposure-effect factors for micro/nanoplastics potential physical impacts on the aquatic environment (marine and freshwater).

5.04.T-02 Effect Factor (EF) for Macroplastic Debris Entanglement: A Field-Based Species Sensitivity Distribution (SSD)

Approach

Marthe Høiberg¹, **John Woods**² and **Francesca Veronesi**³, (1)Energy and Process Engineering, Norwegian University of Science & Technology (NTNU), Trondheim, Norway, (2)Norwegian University of Science and Technology (NTNU), Norway, (3)NTNU, Norway

The input of non-degradable plastic waste to the natural environment is projected to further increase and the harmful impacts that it has on marine species are well known. However, there exists no operational methodology in life cycle impact assessments (LCIA) that accounts for this side effect of mismanaged plastic products. As the marine environment in general is underrepresented in the LCA framework, advancing novel impact assessment models pertaining marine ecosystems is instrumental in making the analyses more comprehensive. One of the most well documented ways through which plastic debris may affect marine fauna is entanglement, but a global overview of the impacts of this stressor is missing. Estimates of global plastic debris concentrations are not sufficient as proxies for impact, as the mere presence of plastic debris does not imply that all present species will be affected. As such, a potential effect factor (EF) should be based on estimates of entanglement prevalence, to account for interspecific differences in sensitivity to this stressor. By creating a field-based species sensitivity distribution (SSD) with entanglement rates gathered from 20 species, we model the potentially affected fraction (PAF) of species globally, and present a spatially explicit EF. The predicted EF was found to vary globally from 1.8×10^{-3} to 2.9×10^{-1} PAF/kg.km⁻². The modelling approach implies that the size of the effect following an input of plastic debris is smaller in areas with an already high fraction of species potentially affected. As such, known plastic debris hotspots such as oceanic gyres, marginal seas and coastlines were linked to a lower EF value. However, only when the EF is combined with an appropriate fate factor (FF) predicting the distribution of a plastic debris emission, the spatially explicit impacts can be understood in the form of characterization factors (CF). The presented EF is thus a first step in the derivation of a complete CF model. The current work sheds light on the entanglement potential of plastic debris, and can allow for a more valid evaluation of environmental impacts linked to plastic production, usage and subsequent deposition if applied in the LCA framework. Moreover, as LCA is a widely used environmental management methodology, including this impact can contribute towards more sustainable marine ecosystem management.

5.04.T-03 Impact Assessment of Microplastic Emissions in LCA: Preliminary Characterization Factors for Expanded Polystyrene and Tire and Road Wear Particles

Elena Corella-Puertas¹, **Pauline Guieu**², **Alessio Aufoujal**², **Cécile Bulle**³ and **Anne-Marie Boulay**⁴, (1)Chemical Engineering, CIRAIQ - École Polytechnique de Montréal, Canada, (2)AecopaQ, Canada, (3)UQAM, Ecole des sciences de la gestion, Canada, (4)CIRAIQ - École Polytechnique de Montréal, Canada

Although life cycle assessment (LCA) includes a variety of potential environmental impacts (climate change, ecotoxicity, etc.), to date there is no LCA methodology to include the potential impacts of plastic litter. This limits the applicability of LCA as a tool to compare potential impacts of single-use plastics and their alternatives. To address this shortcoming of LCA, the international scientific work group MarILCA (MARine Impacts in LCA) was founded in 2018 with the goal to propose a methodology for assessing (macro-, micro, nano-) plastic litter impacts (marilca.org). Within the MarILCA framework, the new impact category *physical effects on biota* addresses impacts associated with physical effects of plastics such as entanglement (of macroplastics) or ingestion (of microplastics), which ultimately may affect ecosystem quality. This work proposes two examples of preliminary characterization factors (CFs) for assessing potential impacts of microplastic emissions in aquatic environments via the impact category *physical effects on biota*. To develop these CFs, effect factors for assessing the potential impacts of micro- and nanoplastics on aquatic environments proposed by Lavoie et al. (2021) were used. To complete the preliminary CF modelling, simplified fate factors are developed for two types of microplastics: expanded polystyrene (EPS) and tire and road wear particles (TRWP). This exploratory work aims at understanding the relevance of different transport and removal mechanisms influencing the fate of microplastics in aquatic environment, identify challenges and guide research efforts. For EPS and TRWP, this work tested different fate scenarios for the degradation and sedimentation of microplastics. The fate scenarios were based on literature values and expert estimations. The obtained simplified fate factors were integrated into preliminary CFs and applied to a food container case study. The results confirm the potential relevance of marine litter impacts, the need for developing *physical effects on biota* CFs specific to different types of plastics, as well as the importance of modelling the fate of microplastics in more detail to reduce the uncertainty of CFs.

5.04.T-04 "Superfoods": Measuring the Water-Energy-Food Nexus Under a Life Cycle Assessment Approach

Jara Laso¹, **Maria Margallo**², **Ana Fernández-Ríos**², **Israel Ruiz-Salmón**², **Rebeca Abajas**², **Carmen Ortego**², **Francisco José Amo-Setién**², **Sergio Tezanos**², **Ainoa Quiñones**², **Laura Batlle-Bayer**³, **Alba Bala**⁴, **Pere Fullana**⁴, **Rita Puig**⁵, **Merce Balcells**⁵ and **Rubén Aldaco**⁶, (1)Ingeniería Química y Biomolecular, Universidad de Cantabria, Santander, Spain, (2)Universidad de Cantabria, Spain, (3)Escola Superior de Comerç International Universitat Pompeu Fabra (UPF), Spain, (4)UNESCO Chair in Life Cycle and Climate Change (ESCI-UPF), Spain, (5)Universitat Politècnica de Catalunya, Spain, (6)University of Cantabria, Spain

provide shorter abstract

5.04.T-05 Criteria Used to Review Weighting Methods As Part of the UN Environment Life Cycle Initiative's Global Guidance on Environmental Life Cycle Impact Assessment Indicators (GLAM) Project

Marco Cinelli¹, Chris Koffler², Cecilia Askham³, Andrea Amadei⁴, Rosalie Arendt⁵, Till Bachmann⁶, Breno Barros⁷, Anders Bjørn⁸, Luis Dias⁹, Alexis Laurent¹⁰, Masaharu Motoshita¹¹, Lea Rupcic¹², Serenella Sala¹³, Joao Santos¹⁴, Laura Scherer¹⁵, Bengt Steen¹⁶ and Ryosuke Yokoi¹¹, (1)Poznan University of Technology, Netherlands, (2)Sphera, United States, (3)NORSUS AS, Kråkerøy, Norway, (4)European Commission Joint Research Centre, Italy, (5)TU Berlin, Department of Environmental Technology, Germany, (6)EIFER, Karlsruhe, Germany, (7)Federal University of the Semi-Arid Region – UFERSA, Brazil, (8)John Molson School of Business, Concordia University, Canada, (9)University of Coimbra, Portugal, (10)Technical University of Denmark, Denmark, (11)National Institute of Advanced Industrial Science and Technology (AIST), Japan, (12)Danish Technical University, Denmark, (13)European Commission - Joint Research Centre, Italy, (14)University of Twente, Netherlands, (15)Leiden University, Netherlands, (16)Chalmers University of Technology, Afghanistan

In life cycle assessment (LCA), weighting enables evaluation of the relative significance of impact categories. Notwithstanding the development of several methods over the past three decades, there is yet no consensus as to which methods should be applied and when. This major research question has been taken up as part of the United Nations (UN) Environment Life Cycle Initiative's Global Guidance on Environmental Life Cycle Impact Assessment Indicators (GLAM) project. As part of the GLAM project, a working group has investigated weighting with two main objectives: (i) to develop guidelines for choosing weighting methods for LCA and (ii) to analyse, recommend and apply at least one method (or combination of methods) to obtain at least one set of global weights, which LCA practitioners could use by default when they do not wish to compute or use other weights. As part of the first objective, the subtask identified and reviewed a large set of weighting methods that could be suitable candidates. The methods were grouped into four categories: MCDA (Multiple Criteria Decision Analysis), monetary, data-driven and distance to target methods. Each method was reviewed by at least two team members based on a set of criteria defined by the group, as a step along the way to identifying which methods are most suitable for GLAM recommendations. The criteria are defined as follows: 1. Independence from the set of systems being evaluated, 2. Reproducibility of the weights, 3. Peer review, 4. Method transparency, 5. Coverage of GLAM areas of protection (AoP), 6. Uncertainty characterization, 7. Communicability, 8. Accounting for differences in utility for the same impact, 9. Association with AoP units, 10. Geographical resolution, 11. Global coverage, 12. Application demonstrated in case studies, 13. Required resources to apply the method, 14. Required technical and calculation infrastructure, 15. Representativeness, 16. Bias. Each criterion has been used to assess the different individual weighting methods in terms of their capabilities in principle. An iterative process has been developed in which the criteria have been harmonised, alongside the method reviews themselves. The developed criteria and reviews will be the basis on which the group aims to identify methods that can be recommended and applied to calculate weights at the global level to achieve objective (ii).

5.04 Life Cycle Impact Assessment modeling and application (Part II)

5.04.T-06 Development of Human Health Damage Factors for Climate Change

Lea Rupcic¹, Alexis Laurent², Annie Levasseur³ and Olivier Jolliet⁴, (1)Section for Quantitative Sustainability Assessment (QSA) DTU Environmental and Resources Engineering, DTU (Technical University of Denmark), Lyngby, Denmark, (2)Technical University of Denmark, Denmark, (3)Construction Engineering, École de technologie supérieure, Canada, (4)University of Michigan, United States

Climate change directly impacts human health through complex causal pathways by increasing temperature and precipitation, causing heat waves, fires, droughts, and floods. Indirectly, ecological and social disruptions, such as crop failure or population displacement due to natural catastrophes, are responsible for malnutrition, death by violence, or different mental issues. Those effects are not well covered in existing Life Cycle Impact Assessment methods. Current damage modeling is associated with damage factors covering five main health damage issues, i.e., malaria, diarrhea, cardiovascular diseases, malnutrition, and drowning. Since then, new climate-change-related and epidemiological studies have been published, and there is a need for this knowledge to be integrated into LCIA. Therefore, the aim of this study is to: i) identify all climate change impact pathways leading to human health damages, and ii) provide damage factors for the identified impact pathways by using the most recent epidemiological data. We illustrate this by presenting results of damage factors (DF) due to heat waves. We considered four emission scenarios (RCPs) and two adaptation scenarios in our model (no adaptation and hypothetically full adaptation). Our results show an increase in human health damages due to heatwaves caused by increased radiative forcing. As expected, DF values are lowest when considering adaptation. The lowest DFs are observed for RCP2.6, when no adaptation is considered, due to the lowest temperature increase, and for RCP8.5 when considering full adaptation (thanks to high adaptation measures). Observed variations between scenarios are within one order of magnitude. Compared to LC-impact and IMPACT World+ endpoint LCIA methods, our results show a 20% increase in DFs in case of full adaptation and 519% without, respectively. Our work demonstrates the relevance of better characterising climate change damages, so the LCIA modelling can ensure more accurate results for climate change damage assessment, and hence be better support for decision-making from LCA studies. We thus recommend the implementation of our new human health damage factors for climate change in LCIA.

5.04.T-07 Integrating Dynamic Modelling Into Life Cycle Impact Assessment for Quantification of Biomass Removal by Fisheries

Chloe Stanford-Clark¹, Eleonore Loiseau², Cécile Bulle³ and Arnaud Hélias⁴, (1)UMR ITAP - Elsa, Montpellier, France, (2)UMR ITAP, France, (3)UQAM, Ecole des sciences de la gestion, Canada, (4)Irstea, France

Fisheries are a globally important nutritional source increasingly suffering from over-exploitation. To improve the sustainability of this non-domesticated global food source, the full extent of impacts caused by fishing activities from the moment of extraction must be well understood. Life Cycle Assessment (LCA) is a method increasingly relied upon to quantify impacts of human activities on the environment and preside over preferred choices for the environments and ecosystems. It is therefore critical that

impact pathways accomplished through Life Cycle Impact Assessment (LCIA) methods are properly quantified. However impact pathways relating to marine ecosystems are a particularly underdeveloped area of LCIA, in comparison to their terrestrial counterparts. Pioneering work has recently proposed a first characterisation of the impact of biomass removal by fisheries on ecosystem quality. A new approach is now presented to develop this characterisation further. Following UNEP-GLAM Phase 3 recommendations to incorporate ecosystem dynamics into the characterisation of this impact, the approach integrates dynamic ecosystem modelling into the LCIA framework. This novel approach enables changes to be captured at the scale of the ecosystem, using an adaptation of time-dynamic trophic model Ecopath with Ecosim. In addition to the direct impacts of biomass removal of target and discarded species, the first output presented from the approach quantifies the subsequent indirect ripple effects through the trophic web, in conjunction with the natural background fluctuations of species. The first results are a midpoint characterisation of biotic change derived from the ecosystem model, allowing the exploration of changes occurring at the ecosystem level. The next step of the approach is its application to Characterisation Factor modelling for the computation of endpoint damage indicators. This can be applied to Areas of Protection (AoP) such as Ecosystem Quality, through a measure of biodiversity loss at regional and global scales, a metric of critical importance within environmental management and conservation decision-making. The outputs are also relevant for application to the Resources and Ecosystem Services AoP. Both pathways provide a step towards highlighting the need for improvement in the balancing act between use and conservation of natural capital and their source ecosystems using LCA.

5.04.T-08 Proposition for a Methodological Framework to Consider Ecosystem Impacts in the Life Cycle Impact Assessment of Offshore Wind Farms

Yoann Baulaz¹, Melanie Douziech², Paula Perez-Lopez³, Nolwenn Quillien⁴, Emma Araignous⁴ and Francesca Verones⁵, (1)France Energies Marines, Plouzané, France, (2)Agroscope, France, (3)MINES ParisTECH - OIE Research Center, Sophia Antipolis Cedex, France, (4)France Energies Marines, France, (5)NTNU, Norway

The development of offshore wind farms is booming with an increasing number of higher and more productive turbines, favored by ambitious roadmaps for energy transition. Life cycle assessment is one of the most complete and mature approaches to estimate the environmental impacts of an offshore wind farm project. Nevertheless, a number of methodological hurdles still have to be overcome to comprehensively analyze the effects of marine renewable energy sector. Among these challenge are the lack of appropriate indicators for the inclusion of ecosystemic impacts during the construction and operation phases of the OWF or the scarcity of ecological data in the marine environment. To address these gaps, we present a methodological framework to model ecosystem modifications due to offshore wind farms and we develop a path to take into account these changes in the life cycle impact assessment (LCIA) step. This framework is based on the identification of impact chains leading to marine ecosystem damage and the identification and characterization of medium-term impacts for which biophysical data exists in the marine environment. This conceptual model, original in its structure, combines both impact chains, classically used in LCIA framework, with an ecosystemic approach, allowing to identify which trophic compartments are affected by which impact chains and the consequences this has on species biomasses. As a result, the characterization of these different impact chains can be translated into new indicators for LCIA using the potentially disappeared fraction of species (PDF) and the potentially modified fraction of functional habitats (PDFH) as measures of the different types of OWF impacts. This framework makes it easier to avoid the risks of double counting in the LCIA framework, to apprehend information gaps and to potentially consider cumulative impacts. It represents then the first step towards the incorporation of OWF impacts on ecosystems in the LCIA framework, that could improve strategic marine planning in the context of marine renewable energy development.

5.04.T-09 Addressing the Triple Planetary Crisis -- a Planetary Boundary Based Life Cycle Assessment of Sugar in Pakistan

Hafiz Usman Ghani¹, Morten Ryberg², Michael Z. Hauschild³ and Shabbir H. Gheewala⁴, (1)King Mongkuts University of Technology Thonburi, Thailand, (2)Technical University of Denmark (DTU), Denmark, (3)Technical University of Denmark, Denmark, (4)King Mongkuts University of Technology, Thailand

The triple planetary crisis — climate change, biodiversity loss, and pollution — has emerged as an urgent environmental challenge posing an existential threat to human life on planet earth. The production of food is an interesting case in that it is essential for human beings but contributes adversely to these environmental issues. The recent advances in absolute sustainability assessment could help to overcome these issues by identifying opportunities for reducing the environmental impacts within the carrying capacity of planet earth. This study has therefore applied a planetary boundary-based life cycle assessment to sugar in Pakistan. The life cycle impacts were calculated for impact categories including global warming, biodiversity loss, and freshwater and marine eutrophication (i.e., pollution). The study revealed that under the existing production situation, the impact of sugar was within the allowable planetary boundary limits for fresh eutrophication, but not for climate change, marine eutrophication, and biodiversity loss. The enhanced use of byproducts and the use of a more efficient energy system resulted in improving the environmental performance. It could be seen that the use of existing best practices with target driven values could greatly help address the current environmental crisis.

5.04.V-01 Temporally-Explicit Abiotic Depletion Potential (TADP) of Mineral Resources Based on Future Demand Projections

Ryosuke Yokoi¹, Takuma Watari² and Masaharu Motoshita¹, (1)National Institute of Advanced Industrial Science and Technology (AIST), Japan, (2)National Institute for Environmental Studies (NIES), Japan

The depletion potential of metals is one of the main impact categories in life cycle impact assessment (LCIA), and models for assessing it have been heavily debated. Although the depletion potential depends on not only current status but also future status,

such as future demand and recycling, most existing models are based on the only current status. In this study, we extend the abiotic depletion potential (ADP), which is one of the widely used existing characterization models. We propose the extended characterization model: temporally-explicit abiotic depletion potential (TADP), which allows the assessment of depletion potential of metals from different time perspectives considering future metal demand and availability of secondary metals. ADP is one of the main characterization models for mineral resource depletion, quantifying the depletion potential by dividing the extraction rate by the square of a natural stock estimate. In the existing ADP, the current annual extraction is applied for the extraction rate. We extend the ADP by applying the average extraction rate until the target year. The average extraction rates are estimated for 2010-2100 based on dynamic material flow analysis and logistic regression analysis. We calculate the TADPs for six major metals (aluminum, copper, iron, lead, nickel, and zinc) by five SSPs (shared socio-economic pathways), which are represented as relative values against iron (i.e., reference metal is iron). The results show that TADPs for all metals and all SSPs increase compared to those for iron by considering the future changes in total demand and recycling. It implies that the existing models assuming constant extraction amounts (i.e., ADPs) may overestimate the depletion potential of iron compared to the other metals. We show that changes in the relative significance of metals by TADPs compared to the original ADPs may have a great effect on the results of LCIA. Furthermore, we show that the time perspective will affect the relative significance of metals. From the short- and medium-term perspectives, copper exhibits the greatest increase of TADPs compared to the original ADPs (increase in maximum by approximately 1.9 times compared to the existing ADP). On the other hand, from the longer-term perspective, lead and zinc exhibit greater increases in TADPs compared to the original ADPs (increase in maximum by approximately 2.8 times compared to the existing ADP).

5.04.V-02 The Development of LIFE Cycle Impact Assessment Characterization Factors for Desertification

Runya Liu¹, Haruka Ohashi², Tetsuya Matsui², Akiko Hirata² and Norihiro Itsubo³, (1)Tokyo City University, Yokohama, Japan, (2)Forestry and Forest Products Research Institute, Japan, (3)Tokyo City University, Japan

Along with the acceleration of climate change and expansion from anthropogenic activities, the desertification's impacts are projected to be profound. Drylands area is occupying 42% of earth's surface land with responsible to hold 38% of the global population, which has a significant meaning to our planet. In aims of sustainably developing of society, we applied the LCIA concept to analyze desertification with related impacts so that we can provide a more inclusive quantitative vision for stakeholders. Thus, firstly we proposed the framework for desertification as an extended LCIA midpoint to land use. Then we analyzed and predicted the desertification under different scenarios and try to bridge the characterization factor between inventory to the midpoint. Finally, we incorporated the model from an ecological way to evaluate biodiversity loss as an endpoint to desertification and complete the challenging view of the connection between desertification and biodiversity. As the primary results show the drylands area in 2015 is 53.1 million km². At meanwhile, we compared our results of desertification area with former studies, a report from the united nation for global drylands reported the dryland zone in 2011 was 50.80 million km². As for characterization factors between inventory to the midpoint, the intensity shows a higher potential vulnerability around central Asia to the black sea, northeast Australia and central America, the CF range from -7.62E-07 Ha/tCO₂ to 4.63E-06 Ha/tCO₂ among 5 GCMs. Most of those locations were under a highly warming level and high-water consumption.

5.04 Life Cycle Impact Assessment modeling and application (Poster)

5.04.P-We232 Toward Operationalizing the Fate of Water Consumption in LCA Using Depletion Factors and Tendencies

Eleonore Pierrat¹, Martin Dorber², Inge de Graaf³, Alexis Laurent⁴, Martin Rygaard⁵, Michael Z. Hauschild⁴ and Valerio Barbarossa⁶, (1)DTU (Technical University of Denmark), Denmark, (2)Norwegian University of Science and Technology (NTNU), Norway, (3)Wageningen University, Netherlands, (4)Technical University of Denmark, Denmark, (5)DTU Environment, Denmark, (6)Leiden University, Netherlands

Freshwater dependent ecosystems are under multiple pressures, including water resources depletion due to human consumption. Life Cycle Impact Assessment (LCIA) methods usually focus on one aspect of the water cycle (e.g. streamflow), without accounting for its connections to the other compartments of the water cycle. New LCIA methods assessing the impacts of water consumption should reflect the fate of water consumption i.e. the complex transport of water between the water cycle compartments (e.g. surface, groundwater, and atmosphere), so that impacts on different freshwater ecosystems could be modelled. Our study aims to operationalize the fate of water consumption and we illustrate potential applications in LCIA. We developed depletion factors (DF) and depletion tendencies (DT) that reflect long-term consequences of freshwater consumption on freshwater resources available for ecosystems and human communities in four compartments of the water cycle and at the regional scale. DF represent depletion (between 1960 to 2010) of streamflow and groundwater storage and changes in evapotranspiration and soil moisture caused by blue water consumption and are expressed in m³ depletion per m³ consumption in a river basin. DT represent the recent dynamics of depletion (m³.yr⁻²/m³.yr⁻²) showing the change in depletion associated with the change consumption from 2000 to 2010. They are build on the outputs of a state-of-the-art global-scale surface water-groundwater model (PCR-GLOBWB 2.0). We calculated DF and DT for 8,664 basins, covering 93% of the landmass where water consumption is significant (i.e. excluding deserts and permanently frozen areas). Using DF and DT as fate factors would promote harmonization across LCIA methods, and enable new developments providing one element of the characterization factors.

5.04.P-We233 Ecotoxicity in LCA: How to Guide Practitioners Towards Sound Decision Making for Business?

Anne Asselin¹, Aurore Wermeille², Céline Gentil-Sergent³, Magdalena Czyrnek-Delêtre⁴, Célia Chamillard⁴, Florian Diot-Néant⁴, Jade Garcia⁵ and Philippe Osset⁶, (1)Sayari, Saint Germain en Laye, France, (2)Sayari, France, (3)ITAB, France, (4)I-Care, France, (5)SCORE LCA, villeurbanne, France, (6)SCORE LCA, France

Impacts on ecosystems from chemical substances emitted to the environment are of growing concern among the population and in business. In LCA, ecotoxicity is often not analysed, and if it is, results are hardly communicated because they are deemed not robust. We aim to answer the question: how to use current ecotoxicity LCA indicators for business decision making? **Objective:** Our objective is fourfold: i) make an inventory of existing ecotoxicity methods and indicators in LCIA; ii) analyse the foundations of these indicators, understand the methodological choices and calculation methods; iii) test methods on case studies; iv) Set up recommendations for practitioners. **Method:** We analyse and compare five methods, using notably GLAM recommendations and criteria as a basis: USEtox 2.12, ReCiPe 2016, LC-Impact, Impact World+ and EF3.0, both in their native format and as available in SimaPro (except for LC-Impact). In order to provide relevant recommendations, i) we map native methodology and CFs' in term of scope (substances covered), impact pathway(s), target media, time horizon(s), underlying data and link with risk assessment methods and data; ii) we analyse the implementation in SimaPro, and related choices made by software developers; iii) we apply methods on substances (3 organics, 2 metallics and 1 inorganic non-metallic) per compartment and sub-compartment and 2 processes (maize grain production and waste water treatment fromecoinvent). **Results:** The lack of terrestrial and marine ecotoxicity indicators in 3 of the 5 methods is changing the way results can be interpreted. For a given substance, native methods and software application do not lead to the same results linked to missing software updates and adaptations of the method, mostly due to absence (or simplification) of spatialization and mapping of emission compartments. We see a notable difference for metals, where time horizon (100 years of infinite) matters. For the two ecoinvent processes studied, we observe differences in results according to the methods used, due to relative importance of CFs between substances and emission compartments between methods. We also compare CFs' underlying data between methods; we notice differences and limitations. **Recommendations:** These results will be followed by recommendations to practitioners, that are still under development. They will cover use of methods and result interpretation, aligned with GLAM and actionable by practitioners.

5.04.P-We234 Problems From Including Technospheric Parameters in Characterization Factors for Natural Resources

Rickard Arvidsson¹ and Björn Sandén², (1)Environmental Systems Analysis, Chalmers University of Technology, Gothenburg, Sweden, (2)Chalmers University of Technology, Sweden

The life cycle inventory (LCI) analysis generally considers a product system in the technosphere, whereas the life cycle impact assessment (LCIA) is generally concerned with impacts in nature. However, in LCIA methods for natural resources, we have noticed a tendency to include technospheric parameters. This practise, which deviates from the predominant use of parameters related to environmental processes in characterization factors for emissions, has not received much attention in the LCA community. Here, we discuss a number of problems arising from such inclusions. Three types of technospheric parameters found in characterization factors for natural resources were analysed: (i) extraction rates, (ii) recycled contents, and (iii) prices. Extraction rates vary over time, and frequent updating is therefore needed to avoid outdated characterization factors. Furthermore, the inclusion of extraction rates in the characterization factors creates an interdependency between the LCI analysis and the LCIA, since extraction rates are also part of the inventory modelling. We show that such interdependencies can potentially lead to counterproductive information. Regarding recycled contents, when inventory data with recycled content are matched with characterization factors also taking recycled content into account, the benefit of recycling is double counted. Furthermore, it introduces a risk of inconsistency: the recycled contents in the characterization factors may not match those in the LCI analysis. In addition, characterization factors based on recycled contents are also time sensitive. Prices are commonly used in economic allocation in the LCI analysis. When they are also used in characterization factors, there is a risk of inconsistency if these prices are not the same as those used in the allocation. In addition, prices are very time sensitive, potentially fluctuating notably even on a daily basis. There are possible solutions to some of these problems, such as frequent updating of characterization factors and avoiding economic allocation. However, these solutions come at a cost. For example, frequent updating of characterisation factors is work intensive, and economic allocation may be otherwise recommendable in some studies. For the LCI-LCIA interdependency, we see no obvious solution. Considering the identified problems, we recommend further critical discussions on the inclusion of technospheric parameters in characterization factors for natural resources.

5.04.P-We235 Impact Evaluation of Circular Economy Strategies Including Resource Dissipation Within Life Cycle Assessment: Literature Review and Methodological Framework

Jair Santillán-Saldívar¹, Emmanuelle Cor², Stéphanie Muller³, Antoine Beylot³ and Elise Monnier², (1)Université de Bordeaux, France, (2)CEA- Commissariat à l'Énergie Atomique et aux énergies Alternatives, France, (3)Bureau de recherches géologiques et minières BRGM, France

The increasing level of resource consumption over the past decades led to the development of strategies that fall under the paradigm of the Circular Economy (CE). Life cycle assessment (LCA) is proposed to evaluate the impacts of CE strategies and it is arguably able to support decision-making processes related to the Areas of Protection (AoP) Ecosystem Quality and Human Health; however the same level of consensus is not applicable when measuring impacts in the AoP Natural Resources. Various methods address the impacts of mineral resource extraction, focusing on the questions of resource depletion and criticality; however, Resource Dissipation (RD) remains under discussion; there is a limited number of proposals to assess the impacts of dissipative losses. As part of the DissipaLoop project, supported by the French Alternative Energies and Atomic Energy Commission (CEA) and the French Geological Survey (BRGM), this contribution aims to identify methodological gaps and provide recommendations on the evaluation of CE strategies through LCA to support decision-making processes; for this case, the introduction of a recycling technology. Three literature reviews were conducted. One on the links between LCA, CE and RD. Next, an extension of the existing reviews on CE followed by a multi-criteria process of classification to select metrics that support the objective of the study. Finally, a review on RD was extended to identify developments on the impact assessment of dissipative flows. A methodological framework was constructed for the evaluation of CE strategies through LCA. The study of CE

metrics allowed selecting seven that could inform on the impacts of these strategies. Among the assessment methods focused on RD, it was identified that an unexplored pathway is the measure of lost value due to potential resource dissipation. The development of the framework allowed identifying how the concepts of CE, LCA and RD connect, with special focus on the methodological gaps for the evaluation of CE strategies. From the wide range of studied CE metrics, seven can be suggested in connection with LCA to inform the decision-making process regarding new recycling technologies. Finally, an impact pathway focused on potential lost value due to RD was identified. Future work will focus on the development of the identified impact pathway in RD and its testing within the evaluation of a novel recycling technology through LCA and the application of the suggested CE metrics.

5.04.P-We236 Split Gas Approach to Set New Emission Reduction Targets Compatible With 1.5 °C Warming in the Agri-Food SECTOR

Koldo Saez de Bikuna¹, Sofie Lamens² and Alexi Ernstoff², (1)Quantis, Milano, Italy, (2)Quantis, Switzerland

5.04.P-We238 Water Footprint of FOReSt and Orchard Trees: Methodological Gaps and Trends

R. Gemma Raluy, Paula Quinteiro and Ana Dias, University of Aveiro, Portugal

The current challenge of global water scarcity is addressed in Goal 6 of the 2030 Agenda for Sustainable Development ('Ensure availability and sustainable management of water and sanitation for all') aiming to increase global water-use efficiency and ensure sustainable water withdrawals and supply. According to the current water use planetary boundary, which focuses on allowable blue water consumptive use, water use is categorized as a global safe operating space, in spite of boundary transgression risk in some regions. However, it has been highlighted the need of understanding how climate and living ecosystems respond to changes in the different forms of water on Earth. Trees have a relevant role in the water cycle. They can be rain-feed, use groundwater water and, at small scale, be irrigated. Blue water includes surface and ground water, while green water represents rain water. Trees also release water through evapotranspiration (ET) and, thus, disturbances in tree management affect ET and, consequently, atmospheric moisture transport and water availability. The aim of this review is to identify how water footprint (WF) applied to trees (forest and orchard trees) is currently being addressed, and which are the methods used, methodological gaps and main challenges for a consistent and harmonized WF scarcity assessment. The review used different databases as search engine, focused on studies published in peer-reviewed journals, considering keywords focused on forest and orchard trees, WF measurements and methodological choices. The final articles sample (47 publications) was categorized as case study (35), methodological development (1), overview (4), mixed approach (5) and review (1). Trees located in Europa (with Italy in the lead) and Asia represented the highest number of studies, followed by global scale analysis. Olive and oil palm trees were the most analyzed within case studies and mixed approaches, while forest was covered in overviews, methodological development and review. Spatial and temporal resolution were features indicated in almost 40% and 90% of the articles sample, respectively. This review shows that for obtaining a consensual and harmonized assessment of the WF scarcity of forest and orchard trees there is still a pathway to be followed. Further methodological improvements are crucial for a better understanding of the relationships between green and blue water in agroforestry systems, including the effects of edaphoclimatic conditions.

5.04.P-We239 Introducing Impact of Marine Plastic Debris on Ecosystem Service to LCIA

fei song¹, Francesca Veronesi², Martin Dorber³ and Johan Pettersen³, (1)The Norwegian University of Science and Technology, Norway, (2)NTNU, Norway, (3)Norwegian University of Science and Technology (NTNU), Norway

Around 40% of the world's population nowadays is located in the coastal area, whose life is closely associated with marine ecosystems and their services, such as food provision, storm protection, recreational opportunities and biodiversity. However, marine ecosystems are increasingly confronted with many anthropogenic stressors such as plastic debris and invasive species, affecting many ecosystem services. Unfortunately, an operational impact category for marine ecosystem services within the framework of life cycle impact assessment (LCIA), is missing, leaving a knowledge gap between current status and ecosystem protection policy. We try to narrow this gap, by building an effect factor for microalgae's carbon sequestration in response to marine plastic debris, as marine microalgae are responsible for 40% of the total CO₂ absorption in the biosphere. In our study, we collect growth inhibition rate data for different microalgae and polymers with different sizes and concentrations. This data is used to construct spatial-differentiated species sensitivity distributions (SSDs), which are used as the basis to calculate effect factors of carbon sequestration loss. The result provides the first effect factor quantifying impact on ecosystem services. In addition, our results lay the foundation for future marine ecosystem services assessment in LCIA. The next stage of our work will be to develop a fate factor, which will enable the development of complete characterization factor for impacts on carbon sequestration.

5.04.P-We240 Hybrid Consumption-Based Normalization Approach for the Life Cycle Interpretation in the Plastic SECTOR: A Proposal

Alessandro Marson¹, Andrea Fedele², Filippo Zuliani², Sara Toniolo², Antonio Scipioni² and Alessandro Manzardo², (1)University of Padova, Padova, Italy, (2)University of Padova, Italy

Life cycle assessment (LCA) is widely used for the comparative assessment of the environmental performances of materials and processes. The strength of LCA is the ability to analyze impacts in multiple environmental aspects throughout the life cycle of the system being analyzed. If the objective of the study is the analysis of the environmental profiles of a material as well as the decision support in the comparison and choice between different alternatives, tools for achieving a synthesis of multicriteria results become necessary. In this regard, the LCA reference standards describe the optional normalization (calculating the

magnitude of the indicators of categories relative to the reference information) and weighting procedures. Even if practitioners perceive normalization and weighting process negatively due to uncertainty and loss of robustness, their contribution to the interpretation and decision making of results is recognized. Typical problems of external normalization are related to uncertainty linked to the data of the reference system, discrepancies between the substances of the two life cycle inventories (analyzed system and reference system), inverse proportionality and the large amount of data required. The aims of this work are: (i) present a hybrid (internal-external) consumption-based normalization approach applicable in the context of cradle-to-gate analysis of plastic materials based on the annual European plastic demand, (ii) evaluate the variability of the normalization set considering the years 2005 and 2019 as reference. The weighting procedure is not addressed in this work. For this work, aiming to present normalized environmental profiles (cradle-to-gate, declared unit 1 kg) of three plastic materials (PP, PVC, PLA) a normalization set was built on the basis of the European plastic demand starting from the data provided by Plastic Europe for the year 2005 and 2019 and the secondary data proposed by Ecoinvent 3.6. Sets of impact categories and methods proposed by PEF were used. The presented normalization approach is a proposal for a better interpretation of LCA results in the plastic sector. Due to the limited amount of data required, continuous updating over time is possible, as well as the establishment of a reference in line with the goal and scope of the study. The use of common secondary data and methods allows us to address the main problems associated with external standardization approaches.

5.04.P-We241 Integration of New Climate Change Characterization Factors for the Aircraft Life Cycle Assessment

Tiphaine Gaillot, IFP Energies nouvelles, France

Air traffic accounts for 11% of world fuel consumption and 2% of world CO₂ emissions (IATA, 2017). The cumulative emissions from 1940 to 2018 are 32.6 billion tons of CO₂ (approximately 50% have been emitted in the past 20 years) (Lee et al., 2021). Most of these emissions occur during the cruise phase. Life Cycle Assessment (LCA), is used as a reference method for air transport environmental assessment. As a regulatory reference, Global Warming Potential (GWP) is nowadays the most strategic impact category for air transport. Aircraft emissions are mostly located at the level of the upper troposphere and the lower stratosphere during the cruise phase according to the flight of the aircraft (courts, medium and long haul) (IPCC, 1999). Emitted molecules have a different radiative forcing and as a consequence a different impact on climate change depending on the altitude at which the molecule is emitted (Wahner et al., 1995 ; IPCC, 1999 ; Jungbluth and Meili, 2019 ; Matthes et al., 2021). This specification is not currently considered by the LCA characterization method (IPCC, 2013) which only considers that emissions are on the ground. The objective of this study is to integrate the impact characterization factors specific to high altitude emissions into the LCA. The functional unit consists of transporting a person over a distance of one km in a long-haul aircraft using conventional fuel (jet type A-1). The plane, the airport, the kerosene, the ground emissions, and the high-altitude emissions are considered. The characterization factors as well as the high-altitude emissions from Lee et al. (2021) are integrated. The results show that considering Lee et al. (2021) high-altitude emissions and characterization factors increase GWP impacts by 102%, from 9.79 E-02 kg CO₂eq (kg of CO₂ equivalent per person per km) for the base case scenario compared 1.98E-01 kg CO₂eq/pkm with Lee et al. (2021) values. High-altitude emissions are strategic for LCA of air transport as it represents the biggest part of the total impact. For Lee et al. (2021) scenario, high-altitude emissions' impact represents 91% of the total impact (plane, airport, kerosene, ground and high-altitude emissions). It represents 82% for the base case scenario. This increase is mostly due to the integration of Lee et al. (2021) new characterization factors of nitrogen oxides (NO_x) which had not been calculated for the emissions at altitude and which is now at a GWP of 114.

5.04.P-We242 Towards a Safe Circular Economy - Monitoring Strategy for Substance of Concern

Lise de Boer¹ and Natascha Spanbroek², (1)National Institute for Public Health and the Environment (RIVM), Nederland, (2)Dutch National Institute for Public Health and the Environment (RIVM), Netherlands

The EU's chemicals strategy for sustainability aims for a toxic-free environment. In addition, the current linear economy should transition to a circular economy to deal with material use and associated environmental impacts. In such an economy, raw materials are continually reused in order to minimise waste. Examples of developments in the transition to a circular economy include the increasing use of separate collection and recycling, but also the emergence of new chemical recycling methods and the renewed focus on re-using and repairing products. However, (reused) materials can contain hazardous substances, which can harm the environment and human health. As long as substances of concern are used in products and materials, these substances could re-enter the product chain in a circular economy. It is crucial for a safe circular economy to know what will happen to substances of concern when products, parts and materials are used in a subsequent application. This is particularly relevant if the new application is different from the original use. This might lead to new unintended exposure of workers, users and the environment to substances of concern. Three major challenges for a safe circular economy are identified [1]:

- Availability of information on substances of concern in the supply chain
- Expanding responsibility throughout the entire product chain
- Safe handling of substances of concern in a circular economy where phasing out is not possible

All in all, a circular economy is not necessarily safe. However, the transition to a circular economy requires a different approach to substances of concern, and offers momentum to take a safer, more preventive approach to coping with these substances and their risks. It is important to know whether a product or material is safe for people and the environment. However, it is not easy to get a complete overview of substances of concern in materials. There are many kinds of these substances that are present in a many different materials and products. RIVM has prepared a draft method for determining and monitoring the risks posed by substances of concern in a circular economy [2]. This monitoring method makes it possible to analyse at which location in the value chain of production, use, and (waste) processing substances of concern can be present and where they may cause risks. Using these insights, it is for example possible to show how government and industry can make efforts for safe processing of materials.

5.05 Prospective assessment of emerging technologies and emerging product systems in a life cycle perspective (Part I)

5.05.T-01 Prospective LCA of Bio-Based Products: A Scenario Methodology and Lessons Learnt From the PLANET BIO Project

Bernhard Steubing¹, Stefano Cucurachi¹, Sabine Langkau², Matty Janssen³, Flora Siebler⁴, Nicolas Navarre⁵, Carla Caldeira⁶ and Serenella Sala⁶, (1)CML Leiden University, Netherlands, (2)Fraunhofer ISI, Germany, (3)Chalmers University of Technology, Sweden, (4)Institute of Environmental Science, CML Leiden University, Netherlands, (5)Faculty of Science, Leiden University, Netherlands, (6)European Commission - Joint Research Centre, Italy

Prospective LCA aims at evaluating the potential impacts of future technologies and thereby guiding their development. Within the project “Prospective LCA for Novel and Emerging Technologies for BIO-based products” (PLANET BIO), state-of-the-art methodological guidance was compiled to perform prospective LCA for bio-based products. More specifically, guidance addresses aspects that are particular to prospective LCA across the 4 phases of LCA, the development of scenarios, the modeling of biogenic carbon flows, and the handling of uncertainties. Here we provide an overview of this guidance. We then focus on one aspect particularly, which is a novel methodology for the development of scenarios, which often lacks an explicit treatment in prospective LCAs. We present a practical framework for developing scenarios and conducting scenario analyses that should help LCA practitioners to a) develop better scenarios and b) be more explicit in describing how the scenarios were developed. This should not only increase transparency and reproducibility, but should also help the reader to better understand which parameters may be key in different possible futures and to foster the discussion about possible future developments rather than just focusing on LCA results relating to these. The core scenario methodology consists of 4 steps as part of the inventory analysis phase: i) the identification of key parameters, ii) the development of specific sub-scenarios for each parameter, iii) the creation of overall scenarios and narratives, and iv) the implementation of these scenarios in LCI models. Specific tools to support the work in each of these steps are described (e.g. cross-consistency analysis and concepts borrowed from morphological analysis). A key element of the work is the combination of a causal loop diagram with an LCA flow chart, which aims at linking in a visually explicit way the technology parameters, big-picture surrounding parameters, and the LCI model itself. This diagram can be a key element during scenario development, but also for the further communication of scenarios to different stakeholders.

5.05.T-02 Methods to Environmentally Assess Cleanroom Facilities for Emerging Technologies

Flora Siebler¹ and Stefano Cucurachi², (1)CML Leiden University, Afghanistan, (2)CML Leiden University, Netherlands

Predictive LCA is a valuable tool for anticipating and ideally avoiding the environmental impacts of new technologies. Many of these technologies, especially those involving nanoscale processes such as semiconductor manufacturing, require defined clean spaces to ensure high quality end products. However, the facilities that function as cleanrooms are not well standardized, only the output that a cleanroom provides must meet a set of defined standards. The lack of standardization in cleanroom design presents a challenge for LCA analysts, who have only a handful of outdated sources, limited LCI data, and few studies with real measured data to draw upon. Such challenges do not allow the LCA analyst to effectively quantify, prevent, and minimize the environmental impacts of new technologies that require the use of cleanrooms. Since cleanroom maintenance involves a significant amount of energy, the lifecycle steps that must take place in these defined spaces can be an important factor in evaluating the overall sustainability of incumbent and new technologies. By considering parameters such as energy requirements for cooling and heating, or future energy mixes, we explore a large solution space of possible combinations. All of these different scenarios allow us to quantify the impact of cleanrooms under a variety of real-world conditions. We were able identify possible trade-offs between relevant parameters depending on ISO classification, location, and climate. For example, environmental impacts are closely related to the locally available energy mix. However, we can show that for ISO classes 6 to 9, energy requirements for heating and cooling can play an important role in the choice of cleanroom location. Depending on the required performance, we can directly rule out scenarios with very high and undesirable environmental impacts. In addition, we provide usable LCI data and scenarios that can support the LCA analyst in need of such data. Beyond this specific case study, we also provide a combination of techniques that can streamline the evaluation of systems that depend on a variety of parameters. Our work also aims to broaden the focus of cleanroom designers on the sustainability of this service and whether, for example, location plays a role in deciding where to establish and operate future cleanrooms.

5.05.T-03 Dealing With Future Developments of Wind Offshore Energy for Integration Into an Energy System: How to Incorporate Environmental Aspects?

Alicia Maria Benitez Britos¹, Christina Wulf², Bernhard Steubing³, Wilhelm Kuckshinrichs¹ and Jutta Geldermann⁴, (1)Forschungszentrum Jülich GmbH, Germany, (2)Forschungszentrum Juelich GmbH, Germany, (3)CML Leiden University, Netherlands, (4)University of Duisburg-Essen, Germany

Life cycle assessment (LCA) is a standard methodology to assess the environmental impacts of technologies. Many LCA studies prove that wind energy has a low impact on climate change and, thus, is often suggested for the decarbonization of the electricity sectors in different countries. In addition, the LCA studies provide indicators of the environmental performance during the construction, installation, and operation of wind turbines. Yet, these indicators might capture technology development of wind energy meagerly because of the LCAs static approach that depends on the database for background data which is often much older than foreground data. In the meantime, technology evolves and innovates. That is why the integration of LCA indicators into energy systems models is not straightforward. Energy system models provide scenarios that address different visions of the future. Therefore, the environmental aspects of energy systems should grasp technological development, if possible, from two perspectives. First, the life cycle inventory (LCI) should include changes in the foreground according to the future development of the most relevant parameters. Second, the LCI

should consider technical and temporal adjustment of background processes, like the market share of resources and utilities. This study focuses on the inventory of wind offshore electricity generation and considers upscaling of wind turbine components. This work applies the scenario development method for wind offshore energy in Germany using the Superstructure approach in the LCA opensource software Activity-Browser, which employs future LCI provided by the Premise initiative. The study sets up scenarios adapted for Germany to reflect expected future trends for wind offshore. The aim is to obtain specific impact indicators and integrate them into an electric system model for assessing optimal operation strategies for future power plant fleets regarding economic, technical, and environmental aspects.

5.05.T-04 Application and Adaptation of a Scale-Up Framework for Life Cycle Assessment to Resource Recovery From Waste Systems

Nilay Elginoz Kanat¹, Isaac Agyeman², Göran Finnveden², Roland Hischier³, Tomas Rydberg¹ and Zeynep Guro², (1)IVL Swedish Environmental Research Institute, Sweden, (2)Royal Institute of Technology (KTH), Sweden, (3)Empa – Swiss Federal Laboratories for Material Science and Technology, Technology and Society Laboratory, Lerchenfeldstrasse 5, 9014 St. Gallen, Switzerland

Introducing Life Cycle Assessment (LCA) in the design stage enables determining hotspots in an emerging technology and may lead to process improvements. Full-scale plant data is not yet available for emerging technologies at low technology readiness levels, which is one of the major challenges of early stage LCAs. This study tested an engineering-based upscaling method, adapted it to biochemical resource recovery processes, and checked the validity of the results as compared to data from real full scale operations. The study displays substantial difference between the methane production amount in actual plants (scenario 1) and conceptual plants based on raw lab-scale data (scenario 2). On the other hand, when a conceptual plant was designed based on pilot plant data or modified lab-scale data taking into account the reaction kinetics (scenarios 3-4), the LCIA results of the conceptual cases were reasonably similar to the actual case. For those scenarios, it may be claimed that the difference in the results are fairly limited and within ranges that can be expected. In line with other studies [6] it is recommended to be careful when comparing emerging technologies with their incumbent counterparts not to unfairly disqualify emerging technologies in their early design stages.

5.05 Prospective assessment of emerging technologies and emerging product systems in a life cycle perspective (Part II)

5.05.T-06 Technology Learning Effects in Prospective LCA: Rule of Thumbs Derived Using LIFE Cycle Inventory Databases

Nils Thonemann¹, Karen Saavedra Rubio² and Alexis Laurent³, (1)Danish Technical University, Lyngby, Denmark, (2)Department of Environmental and Resource Engineering, QSA section, DTU (Technical University of Denmark), Kgs. Lyngby, Denmark, (3)Technical University of Denmark, Denmark

Considering environmental impacts in the early stage of product design gets increasingly essential. This is because degrees of freedom in the early design stage are greater than in a later stage of design. On the other hand, uncertainty decreases throughout technology development as decisions are taken, and the observed process becomes clearer and more data is available. In order to provide data in an early design stage and scale this data to a future point in time, upscaling schemes are needed to fill data gaps. A method for upscaling are so-called learning curves. Learning curves can examine historic development rates of technologies and can be extrapolated into the future to estimate technology learning effects. This approach has already been used in economics to analyze the correlation between production and costs and preliminary to the development of environmental impacts. In this work, different versions of the LCI database ecoinvent are used to derive scaling factors. Each of these databases is analyzed using the Brightway 2.5 LCA framework by calculating the environmental impacts of each process. Via mapping processes producing the same reference product in the same geographical location of each database, the environmental impacts of each process can be compared throughout the databases. Following this approach, it can be concluded that, for example, the GWI is by 0.5 % when comparing ecoinvent 3.1 with ecoinvent 3.8. The results show the applicability of the method and indicate potential technology learning over time based on LCI databases. These findings will be helpful in the application of prospective LCA. However, product- or sector-specific scaling factors could lead to an even more insightful analysis.

5.05.T-07 Modelling Biological and Techno-Operational Uncertainty in Ex Ante LCA of Microalgal Molecule Productions

Pierre Jouannais and Massimo Pizzol, Aalborg University, Denmark

On the ground of their mostly unexplored phylogenetic and biochemical diversity, microalgae are being explored in a search for new high value and promising molecules such as food supplements, nutraceuticals or pharmaceuticals. The literature shows a high variability of the environmental impacts associated to microalgae products due to diversity of strains, locations, cultivation periods and technologies. As no industrial scale process data is available for microalgae, LCA studies rely either on laboratory and pilot scale results or on assumptions on productivities in given production systems. However, we do not know to what extent the assumptions and results from these previous studies can be generalized to novel strains. Biophysical models have shown how different strains behave and grow distinctly in different photobioreactors (PBR). For a novel strain and molecule, we thus cannot forecast yet which PBR geometry and which operational parameters (biomass concentration and flow rate) will allow a certain productivity. To integrate this uncertainty in the Ex-ante LCA of novel microalgae products, we propose and test a parametrized and consequential LCA model combined with a stochastic approach. The deterministic model relies on 60 interacting and independent parameters covering the biological, techno-operational, physical and geographical dimensions and dynamically simulates the microalgal molecule production in any location and season. An extended stochastic Fourier Amplitude Sensitivity Test (FAST) is performed to propagate the uncertainty on 6 parameters associated to the PBR design, operation and

thermoregulation to the environmental impacts. The model is tested for a realistic strain cultivated in Aalborg; Denmark and Granada; Spain and shows that thermoregulation is a key and overlooked environmental hotspot, both in absolute value and in uncertainty. The results highlight the necessity, for Ex-ante assessments, to go beyond simplistic assumptions on areal productivities as little variation of the cultivation system and operation may lead to significantly different impacts. Despite uncertainty, the model shows little overlapping for the environmental impacts between the two locations and thus demonstrates its applicability as a decision-making tool. This work and model eventually aim at exploring the future environmental impacts of microalgae productions through comprehensiveness, uncertainty integration and transparency.

5.05.T-08 LCA of Emerging Transportation Systems in Pilot Operation Including Scenario Analysis

Susanne Hanesch¹ and Liselotte Schebek², (1)Fachgebiet Stoffstrommanagement und Ressourcenwirtschaft, TECHNISCHE UNIVERSITÄT DARMSTADTIWAR, Darmstadt, Germany, (2)Technische Universitaet Darmstadt, Germany

Mobility solutions with low climate impact are needed to reach a sustainable transport sector. In order to decarbonise the sector, a large number of emerging e-mobility technologies are currently being developed, in which the energy source is changed from fossil fuels to electricity. Life Cycle Assessment (LCA) is used as a tool to evaluate these technologies regarding their contribution to achieve the climate targets in the future. However, different technologies have different technology readiness levels (TRL) and moreover, the underlying mobility concepts will evolve during the process of technology development and early phases of application. Consequently, this has to be included in the ecological assessment for a comparison to established transport technologies. Our work shows a comparative LCA of the two freight transport alternatives *conventional truck* and *overhead line hybrid truck* (OH truck). The data input comes from the implementation and operation of a real field trial in Germany. The field trial, where local transporters deliver goods from the depot to the destination over the realised eHighway track of 5 km in each direction, provides pilot operation data. From this data, an inventory is created and a reference LCA is performed, which refers to TRL 6 of the field trial. In a second step, the approach is extended to a possible development state that includes real-world application of TRL 7. To perform this, a scenario approach is developed. In the scenario approach, the deployed eHighway track remains the same, but with higher vehicle utilisation. For the OH truck, several technological improvements are assumed. These future improvements consider the transformation potential of the technology under development. Despite the varying data availability and uncertainty associated with emerging technologies, it was possible to identify and model the future performance of the new transport system. The results obtained from a transparent and structured methodological approach could increase the comparability of the two transport alternatives. The outcomes show large differences between the actual state assessment and the assessment taking into account the scenario approach. By considering future improvements of the emerging product system, greenhouse gas reductions amounting to half of the budgeted climate targets can be determined for the OH truck compared to conventional freight transport.

5.05.T-09 Parameterized Life Cycle Inventories for Representative Life Cycle Assessments of Future Energy Scenarios: Application to the French Heating SECTOR

Melanie Douziech¹, Romain Besseau², Raphaël Jolivet², Bianka Shoai-Tehrani³, Jean-Yves Bourmaud³, Guillaume Busato³, Mathilde Gresset-Bourgeois³ and Paula Perez_Lopez⁴, (1)Agroscope, France, (2)Mines Paris, PSL Research University, France, (3)RTE, France, (4)MINES ParisTECH - OIE Research Center, Sophia Antipolis Cedex, France

Life Cycle Assessment (LCA) is a worldwide accepted methodology to estimate the environmental impacts linked to the life cycle of a product or service. Despite its standardization, practitioners face challenges when applying LCA, especially in the field of future technologies. A major one relates to integrating future systems within an ever-evolving background, e.g. changed composition of the supplied electricity to future technologies. Coupling outcomes of Integrated Assessment Models to foreground LCA systems is one solution sometimes applied. While being extremely comprehensive, this computation-intensive approach does not offer the flexibility to easily assess the influence of changes in background elements on the environmental impacts of the studied foreground system. Here, we show how life cycle inventories of background processes can be parameterized and combined to parameterized foreground inventories to estimate the environmental impacts of future energy production and consumption trajectories. The evolution of the French heating sector until 2050 is used as case study. First, parameterized LCA models of electricity and gas production technologies likely to play a role in future energy mix were developed based on 7 to 28 parameters each for a functional unit of 1kWh of energy produced. Second, parameterized LCA models for heat pumps, gas and oil boilers, electrical heater, district heat, and wood heater, thus the foreground, were defined using 1 to 6 parameters each. The modelling relied on the *lca_algebraic* library, a new layer above the *Brighway2* open source Python library for LCA. Third, the background and foreground LCA models were combined. Finally, the environmental impacts of three consumption trajectories of the French heating sector coupled with two power mix scenarios were estimated using the combined parameterized LCA models. The consumption trajectory relying on an increased energy sufficiency trajectory had less impacts on freshwater eutrophication, ionising radiation, acidification, and climate change than the other two trajectories representing an evolution following the technological developments of the French Environmental Regulation 2020 and a lower efficiency respectively. This was observed for both power mix scenarios. The parameterization and combination of background and foreground LCA models allows to flexibly estimate the environmental impacts of future technologies or systems while ensuring their representativeness.

5.05.T-10 Prospective Life Cycle Assessment of a Cobalt Fischer-Tropsch Catalyst

Anne E.M. van den Oever¹, Daniele Costa² and Maarten Messagie¹, (1)Vrije Universiteit Brussel (VUB), Belgium, (2)Evergi/MOBI, Vrije Universiteit Brussel (VUB), Brussels, Belgium

The Fischer-Tropsch (FT) catalyst production, use, and end-of-life phases are often omitted or simplified in Life Cycle Assessments (LCA) on FT products since the data required to model these stages are generally not publicly available.

Consequently, the effects of the catalyst on the whole life cycle of FT liquids are not known. This study presents the prospective LCA of a novel Co-based FT catalyst, in the scope of the REDIFUEL project (funded by European Union's Horizon 2020 research and innovation programme under Grant Agreement no. 817612). The main objectives were to evaluate different future production pathways and identify a best-case and a worst-case scenario. The foreground was modelled with upscaled data from lab-scale experiments and patents. Different hydrogen production sources were considered, and the effects of two different end-of-life scenarios (regeneration and recycling) were analyzed. The assessment considered the years 2030 and 2050 and a superstructure prospective background database was constructed with the Python library premise. The selected storylines for this database were the SSP2-base (no climate policy) and SSP2-pkbudg900 (1.5 °C climate target). The results showed that the climate change impact of the catalyst depends mainly on the end-of-life scenario chosen. Regeneration and direct reuse of the catalyst led to a 65-80% lower impact than recycling. Using different background scenarios lowered the impact by 10% (SSP2-Base-2030) to 38% (SSPS2-PkBudg900-2050) compared to the Ecoinvent database. The hydrogen source affected the results too. Of all options, H₂ from autothermal reforming of natural gas had the highest impact. The best case for Co-based FT catalyst production is the scenario with regeneration at the end-of-life and ATR of biomass for hydrogen production consumed in all processes. In the worst-case, the catalyst is recycled with metal recovery, while the hydrogen is produced via autothermal reforming of natural gas. Although the prospective background database had an important effect on the results, the different end-of-life options were more influential, making this life cycle stage the primary concern of a prospective LCA of Co-based catalysts. The next steps in this work are analyzing other environmental impact categories and assessing the contribution of the FT catalyst to the bioproducts life cycle.

5.05 Prospective assessment of emerging technologies and emerging product systems in a life cycle perspective (Virtual Only)

5.05.V-01 Goal and Scope Definition of Life Cycle Assessment Applied to Emerging Technologies: FineFuture Flotation in Mining Industry

Hazem Eltohamy¹, Giuseppe Cecere² and Lucia Rigamonti², (1)Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy, (2)Politecnico di Milano, Italy

Froth flotation is one of the most frequent methods employed to concentrate precious minerals for downstream refining stages. Currently an enhanced flotation technology is being developed under FineFuture (FF) project, funded by the European Union Horizon 2020 research and innovation programme (grant agreement No 821265). The project will advance the basic understanding of fine particle flotation phenomena (below 20 µm in size) and lead to the creation of ground-breaking technological solutions. If proves effectiveness, this technology will have the potential to valorise fine mineral particles rather than disposing them as waste. However, this does not necessarily guarantee the technology's environmental sustainability. While Life Cycle Assessment (LCA) is a consolidated method to assess potential environmental impacts of in-operation systems, current LCA framework exhibits some challenges when applied to emerging technologies. In this proposal, we show the decision-making process in the goal and scope phase, and data collection approach applied to two industrial case studies within FF project. The first case study is Grecian Magnesite whose main products are magnesite concentrates (MgCO₃) and magnesia (MgO). The innovative flotation technology is expected to be used on residual fines (< 4 mm granular size) from beneficiation washing units that are now unexploited, or on low-quality MgCO₃ concentrates (< 90% MgCO₃) after beneficiation stage to acquire higher concentrations of MgCO₃. The second case study is Eramet for manganese (Mn) concentrate production. The technology here will target tailings which are the discarded residues of manganese beneficiation process, yet they contain a considerable amount of Mn. For both case studies, the LCA is a comparative one between current systems of beneficiation, and future system with FF flotation implemented. By applying LCA in this way, it will be possible to assess the most environmentally sustainable solution and identify any shortcomings of the emerging technology in early technology readiness level (TRL). LCA can be a reliable evaluation tool for novel technologies if methodological challenges could be overcome. Real-world studies like this can push towards methodological developments of LCA based on real experience of current method's drawbacks. These developments can provide a solid foundation for furthering the application of LCA to emerging technologies by confirming its effectiveness in real-world cases.

5.05.V-02 Life Cycle Assessment of a Heterogenised MOLECULAR Complex on Porous Carbon Support With Poly-Ionic Liquids Incorporation for CO₂ Electroreduction in Water/Ionic Liquid Media

Domenico Grammatico¹, José Jorge Espí Gallart² and Frederic Clarens², (1)IPREM-University of Pau and Pays de l'Adour, France, (2)Eurecat, Spain

Electroreduction of CO₂ is one of the ways to valorise CO₂ as a source of carbon. The development of molecular catalysts for CO₂ electroreduction within electrolyzers requests their immobilisation on the electrodes. While various methods have been explored for the heterogenisation of homogeneous complexes, mainly introducing functionalities to the molecular catalysts, we here report different porous bio-inspired carbon materials as a support for a well-known molecular catalyst with the particularity in addition to exploring its environmental profile. This cathodic hybrid material has been tested for CO₂ electroreduction using a mixture of an ionic liquid and water as the electrolyte. The feasibility of such a system on an industrial scale needs a study focused on a low environmental and economic impact process. A life cycle assessment (LCA) analysis has been performed considering the three different carbon materials scenarios and evaluating the more environmentally friendly to incorporate the environmental perspective to the product development. A cradle to gate approach was used, trying at the same time to overcome the limitation about the low technological readiness level (TRL) of the developments. The experimental best-case scenario has been further studied to see the hot spot process/material for the LCA analysis of the CO₂ electroreduction. Since the cathodic hybrid electrode

catalyses the conversion of CO₂ into a mixture of carbon monoxide and formic acid, with a selectivity that depends on the applied potential and the water content in the electrolyte, the different CO₂ electrocatalytic scenarios are studied. The best scenario is identified by considering the variation of the most important parameters such as potential applied, current density obtained, products selectivity and water content in the electrolyte. These results emphasise the advantages of integrating molecular catalysts onto such porous carbon materials for developing novel, stable and efficient, catalysts for CO₂ reduction, which allow the low loading of noble metal as a catalyst and pave the way toward a more scalable process.

5.05.V-03 Life Cycle Assessment of Bioinspired Electrode Materials for Hydrogen Evolution, Alternate to Carbon-Based Economy

Afridi Zamader¹, Bertrand Reuillard², Laurent Billon³, Gustav Berggren⁴, Vincent Artero², José Jorge Espí Gallart⁵ and Frederic Clarens⁵, (1)Dept. Chemistry-Ångström, Uppsala University, Uppsala, Sweden, (2)CEA Grenoble, France, (3)Univesrité of Pau (UPPA), France, (4)Uppsala University, Sweden, (5)Eurecat, Spain

Water electrolysis using solar energy is regarded as one of the most sustainable techniques for hydrogen production due to its relatively low emissions of greenhouse gases^[1]. However, current electrolyser technologies for the splitting of water into O₂ and H₂ usually rely on the use of rare and expensive platinum at the cathode for the hydrogen evolution reaction (HER) and iridium or ruthenium at the anode for the oxygen evolution reaction (OER)^[2]. In nature, [FeFe] hydrogenase enzymes have attracted tremendous attention for their reversible hydrogen production with remarkable catalytic rate (6000–9000 molecules H₂. S⁻¹ per site) using only earth abundant metals^[3]. Industrial usage of such enzymes is limited due to their extreme oxygen sensitivity and fragility^[4]. However, they became valuable blueprints to develop bioinspired catalyst for large-scale hydrogen production as a promising alternate to carbon-based economy^[5]. In order to make a durable and efficient solar-fuel conversion and integrate such catalysts into an industrial scale, it is necessary to combine bioinspired system with functional support (electrodes, semiconductor, nanoparticle, etc.)^[6]. However, despite the importance of assessing the environmental impacts^[7] of such system, studies based on sustainability of such bioinspired system are yet to be reported. Our recent work focuses on the preparation of oxygen stable hydrogen evolution catalyst (HEC) by embedding [FeS(CO)₃]₂ core, a functional mimic of native enzyme, within functional polymers structures, based on recently reported metallopolymers^[8]. Specifically, we are developing a methodology to anchor these metallopolymers onto nanostructured electrode substrates such as multiwalled carbon nanotubes (MWCNTs) in a stable manner. Our final goal includes exploring the sustainability of resulted system (electrode-catalyst-electrolyte) through Life cycle assessment (LCA). This has allowed thorough ‘Simparo’ software considering the system boundaries of ‘cradle to gate’ and functional unit of ‘1 kg of H₂ production’ using ‘Recipe 2016 midpoint’ as a calculation method. Our preliminary results revealed that the newly synthesised metallopolymer on MWCNTs showed high improvement with two times higher turnover number (TON), more than twice durability for hydrogen production under catalytic condition and three times lesser environment impact for ‘1 kg of H₂ production’ as compared to that of previously reported metallopolymer^[8]. **References** 1. Appl. Energy, 2019, **237**, 862–872. 2. J. Am. Chem. Soc., 2015, **137**, 4347–4357. 3. ACS Catal., 2020, **10**, 7069–7086. 4. Proc. Natl. Acad. Sci., 2009, **106**, 17331–17336. 5. Sustain. 5.05.V-04 Measuring the Reuse Potential of Building Materials: Literature Review and Development of a Reuse-Potential Indicator

Ambroise Lachat¹, Tiffany DESBOIS², Anne Sophie Colas³ and Adélaïde Feraille¹, (1)ENPC, France, (2)Cerema, France, (3)Université Gustave Eiffel, France

The Building and Public Works sector is responsible for half of the extraction of raw materials and energy consumption at European scale. It is also responsible for the production of 227 million tons of waste in 2014 (43 Mt for buildings in France including 23 Mt resulting from demolition). In order to remediate the resource-intensive consumption of this sector (and all sectors in general), waste hierarchy has been introduced by the European Union since 2008. It prioritizes reuse of waste over recycling. Hence, reuse is considered as the best waste recovery method at the end of the life cycle of an object and it is promoted by governments. In this context, many initiatives have emerged in the field of building materials to attempt to generalize reuse practices (Interreg FCRBE, Rotor, Mobius réemploi...). One of the challenges of this issue is to identify and measure the reuse potential of building elements. The BAMB project (Buildings As Material Banks) defines reuse potential as a measure that expresses the likelihood that the parts of that assembly can be disassembled simply, fast and without damage, and thus reused. In this work, a quick literature review on reuse potential will be presented, with its definition(s) and initiatives to construct an indicator of reuse potential of objects. Mains strengths and weaknesses of such indicators will be highlighted. Finally, based on observations from the literature review, we will develop a reuse-potential indicator adapted to load-bearing building components. Thereby, the study will highlight advances in current research and add a contribution on reuse-potential indicators for building materials which are a key element to spread and generalize reuse practices.

5.05.V-05 Proposition of a Life Cycle Assessment Study for the Synthesis of Proton-Conducting Membranes for the eSCALED Polymer Electrolyte Membrane (PEM) WATER Electrolysis Device (Artificial Leaf)

Karell Bosson¹ and José Jorge Espí Gallart², (1)Université de Pau et des Pays de l'Adour, France, (2)Eurecat, Spain

The proton-conducting membrane is a key component of PEM electrolysers. Indeed, the membrane prevents electron transport and mixing of components coming from both electrodes. The thinness of the membranes allows a better transfer of protons between both electrodes. To be effective, the membrane must be durable. Meaning that it should have a good chemical, and mechanical stability; a high proton conductivity and be compatible with the electrode's materials. To date, the commercially available PEM displaying good performances is Nafion®. However, Nafion® fabrication is a complex multistep process. This

factor contributes to the high cost of the membranes. In the matter of reducing the cost of PEM while improving the conductivity, mechanical and thermal properties of the membranes, we developed a membrane based on partially sulfonated poly(pentafluorostyrene) (PPFS) and a second polymer providing more flexibility to the membrane. Membranes were made with poly(butyl acrylate) (PBuA) and bio-based poly(menthol acrylate) (PMA) as second materials. Block and statistical copolymers were synthesized using both copolymer systems. With lower amounts of sulfonated PPFS and thanks to materials' organization, block-copolymers were found to have better conductive properties than their statistical counterparts. Life Cycle Assessment (LCA) methodology has been applied to evaluate the environmental impact and accumulated energy requirements related to the manufacturing of the eSCALED proton-conducting membranes. This assessment allows investigating and identifying the environmental impact hotspots of membrane manufacturing process, thus, enhancing the sustainability of the technology in its future upscaling. The cradle-to-gate LCA being performed compares the environmental impacts of two different synthesis techniques to obtain sulfonated block and statistical PPFS/PBuA. Moreover, by using less PPFS in the case of block copolymers, the overall environmental impact of the membrane should be lowered. Additionally, our goal is to determine if using a bio-sourced polymer (PMA) better the environmental impacts of the membrane elaboration compared to PBuA. Our preliminary results showed that at a laboratory scale, the highest impact comes from the energy inputs used for the synthesis of polymers and not the actual chemical used to make the membranes. Hence, reducing energies used during polymerization could help optimize the membrane elaboration processes.

5.05 Prospective assessment of emerging technologies and emerging product systems in a life cycle perspective (Poster)

5.05.P-Th156 Prospective LCA of Perovskite Solar Cells for Building Integrated Applications

Federico Rossi¹, Maria Laura Parisi², Riccardo Basosi² and Adalgisa Sinicropi², (1)University of Siena, Siena, Italy, (2)University of Siena, Italy

Perovskite solar cells (PSCs) are innovative photovoltaic devices that are expected to become commercial in the near future. For this reason, scientific research is doing a great effort to improve their lifespan, power conversion efficiency (PCE) and stability. On the other hand, industrial research is trying to optimize the fabrication of these devices by reducing the energy and the materials demand for their manufacturing; moreover, the analysis of PSCs real world operation is another important research topic. The study presented in this abstract is a prospective life cycle assessment (LCA) where future scenarios related to the technological development of PSCs and to the industrial scale-up of their manufacturing are used to predict the potential environmental benefits of this technology. Particularly, we assume that PSCs are used in a building integrated photovoltaic (BIPV) system located in Cyprus. From the methodological point of view, a prospective LCA analysis is usually performed grounding on some foreground scenarios defined by the analyst. In this study, three scenarios regarding the evolution of PSCs operational parameters are considered: a pessimistic, a realistic and an optimistic one. Moreover, an industrial-scale production line for PSCs is modelled by processing primary data retrieved from an existing laboratory-scale process. The LCA model is developed using Ecoinvent 3.7: this database has been merged with a superstructure, built as an excel file, uploaded in the open-source software Activity-Browser that allows to create background scenarios estimating the future changes of Ecoinvent processes. For example, the future national electricity mixes will be strongly different in long-term scenarios. The methodology described in the previous paragraphs allows to calculate the environmental footprint of a BIPV system constructed in Belgium and installed in Cyprus between 2020 and 2060 compared with the electricity mix of Cyprus. The results show that at the current status, the BIPV system equipped with PSCs has a high impact in terms of Global Warming Potential. However, the energy produced by the BIPV systems installed between 2025 and 2040 will be much more sustainable than the grid electricity. This evidence results from a higher maturity of PSCs and from the consumption of more sustainable energy during the construction.

5.05.P-Th157 Applying a Systematic Scenario Methodology Within Prospective LCA: A CASE Study of PHA Production

Mateo Saavedra del Oso¹, Miguel Mauricio-Iglesias², Almudena Hospido² and Bernhard Steubing³, (1)Department of Chemical Engineering, Universidade de Santiago de Compostela, Santiago de Compostela, Spain, (2)CRETUS (Cross-Research in Environmental Technologies), Universidade de Santiago de Compostela, Spain, (3)CML Leiden University, Netherlands

PHA production from carbon-rich waste streams by mixed microbial cultures (MMC) can diminish both environmental impacts and production costs. However, these processes are still at low technology readiness level (TRL 5-6). At this level there are still opportunities for major adjustments. Prospective life cycle assessment (pLCA) can be a useful tool to ensure that environmental guidance is included in the development of PHA production by MMC. This research intends to provide insights on the systematic scenario methodology within pLCA of a biobased emerging technology, such as PHA production by MMC. A 4-step process was followed to build the scenarios. The (1) identification of influencing parameters was carried out by applying a PESTEL analysis and causal loop diagram (CLD), where parameter influence and correlations are depicted. After that, (2) sub-scenarios for each parameter under different narratives were constructed. The (3) creation of consistent scenarios from sub-scenarios was carried out through a morphological field analysis. Finally, (4) these scenarios were implemented in the life cycle inventory model. In step (1), an in-depth review of PHA production, which included meetings with technology developers, was carried out to identify the influencing parameters, namely the bioeconomy and environmental policies, type of feedstock, scale and process performance parameters. A hybrid CLD, which describes the influences and correlations between these parameters and the flow chart model, was developed. The construction of sub-scenarios (2) and the upscaling was carried out based on advanced process calculations and pilot-scale data. Consistency check allowed verifying which combination of sub-scenarios for each parameter are most likely to happen. Through the morphological analysis, 4 different scenarios were created: (1) a small-scale on-site production plant within a juice beverage facility under "business as usual" bioeconomy policies, (2) a large-scale production plant that uses fruit waste as feedstock under ambitious bioeconomy policies, (3) and (4) a large scale on-site production plant within an urban waste

and wastewater biorefinery under ambitious bioeconomy policies and low (3) and high (4) process performance parameters respectively. This work demonstrates the utility of combining a systematic scenario methodology with prospective LCA, providing insights of how this emerging biobased process can be developed in a future framework.

5.05.P-Th158 Developing Industrial-Scale Inventories of Energy-Intensive Processes for Bio-Based Activated Carbon Manufacture and Comparison With Data at the Laboratory-Scale

Edis Glogic¹, Kamal Kamali² and Guido Sonnemann³, (1)University of Bordeaux, France, (2)Universite de Bordeaux,, France, (3)University of Bordeaux - ISM, France

Using the life cycle assessment (LCA) to evaluate the environmental impacts of emerging technologies faces challenges in collecting the data needed to carry out the analysis. Inputs of materials and energy and outputs of emissions are not readily available or cannot be easily estimated and scaled-up to resemble industrial operations which is necessary to adequately evaluate impacts of these systems and facilitate comparison with concurrent incumbent systems. The current study demonstrates how the aforementioned challenges are addressed in assessment of bio-based activated carbon synthesis. The study showcases how the challenges to data upscaling can be overcome for the processes of activation and carbonization of biochar, and how derived estimates compare to energy consumptions measured in the laboratory settings. The calculation of energy for carbonization and activation involves approximation of several energy flows including the energy consumed to heat the biomass, energy released from the biomass and output gasses, and energy losses from the reactor and output gasses. To quantify these multiple flows we combine information from secondary literature with stoichiometry and fluid dynamics calculations. The laboratory-scale inventory is measured directly or approximated taking into account the power consumption of the equipment. The results demonstrate the approach involving several techniques to approximate industrial-scale data for carbonization and activation processes that are then compared with energy collected at the laboratory scale. Comparison is carried out both directly and at the level of final LCA results. Therefore, the study offers an interesting showcase into dealing with data collection amidst significant gaps and scale-up challenges as one a major bottleneck in the assessment of emerging technologies in LCA.

5.05.P-Th159 Environmental Learning Curves and Their Prospective Applications

Mitchell van der Hulst¹, Mark Huijbregts², Rosalie van Zelm² and Mara Hauck³, (1)Environmental Science, Radboud University, Nijmegen, Netherlands, (2)Radboud University, Netherlands, (3)Netherlands Organisation for Applied Scientific Research (TNO), Netherlands

Emerging technologies tend to have a higher cost, lower efficiency and larger environmental impact when compared to an incumbent, which puts them at a disadvantage. This is because incumbents already underwent several iterations of optimisation. Prospective life cycle assessment (pLCA) aims to take into account the optimisation processes to which the emerging technology will be subjected. This makes hotspot analysis of the emerging technology and comparison to the incumbent more informative. One of the methods that is increasingly proposed, but has not seen much development for pLCA application yet, is the application of the learning curve concept. Environmental learning curves (ELCs) are based on the assumption that the environmental impact of a process correlates to how much one has learned about this process and that this correlation can be described with a power law. The ELC describes what happens to the environmental impact of an emerging technology when one increases the “amount of learning”, e.g. by producing more units or installing more production capacity. When a projection is available for the learning parameter at a future point in time (e.g., “by 2030, cumulative production is projected to be 1 million units”), the environmental impact at this future point in time can easily be extrapolated through the ELC. Such straightforward extrapolation is the reason why ELCs are considered the way forward in pLCA of emerging technologies. However, key challenge in application of ELCs for assessing emerging technologies is the reliance on observations and available data in current approaches. Application of ELCs is particularly challenging when assessing emerging technologies, due to absence of historic data and few reported environmental learning rates available. The goal of this study is therefore to present how ELCs can be applied in pLCA to project environmental impacts of emerging technologies at a future point in time. For materials that go into an emerging technology, simple one-factor ELCs are constructed with empirical data using Wright’s law and these individual ELCs are subsequently combined into a component-based ELC for the emerging technology. An example for electricity consumption in primary aluminium production shows that the learning effect on the component level can be substantial, with greenhouse gas footprints projected to reduce by 13% when the energy intensity of the process is subjected to the learning effect.

5.05.P-Th161 Prospective Assessment in the Search for Optimised Pathways for Valorisation of Side Streams in Paper Industry

Polina Yaseneva¹, Parminder Kaur Aulakh² and Alexei Lapkin², (1)Cambridge Institute for Sustainability Leadership, University of Cambridge, Cambridge, United Kingdom, (2)University of Cambridge, United Kingdom

With imminent threat from climate change there is an urgent need in transition to circular and sustainable production systems. However, the question remains how do we assess future environmental sustainability of a system that is of low technology readiness level in a robust way? The question becomes even more complex when considering chemicals production systems due to variability of potential production pathways and chemical feedstocks for the same target molecules. Therefore, to analyse and compare environmental and economic effects of different emerging production systems (aiming at the same chemical) in the absence of robust scale-up data, it is necessary to integrate life cycle assessment (LCA) with process modelling: this allows for scale up and optimisation of important production steps (such as separation and purification) before feeding the data into an LCA model. We illustrate this approach on a topical problem of selecting the optimal bio-resource and the production technology to reach a key intermediate molecule. Industrial streams containing bio-feedstocks are attractive potential sources of functionalised molecules, that can enter chemical supply chain as higher value intermediates, rather than be used for energy generation.

Specifically, in the case of the paper industry side streams, terpenes contained in crude sulphate turpentine (CST) and waste streams from other wood pulping processes, could be used as a starting point in the synthesis of a broad range of functional molecules. Bio-feedstocks, however, are not clean and are characterised by significant variability and, often, heterogeneity. Frequently, there may be more than one possible choice for the bio-feedstock source of the molecules of interest. Therefore, identification of the most promising chemical route in early stage process development should, ideally, be accompanied by the evaluation of the combined system of a feedstock and the relevant purification technology options, as a more holistic analysis. Thus, integration of process modelling for generating technological scenarios with life cycle assessment (LCA) for subsequent evaluation of environmental impacts and costing is the most appropriate method of evaluating this holistic problem. In this paper we *integrated process modelling approach into comparative LCA of production of an intermediate molecule nopinone from two alternative paper industry streams containing terpenes, with the aim to identify optimal production route.*

5.05.P-Th162 Prospective Life Cycle Assessment of an Anion Exchange Membrane Water Electrolysis

Elke Schropp¹, Bernhard Steubing², Christian Bernäcker³, Lars Röntzsch³ and Matthias Gaderer⁴, (1)Professorship of Regenerative Energy Systems, Technical University of Munich, Straubing, Germany, (2)CML Leiden University, Netherlands, (3)Fraunhofer Institute for Manufacturing Technology and Advanced Materials IFAM, Germany, (4)Technical University Munich, Germany

Hydrogen is being discussed as a future energy carrier that will play an important role in a future climate-friendly and decarbonized energy system. Particularly water electrolysis is considered a key technology in this transition process, as this technology enables the production of hydrogen by electrochemically splitting water with electricity, preferably from renewable energy for environmental reasons. There are essentially three different water electrolysis technologies. While the solid oxide electrolysis (SOEL) operates at very high temperatures, the alkaline electrolysis (AEL) and the proton exchange membrane electrolysis (PEMEL) represent two low-temperature technologies that are already commercially available. Considering low-temperature electrolysis, the anion exchange membrane electrolysis (AEMEL) currently attracts wide attention. Similar to the AEL technology, the AEMEL operates under an alkaline environment that enables the use of platinum-group-free, non-noble catalysts thus enabling the use of cheap and abundant materials. The integration of a non-porous membrane, as in PEMEL, allows the AEMEL to be fed with pure water and reduces the Ohmic losses facilitating higher current densities and, thus, more compact electrolysis plants. However, the AEMEL technology is at an early stage of development. This study evaluates the environmental performance of an AEMEL using a prospective life cycle assessment, which aims at assessing the environmental impacts of emerging technologies in a more distant future when the technology has achieved higher maturity comparable to that of the incumbent technologies. In this case, the incumbent technologies are the AEL and the PEMEL. The advantage of assessing environmental impacts at a low level of maturity is that at this stage, development can be directed toward good environmental performance. For electrolysis technologies, among the different impact categories, the global warming potential and the use of critical raw materials are often discussed in more detail. This pLCA study shows the future environmental performance of AEMEL compared to the AEL and PEMEL technology and gives an outlook on the future perspective of hydrogen production.

5.05.P-Th163 Life Cycle Assessment Applied to Carbon Capture Technologies for Biohydrogen Production From Waste

Suviti Chari¹, Gema Amaya Santos², Alex Sebastiani³, Andrea Paulillo², Paola Lettieri³ and Massimiliano Materazzi³, (1)UCL, London, United Kingdom, (2)Chemical Engineering, University College London, London, United Kingdom, (3)University College London, United Kingdom

This research work focuses on a complex product system that a) produces hydrogen as the main product b) captures and permanently sequesters carbon dioxide c) utilises biomass waste feedstocks, thereby diverting its fate from landfill or incineration and d) generates electricity as a co-product. This research investigates the environmental performance of carbon capture technologies for the Biomass-to-Biohydrogen process (Bioenergy with CCS or BECCS) by employing a combination of process engineering simulations, technology expert knowledge, commercial-scale proxy technologies as well as lab-scale studies. An LCA was conducted on a complete commercial scale plant converting 110,000 tonnes per annum of waste wood to 50 MWh of grid-quality hydrogen with a focus on four conventional carbon capture technologies, namely, amine scrubbing via monoethanolamine (MEA), Benfield, Selexol® and Rectisol® and an additional emerging technology, Sorption Enhanced Water Gas Shift (SEWGS). Extensive analysis was conducted on the effects of changing system boundaries and functional units, yielding varying results. However, results pointed to a common ranking amongst technologies with respect to climate change category; SEWGS outperforming other technologies, and MEA and Benfield, chemical adsorption-based technologies, performing the poorest. Among the physical adsorption technologies using solvent, Selexol fared better than Rectisol. All other impact categories were analysed, yielding a similar ranking. The work highlights the importance of BECCS as a negative emissions technology and the further environmental benefits of using a physical absorption technology for carbon capture, particularly SEWGS. This research work provides a real-world application of LCA to a BECCS system producing Biohydrogen from waste and addresses some methodological complexities of prospective LCAs in order to progress from pilot/demo scale towards commercial scale production.

5.05.P-Th164 Prospective Life Cycle Assessment of Carbon Capture and Utilization by Artificial Photosynthesis

Lukas Lazar¹ and Andreas Patyk², (1)Karlsruher Institut für Technologie (KIT) - Institut für Technikfolgenabschätzung und Systemanalyse, Karlsruhe, Germany, (2)Karlsruhe Institute of Technology (KIT), Germany

To avoid further risk increases by not exceeding the 1.5°C global warming level, the Intergovernmental Panel on Climate Change (IPCC) advises to reach net negative CO₂ emissions after 2050 according to the SSP1-1.9 scenario. Hence, new technologies for large-scale CO₂ removal will be necessary applying Carbon Capture Storage and Carbon Capture Utilization. However, ensuring

permanent negative CO₂ emissions and in the same time not critically increasing other environmental impacts remains a challenge. An emerging technology which could fill in the gap between carbon dioxide capturing and carbon dioxide utilization or storage, is Artificial Photosynthesis and particularly the photocatalytic reduction of CO₂ to value-added chemicals. Thereof, the utilization path inheres the further advantage of avoiding the impacts related to the conventional production of these chemicals, while in the same time using CO₂ from the ambient air or biomass which potentially leads to net negative CO₂ emissions. However, even if the lowering of CO₂ emissions can be ensured, the widespread application of renewable technologies leads to an increase in land use and material demand due to their dependence on the use of highly dissipated energy. Therefore, it remains necessary to assess the environmental performance of photocatalytic CO₂ reduction regarding its climate change impacts as well as other environmental categories and additionally taking into consideration the very low Technological Readiness level of this technology. Hence, we apply a prospective Life Cycle Assessment of an emerging technology with background data exchange using Integrated Assessment Model scenarios to allow a first estimate of the technology's performance within potential future technospheres. On a system level, we compare two different CO₂ scenarios for the photocatalysis and two different photocatalytic pathways: the photocatalytic CO₂ reduction with a modified parabolic trough collector as solar reactor and the photoelectrocatalytic CO₂ reduction assuming a reactor inspired by photovoltaic technology. We investigate the production of synthesis gas, hydrogen peroxide and methane as promising by-products of the carbon dioxide utilising Artificial Photosynthesis system and compare these to the carbon dioxide capturing and geological storage by Direct Air Capture. The results give a first estimate of the CO₂ removing performance of possible Artificial Photosynthesis systems as well as its performance considering potentially conflictive environmental categories such as land and resource use. Thereof, first conclusions and recommendations about the cross-technology performance as well as optimisation demands and potentials within the emerging technology are given.

5.05.P-Th165 Prospective Life Cycle Assessment on Lab Scale Direct Air Capture System

Anne Ottenbros¹, Melinda de Jonge², Hans de Neve³, Marco Arts³, Dries van Eyck³, Jasper Simons³, Rosalie van Zelm⁴ and Mark Huijbregts⁴, (1)Radboud University Nijmegen, Nijmegen, Netherlands, (2)Radboud University Nijmegen, Netherlands, (3)Carbyon, Netherlands, (4)Radboud University, Netherlands

To combat global warming, various direct air capture (DAC) technologies are in development to extract CO₂ from the atmosphere. DAC technologies are still in a relatively early stage of development and thereby highly expensive to implement on a large scale. The start-up company Carbyon is currently developing a new technology to remove CO₂ from the atmosphere that can reduce costs by a factor of 10. This technology can adsorb and regenerate CO₂ within a cycle of 60 seconds, i.e. as fast swing process. However, the question remains what the net CO₂ gain is from this new technology and whether that CO₂ profit can still be optimized in the further development of this technology. The goal of this research is to provide recommendations to optimize the net CO₂ gain from direct air capture (DAC) via the new Carbyon process. With a prospective life cycle assessment, the environmental benefits and impacts of the Carbyon DAC system on industrial scale are determined, with focus on how the electricity is supplied and how the captured CO₂ is either utilized or stored. Specifically, climate change, land and water use as environmental impacts are included. The environmental performance of the Carbyon DAC system are also compared with existing DAC technologies.

5.05.P-Th166 Life Cycle Assessment Comparison of Large Scale Hydrogen Delivery Options

Alessandro Arrigoni¹, Francesco Dolci², Rafael Ortiz Cebolla² and Eveline Weidner³, (1)JRC, Netherlands, (2)JRC, European Commission, Joint Research Centre, Nederland, (3)JRC, European Commission, Joint Research Centre, Netherlands

Green hydrogen is expected to play an important role in European decarbonisation efforts. A previous JRC study showed that sourcing hydrogen from a location where renewable energy is cheaper, can be more cost effective than producing it locally. However, the environmental impact of transporting large amounts of hydrogen over long distances, has not been fully understood yet. Our work aims at advancing this field by comparing the life cycle greenhouse gas emissions of three options for delivering hydrogen: hydrogen compression, liquefaction, and chemical bonding to other molecules (i.e., using ammonia, methanol, or liquid organic compounds as hydrogen carriers). The goal is to understand whether transporting hydrogen could make sense from a climate change perspective, and if so, which is the option with the lowest global warming impact. Emissions are assessed from hydrogen production, through its conversion into a suitable carrier, and finally to the shipping and supply of pure hydrogen to an industrial user. A distance compatible with the European territory was considered: i.e., production in Portugal and end-use in the Netherlands. Preliminary results show that all the delivery options would guarantee a supply of hydrogen with a lower global warming potential than electrolytic hydrogen produced from local grid electricity. This is not expected to change within the next ten years, since most European grid mixes will still partially rely on fossil fuels (carbon intensity of the EU grid in 2030 assumed to be 150 g CO₂e/kWh). However, depending on the efficiency of renewable electricity generation and on the source of energy used along the supply chain, shipped green hydrogen could generate more greenhouse gas emissions than local hydrogen produced via steam methane reforming. This is not valid for 2030, when the life cycle of 1 kg of shipped green hydrogen is expected to emit approximately 2 kg of CO₂e. Liquefaction appears to be the least greenhouse gas intense delivery solution, thanks to the lower volumes transported and the lack of an energy intensive transformation process at the delivery site. Nevertheless, much of the Infrastructure for large scale hydrogen delivery does not yet exist, and therefore assumptions on technologies and emissions are subject to a high degree of uncertainty. More primary data on hydrogen technologies and alternative delivery options (e.g., dedicated pipelines) are necessary to increase the accuracy of our estimates.

5.05.P-Th167 eSCALED: A Collaborative Approach for Studying the Life Cycle Analysis of the Components and Assembly of an Artificial Leaf for Renewable Hydrogen Production and CO₂ Utilisation Using Novel Molecular Catalysts and Materials

Andrew Howe¹, Bruno Filipe Pinto Branco², Afridi Zamader³, Domenico Grammatico⁴, Karell Bosson⁵, Olivera Vukovic⁶, José Jorge Espí Gallart⁷ and Frederic Clarens⁸, (1)SMC, Uppsala University, Uppsala, Sweden, (2)Eindhoven Technical University, Netherlands, (3)Uppsala University, Sweden, (4)IPREM-University of Pau and Pays de l'Adour, France, (5)Université de Pau et des Pays de l'Adour, France, (6)TU Eindhoven, Eindhoven, Netherlands, (7)Fundació EURECAT, Cerdanyola del Valles, Spain, (8)Fundació CTM Centre, Afghanistan

The current transition to sustainable energy sources is leading to the creation of new environmental policies. Together with these policies comes the growing importance of objectively quantifying the environmental impacts of emerging sustainable technologies. Artificial photosynthesis is one of these emerging technologies as it is considered a suitable replacement for fossil fuels. Inspired by nature, an artificial leaf produces H₂ or hydrocarbons by converting water and CO₂ using solar energy. However, its implementation in a real life scenario is quite complex. The materials, synthesis procedures, equipment that are required raise issues regarding the sustainability of such energy source. As example, the main reactions in an artificial leaf, oxygen and hydrogen evolution, usually require electrocatalysts based on noble metals such as iridium, ruthenium and platinum. The eSCALED project seeks a collaborative approach to Life Cycle Assessment (LCA) to generate a compilation and evaluation of the inputs, outputs, and potential environmental impacts. This data will then be used to generate a better understanding of the environmental implications and net benefits of manufacture and use of this technology, with each researcher modelling each novel component of the device, such as the electrodes for water oxidation, hydrogen production, electrodes for catalytic carbon dioxide reduction, proton conducting membrane, multijunction solar cells and their assembly into the final device to get a measure of the performance and efficacy of the device as a whole. During this stage, the *primary energy requirement*, that includes all energies related to the extraction of natural resources, preparation of upstream materials and each step required to manufacture the device. The environmental cost for each component part of the artificial photosynthesis device will be simulated using a cradle-to-gate approach to individually analyse the environmental implications of each stage and identify the stages where the highest environmental impact and provide a full explanation of the net benefits and opportunity costs of using this technology. Secondly, a techno-economic analysis focused on the externalities were performed to estimate the costs per kg of hydrogen. The final aim is to give an overview on the environmental and economic aspects of an artificial leaf to have a more informed view on the possible up-scaling this technology for wider use in the energy sector.

5.05.P-Th169 Life Cycle Assessment of an Industrial Vanadium Flow Battery - Identification of Environmental Potentials

Nick Blume¹, Thomas Turek² and Christine Minke³, (1)Research Center Energy Storage Technologies, Clausthal University of Technology, Goslar, Germany, (2)Clausthal University of Technology, Germany, (3)Leibniz University Hannover, Germany

Energy storage systems are becoming increasingly important for a successful energy revolution and will therefore become the focus of attention in the future. Not only renewable energies have to be analyzed for efficiency and sustainability, but also the environmental impact of intermediate storage systems has to be examined in and for the future. A particularly promising stationary battery is the vanadium flow battery (VFB), because of its unique properties for industrial applications. Most outstanding are the independent scalability of the battery's capacity and power, as well as its non-flammability. The VFB offers many advantages to store the energy efficiently and with low emissions. The VFB can run an above-average number of charge/discharge cycles while temporarily storing the energy almost loss-free over a long period of time. In flow batteries, the energy is stored in an electrolyte in chemical energy form, this electrolyte has a significant share in the emissions of a VFB. The basis of the electrolyte is vanadium, which is found primarily in small amounts in iron ores and is therefore responsible for a large proportion of the electrolyte's emissions. In the future, technological advances may prevent most of the emissions from the electrolyte. This development is examined in a prospective LCA of this emerging technology based on the two most important parameters. First, the electrolyte can be processed with little effort and thus can theoretically be used indefinitely. Another point is the processing of the iron ore respectively the steel production with green hydrogen, whereby the vanadium as a by-product causes significantly less emissions. The basis of the study is the modeling of vanadium pentoxides using primary data from a mine in South Africa, based on the data, the correlation of the parameters and their effects is evaluated in a global sensitivity analysis. The emissions and future potential of batteries have only been analyzed to a limited extent to date. No dependence on critical raw materials exist due to these new approaches and likewise, the VFB is a particularly sustainable battery. In politics and economics, the VFB is often not taken into account due to the cost of the system. The two parameters presented have a significant impact on the reduction of emissions, but also the reuse leads to a significant reduction of costs.

5.05.P-Th170 Prospective Life Cycle Assessment of a Sodium-Ion Battery Focusing on Climate and Resource Impacts

Sanna Wickerts¹, Rickard Arvidsson², Anders Nordelöf³, Patrik Johansson⁴ and Magdalena Svanström⁴, (1)Environmental systems analysis, Chalmers University of Technology, Gothenburg, Sweden, (2)Environmental Systems Analysis, Chalmers University of Technology, Gothenburg, Sweden, (3)Environmental Systems Analysis, Technology Management & Economics, Chalmers University of Technology, Göteborg, Sweden, (4)Chalmers University of Technology, Sweden
